Farm Credit System. The banks and associations that comprise the borrower-owned cooperative Farm Credit System provide credit and related services to farmers, ranchers, producers and harvesters of aquatic products, agricultural and aquacultural cooperatives, rural home-owners, and certain businesses involved in the processing of agricultural and aquacultural products.

The United States is currently divided into seven farm credit districts. The seven Farm Credit Banks provide a source of funds, as well as supervision and support services to Federal Land Bank Associations (FLBAs), Production Credit Associations (PCAs), and Agricultural Credit Associations (ACAs).

FLBAs make 5- to 40-year first-mortgage loans for land and capital improvements. Loans may not exceed 85 percent of the market value of the property taken as security unless guaranteed by a federal agency. PCAs make short and intermediate term loans for operating expenses, capital purchases, and capital improvements. Producers and harvesters of aquatic products may receive terms of up to 15 years. ACAs are associations created by the merger of one or more FLBAs and PCAs and therefore, have the ability to make short-, intermediate-, and long-term loans.

The other lending arm of the Farm Credit System is composed of the Banks for Cooperatives (BCs). The BCs offer a complete line of credit and leasing services to agricultural cooperatives, rural utility systems, and other eligible customers. BCs require at least 80 percent of the voting control of the cooperative be in the hands of farmers, ranchers, or producers and harvesters of aquatic products. A cooperative must also do at least 50 percent of its business with or for its members. The BCs may also finance joint ventures between eligible cooperatives and private firms, as long as the cooperative has a controlling interest. Two banks, each with a national charter, comprise the BC system. CoBank, the National Bank for Cooperatives, which is headquartered in Denver, Colorado, also finances agricultural exports and provides international banking services for the benefit of US farmer-owned cooperatives. The other BC is the St. Paul Bank for Cooperatives, which is headquartered in St. Paul, Minnesota. The St. Paul Bank is in the process of being merged into the National Bank for Cooperatives.

Life Insurance Companies. In the past, life insurance companies were primarily real estate mortgage lenders. Recently, however, several companies have broadened their lending activities to cover all phases of agricultural and aquacultural lending activities. The primary limitation for many borrowers is that these companies tend to limit their lending to larger loans and concentrate on only the most creditworthy borrowers.

Government Funding Sources

The Small Business Administration. The SBA provides both guarantees and direct loans to aquaculture operators. SBA loans may be used for the purchase and improvement of land or buildings, construction, machines and equipment, operating expenses, and refinancing of debts. SBA also provides disaster loans in authorized areas.

Farm Service Agency. The FSA provides both guarantees and direct loans to aquaculture operators. The various types of FSA loans that can be obtained for aquacultural purposes are as follows:

a. **Farm Ownership and Loan Guarantees** are made to help eligible applicants become owner-operators of family farms; to make efficient use of land, labor and, other resources; and to enable farm families to have a reasonable standard of living. These loans can be made for the purchase and development of real estate, including water resources.

b. **Operating Loans and Loan Guarantees** are made to operators of family farms and to applicants wanting to become operators of such farms. These loans can be used for financing and refinancing equipment, for livestock or fish purchases, for family living and farm operating expenses, and for minor land or water improvements. Objectives of the program are to improve living and economic conditions and to help operators become established in a sound system of aquaculture or agriculture. The combined farm ownership and operating loan limit is $400,000 for direct loans and $700,000 for guaranteed loans.

c. **Emergency Loans** are made in counties where property damage or severe production losses occur as a result of a natural disaster or because of other emergency situations. The funds can be used for major adjustments, operating expenses, and other essentials, to enable borrowers to continue their operations. This program involves only direct loans and has a loan limit of $500,000 or the amount of loss sustained, whichever is less.

Borrowers under the direct farm ownership and operating loan programs may qualify for the special limited resource loan program. Eligible borrowers qualify for initial interest rates, which are approximately half the normal loan rate, but this rate will adjust upward as the borrower's ability to pay improves.

Rural Development. Rural development provides only loan guarantees under the Business and Industrial

(B and I) Loan Program. The B and I guarantees promote development of business and industry, including aquaculture, in cities and towns with less than 50,000 population. However, applications for projects in open country, rural communities, and towns of 25,000 people or fewer receive preference. These loans can be made for conservation, recreation, tourism, and the development and utilization of water for aquacultural purposes, as well as for aquacultural related businesses, such as processing plants. Loans of less than $2 million are eligible for a 90 percent guarantee; those between $2 and $5 million, an 80 percent guarantee; those between $5 and $10 million, a 70 percent guarantee; and those between $10 million and $25 million, a 60 percent guarantee.

State Loan Programs. Many states offer financial assistance programs that target beginning farmers, nontraditional enterprises, and rural economic development. Some states offer direct loans, others, loan guarantees, and still others, linked deposit programs. In linked-deposit programs, the state makes deposits in participating financial institutions at less than the going market rate of interest. The financial institution, in turn, passes these reduced rates on to borrowers who qualify for the loans under the program.

RECOMMENDATIONS

At this time, several things must be done to improve the ability of aquacultural producers to obtain necessary financing. The first and most important is a coordinated effort to educate lenders, producers, potential investors, and financial regulators about the aquaculture industry. Second, there is a need for qualified appraisers with the experience and training to assess the collateral value of equipment and improvements employed in aquaculture. Finally, the aquaculture industry needs a readily available insurance program to insure producers of established aquacultural products against potential disasters.

Three other areas that merit further study and education include alternative uses of assets if a venture fails, alternatives to the ownership of land and capital improvements, and market or production contracts. One obvious example of an alternative use of assets is the use of ponds for water storage for agricultural irrigation or municipal use. Alternatives to land and capital purchases that need exploration include long-term renewable leases for land and leasehold improvements. This would include an analysis of the risks to the lessor and the lessee and studies of alternative lease terms and arrangements. Contractual arrangements need to be studied and evaluated in terms of the risks involved, their impact on market performance, and the economic costs and benefits to the parties involved. Additional information is available in the references listed (1–3).

FISHERIES MANAGEMENT AND AQUACULTURE

Nick C. Parker
U.S. Geological Survey
Lubbock, Texas

OUTLINE

FISHERIES MANAGEMENT AND AQUACULTURE

National and international discussions and debates have been held to compare the value of wild native fish, especially trout and salmon with those produced in hatcheries (1,2). Strong debate has raged for years on the U.S. west coast concerning the management of Pacific salmon stocks (3). Concerns have been expanded to question nearly all aspects of fisheries management and especially the role of hatcheries and fish culturists (4).

Fisheries scientists and anglers alike are biased by their personal experiences, and the biases start with the most fundamental of terms. What do we mean when we refer to "wild" fish and particularly to "wild trout" or "wild salmon?"

Webster's New World Dictionary defines wild as "living or growing in nature; not tamed or cultivated by man." Does a fish captured from the wild and moved into a hatchery as broodstock immediately cease to be wild? Would progeny from such a fish be wild if they were immediately returned to the waters from which the parent stock were taken? Would they be wild if maintained in captivity for one day, one month, one year, or one generation?

WILD TROUT

A survey of fish culturists on national fish hatcheries found that 82% believed that wild trout could be produced in hatcheries (5). The majority, 65% of respondents, would expect the progeny of wild fish to become domesticated in five generations. The definition of "wild trout" as viewed by 51% of those fish culturists would not preclude fish from being produced in public hatcheries or in commercial fish farms.

OUR CHANGING WORLD

Continual adaptation and change are necessary for biological organisms, political systems, businesses, and managers of natural resources to maintain their positions in the world. Just as Darwin's finches adapted to minimize competition and to survive side by side, aquaculturists, anglers, natural resource managers, including fisheries managers, and others must adapt to rapidly changing conditions. Aquaculture, which has been described as "the emerging giant," has drastically altered management of some aquatic resources and has the potential to alter others. Change in U.S. fisheries (and global fisheries) has been ongoing for hundreds of years. However, the rapid rise in the human population is forcing change at an unprecedented rate.

THE FIRST FISHERIES MANAGERS

The first professional managers of natural aquatic resources in the United States were probably the fish culturists, now known as aquaculturists, who lobbied Congress in 1871 to establish the U.S. Fish and Fisheries Commission, with Spencer F. Baird, Assistant Secretary of the Smithsonian Institute, as the first commissioner (6). These early managers also persuaded Congress to appropriate funds for the propagation and introduction of shad (*Alosa* spp.), trout (Salmonidae), and other valuable fishes throughout the country. The goals of both public officials and private producers were to provide fish for the food market and to provide species acceptable to Europeans in the New World. To help meet this goal, they first introduced the common carp (*Cyprinus carpio*) into this country from France in 1831 or 1832 and, by

1875, the fish were well established in California and New York (7). With some fanfare and at the request of Spencer Baird, Congress appropriated $5,000 in 1877 to construct culture ponds to rear common carp on the grounds of the Washington Monument. Over the next several years, farm-raised fish, including brown trout (*Salmo trutta*) and common carp, were promoted by private aquaculturists and government officials to increase angling opportunities. These culturists voiced their concerns about dams, siltation and pollution from manufacturing plants, sawmills, and other industrial and municipal sources. Fish culturists sought to preserve the aquatic environment to support fish and fishing.

After the death of Spencer Baird in 1887, the value of cultured fish in the management of natural resources began to be questioned and funding for research became more limited. By 1897, when *A Manual of Fish Culture* (8) was published by the Commission, fish culture was a well-developed practice in federal fish hatcheries as well as in the private business sector. The manual contained descriptions for the culture of more than 40 species or groups of finfish, plus lobsters, oysters, clams, and frogs. Fry produced in hatcheries were widely stocked along the Atlantic Coast from about 1870 to 1900; the programs then were abandoned, because they did not appear to influence commercial landings of American shad (*Alosa sapidissima*), striped bass (*Morone saxatilis*), or other estuarine fishes.

Conflicts of Aquaculturists and Natural Resource Managers

Now, about 100 years later, resource managers view aquatic resources as part of the public domain and consider hatchery-produced fish an important tool to manage these aquatic resources (9). Private producers of fish view aquaculture as agriculture in the aquatic environment and believe the products produced should be treated no differently from poultry, beef, or soybeans. The opposing views of natural resource managers and private fish producers are a major source of conflict. For example, aquaculturists rear striped bass as a food fish for sale in restaurants and grocery stores, whereas fisheries managers rear striped bass in hatcheries for release into public waters as game fish for anglers.

Role of Hatcheries

The popularity of public hatchery programs has cycled from high to low to high in about 30-year periods as support for stocking fish in public waters and the perceived benefits of managing aquatic resources have been alternately promoted and questioned. Habitat alteration — including dams, diversions, channelization, and pollution — and the growing demand for fish and fishery products have increased the need for hatchery-produced and farm-raised fish. State and federal hatcheries are expected to become increasingly important as tools to preserve biodiversity by maintaining rare, threatened, and endangered genotypes. Hatcheries are important educational tools and will most likely continue to be used to produce fish in support of innovative programs such as fishing in urban parks, shopping malls, and other nontraditional environments

as resource managers seek to broaden support for fishery programs, attract new anglers, and educate the public about aquatic resources and the increasing demand for those resources.

INTERNATIONAL DEFICITS IN FISH

In recent years, the import of fish and fishery products into the United States (US$9.4 billion in 1997) has been exceeded in value only by the import of petroleum products (US$49 billion in 1996). The value per unit weight of fish and fishery products has increased steadily since the 1950s, reflecting the growing demand in world markets. Recent records from the Food and Agricultural Organization (FAO) of the United Nations show that the volume of fish and fish products traded among 167 nations was about 14% greater than the volume produced, indicating multiple exchanges at the wholesale level before final sale to consumers.

The rapid expansion of the aquaculture industry to produce farm-raised catfish, salmon, shrimp, and other species has been driven by increased demands on finite stocks. The concentration of much of the world's population along seacoasts and inland waterways has resulted in loss of aquatic habitat, environmental degradation, and intense fishing pressure; together, these perturbations have decimated many wild stocks. Resource managers and aquaculturists are evaluating both the risks and benefits of using introduced, transgenic, polyploid, hybrid, and reproductively sterile aquatic organisms to provide the fish and fisheries products demanded by world markets for food and recreation. The greatest challenge in fisheries management may be to maintain genetic stocks of native fishes and still provide the recreational fishing opportunities and food fish production demanded by growing world markets.

Channel catfish (*Ictalurus punctatus*) and rainbow trout (*Oncorhynchus mykiss*), the most commonly cultured fishes, are defined as agriculture crops in some states — channel catfish in Mississippi, trout in Idaho, and all farm-raised aquatic organisms in Missouri. These farm-raised fish are not regulated by the state conservation and natural resources agencies. Other species, such as striped bass, red drum (*Sciaenops ocellatus*), and largemouth bass (*Micropterus salmoides*), are now attracting the interest of commercial producers (10) and may ultimately force changes in existing regulations. Will these changes harm or benefit anglers, commercial operators, consumers, and the nation's aquatic resources?

Demand for Game Fish Increases

According to a survey conducted by the U.S. Fish and Wildlife Service in 1996, 35 million anglers spent $72 billion in 620 million-angler days fishing (11). Sport fishing is projected to double by the year 2030. The fishing pressure on public waters is expected to increase much more rapidly than the ability of the resource to produce. Even today, some anglers have abandoned public waters to fish in more productive private waters. The public waters of Texas yield slightly less than one legal-size bass in 10

hours of fishing, whereas 30–40 bass can be taken from privately owned and managed lakes in only 3 or 4 hours. Land owners are willing to buy catchable-sized fish to be stocked into private ponds for recreational purposes. For example, a company in Bryan, Texas has sold 1 kg (2.2 lb) rainbow trout to landowners in Texas to stock for recreational fishing during the winter months, and warmwater species such as channel catfish demand a premium price when available in large size.

Other aquaculturists are producing hybrids of striped bass and white bass, Florida strain largemouth bass, and other warmwater species for food and recreation. In Danbury, Texas, some anglers have paid $900 per day for the opportunity to catch 3 kg (6.6 lb) trophy-sized bass in private waters, and other fishermen routinely pay $90 in the off-season and $165 per day in the peak season to catch 1 to 2 kg (2.2 to 4.4 lb) fish (12). Largemouth bass are reared in protected nursery ponds and then transferred into larger ponds for recreational use.

At a fish farm in Danbury, Texas, anglers may catch and release multiple fish, but keep only their largest one as a trophy. Various personal services, such as catering of meals and use of lodges and equipment, are included in the $300–900 daily charges, but fewer services are provided for the $90 per day charge. Are these practices the same as sport fishing in public waters? Are they indicative of future practices? Or are they just an innovative way to market an agricultural crop as a recreational event?

States require most anglers fishing in state waters to have a valid recreational fishing license. However, in some states, such as Alabama, Arkansas, and Missouri, anglers fishing in privately owned water for farm-raised fish are exempt from licensing requirements. Although private fishing establishments provide recreational opportunities, the catch of fish is frequently so high that it resembles a supermarket activity. In a single day, anglers have harvested more than 500 kg (1,100 lb) of channel catfish from a 0.1 ha (0.4 ac) pond in Longview, Texas. Do activities such as these relieve the fishing pressure on public waters? Aquaculturists believe that they do — at least, they provide recreational opportunities in excess of those available on public waters. To the extent that fishing in private waters removes fishermen from public waters, these programs work in concert with, not in conflict with, public programs.

Game Fish or Food Fish?

Natural resource managers have often been reluctant to allow the sale of farm-raised fish. The two major obstacles preventing the sale of the hybrids of striped bass (*M. saxatilis*) × white bass (*Morone chrysops*) were identified (13) as (*1*) the inability of enforcement agencies to distinguish farm-raised hybrids from wild-caught striped bass that are prohibited from sale in many states, and (*2*) laws prohibiting the sale of striped bass because it is a game fish. Producers of channel catfish and trout faced these same obstacles as they developed commercial markets for farm-raised fish. How were conflicts resolved? Today, both farm-raised catfish and trout can be legally sold in all states. Before 1960, when there were only 160 ha (400 ac) of commercial catfish ponds, there were

significant commercial fisheries for catfish in inland waters, such as the Tennessee and Mississippi Rivers. Today, after numerous incidences of environmental degradation, including release or spills of mercury, PCBs, chlorinated hydrocarbons, and other toxicants and contaminants, the public no longer associates quality and safety with wild-caught species, but more frequently with farm-raised products. In 1987, about 182,000 MT of farm-raised catfish and 23,000 MT of farm-raised trout were processed as food fish. Existing catfish processing plants had the capacity to process more than 227,000 MT/yr. Many other farm-raised fish were sold directly to consumers as food, while still others were sold for restocking as recreational fish. The development of the catfish and trout industries appears to have almost eliminated the importance of the commercial catch.

Fishing pressure on wild stocks of these inland species may continue until the last fish is caught, but the relative value of the wild fish as food fish will decline as farm production increases. The commercial production of Atlantic salmon has similarly expanded at a phenomenal rate in the 1980s and 1990s. About 50,000 MT of farm-raised Atlantic salmon were imported into the United States in 1987, whereas commercial landings from the Atlantic Ocean were only about 10,000 MT. Based principally on aquaculture production, the import of Atlantic salmon exceeded 55,000 MT in 1997. Foreign investors from Norway, Sweden, Iceland, and Japan have recently established several netpen fish farms to culture both Atlantic and Pacific salmonids in North America. Most of these farms have been placed in Canadian waters, primarily British Columbia, because regulations there are less restrictive than in the United States. Alaska fishermen recognize the threat of this foreign competition, and even though they would prefer to continue to fish for wild stocks, they recognize the potential profit of netpen culture and are ready to "jump on the band wagon and farm salmon" when state laws are modified to permit that activity.

Aquaculture Production

In 1996, aquaculturists produced about $41.5 billion worth (26.4 million MT) of farm-raised fish globally, and United States aquaculture accounted for $736 million (393,000 MT) of the world total (14). This production is based on the techniques pioneered by early culturists, as recorded in the 1897 *Manual of Fish Culture*. Today, of the 24,618 species of finfishes (15), only 179 species are cultured for food. Another 134 species are used for bait, and 19,800 species are used in the ornamental trade (15). However, we are learning to culture additional species, and one of the most valuable exports of United States science today is aquaculture technology. In 1989, a survey of 275 computer bases revealed that the terms "fish culture" or "aquaculture" occurred fewer than 2,000 times cumulative in the top seven databases (16). In 1998, an electronic search of one database, AGRICOLA, for the terms "aquaculture," "fish culture," and "fish hatchery" yielded 2,442 entries, while a search of the Excite® database for these same terms on the World Wide Web located 23,706 documents. Although today's fish culturists no longer hang dead carcasses above the raceways to feed fish with insect larvae, many of the techniques now available to aquaculturists and the training received by fish culturists in the United States can be traced back to the pioneering works of fish culturists and their practices as described in the *Manual of Fish Culture*. Today's fish culturists must be proficient in other subject areas not found in the 1897 manual, such as the use of fisheries chemicals, knowledge of genetics, use of computers, awareness of regulations, and, most importantly, the ability to work not in isolation but in view of an increasingly demanding public — customers, regulators, and anglers.

Demand for Food Increases

The demands for fish and fishery products in the United States are expected to expand faster than the supply of fish will expand. Imports of fish and fishery products into the United States were valued at $365 million in 1960, $7.6 billion in 1986, and $14.5 billion in 1997 when the imports consisted of $6.7 billion worth of nonedible products (animal feeds, industrial products, etc.) and $7.8 billion for edible fishery products. The annual per-capita consumption of fish increased over 20% from 1975 to 1986, when the per-capita rate reached 6.7 kg (14.7 lb); it is expected to be 13.6 kg (29.9 lb) by the year 2020. The world's catch of fish (millions of metric tons) was 27 in 1954, 57 in 1966, 74 in 1976, 83 in 1984, 90 in 1986, 101 in 1989, and has remained level or declined slightly since then. The catch has increased with the demand only because previously unused resources — those formerly classified as trash fish — are now being captured and processed into consumer-acceptable forms, such as imitation crab, lobster, shrimp, and scallops. The ocean's resources are recognized as finite, having an estimated maximum sustainable yield of about 100–120 million MT. The expansion of demand in a market with limited supply is expected to continue to drive prices up and make fish farming even more lucrative than it is today, when more than 25% of the global fish supply (fish and shellfish) is produced by aquaculture. Global aquaculture has increased from 7% of the total fish in 1950 to 29% by 1996. Aquaculture production of nonfood items has increased from 3 million MT in 1950 to 31 million MT in 1997. Since 1960, worldwide aquaculture has grown at an annual percentage rate of 10.9%.

Distinguishing Between Wild and Farm-Reared Fish

Aquaculturists, resource managers, and law enforcement personnel have tools and techniques today that were not available when many of the rules and regulations were written to protect aquatic resources. For example, few of the states' laws address hybrid fish. In some states (e.g., Maryland), hybrid striped bass were considered to be striped bass for purposes of regulation. In other states (e.g., New Jersey and Massachusetts), hybrids were not even mentioned in the regulations. Some states (e.g., Florida, Virginia, North Carolina, Georgia, and Mississippi) began to reexamine and modify their laws in 1987 to allow for possession and sale of farm-raised striped bass and hybrids (17).

The availability of reproductively sterile hybrids and triploid fish has promoted some states, in response to anglers, boaters, and owners of lakefront property, to reevaluate and modify their regulations for some species. For example, in 1978, grass carp (*Ctenopharyngodon idella*) had been in at least 35 states at one time or another, regardless of the species legal status. By 1987, however, 12 states had no restrictions on the species, 15 had specific policies for them, 4 permitted research with triploid forms, and the other 19 states technically prohibited all grass carp, even though some exceptions were made (18). Presumably sterile hybrids of grass carp × bighead carp (*Aristichthys nobilis*) were first legalized in some states, but preference shifted to the use of triploid grass carp. For grass carp, the impetus to modify state regulations came not only from the producers, but also from state fishery biologists seeking to use these herbivorous fishes for biological control of aquatic vegetation in public waters.

Producers of triploid grass carp use specialized medical equipment [a coulter counter device that is used in clinics and hospitals to count blood cells (about $20,000 each)] to verify that each fish certified as a triploid does indeed have three and not two (diploid) sets of chromosomes. The equipment and procedures for this test are expensive; the test cannot be performed in the field by law enforcement personnel. Nevertheless, the procedures and paper trails established seem to provide a workable solution acceptable to law enforcement personnel, resource managers, and aquaculturists.

The production of monosex (either all-male or all-female) populations is another tool available to aquaculturists and resource managers to limit reproduction of fish. A considerable amount of research has been conducted to develop monosex populations of tilapia to limit reproduction in culture ponds (19). Techniques used include the production of hybrids with highly skewed ratios of males and females and the production of an all-male population by feeding androgenic steroids to immature genetic females to induce sex reversal (20). Other techniques used to alter sex ratios include gynogenetic production of female fish by fertilizing eggs with sperm that has been irradiated with ultraviolet light to denature the genetic material, the DNA. Once development of the egg has been activated by the irradiated sperm, eggs are shocked by exposure to heat, cold or pressure to disrupt normal cell development and produce a diploid zygote with no genetic contribution from the male (21). Some of these resulting all-female fish can then be fed androgenic hormones to produce functional males (genetically female) and mated back with their siblings to produce a second generation of all-female fish (22).

When these techniques are further perfected, they will allow aquaculturists to produce not only monosex fish, but also fish with selected traits, such as rapid growth, disease resistance, and tolerance to high or low temperature. It is expected that desirable traits can be propagated in cultured species much more rapidly with these techniques than through the normal process of selective mating.

Similar techniques will almost assuredly be used to produce sterile exotic fish for recreational fishermen. If anglers will pay $300 to $900 per day for the opportunity to catch a trophy-sized largemouth bass weighing 3 to 4 kg (6.6–8.8 lb), what would they pay to catch a 50 kg (110 lb) freshwater fish? Several exotic species, including Nile perch (*Lates niloticus*), reach or surpass this size. How long will it be before reproductively sterile exotic fish are available in private waters to anglers? Once trophy-sized sterile exotics are available, will there be a demand for put-grow-and-take fisheries in public waters? Will sterile classification reduce the threat to native stocks enough to make these fish acceptable? If grass carp can be used as an example, it is reasonable to expect to see other sterile exotics produced by fish farmers and in-state hatcheries stocked by resource managers for sport fishermen.

Law Enforcement

In several states, laws have been modified or regulations developed to allow the possession, culture, and sale of farm-raised fish as food fish, bait, or for restocking. In other states, regulations prohibit the sale of all game fish as food fish, but do not limit the possession, culture, and sale of fish for restocking. Laws designed to protect game fish appear to be one of the major restraints limiting expansion of aquaculture in many states and the expansion of culture of species other than catfish and trout. Law enforcement personnel are probably not unwilling to distinguish between wild-caught and farm-raised fish, but cannot do so within their existing budgets and with field techniques now available to them. Prohibition on sale of game fish as food fish creates an illegal market somewhat similar to that for alcohol during the era when all sales of alcoholic beverages were illegal in the United States. The increasing demand for fish and fishery products is expected to stimulate the illegal market. However, farm-raised fish could fill the market and reduce poaching of wild stocks. Poaching pressure would decline only when economic incentives were lowered to make it unattractive; some enforcement personnel do not expect the aquaculture production of highly desirable fish, such as hybrid striped bass, ever to be abundant enough to meet the market demand. Some enforcement personnel further believe that protecting wild stocks of fish from poaching in the presence of legal sales of farm-raised fish creates enforcement problems that could be even greater than the enforcement problems resulting from alcohol sales during prohibition.

Tools that law enforcement personnel could use to distinguish between wild and cultured fish are now being used in other areas of law enforcement. Forensic scientists are developing techniques (i.e., capillary zone electrophoresis-mass spectrometry, CZE-MS) that will sample volumes one-billionth of a liter in size to detect and analyze compounds at concentrations one-thousandth of that possible with existing techniques. The analyses of fragmented DNA molecules yields genetic fingerprints that have been used to provide positive identification of individuals when the only evidence at the scene of a crime was a small sample of dried blood, semen, or other tissue. The evolution of modern molecular genetic techniques and associated technical terms such as DNA probes, plasmids, recombinant DNA, transgenics, ploidy manipulation, and sex reversal, may seem foreign and confusing to many biologists, and even more so to the layperson. However,

special applications of molecular genetic techniques in the field of fishery science include production of monosex populations, polyploid fish, and use of DNA probes to identify or classify unknown tissue samples and biopsies by species, sex, geographic origin, or specific genotypic traits. The technique of electrophoresis with isoletric focusing has been used to determine species of raw muscle tissue to distinguish between trout and salmon and to identify the four species of *Morone* and their congeneric hybrids.

The equipment for electrophoresis and other analytical assay techniques is commonly available in most universities and even in some fish hatcheries. Other techniques to distinguish between wild and cultured fish include analysis of daily growth rings on scales or otoliths, scale-shape analysis, elemental composition of scales and bone, lipid profile analysis, detection of such tracer compounds as tetracycline and calacine in farm-raised fish, and morphometric differences. Some of these techniques have been used to distinguish striped bass taken from freshwater from those taken from saltwater and between Chesapeake Bay and Hudson River stocks. These and other sophisticated techniques are routinely used in forensic laboratories (23), but may require more laboratory support than current fish and wildlife enforcement budgets provide unless priorities are altered. These techniques, in conjunction with paper trails to document source and movement of farm-raised fish, are tools that are now available to enforcement personnel. It is expected that, if there is a real market for field test kits that would allow enforcement personnel to distinguish between farm-reared and wild fish, such products will be developed. Law enforcement personnel now use a field kit that detects lead, to distinguish between game taken with a bow and arrow and that taken by gunshot. Similar field tests may be developed to detect trace elements in farm-raised fish. For several years, kits have been available that enable diabetics to monitor their blood sugar and for women to test for pregnancy. Pharmaceutical firms are attempting to develop a simple and rapid test to detect the virus responsible for AIDS—the fatal autoimmune deficiency syndrome. Similar on-the-spot tests used in the medical field can very likely be adapted to detect chemical and biochemical differences in cultured and wild fish. It is even conceivable that, through bioengineering, future cultured fish may have hidden marks that become visible or undergo a color change when exposed to ultraviolet light or some other activator. A blue microbe has been developed (and patented) that will degrade PCBs; the blue color allows the organism to be easily traced in the environment and distinguished from other wild-type bacteria.

Techniques available to law enforcement personnel today include the use of various markers and tags to identify fish and trace them through the market system. For example, fish have been marked with tetracycline (which fluoresces under ultraviolet light), fluorescent pigments, and color-coded plastic chips (Microtaggants) (24). Some law enforcement personnel have used these materials to mark fish in illegal nets and then to trace them through the market system. In at least one case, passive inductive transponders (PIT) tags were used to identify fish stolen from a U.S. Fish and Wildlife Service (USFWS) laboratory in Marion, Alabama. The PIT tag is a small glass-encased electronic device that can be implanted, with the aid of a special syringe, in fish or other animals. The PIT tag derives power from an external transmitter to drive an internal transmitter and broadcast a unique 12-digit hexadecimal number detected and displayed on a monitor. Another type of small internal tag, the coded-wire tag, was used to mark about 1.2 million hatchery-reared striped bass that were released into Chesapeake Bay from 1985 through 1987, and it has also been used to mark hundreds of millions of salmonids along the Pacific Northwest coast of the United States and throughout the world. Similar techniques might be used by management biologists to access stocks in inland reservoirs. Law enforcement personnel could then use these tags to identify fish taken from state waters.

In August 1987, at a conference on aquaculture in South Carolina, law enforcement personnel proposed a resolution that all states establish a 12-digit numbering system to individually identify all hybrid striped bass produced on farms for the food fish market. Under the proposal, each fish would bear a unique tag. This proposal failed to gain support of the aquaculture industry and strengthened the resolve of aquaculturists that aquaculture is agriculture. Pressure by aquaculturists increased to have hybrid striped bass classified as farm products not controlled by natural resource managers.

How will aquaculturists and resource managers deal with other cultured species—red drum, orangemouth corvina (*Cynoscion xanthulus*), Florida pompano (*Tranchinotus carolinas*)—and the numerous hybrid crosses that will surely be made? It seems reasonable that cultured fish will become much more important in the American economy. The culture of Florida pompano was of interest a few years ago, but never developed into an economically viable commercial industry. The Florida pompano fishery is now almost nonexistent due to overharvest. Florida pompano have reportedly retailed for $26/kg ($11.82/lb), when particularly scarce, and in 1987, commonly sold for $11/kg ($5/lb) [up from $4.40/kg ($2/lb) in 1974]. Even though earlier attempts to produce Florida pompano on farms failed financially and they are not farm products today, it seems very likely that production will become economically feasible as the demand increases.

Common Goals

Natural resource managers and aquaculturists share important common goals: They continue to evaluate the condition of our aquatic resources and the supply and demand for those resources. For example, trout, catfish, salmon, beef steaks, pork loins, and chicken are not individually numbered as a condition of marketing. Food fish and shellfish, unless specifically identified as an injurious species, may be imported into the United States and are not required to be numbered individually or even federally inspected. Boxes must be clearly labeled to identify contents, shipper, and consignee. So why, the aquaculturists ask, should trade in American-produced farm products be restricted by the cumbersome process of individually tagging selected farm-reared aquatic

species? Although some aquaculturists have attempted to identify all farm-raised crops as agriculture, they recognize the potential impact of cultured fish on wild stocks and work with resource managers to reduce the chances for damage. Until domesticated brood stocks are developed, aquaculturists must depend on wild stocks and work closely with natural resource managers to protect those stocks from overexploitation and genetic alteration. Maintaining high quality in the aquatic environment is of prime importance to both aquaculturists and fisheries managers.

As demand for aquatic resources increases with the continual growth of the world's population, strict preservationists and potential exploiters must both alter their positions and agree to some changes. The combined demands of recreational and commercial fishers exceed the supply of fish on a worldwide basis. Either catches must become severely limited as demand increases, or aquaculture must expand to fill the void. Projections have been made that, within the next 50 years, aquaculture products will equal or surpass the wild production of fish (25). Some sport fishermen in Texas, and other states, have already recognized the value of aquaculture to their interests and have helped to fund and establish hatcheries to culture red drum and other species to be stocked in coastal and inland waters. It appears that aquaculture holds tremendous potential for recreational anglers, consumers, and producers, and it could become an even stronger tool for natural resource managers.

STRIPED BASS RESTORATION ALONG THE ATLANTIC COAST

An example of the role of aquaculture in fisheries management is found in the story of striped bass along the Atlantic Coast. Stocks of adult striped bass (*M. saxatilis*) were extremely low from 1980 to 1987 along the Atlantic seaboard, especially in Chesapeake Bay. In an effort to rebuild those stocks, the Atlantic States Marine Fisheries Commission (ASMFC) developed a coastwide management plan for anadromous striped bass. The plan included a stocking and evaluation program developed by a technical advisory committee composed of representatives from all coastal states from Maine to North Carolina, the U.S. Fish and Wildlife Service (USFWS), and the National Marine Fisheries Service. The committee prepared a report that provided guidance for restoration programs for striped bass along the Atlantic coast. In 1985, the USFWS, Maryland Department of Natural Resources (MDNR), and the state of Virginia entered into a cooperative agreement to develop a striped bass stocking program in Chesapeake Bay. The USFWS assigned a coordinator to assist the coastal states in implementing this program. By January 1988, 1.35 million striped bass, reared in hatcheries and tagged with binary-coded wire tags, of which 23,250 were also marked with internal anchor tags, were stocked back into Chesapeake Bay. Tags from that program and others along the Atlantic coast were collected by personnel of the coastal states and returned to evaluate the effectiveness of the program.

Several factors that may have contributed to the decline in abundance of striped bass in Chesapeake Bay were reviewed in recent studies, summarized in the Emergency Striped Bass Research Study Reports of USDI and USDC (26,27). Because of the potentially synergistic and masking effects of interacting causes, no single reason for the decline was identified.

Suggested causes of the decline included contaminants, predation and competition, availability of acceptable and nutritionally adequate prey for younger fish, water-use practices, disease, natural climatic or random environmental events, and overexploitation. Of these factors, contaminants, prey availability, nutrient overenrichment, and water-use practices were important in localized situations, on either a temporary or sustained basis. However, two primary factors appeared to exert significant control over striped bass populations: (*1*) A large component of random environmental or abiotic events that influenced, either positively or negatively, the survival of eggs to the juvenile stage, and (*2*) overexploitation or excessive fishing mortality, which reduced survival from the juvenile to the spawning adult stage.

Because of the limited stock of adult striped bass (28) and extensive reproductive failure within Chesapeake Bay (29), USFWS and MDNR signed a cooperative agreement in 1985. That agreement was to implement an experimental program to evaluate hatchery-reared striped bass in Chesapeake Bay. In 1986, the state of Virginia and USFWS also signed a cooperative agreement, the goal of which was to investigate the feasibility of using artificial propagation to supplement the spawning stocks of striped bass in Maryland and Virginia. The program was considered a pilot program and not a full restoration program based on stocking hatchery-reared fish. Under cooperative agreements, USFWS committed six federal hatcheries to the production of striped bass 15- to 20-cm (6–8 in.) long, commonly known as phase II fish, to be reared from fry provided by MDNR and Virginia.

The intent of these efforts was to maintain the viability of the resource by artificial means, (i.e., by stocking hatchery-reared fish) until the quality of the habitat improved, the fishery was brought under coordinated control, and natural reproduction and recruitment were restored.

Biologists and managers voiced concerns about the potential effects of Atlantic coast striped bass restoration actions on native stocks. A committee, working under direction of the ASMFC, was formed to represent the states bordering the migratory range of striped bass along the Atlantic coast, from Maine to North Carolina. Seven charges were assigned the committee (30).

The first charge was to develop an inspection system to ensure that no pathogens were present on eggs or larvae shipped into other states and then returned to Maryland to be stocked in Chesapeake Bay. The committee's second charge was to review tagging programs for striped bass and recommend a coordinated tagging system for all stocked fish. The third charge was to develop procedures to evaluate the stocking restoration program to determine its effectiveness and when it should be terminated. In charges four and five, the committee was to assess the

threat posed by stocking programs to the genetic integrity of native striped bass along the Atlantic coast, and to make recommendations regarding time, size, and strain of fish to be stocked. The sixth charge was to review stocking programs in each Atlantic state to ensure they did not conflict. The final charge was to determine if hatchery reared fish stocked along the Atlantic coast would mature, return to the areas where stocked, and spawn.

Actions to Control Disease

Because infectious diseases may cause mortality under certain conditions found in a hatchery or a large-scale tagging center, it was extremely important to have all stocks of striped bass sampled for pathogens before a tagging program was started. Obviously, neither aquaculturists nor fisheries managers wanted to release infected juvenile striped bass into the natural environment where they could pass diseases to uninfected wild fish. Subsequent undetected releases of large numbers of infected fish would also bias tag returns for that particular cohort. An undetected kill of a large percentage of pathogen-positive fish could result in a critical bias if known numbers of tagged striped bass were used in extensive mark-recapture experiments.

Reduced Effort Effect. Because of the Maryland moratorium of taking striped bass in Chesapeake Bay, and because of greatly reduced commercial and sport harvests along the Atlantic coast, more help was needed from state and federal agencies to sample the wild stock of coastal migratory striped bass. The temporary loss of samples, formerly supplied by fishermen, required public agencies to develop a large-scale assessment program to evaluate the status of the striped bass population. Therefore, more time, energy, and money were spent by state and federal agencies to obtain fishery-independent data on the coastal migratory stock. Excellent interagency cooperation and use of one state's field-sampling program to obtain data to meet another agency's needs became the normal operational procedure. Through 1987, all adult striped bass used in the restoration program were screened for the infectious pancreatic necrosis (IPN) virus. Gamete samples were obtained by biologists during manual spawning, and fry samples were collected and analyzed where natural spawning had occurred and gamete samples were not readily available. No positive IPN samples were identified, and only fish free of the IPN pathogen were stocked.

A Tagging Program

The traditional method of marking, by clipping adipose fins, in salmonids that carry binary-coded wire tags does not work with striped bass, which lack an adipose fin and quickly regenerate other fin clips. Instead, biologists must sample or subsample large numbers of fish to obtain tag returns. Portable detection units must be used by field crews to document the presence or absence of tags in fish.

Because portable tag detectors are capable of detecting minute disturbances in a magnetic field, they are difficult to use in rolling seas, in the presence of large metal booms and winches, and on board vessels where the vibrating diesel engines produce positive readings. Thus, with certain vessels used in fishery research along the Atlantic seaboard, biologists were not able to use existing portable tag detectors. Because the problem was unique to striped bass being tagged with binary-coded wire tags, biologists worked closely with the manufacturer of the equipment to document problems encountered in field sampling. The subsequent generation of portable detectors for coded wire tags contained a shielding mechanism to prevent interference from vibration and movement. Also, the new design enabled field crews to quickly sample large numbers of striped bass, whether they were captured commercially or during the biological sampling program.

All striped bass released in 1986–1988 were marked with binary-coded wire tags, a method (31) that allows identification of thousands of different groups. A tagging center was developed to tag fish returning to Maryland from various hatcheries along the Atlantic coast. Large circular holding tanks (2.1 m × 0.9 m) supplied with 10 ppt saltwater and an extensive recirculating, liquid-oxygen injection system [10–15 mg/L (ppm)] were used to hold fish for as long as 12 hours before tagging. Coded wire tags were placed in the adductor mandibularis muscle (a muscle below the eye) of phase II striped bass (32).

For the tagging operation, a specially modified trailer (12 m × 2.5 m) was used that held six coded wire tagging machines and quality control units, as well as large temporary holding tanks for anesthetizing fish. Large tanks outside of the trailer were used to hold fish for post-tagging recovery from the anesthetic. Tagging equipment was used to inject a binary-coded wire tag 1.07 mm long and 0.254 mm in diameter into each fish through a 24-gauge hypodermic needle. Fish were aligned visually to the hypodermic needle, without the aid of a guiding head mold, and impaled manually on the injector needle; the tag was then injected through the hypodermic needle into the adductor muscle. The tagging machine was adjusted so that the needle was extended and stationary at the start of each cycle. Tags were magnetized in the needle before the machine was cycled. Up to 25,000 fish (over 4,000 per machine) were tagged daily with binary-coded wire tags, of which 500 also were marked with internal anchor tags. The typical tagging crew consisted of 12 members: six to operate the six machines, three to handle fish for the machine operators, two to insert the internal anchor tags, and one to maintain the records. Tagging mortality was less than 1% when water temperature was less than 15 °C. Fish were held in highly oxygenated salt water, and 1 mg/L (ppm) of tricaine methanesulfonate was used as an anesthetic during the tagging. Tags were placed only in the left adductor mandibularis muscle to ensure proper tag placement and to localize the area to be searched for coded wire tags during coastal sampling programs. All binary-coded wire tags showed agency code, year stocked, hatchery producing the fish, and stocking location. Short-term tag retention of coded wire tags averaged about 96%. X-rays showed that the coded wire tag was almost immediately encapsulated within the adductor muscle mass, thus the potential for tag loss was low. Apparently the few tags lost during this procedure worked loose within 24 hours of injection.

Subsamples were marked with an internal anchor tag (a 5-mm × 20-mm toggle attached to a 75-mm streamer) inserted just posterior to the left pectoral fin, while it was compressed to the body. A scale was removed at the point of tag insertion, and a vertical incision about 5 mm long was made with a curved scalpel blade, through the peritoneum, but not deep enough to damage internal organs. The anchor of the tag was inserted through the incision and set in place with a gentle pull on the streamer. All streamers were treated with an algicide. Anchor tags were used to obtain additional information on coded wire tag retention in the wild, exploitation rates, movement, and growth. They also served as indicators of movement of fish marked with binary-coded wire tags outside the sampling areas.

Numerous surveys were conducted coastwide to obtain tag returns for program evaluation. Survey techniques included coordinated sampling by state, private, and federal agencies. Sampling in Chesapeake Bay was conducted with beach seines, gill nets, trawls, and by electrofishing. All fish within the possible size-range of stocked tagged fish were checked for the presence of tags. At this point in the cooperative restoration program, fish that tested positive for binary-coded wire tags were not sacrificed to obtain additional data.

Along the Atlantic seaboard, additional surveys and adult striped bass tagging programs were established. All striped bass four years old or less when captured were surveyed for binary-coded wire tags as part of a coordinated coastal effort to obtain information on movements, migration, and exploitation of hatchery-reared and tagged fish.

Maintenance of Genetic Integrity

All hatchery striped bass involved in this large-scale tagging program were identified through the hatchery phase by lot numbers and parental rivers of origin. All fish were tagged and released only into their natal rivers. Techniques used to ensure this arrangement included careful record keeping, coordination of assigned binary-coded wire tag codes with the tag manufacturer to ensure correct stocking location designation, use of a central tagging location, and coordination to help ensure that the correct tagging codes were used each day.

Size, Source, and Time of Stocking

In the Chesapeake Bay striped bass restoration program, all stocking was with tagged phase II (15−20 cm TL) striped bass, except for an experimental stocking in June−July 1987, of phase I (35−50 mm long) fish performed to test marking methods and tag retention. In phase I striped bass, tag placement in the adductor muscle was perpendicular to the body axis. Tagging machines were used with the tag injection needle in the stationary mode. Standard length (1 mm) binary-coded wire tags were used. About 15,800 phase I fish were tagged and released into the Patuxent River, Maryland. Posttagging, overnight mortality rates averaged 1% during two test periods. In a control group of 3,000 phase I fish, tag retention was 97% after 6 months.

State Programs Are Nonconflicting

Each year, coastal states engaged in stocking and tagging of Atlantic coast striped bass held a review meeting. This enabled the subcommittee to verify compliance with stocking and tagging guide lines.

Recommendations for an Evaluation Program

All coded wire and internal anchor tag returns have been coordinated for the cooperative tagging program by the USFWS. Most internal anchor tag returns were obtained by collect phone calls to the USFWS, Annapolis, Maryland. Each caller was asked by trained personnel to answer a standard questionnaire over the phone. A central depository and database organizational protocol was developed.

Application to Other Programs

The pilot restoration program for striped bass operated smoothly. Its operational success was attributed largely to the decision-making process and cooperative efforts of all Atlantic coast states, the federal agencies involved, and the private sector. Both fisheries managers (state and federal) and aquaculturists (hatchery managers, fish culturists) jointly developed and modified the program to accommodate special needs or address specific problems. The success of the program was greatly increased by the willingness of the states and federal agencies to collect and share data, to collect and spawn brood fish, and to provide fry to be reared in federal and private hatcheries.

Public support and involvement in the program was encouraged and maintained through a series of educational activities, including news releases, press conferences, videotapes, and conspicuous involvement of high-level public officials at ceremonial releases of striped bass in the Chesapeake Bay or other coastal waters. The reward system established for return of the external portion of the internal anchor tag was increased awareness and public support for the program. Establishment of a central processing point for all tags increased chances for success of the program by reducing the confusion and duplication associated with multiple tag-return sites.

CONCLUSION

It should be obvious that not all fish culturists hold the same views regarding the value of hatchery or farm-raised fish for stocking in public waters or the role of hatcheries in striped bass or wild trout programs. However, given the opportunity, almost all culturists would like to produce fish of a quality equal to that of wild fish (some apparently now believe that they do so). Major obstacles recognized by most respondents in the survey of hatchery managers producing trout for stocking were inadequate budgets, excessively high production quotas, and compliance with established procedures for control of selected fish diseases. Hatcheries were seen as an aid to manage and maintain populations of wild trout as they have been for striped bass and other species. Culturists recognized the importance of proper habitat to maintain healthy populations of wild

trout and other aquatic species. They also recognized that the growth of the human population and the increasing demands of anglers cannot be met by wild fish alone. There is a recognized need for put-and-take fisheries in urban environments and the need to use hatchery-reared fish to restore stocks in areas where habitat has been degraded.

As beauty is in the eye of the beholder, so may wild fish be in the eye of the angler, culturist, or manager. No fish culturist wants to produce fish without fins or those described as "swimming sausages with scales." However, they do want to use hatcheries as appropriate to support programs for restoration of wild trout, striped bass, and other species, and to provide angling opportunities for those unable to fish in pristine waters for wild trout.

Bibliography

Japanese flounder, *Paralichthys olivaceus*, belonging to the family Paralichthyidae, can be found throughout Japanese waters, with the exception of the Pacific coast of Hokkaido (1) (Fig. 1). This fish is one of the most familiar species to the Japanese and is traded at high prices. Therefore, Japanese flounder is one of the most important target species for stock enhancement and aquaculture in Japan. Flounder culture is a relative newcomer to aquaculture, but has already established a third position ranking in marine finfish culture, with production exceeding landings since 1990 (2) (Fig. 2).

BIOLOGICAL CHARACTERISTICS OF JAPANESE FLOUNDER

Japanese flounder can be found from the coasts of Sakhalin and Kuril in Russia to the Yellow Sea and the East China Sea of China (1), and Japan's natural resources may consist of several regional populations (3). Especially dense populations exist along the coast of the Sea of Japan affected by Tsushima current, the north Pacific coast of Honshu, and the Seto Inland Sea. Fishermen catch flounders by hook and line, gill-net, trawl, and fixed nets. Annual landings fluctuate between 5,500 and 8,300 tons (Fig. 2).

Because of the wide distribution, there is a large variation in growth and maturation (3). Wild fish grow to 15–30 cm (5.9–11.8 in.) and 50–76 cm (19.7–27.6 in.) total length (TL) within one year and five years, respectively (2), and females show significantly better growth performance than males (3). Flounder spawn in coastal waters shallower than 50 m (160 ft) depth at 12–17 °C (54–63 °F) (3). The spawning season starts in late winter in the southern waters, and finishes in early summer in the northern waters, as temperature increases (3). During a spawning season, males greater than 30 cm (12 in.) and females greater than 40 cm (16 in.) spawn repeatedly (3).

Fertilized eggs [0.9 mm (0.035 in.) in diameter] are buoyant and nonadhesive. The larvae are planktonic and have bilaterally symmetrical body forms for about one month after hatching. During the latter part of the larval stage, larvae start to form asymmetric bodies and shift to a benthic life through a remarkable metamorphosis, in which the right eye migrates to the opposite side of the head (4). The juveniles inhabit sandy shallow waters and feed mainly on mysid shrimp (3,5). When juveniles grow to 5–10 cm (2–4 in.) TL, their feeding preference shifts to piscivorous (3,5). They grow to adulthood in the coastal waters, and then some migrate to the southwest to spawn.

HISTORY AND OUTLINE OF FLOUNDER CULTURE

First in production among maricultured fishes in Japan is yellowtail, *Seriola quinqueradiata*, and second is red sea bream, *Pagrus major*. Thereafter come Japanese flounder, tiger puffer, *Takifugu rubripes*, and striped jack, *Pseudocaranx dentex* (Fig. 3). Japanese flounder culture began on the assumption that juveniles could be produced in hatcheries. The first successful flounder fry production was by Kinki University in 1965 (6). That success opened a new window for aquaculture, and the technology for mass fingerling production was established during the 1980s. From 1980, cultured flounder production in Japan expanded very quickly (Fig. 2) and appeared in the fisheries statistics in 1983 for the first time (7). Since 1990, cultured production numbers have exceeded those of wild fishlandings, and the production by aquaculture was 7,292 tons in 1994. The marketable size of cultured flounder is 500 g–1 kg (1.1–2.2 lb). Flounder culture started both in land-based tanks and net cages, but net cage culture nearly disappeared within 2 to 3 years because of the inability to avoid high temperatures during the summer season and a relatively low selling price. Therefore, most flounder are now produced in land-based tanks (Fig. 4). Flounder grow at an optimum temperature range of 10 to 25 °C (50–77 °F), and shows highest growth at around 21 °C (70 °F). High mortality is observed at temperatures higher

Figure 4. Land-based tank culture of Japanese flounder in Mie prefecture.

than 25 °C (77 °F) during the summer season, but the fish can withstand low temperatures during the winter.

Japanese flounder culture is based mainly in the western part of Japan. Five prefectures, Ehime (28.2%), Kagoshima (13.7%), Nagasaki (9.9%), Oita (14.1%) and Mie (8.7%) produced about 75% of the total production in 1994 (Fig. 1) (2). Japanese flounder has the following advantages for aquaculture: (1) ease of obtaining fingerlings supported by an established hatchery system, (2) high efficiency of feed utilization and good growth, (3) high market price, and (4) no requirement for fishery rights because of the land-based tank culture (8). When cultured flounder first appeared in the statistics, their selling price was higher than that of the wild fish for two reasons: (1) cultured fish were sold as live fish with uniform sizes, and (2) wild fish of various sizes were not always sold alive (Fig. 2). Later, as flounder culture increased, the selling price became stable and similar to that of the wild fish. In 1989, the price of wild fish surpassed that of cultured fish and then both prices dropped. The price of cultured fish dropped more quickly, to about half that of wild fish. These price changes were attributed to the following reasons: (1) shift of wild flounder from fresh to live fish, (2) overproduction of cultured fish, and (3) deterioration of economic conditions in Japan.

PRESENT STATE OF FLOUNDER CULTURE

Fry Production

Egg Taking and Hatching. Fertilized eggs are collected from natural spawning by brood stock raised in captivity (9,10). Tank-spawned eggs are usually of higher quality than stripped and artificially fertilized eggs. Maturation is typically controlled by photoperiod and temperature so that fertilized eggs can be obtained nearly year round (11). After the elimination of dead eggs, fertilized eggs are incubated in nets or polycarbonate tanks. Clean seawater and gentle aeration are supplied to the incubated eggs. Water temperature is maintained at 15 °C (59 °F) to achieve better hatching rates and lower rates of deformity (12). Usually, rearing tanks are stocked with eggs just before hatching, or recently hatched larvae.

Larval Rearing. Stocking densities of newly hatched larvae are adjusted to $15-20 \times 10^3$ ind./m^3 and $30-50 \times 10^3$ ind./m^3 in large ($20-100$ m^3) and small rearing tanks ($1-10$ m^3), respectively (14). When high-density culture is begun in small tanks, restocking to several tanks or transfer to the larger tanks is necessary to reduce stocking density as larvae grow. Rearing temperature should be maintained at $18-20$ °C ($64-68$ °F) during this period. Newly hatched larvae develop by themselves, with their own yolks and oil globules, for 2 to 3 days after hatching. At 7 to 9 days after hatching [7.0 mm (0.28 in.) TL], the anterior three dorsal fin rays start to elongate (15). At about 20 days after hatching [larger than 10.0 mm (0.4 in.) TL], larvae begin to metamorphose with right eye migration. At 25 to 30 days after hatching, larvae start to settle as the climax of metamorphosis is reached. At 30 to 35 days after hatching, larvae transform to juveniles.

An extremely simple feeding regime is established, beginning with rotifers (3 to 20 days after hatching), brine shrimp (10 to 35 days after hatching), and then artificial diets (20 to 35 days after hatching) as fish grow (13). The survival rate from hatching to juvenile in mass production is sometimes higher than 90% in large tanks (13). Albinism had been frequently observed, with an extremely high percentage of occurrence (50–80%), but now has been nearly overcome with the improvement of larval diets (14).

Juvenile Rearing. Juveniles are raised on artificial diets in land-based tanks, or net cages installed in land-based tanks, until reaching 3–5 cm (1.2–2.0 in.) TL. In case of excess stocking density or a deficiency of feed, inferior juveniles with darker pigmentation are forced to swim near the surface, and mortality increases as a result of biting or cannibalism by larger fish. During this phase, it is important to maintain a reasonable stocking density, feed sufficiently, and grade fish by size, to avoid cannibalism. Most of the juveniles used in culture are provided by private hatcheries. The selling prize per individual is 100–150 yen (US$0.83–1.25).

Diseases During Fingerling Production. Diseases contracted during fingerling production can sometimes become very serious, because of the difficulties in detecting

the reasons for mortality and in providing proper treatments. Recently, disease problems during this phase have become more prevalent, due to the frequent outbreaks of viral diseases. The most common diseases are vibriosis (caused by *Vibrio anguillarum*), bacterial enteritis (*Vibrio ichthyoenteri*), epidermal hyperplasia (flounder herpes virus), and nervous necrosis (striped jack nervous necrosis virus) (15).

Culture to Marketable Size

Fingerlings are raised to marketable size in land-based tanks and shipped as live fish. Advantages of land-based tank culture are as follows: (*1*) easy observation and better care, (*2*) agreement with the flounder's settling behavior, (*3*) easy environmental control, and (*4*) easy entry into the industry by investors and culturists who do not have fishery rights. Disadvantages of land-based tank culture include (*1*) the high costs of facilities, (e.g., tanks and pumps), (*2*) the high operating costs for electricity, (*3*) the possibility of extermination of a crop by accident, and (*4*) the necessity to renew facilities every several years because of fouling organisms and corrosion by sea water (16).

Selection of Sea Water and Site. The seawater and site for flounder culture should be considered from both biological and economic aspects. Seawater should satisfy a number of conditions: (*1*) the temperature should be within the optimum range as long as possible, (*2*) dissolved oxygen should be at a high enough level, (*3*) there should be no risk of extreme decreases in salinity by inflowing rivers, and (*4*) there should be no effects from red tide or pollutants. Offshore bottom water or saline well water fit these criteria. However, saline well water usually needs additional aeration because of low dissolved-oxygen levels. A suitable site for flounder culture should satisfy the following demands: (*1*) low land cost, (*2*) good access to the shore line, (*3*) small change in elevation from sea level, to save electricity for pumping, (*4*) easy access to market and supply outlets, and (*5*) protection from natural disasters (16).

Facilities. The minimum facilities requirements for land-based tank culture include a pump system, plumbing for water supply and drainage, aeration, and tanks. Tank size ranges from $4-10 \text{ m}^2$ $(40-100 \text{ ft}^2)$ for juveniles to $30-100 \text{ m}^2$ $(320-1080 \text{ ft}^2)$ for growout populations. Because Japanese flounders sometime jump when they are frightened, the rim of the tank should be $30-50 \text{ cm}$ (12–20 in.) above the water surface [$50-100 \text{ cm}$ (20–40 in.)]. The bottom of the tank slopes downward to the center to drain uneaten feed and feces. Tanks need roofs to shade them from direct sunlight to prevent algae growth and over heating and to keep fish calm.

Stocking Density. A rough standard for stocking density is $5-15 \text{ kg/m}^2$ $(120-340 \text{ lb/ft}^2)$, within optimum temperature ranges and at a flow rate of $10-12$ exchanges/day (16). Overstocking decreases growth and feed efficiency and increases the possibility of disease outbreaks. A commercial farmer in the Mie prefecture established the stocking standard in relation to fish size shown in Table 1.

Table 1. Standard Stocking Density in Land-Based Tanks

Total Length (mm)	Body Weight (g)	Stocking Density ind./m^2	Stocking Density kg/m^2
5	1.5	800	1.2
10	10	200	2
15	60	95	5.7
20	85	50	4.3
25	140	35	4.9
30	320	22	7
35	460	17	7.8
40	800	13	10.4

Feeding and Growth. Prepared diets are popularly used for both juveniles and larger fish. Dry pellets typically contain protein (48–56%), lipids (6–14%), and ash (<17%). The size of the feed pellets should be as large as the fish can swallow. Frequency of feeding is 3 to 4 times per day during the juvenile stage and decreases to 1 to 2 times per day as the fish grow. Feeding rates should be adjusted to 6–10% of body weight at juvenile stage, 0.4–2.2% at 20 cm (8 in.), 0.3–1.8% at larger than 30 cm (12 in.), and less than 0.2% in the winter at $12-13\,°C$ (54–55 °F). Fish stop feeding at temperatures higher than $27-28\,°C$ (81–82 °F). Flounder culture in Japan is widely distributed across western Japan, so growth is different from place to place because of the timing of fingerling introduction, seasonal changes in water temperature, culturing procedures, and environmental conditions. Several examples of growth in land-based tanks are shown in Figure 5 (17).

Disease. Common bacterial diseases contracted during culture are vibriosis, *V. anguillarum*, gliding bacterial disease, *Flexibacter maritimus*, and edwardsiellosis, *Edwardsiella tarda* (Fig. 6). White spot disease, *Cryptocaryon irritans*, and ichthyobodosis, *Ichthyobodo* sp., are typical examples of protozoan diseases. These diseases frequently occur during the summer season because disease resistance is lower and the culture conditions deteriorate at high temperatures (16).

Stamp smear of liver (**b**). Arrow shows the colony of *E. tarda* [major axis is about 2 μm (8×10^{-5} in.)]. (Photographs were provided by Ehime Prefectural Fish Disease Control Center.)

Shipping and Economic Analyses

The scale of culture ranges from several thousands to tens of thousands of fish per farm. The largest farm, in Mie prefecture, cultures 550,000 fish and employs 50 laborers (Fig. 4). Most farmers sell one-year-old fish until September for the following reasons: (*1*) during the summer season, water temperature will begin to exceed the upper part of the optimum range [25 °C (77 °F)], (*2*) cultured fish can attain marketable size within one year, (*3*) the amount of fish caught in landings becomes extremely small during the summer season, and (*4*) quick rotation of tanks increases economical effectiveness for the fish farmer.

All cultured fish are distributed to consumers as live fish. Fish are shipped to markets in big cities or are bought by brokers from fish farmers and sold directly to restaurants.

In the case of land-based tank culture, the cost for facilities and the cost of electricity make up 15–20% of annual expenses. The selling price and survival rate greatly affect the economic balance, so the early introduction of fingerlings for better growth and better survival until shipping should be considered more carefully. The potential for increasing the selling price of cultured flounder, by controlling the timing and destination of the product, should also be given more attention.

NEW TECHNOLOGY

All Female Production

As females of this species grow much faster than males (3), production of all-female fingerlings for culture has been developed (17). In this species, the phenotypic expression of sex is determined by environmental factors, namely, temperature and feed (fresh fish or artificial diets) during the juvenile stage, together with genetic information (18,19). Recently, the successful production of all-female fingerlings on a mass scale was realized (the first step was the creation of gynogenetic diploids by chromosome manipulation and the retaining of the second polar body). The second step was the creation of sex-reversed functional males from the gynogenetic diploids by steroid hormone treatment. Hybridization between the sex-reversed females (functional males) and normal females was the third step. Finally, adjustment of rearing temperature during the juvenile stage is used to produce all-female fingerlings. These techniques have already been applied in commercial aquaculture (18).

Cloning

Completely homozygous flounders can be produced from the gynogenetic diploids by the blocking of the first cleavage. Each homozygous fish can produce a first generation of the same homozygous offspring from the gynogenetic diploids by retaining the second polar body. A portion of these fish can be transformed to functional males by exposing the fish to hormones or high temperature during the sex determination stage. Hybridization between females and sex-reversed females (functional males) within a cloned population results in the production of homozygous cloned progeny (18). Hybridization between two different cloned populations results in the production of heterozygous cloned progeny (18). Recently, it was revealed that each strain has a different growth potential and disease resistance. Therefore, this method may be useful in the future in selective breeding by commercial aquaculturists (19).

FROG CULTURE

GIANLUIGI NEGRONI
Alveo Co-operative Society
Bologna, Italy

OUTLINE

INTRODUCTION

A majority of the frogs that reach the markets of the world are either frozen or live wild frogs. Wild frogs are in decline due to such factors as pollution, destruction of natural wetlands, and overfishing. Major frog-importing countries are the European Union (EU), Japan, and the United States. Frogs come from many countries where there are ample natural or artificial wetlands, such as rice fields and inundated areas (1).

Capturing frogs is a labor-intensive activity that requires inexpensive labor in nations that have the appropriate natural conditions to produce large numbers of them. For many frog hunters, 2 kg (4.4 lb) a day is considered a typical catch. Capture techniques vary, but all require skill.

One system is to tie a piece of cotton to a hook that is shaken over the frog. Attracted by the motion of the cotton, the frog strikes and is hooked. Another method involves catching frogs at night by blinding them with a light and netting them.

As world consumption has increased and resources have declined, frog farming has come to be of considerable interest to culturists. While there has been a considerable amount of research in this area and some significant results have been produced, raising frogs in large numbers requires a considerable amount of technical expertise (1) as well as the appropriate environmental conditions. Techniques for industrial production of frogs have been developed; these are most widely used in nations with warm climates, since it is possible to produce more crops each year and increase the profitability of frog farming in a warm climate.

FROG BIOLOGY

The information presented here relates primarily to frogs in the family Ranidae, which is the primary family of frogs currently being cultured. Frogs in the family Ranidae, also known as true frogs, number about 250 species (2) and are distributed throughout the world. They generally live close to water and take refuge there when alarmed. They can survive for long periods out of water if the environment is sufficiently humid. Most cultured frogs are of the genus *Rana*. Frogs in the genera *Xenopus* and *Leptodactylus* have been raised, but never in commercial numbers.

The Goliath frog (*Conraua goliath*) can exceed 34 cm (13.3 in.) in body length. It lives in African rain forests, and is very difficult to find. The author worked for one year in Goliath frog habitat and did not see one. Another unusual frog is the burrowing frog (*Rana adspersa*), which lives much of its life cycle in the ground awaiting the rainy season. The burrowing frog is common in the southern desert area of Africa and is considered to be a local delicacy.

Table 1 provides a list of the most commonly consumed and cultured frogs on each continent where frogs occur (3). The table was developed with contributions from many frog farmers, scientists, colleagues, and the author's experience.

Table 1. Scientific Name, Length from Nose to Cloaca, Breeding Approaches, and Supplementary Information by Continent

Species	Length, cm (in.)	Breeding	Notes
South American Frogs			
Batrachophrynus microphtalmus	20 (7.8)	Under study	Totally aquatic, cold resistant
Caudiverbera caudiverbera	20 (7.8)	None	Locally consumed
Ceratophrys cornuta	15 (5.9)	None	Locally consumed
Leptodactylus fallax	15 (5.9)	None	Locally consumed
Leptodactylus labyrinthicus	20 (7.8)	Under study	Locally consumed
Leptodactylus ocellatus	25 (9.8)	Intensive	Locally consumed
Leptodactylus pentadacylus	25 (9.8)	Under study	Locally consumed
Leptodactylus macrosternum	20 (7.8)	None	Locally consumed
Telmatobius celeus	20 (7.8)	None	Completely aquatic, cold resistant
North American Frogs			
Rana aurora	12(4.7)	None	Not often eaten
Rana catesbeiana	20 (7.8)	Intensive	Most widely used for culture
Rana grylio	16 (6.2)	None	Locally consumed
Rana pipens	15 (5.9)	Intensive	Used in research; locally consumed
Rana hecksheri	15 (5.9)	None	Locally consumed
European Frogs			
Rana ridibunda	10−15 (3.9−5.9)	Extensive	Locally consumed
Rana esculenta	10−15 (3.9−5.9)	Extensive	Locally consumed
Rana dalmatina	10−15 (3.9−5.9)	Extensive	Locally consumed
Rana lessonae	10−15 (3.9−5.9)	Extensive	Locally consumed
Rana temporaria	10−15 (3.9−5.9)	Extensive	Locally consumed
Rana graeca	10−15 (3.9−5.9)	Extensive	Locally consumed
Rana latastei	10−15 (3.9−5.9)	Extensive	Locally consumed
Asian Frogs			
Glyphoglossus molossus	10 (3.9)	None	Locally consumed
Rana acanthi	10 (3.9)	Extensive	Locally consumed
Rana blythi	10 (3.9)	None	Locally consumed
Rana hexadactyla	13 (5.1)	None	Locally consumed
Rana magna	13 (5.1)	None	Locally consumed
Rana moodei	13 (5.1)	Extensive	Locally consumed
Rana tigrina	25 (9.8)	Intensive and extensive	Most widely grown in Asia
Rana crassa	20 (9.8)	Intensive	Exported
Rana limnocharis	15 (5.9)	Intensive	Exported
African Frogs			
Conraua goliath	>30 (>11.8)	None	World's largest
Conraua robusta	14 (5.5)	None	Locally consumed
Pyxicephalus adspersus	22 (8.6)	None	Aggressive with painful bites; locally consumed
Rana fuscigola	>8 (>3.1)	None	Locally consumed
Rana vertebralis	15 (5.9)	None	Locally consumed
Xenopus mulleri	>20 (>7.8)	Intensive in laboratory	Locally consumed
Xenopus laevis	20 (7.8)	Intensive in laboratory	Locally consumed

The most commonly raised frogs are the American bullfrog, *Rana catesbeiana*, and the Asian bullfrog, *R. tigrina*, though many others are reared as pets and for scientific purposes. *R. catesbeiana* (hereafter referred to as the bullfrog) is the most widely raised of the top two species; most of the information contained in this entry is based on work conducted with that species. It has adapted to conditions from temperate to tropical,

and can survive in cold water or at extremely low temperatures.

It is possible to determine the sex of a bullfrog by examining its tympanum, which in males is larger than in females. Male bullfrogs are known for their loud calls during the breeding season. Males have a callus thumb to assist in the making of mating noises. Breeding is prompted by proper temperature, atmospheric

pressure, photoperiod, and humidity. Proper conditions can stimulate breeding in culture so long as the frogs are well fed and not diseased.

Female bullfrogs generally produce about 5,000 eggs, though it is reported that older females can produce more than 20,000 eggs (2). Normally, the male is ready to breed when it starts calling; the female is ready to breed when it exhibits an enlarged belly. The eggs are laid in still water and will hatch in 48–72 hours depending on water temperature. Tadpole bullfrogs may remain in the tadpole stage for as long as two years in temperate climates and can reach a length of 18 cm (7.2 in.) (2). Tadpoles have very long intestines and can digest plant material, while metamorphosed bullfrogs are carnivorous and require high–protein foods.

The stages in the life cycle of the bullfrog are as follows:

- Egg
- Larva
- Phase G1 tadpole
- Phase G2 tadpole (starting metamorphosis with hind legs showing)
- Phase G3 tadpole (front leg developing)
- Phase G4 tadpole (tail being absorbed, front legs out, gills being absorbed, increase in length, change in intestinal system)
- Small frog (froglet) similar to adult, but immature
- Adult

Tadpoles live in the water; metamorphosed frogs can live in the water or on land.

FARMING TECHNIQUES

A considerable amount of information on frog culture is currently available (e.g., Refs. 3–7). Technology is developing rapidly, so it is necessary for those interested in the topic to stay well informed on the subject.

Production methods can be divided into the categories of extensive, semi-intensive, and intensive (4). Each method depends on both environmental conditions and such factors as the cost of feed and labor. An integrated intensive frog farm will have the following components:

- Broodstock area
- Reproduction area
- Hatchery
- Tadpole tank
- Metamorphosis facility
- Growout area
- Processing plant
- Offices and laboratory
- Warehouse

Not all frog farms have all of the components listed. Many purchase only tadpoles or froglets and grow them out to market size. There are other farmers who specialize in producing tadpoles and froglets to supply the growout operators. Frog farmers have been known to form cooperatives or collectives which allow production with reduced risk, more efficiency, and improved sanitary control (6). Collectives usually involve many small farmers.

Extensive Frog Farming

This approach to frog culture can involve rearing frogs in open areas, such as rice fields, or the capture of frog and tadpole specimens from ponds. In many fish farm ponds, frogs and tadpoles are unpopular because they feed on fish food or on the fish that are being cultured. Many fish farmers do not realize that they can obtain additional income by making use of the frogs and tadpoles that live in their ponds.

Extensive rearing is characterized by a shortage of enclosure structures that will protect the frogs from predators; consequently, survival of introduced tadpoles is typically very low (often under 10%). Unless confined, tadpoles and frogs will often leave the area in which they are stocked to search for food. Eggs, tadpoles, and frogs are preyed upon by aquatic birds, fish, snakes, insects, and other creatures that can decimate a frog population.

In developing countries, the capture and restocking of frogs in rice fields can produce a remarkable quantity of marketable frogs. Extensive culture depends on the proper climate, food availability, and limited predation to be successful. It also must be remembered that rice fields and marshes that are subjected to pollution or to chemical treatment are not suitable for frog culture. In China extensive frog-cum-rice farming is common in large rice farms and swampy areas. Production varies from less than 100 kg (220 lb) to a few hundred kilograms per hectare (2.4 ac), depending on the season of the year and food availability. Feed is rarely provided, though the availability of natural feed can be increased by providing lights to attract insects.

Frogs are important to the ecology of rice fields because they control insect pests. Removal of frogs from rice fields can lead to a reduction in rice harvest. India has instituted a ban on frog exports to help ameliorate its problem with low frog populations.

Semi-Intensive Frog Rearing

The semi-intensive approach to frog rearing began in the 1980s and its techniques have remained largely unchanged ever since. To defend frogs from external predators and to prevent their escape, barriers are installed in the rearing areas. This approach can accommodate a considerable number of tadpoles in a central pond, where they will remain after metamorphosis to be captured or reared to market size (5). Because frogs of various sizes may be present in the same system, cannibalism can be a significant problem.

Heavy fertilization is implemented during the tadpole stage to produce phytoplankton and zooplankton, which provide food. The frogs will also feed on macrophytes. The feeding of metamorphosed frogs is based principally on insects that occur naturally in association with the water and those that can be attracted by night lights properly placed inside the enclosures. The frogs will also eat insect

larvae and small fish and will take pieces of liver or kidney that are placed on the water surface. Survival of tadpoles reared to the marketable adult frog stage (around 150 g; 5.2 oz) is usually not more than 15%.

Intensive Rearing

As a result of a decline in the availability of wild frogs, intensive rearing methods have been developed since the 1980s. The previously mentioned systems have always resulted in very low survival rates. Intensive, closed cycle rearing systems involve all phases of culture (production of eggs, tadpoles, and adult frogs) so that there will be no problems with availability from the wild. Some farms also process frogs and produce value added frog products.

With the development of new and better breeding systems, it has become possible to increase survival and produce frogs of standard sizes to meet the demands of both domestic and export markets (1). The largest frog farms are usually found in developing countries because of their favorable climatic conditions and production cost factors. An exception can be found in Taiwan, which has high production levels as a result of heated indoor facilities.

Each stage in the frog's life cycle requires adequate containers designed to minimize stress. Frog farmers often demonstrate a great deal of originality in the technical solutions they adopt for the different frog life stages.

It is possible to split the intensive system into different phases, each of which requires appropriate facilities. Those phases are reproduction and hatchery, tadpoles, and metamorphosis to growout, each of which is described with respect to bullfrog culture.

Reproduction and Hatchery Phase. Selection of broodstock is important because those animals will form the gene pool from which the marketed frogs will be produced. Adult frogs are normally kept separated by sex and age. Frogs are generally ready to mate at one year of age in tropical climates and at two years in temperate areas. Production records of broodstock should be kept for selective breeding purposes.

During the reproductive period, males have a yellow colored throat, a callous nuptial thumb developed to assist in mating, and a nuptial embrace reflex that, together with the loud calls, signal that the male is ready to mate. Each male will actively defend his territory against possible intrusion by other males.

The reproductive condition of females can be determined by calculating an index that relates abdomen perimeter (a) and the distance between the eyes (b). When (a):(b) is more than 3.0, the female is ready to mate. A round-shaped abdomen is a clear indicator of egg development.

Fertilization in bullfrogs is external; the male clasps the female and releases sperm over the eggs as they are extruded. Areas where frogs mate must be protected, isolated, shaded, and quiet. In the Brazilian system, mating cages have 150-L (39.6-gal) water pits where the frogs can spawn. Mating can also be successfully achieved in tanks. Selected pairs of adults are stocked in such systems.

Commercial reproduction systems sometimes employ long open raceways filled with standing water. These systems require less human work than some others, but there is also less genetic control. Short-cut grass and shade are provided between the raceways. Bullfrog males signal their readiness to mate using the powerful bellowing sounds they make. The sound generated by thousands of mating frogs can be quite annoying to people.

Mating generally takes less than 24 hours, after which a new pair can be placed in the reproduction area. This system provides a constant supply of eggs. The spawning pit should be disinfected before each pair of frogs is stocked. Each adult female will produce an average of 5,000 eggs (the maximum is about 20,000). Egg to larvae survival rate often reaches about 80% under good hatchery conditions (7).

Eggs should be transferred on a screen and incubated in stagnant water in the hatchery. The eggs and larvae from each spawn are retained for 10 to 15 days in the hatchery in individual basins or in collective tanks. Individual basins permit the farmer to evaluate hatching success from a particular pair of frogs and to compare growth and other factors.

Environmental factors, such as temperature, photoperiod, solar radiation, and barometric pressure, influence egg production and spawning in bullfrogs. Broodstock maintained in environmentally controlled greenhouses may spawn year-round. Simulated rain can be used to prompt breeding. Air temperature should be maintained around 30–32 °C (86–90 °F). A constant photoperiod of 10 hours light and 14 hours dark should be maintained during the reproduction period.

When female frogs are mature it is possible to inject hormones (such as frog pituitary) to stimulate spawning. As a rule of thumb, the pituitary from one adult female is enough to stimulate a female of similar weight. Trained technicians are necessary to extract, preserve, and inject pituitaries.

Tadpole and Metamorphosis Phase. Tadpoles are kept in tanks or raceways. In less intensive systems, earthen ponds can be used, though these allow for high mortality due to predation. The tadpole phase of the rearing cycle is exclusively aquatic. Optimum density for tadpole growing is 1/L (1/0.25 gal). Under the proper conditions, tadpoles begin to metamorphose after one to three months. During metamorphosis they stop feeding and utilize tail fat reserves for energy. After the tadpole phase, the froglets are collected and transferred to growout facilities. Survival rate from tadpole to metamorphosed froglet is often 80% in tanks and 50% in open-pond systems.

Time of metamorphosis and size during metamorphosis may be influenced by crowding, water pH (8), water temperature, feed availability, or photoperiod. Large tadpoles result in larger froglets. By maintaining temperature in the range of 16 to 20 °C (61–68 °F) metamorphosis will be prevented and large tadpoles can be produced.

Growout Phase. Growout involves rearing frogs to a market size, which can range from 70 to 200 g (2.4 to 7 oz), depending on demand. Growth rates as high

as 1 to 2 g/day (0.03 to 0.06 oz/day) (7) have been reached on some frog farms. A balanced pelleted diet, sometimes manufactured through extrusion, is provided. Good hygiene is maintained throughout the growing period. Survival from froglet to market size can reach 85% under the proper conditions. During the growout period frogs are particularly sensitive to loud noise and direct sunlight, so many facilities are under shade or in greenhouses. Air and water temperature should range from 20 to 32 °C (66 to 88 °F) for good performance. Intensive systems can be stocked at between 10 and 60/m^2 (1.2 yd^2). Densities even higher [as high as 120/m^2 (1.2 yd^2)] have been reported. Table 2 summarizes survival and performance estimates for a well-run intensive frog farming operation.

General Description of Growout Technologies. The growout stage is considered to be the most costly, risky, and difficult phase of frog farming. Frog farming intensities can reach 10 to 120 frogs/m^2 (1.2 yd^2).

The growout phase may be conducted using one of two general techniques. In the wet technique the frogs sit on the floor of a shallow water region of the rearing area, which is covered with a few centimeters (1 cm = 0.4 in.) of water, or they can swim freely in a deeper section of the rearing area. In the semi-wet technique the frogs can choose to stay in or out of water. System selection is based on local climate. In warm climates the semiwet method is used, while in colder climates the wet method with temperature control is mandatory for year-round production. Frogs cannot perform well at low temperatures when out of water. The following are examples of some of the systems currently in use.

Brazilian Systems. Brazil has developed an intensive frog farming industry over the past three decades. There have been as many as 2,000 frog farms in Brazil, though the number may be lower today because of large farms' buyouts of some of the smaller ones. In temperate areas, frogs are raised in greenhouses.

One Brazilian system employs water channels and dry areas, with or without refuge. Shade is provided to prevent exposure to direct sunlight. Groups of channels and refuges are separated by 1 m (3 ft) high walls. Frogs are often selected by size to avoid competition and cannibalism. The channels are flushed daily to eliminate feces and feed debris. Wood or concrete refuge structures are frequently cleaned to maintain sanitary conditions. Normally, there are rows of water channels between rows of refugia. The production areas are usually fabricated from concrete. The Brazilian systems are classified as semiwet. Various institutes and universities are involved in the development of frog farming technology in Brazil. During recent years, a pilot hyperintensive vertical system where froglets are raised to market size of 150 to 170 g (5.2 to 5.9 oz) has been developed. Froglets are placed in 20 cm (7.8 in.) high and 1 m (1.2 yd^2) plastic boxes at densities that are reportedly as high as 1,000/m^2 (1.2 yr^2) (10).

The frogs sit in trays of water with their heads protruding into the atmosphere. The water is frequently changed so it stays clean. The frogs' diet is composed of high-protein pellets. Although the system is still under development, the equipment producer claims a very high productivity rate and high economic return. Pathology is still a problem in this system, however.

Taiwanese System. In Taiwan, frogs are maintained during the winter in heated sheds in 5- to 8-m^3 (6.5- to 10.5-yd^3) tanks at high densities. The water is from 0.3 to 1 m (1 to 3 ft) deep in the tanks and high-protein extruded floating pellets are provided. This is considered a wet system. The system uses water recirculation to save water and energy. A platform may be placed a few centimeters (1 cm = 0.4 in.) under the water surface in growout tanks where the frogs can sit with just their heads out of the water. All operations are highly mechanized, which makes it possible for two to three people to produce more than 100 tons/yr.

Pathology laboratories are incorporated into the facilities to monitor frog health status, which is often a limiting factor if not properly managed. Hyperintensive Taiwanese systems can generally rear frogs at densities of 50 to 90/m^2 (3.2 ft^2), though densities of up to 120/m^2 (3.2 ft^2) have been realized.

Chinese Systems. China has a long tradition in aquaculture, including frog farming. Frog culture that can be considered intensive is generally conducted in small units, in rural areas that are concentrated in southern and central China where the climate is suitable. Earthen tanks that are 100 to 200 m^2 (120 to 240 yd^2) and are 1 m (3.2 ft) deep are enclosed by 1 m (3.2 ft) high walls. Normally, an inlet channel provides each facility with several daily pondwater changes. Dry fish and other protein-rich feed materials are provided on a little wooden island in the pond where the frogs rest and feed.

Large cooperative frog farms of more than 1,000 ha (2,500 ac) employ the extensive-system approach in swampy areas and rice fields. Production rates range from 100 to 300 kg/ha (2.5 ac). In these cooperatives, hatcheries provide the tadpoles that are used to stock the growout areas. Fertilization, and the reduction of the pests that the frogs prey upon, are believed to increase rice production.

Mexican System. The Mexican system is considered to be of the intensive wet type. The system involves rearing frogs on the bottom of tanks that are filled with water

Table 2. Expected Survival Rate for Various Stages in Frog Culture and Anticipated Performance Parameters in a Well-Managed Intensive Frog Culture Facility

Parameter	Value or Result
Survival	
Egg to larvae	80%
Tadpole to froglet	75%
Froglet to 170 g (5.9 oz)	85%
Age at Maturity	1–2 years
Eggs in average spawn	5,000
Tadpole stocking density	1–20/L (0.26 gal)
Froglet stocking density	3–50/m^2 (1.2 yd^2)
Food conversion ratio for tadpoles[a]	1.5
Food conversion ratio for froglets	1.2
Time for tadpole stage	30–90 days
Time from froglet to 170 g (5.2 oz) frog	100–180 days

[a]Food conversion ratio is calculated as dry weight of feed offered per unit time divided by wet weight of gain during the same period of time.

to the shoulder level of the animals. Frogs are reared in sheds that provide quiet, shaded areas to reduce stress. Tarpaulin covers are used to provide the shade. Extruded pellets produced in the United States and that cost US$1/kg (2.2 Ib) are fed to the frogs.

Patented reproduction units permit accurate selection and can be operated with low manpower costs. The system has been sold abroad and employed with good results.

PATHOLOGY

Frogs, like other aquatic animals, are subject to various types of pathology, including problems caused by viruses, bacteria, fungi, and parasites (9,10). Presently, there are no vaccines available for use by frog producers (10).

Maintaining clean conditions in the culturing environment is critical to health maintenance. Frogs are also particularly sensitive to stress. Cannibalism can become a major problem when frogs are not well fed or are stocked as mixed sizes. Ulcerations or skin lesions (particularly on the head and extremities) are signs of improper nutrition, bacterial infections, parasitism, or mechanical trauma. "Red-leg disease," the best known and most common bacterial problem, can cause mass mortality on commercial farms. The disease is related to overcrowding, diet deficiency, poor quality water, inadequate lighting, or improper temperature. Rectal prolapse, where the large intestine protrudes from the cloaca, is also a condition related to several factors, including temperature, diet, and parasitism.

Bacterial diseases are common in frog farming. Bacteria isolated from farmed bullfrog blood have included *Streptococcus* spp., *Flavobacterium ranicida*, *Pseudomonas* sp., *Aeromonas* sp., *Mima polymorpha*, *Citrobacter freundii*, and *Staphylococcus* sp. (11–15). Studies support the theory that red leg is caused by a complex interaction of different bacteria that are common inhabitants of the aquatic environment, and the frogs that become pathogenic when they are stressed (14,15). Bacteria isolated from frogs with red leg have included *Aeromonas hydrophila*, *Pseudomonas aeruginosa* and others. Those bacteria may also occur in tadpoles and can cause metamorphosis problems. Skin ulcerations help the proliferation of septicemic disease. In red-leg infected frogs, fat tissue analyses show higher concentrations of bacteria than in blood (15).

Other less common bacterial diseases associated with frog farming include encephalitis, conjunctivitis, mycobacteriosis, bacterial mouth disease, and general edema. Taiwanese specialists have come to the conclusion that proper culture system management significantly influences the development of bacterial epizootics. The three most important factors are stocking density, feed type, and prophylaxis.

Because of their delicate skin, frogs are very sensitive to bacterial diseases; consequently, appropriate cleaning and disinfecting operations must take place frequently, particularly in intensive systems. It is very important to maintain high water quality in the tanks. For dry systems, cleaning and disinfecting all cage surfaces fairly often is a good practice (11–13).

Frogs suspected of harboring pathogens or showing signs of disease should be isolated and treated. It may be necessary to contact a specialized laboratory to obtain definite identification of a disease. An isolated area should be constructed for quarantine of frogs brought to the facility. This will reduce the chance of the disease being introduced from outside. Dead frogs should be incinerated to avoid the possible spread of infectious diseases.

Saprolegniasis is the most common fungal disease in frog. It is common among eggs and tadpoles in low-quality water. It can be treated by dipping the eggs in a 5% salt (sodium chloride) solution for two minutes (9). Parasitic nematodes, cestodes, and trematodes are present in wild frogs but cause few problems in farmed frogs (16).

Though frogs naturally live in stagnant water, the water quality in culture tanks must be controlled. Frogs are very sensitive to coliform bacteria in water. Growth of bullfrogs slows at temperatures below 15 °C (60 °F); the optimum temperature is between 28 and 32 °C (84 to 88 °F) for normal reproduction and physiological development. A pH range of 6.5 to 7.5 is best during tadpole metamorphosis. Natural citrus extract is successfully used to disinfect frog farms.

FEEDS AND FEEDING

Important factors in feeds and feeding include feed costs, feeding techniques, and feed conversion efficiency (17–19). All of these factors influence the economics of a frog farm. It is very important to know about changes in the digestive system and food habits at various stages in the life cycle and to provide the most appropriate feed (20–23). In some systems, feeds may include insect larvae, worms, or other live foods. Intensive systems employ pellets.

Feeding Tadpoles

After absorbing the yolk sac, tadpole larvae are omnivorous and begin feeding on phytoplankton, bacteria, and protozoa. Some frog farmers encourage algae development on the walls of rearing tanks to enhance the amount of available food. At a later stage, tadpoles begin to feed on rotifers and crustaceans.

Physiologically, tadpoles have a very long digestive system compared to body length. The tadpole's digestive system is adaptable to several types of diet (17). Studies have shown that high-protein diets can considerably accelerate growth and metamorphosis (22). A raw-protein level of 30 (24,25) to 44% (20) is considered appropriate for optimal tadpole growth. Optimal particle size is 0.21 mm (0.008 in.) in diameter (24).

A ratio of 1 : 1 for animal protein versus plant protein (at 40% protein) has led to good results with tadpoles (25). A feed formula that has been successfully used by the author is presented in Table 3. The diet results in optimum growth of healthy tadpoles, but is costly.

The São Paulo Fishery Institute (Brazil) recommends the following feeding protocol for tadpoles:

- 10% of live weight during the first month
- 5% of live weight during the second month
- 2% of live weight during the third month

Table 3. Feed Formulation for Tadpoles in Intensive-Rearing Systems

Ingredient	Percentage of Diet
Fish meal	38.5
Soybean protein	5.5
Brewery waste	16.5
Rice bran	21.0
Powdered milk	5.0
Fish oil and solubles	7.0
Fatty acids	0.5
Vitamin and mineral premix	3.25
Binder	2.15

Water temperature affects tadpole feed utilization, growth, and metamorphosis. Optimum water temperature should range from 20 to 32 °C (68 to 88 °F). During metamorphosis, particularly at the G4 phase, tadpoles stop feeding and rely only on their tail-fat reserves.

Feeding Metamorphosed Frogs

Frogs that have metamorphosed have large, muscular stomachs and short intestinal tracts. They require a high-protein diet. Frogs prefer to feed on moving prey and therefore need to be trained to feed on prepared diets. Frogs have large mouths and can swallow prey that is large relative to their body size. These characteristics have been considered as methods for feeding frogs were developed (26).

One technology consists of feeding live food, such as fish, adult insects, and tadpoles. Problems associated with the use of live feeds include lack of availability and high costs due to manpower demands the method requires. South American frog raisers like to mix 2 to 20% insect larvae (e.g., *Musca domestica*) with feed pellets. The movement of larvae in the pellets induces the frogs to feed on the mixture. Putting pieces of meat, liver, or kidney in the water or on feeding trays is another option, although the author considers it risky because it facilitates the spread of diseases, especially in tropical climates. New technology allows the use of vibrators, which provide motion to pellets without necessitating the use of insects.

The first period after metamorphosis is the most critical. High mortality can occur, particularly in conjunction with newly metamorphosed frogs. Providing insect larvae and brine shrimp (*Artemia* sp.) can help get the frogs through the critical period. Another method is to put extruded floating pellets on the water surface, which move with currents and entice the frogs to feed. This feed is very well accepted by the frogs and can lead to an excellent food conversion ratio. The method is used in intensive systems and requires high-quality pellets. The cost of high-protein extruded and floating pellets can exceed US$1/kg (2.2 lb) but can produce food conversion ratios (FCR = dry weight of feed offered per unit time divided by wet weight gain) of 1.1 to 2.0, depending on pellet quality.

Some studies on adult frog nutritional requirements have been conducted, but more research is needed. The author has successfully used extruded pelleted trout feed that contained 42% raw protein. Pellet size should vary in relation to frog mouth size, but will normally range from 3 to 7 mm (1.4 to 3.3 in.) in diameter.

The frequency and quantity of feedings are related to temperature and frog size. Detailed studies have not yet been conducted, but judging from practical experience, adult frogs of 150 g (5.2 oz) consume from 3 to 3.5% of their body weight daily when fed *ad libitum*. Younger frogs may eat as much as 6% of their body weight daily.

A specimen formula developed by the author for feeding frogs in growout tanks contains the following ingredients: fish meal, blood meal, gelatinized wheat starch, meat meal, fish oil, dry milk, a vitamin and mineral mixture, binder, and dL-methionine. The cost of the feed was US$1/kg (2.2 lb) in Italy. The results were very good; frogs had more than 1 g (0.04 oz) weight gain daily. The proximate composition of the formula is presented in Table 4. It is possible to formulate a less expensive pelleted feed, but frog performance is reduced.

FROG ECOLOGY

With the advent of water pollution and the clearing of swamps, habitat for frogs is disappearing and their cells are heard less and less around the world. Frogs are vitally important in the ecosystem of swamps and humid areas. They are often used as indicators of environmental quality. Where there are frogs, the environment is usually still in good condition. Many countries, both developing and developed, are now protecting frogs. Frog farming can play a key role in the conservation of frogs because cultured frogs can reduce the pressure on their wild counterparts and even supplement wild stocks through stocking programs (7).

It is well-known that frogs are moved around the world and sold for farming and as pets, research animals, and biological pest control agents. The American bullfrog has been introduced to many countries in Latin America (Brazil, Argentina, Venezuela, Uruguay, Paraguay, and others), Europe (Spain, Italy, France, United Kingdom, and Greece), and the Far East (Thailand, Malaysia, Indonesia, and Taiwan) as pets and for farming. In some of these countries there are well-established populations of American bullfrogs that do not appear to have caused problems in local ecosystems (27). Some EU nations have bans against bullfrogs and other species. Certain biologists claim that environmental damage could result from the introduction of frogs in these areas. On the other side of the issue is the fact that imported frogs provide food for various predators.

Table 4. Proximate Analysis of a Frog Growout Pelleted Diet Used in Intensive Frog Farming

Parameter	Percentage in Feed
Moisture	10
Crude protein	44
Crude fat	11
Cellulose	1.5
Ash	14

Excessive wild-frog overfishing can create problems in rice areas, such as those that have occurred in India and Bangladesh where an increase in rice pests was correlated with frog overfishing. The countries reacted with a ban on frog exports. Extensive and semi-intensive frog rearing systems can help contain the rice-pest attacks.

GENETICS

Frogs that are captively bred today have not undergone a great deal of selection, since they were wild a few generations ago. Mass selection is the most common form employed by frog farmers. For certain types of biomedical research, cloned and gynogenetic frogs (28) are selected, but the cost for these is very high; only a large frog farm can provide a budget for genetic research.

A wide variety of sizes of same-aged frogs has been seen on commercial farms and indicates a lack of genetic selection. To increase the gene pool on a frog farm, the farmer can breed bullfrogs from existing farms that are located in widely separated regions or on separate continents. Some frog farms in southeast Asia have developed frogs with improved performance that are also well adapted to frog farming. Progeny and performance testing can produce improved frog strains at low cost. Improvements from selective breeding programs occur more rapidly with frogs than with many other terrestrial animals because of the large numbers of eggs produced per year and the short generation time. It is now possible to control the frog reproductive cycle through the use of environmental control and hormones. When these methods are coupled with genetic selection, we should see dramatic improvement in frog performance in the future (1,29−31).

PROCESSING

Frog slaughtering and processing must respect the internationally accepted HACCP (Hazard Analysis Critical Control Point) system, which helps to ensure that frogs are processed under good sanitary conditions (32−34). The use of a HACCP system is mandatory for frogs shipped to the EU and the United States (35). All seven principles of the HACCP system apply to frog processing:

- Conduct a hazard analysis
- Determine the critical control points
- Establish critical limit
- Establish a system to monitor control of the critical control points
- Establish the corrective action to be taken when monitoring indicates that a particular critical control point is not under control
- Establish procedures for verification to confirm that the HACCP system is working effectively
- Establish documentation concerning all procedures and keep records appropriate to these principles and their application

These principles help frog-processing companies develop programs specific to their plants. Frog processing must be accurately controlled in both abattoir construction design and in the management of the processing activities (7,31).

A good frog-processing plant will have the following facilities:

- Reception room
- Slaughter room
- By-products collection area
- Mechanical room
- Packing room
- Cold storage
- Shipping area
- Employee dressing room
- Water filter (for water used in the processing line)

The last point is often neglected and has been the cause of many problems in frog-processing plants.

The processing plant must be isolated to the greatest extent possible from the exterior environment. In the most advanced frog-processing plants, air is conditioned before entering the exterior environment. The processed frogs must be handled as little as possible, to avoid contamination. *Salmonella*, *Enterococcus*, and *Clostridium* bacteria have been isolated in imported frogs. *Salmonella* in the digestive tract of frogs can contaminate the meat during processing if care is not taken. Only a well-applied HACCP system can prevent dangerous microbial contamination during frog processing.

Ready-to-market frogs are left on the farm for one to two days without eating and are then transferred to the frog abattoir and placed in a tank with ice, water, and a mild disinfectant. The cold stops the activity of the frogs so that they may be easily processed without suffering. Generally only the legs are sold as IQF (individually quick frozen) products. They are packed in polyethylene bags and stored in cold room (32). Frog dressout is usually around 54% in a modern processing plant.

TRANSPORT

Live frogs and tadpoles can be transported by air, truck, or ship. Before packing, the live tadpoles and frogs must be conditioned. They are kept off food for 24 to 48 hours. The author recommends disinfection just prior to packing. Tadpoles of certain sizes can be shipped dry for as long as 12 hours. Small tadpoles are transported in plastic bags that contain water and are charged with oxygen. The time of the travel and the size of the tadpoles influence the number of tadpoles per unit volume of water. Tadpoles of 1 cm (0.4 in.) can be transported at 20/L (0.26 gal) for one day with very low mortality. Temperature is an important factor in tadpole transportation. It is important to keep the temperature low during the transport period.

Live adult frogs are transported in various ways. One way is to use a mesh plastic sac with 2 kg (4.4 lb) of live frogs inside. Several bags can be placed inside a large cardboard box that has holes in it to allow the frogs to breathe. Mortality tends to be very low for this method.

MARKETING

There is very little advertising for frogs, because demand exceeds supply. At the same time, many people have had very few occasions to taste frog meat; many have never tasted frog at all. Frog meat is a traditional food in some areas; in others, it is rather exotic. It is well known around the world as a gourmet food item that can generally be found in upscale restaurants. It is also possible to find fresh frog legs in fish shops and frozen ones in supermarkets. There is still prejudice against frog legs by some consumers.

The majority of farmed and captured frogs in the world are utilized for food consumption. The meat is white, rich in protein, easily digestible, and very low in fat. In European countries, only small frog legs are utilized since Europeans have traditionally had those sizes on their tables (5). In fact, in other frog-consuming countries, you can find larger legs imported from South American and Asian countries, where the customers prefer larger legs. Frog thighs are sold and imported fresh or frozen, depending on the availability, labor cost, and market demand.

The highest frog demand is in traditional frog-fishing areas. People living in humid and wetland regions are traditionally frog consumers: from the Danube to Mississippi and the Yang-Tze Delta (5,36), areas that have been influenced by the French culture (37) are those where frogs are considered a delicacy. Other major consumers and importers are the EU member countries of Belgium, the Netherlands, Italy, and Spain. Frog thighs are considered a gourmet food and always bring a high price in restaurants. In some countries, frogs are eaten whole, after being slaughtered and skinned.

In Europe, frogs are slaughtered at a weight of 60 to 90 g (2.1–3.1 oz), but American and Asiatic consumers often prefer frogs of 170 g (5.9 oz) or larger. European consumers believe that the small frogs have a better taste than the larger ones.

The selling price in the United States was about US$7/kg (2.2 lb) in 1997 for imported live frogs of 6–7 individuals/kg weight. In Italy, in 1998, the price was 7,000 lira (US$4)/kg for imported live frogs of 11–12 individuals/kg but 34,000 lira (around US$19) for a clean fresh leg in the supermarket. In France, in February 1997, clean legs in the Rungis market were 28 francs/kg (US$5.20/kg).

Indonesia and China are the biggest exporters to the EU, some countries of which are reexporters of processed frogs. Indonesia and China are major suppliers of frogs to France, which is the largest EU consumer.

Frog legs are popular and are widely marketed, but other products can be made from frogs. Brazil has been a leader in developing such value-added products as frog vinegar, frog pizza, and many other products that permit the use of all the edible frog parts.

Frog farmers have discovered some niche markets that can provide high revenues. Frogs raised in captivity and sold for research and student education are sold not by weight, but by number. There are many tens of thousands of frogs sold for scientific and educational purposes at an average retail price of approximately $15/frog in the United States each year. There is a lack of producers or distributors of frogs for scientific research in Europe. The typical price for one adult frog for use in research in Italy is US$13. Frog skeletons may also be sold for courses in the natural sciences.

Although it is not the first use the author can think of, the utilization of frog skin is a very promising business. Obviously, the infrastructure will need to be developed for skinning and tanning frog skins if a product with consistent quality is to be produced. Frog skin is used by the fashion industry and could also have applications in the treating of burns.

The author has worked in frog bracelet production and faced the problems of inconsistent supply, high skin cost, low quality of raw skin, and poor processing. Only one quality bracelet can be made with one large skin. Often the skins have holes in them and must be discarded. The Italian market accepted frog skin bracelets tanned in several colors; the gross price of one bracelet sold to the retail shop was US$10. Wallets, purses, belts, bikinis, jackets, and other products can be manufactured from processed skins (5). The cosmetics industry has extracted a special oil from frogs that is used to produce creams and other cosmetics (7).

There are good markets for tadpoles, broodstock, frog feed, and equipment associated with rearing the animals (38). A good pair of adult frogs selected for high quality as breeders will cost US$20 or more. Tadpole prices vary depending on size and number purchased.

The pet animal market is very promising. A frog in a small aquarium can be enjoyed by both adults and children. *Xenopus* sp. albinos now appear in pet shops. Frogs with strange shapes, colors, and sizes are valued by hobbyists. Pet animal market demands are expected to rise in the next few years.

Frogs are also utilized to organize games; one of the oldest is the Sacramento International Jumping Frog Competition held yearly in Sacramento, California. Local television broadcasts the event and competitors come from all over the world to participate.

FINANCIAL CONSIDERATIONS

There are many types of frog farming, and one example of the costs involved will not begin to cover all the possibilities. Costs vary among countries, so it is important to do appropriate economic planning before actually initiating development in a particular country; economics are very important in the development of a frog farm (39). Frog farming is more complex than many types of aquaculture. All the investment and management costs must be identified during the development of the business plan.

Table 5 presents an investment cost estimate for a partially integrated frog farm, without processing, with a projected production of 100 tons/yr of live frogs. Total surface area of the facility is 5.5 ha (13.75 ac), using the Taiwanese indoor system of tanks. Table 6 provides an annual operating cost estimate for the facility. The estimates shown in the operation outlined in Tables 5 and 6 are an example of only one type of system. Actual costs

Table 5. Cost Estimates for Construction of a Hypothetical 100-Ton Taiwanese-System Frog Farm

Item	Area	Cost (US$)
Construction costs		
Breeding and hatchery facility	300 m^2 (360 yd^2)	40,000
Tadpole tanks	20 at 10 m^3 (13 yd^3)	40,000
Growout tanks with feeders	200 tanks at 50 m^3 (66 yd^3)	250,000
Laboratory and offices	60 m^2 (72 yd^2)	20,000
Workshop and warehouse	60 m^2 (72 yd^2)	20,000
Packing and shipping room	30 m^2 (36 yd^2)	15,000
Dressing room for personnel	30 m^2 (36 yd^2)	20,000
Equipment		
Electrical and mechanical		20,000
Water supply and filtration		15,000
Pumps		10,000
Other equipment		20,000
Total capital and equipment costs		470,000
Design, legal fees, surveying, etc.		50,000
Total investment		520,000

Table 6. Annual Operating Expense Estimates for Frog Culture Facility in Table 5

Item	Quantity	Cost (US$)
Variable costs		
Feed	150 tons	200,000
Medications		30,000
Repairs (including labor)		10,000
Utilities		15,000
Miscellaneous supplies		50,000
Fixed costs		
Personnel	2 individuals	80,000
Consulting and administrative services		20,000
Overhead		15,000
Maintenance (3% of investment cost)		15,600
Interest payment		10,000
Insurance (1% of investment cost)		5,200
Land lease		5,000
Depreciation (5% of investment cost)		26,000
Total operating costs		481,800
Taxes (10%)		48,180
Grand total		529,980
Gross revenue		700,000
Annual net profit		170,020

will vary depending on specific locale and changes that might occur in the economy, both locally and globally.

The payback period for the hypothetical facility, based on the figures presented, is calculated as the initial investment divided by the average net income before depreciation (40), or

$$\text{Payback period} = \text{US\$520,000/US\$455,800} = 1.14 \text{ years}$$

The payback period indicator of 1.14 years is considered good for an aquaculture facility.

The rate of return on the investment is calculated as the average annual profit divided by the initial investment × 100 (40), or

$$\text{Return on investment} = \text{US\$170,020/US\$520,000} = 32\%$$

A rate of return of 32% can be considered excellent performance for frog farming.

The good economic projections shown in the example are results of a farm that employs high technology and good managers. It requires a high capital investment. Another alternative would be to form a cooperative among a few farmers, each of whom specializes in one aspect of frog culture. In the future, well-managed intensive frog farms may prove to be the only ones that are technically and economically viable.

CONCLUSIONS

This entry has presented a general, brief, and incomplete description of the different possibilities for rearing frogs. New technology is constantly emerging; in fact, the frog industry works hard to develop new approaches. Because of the decline in wild frog populations and the strong increase in demand, frog rearing has become a good investment opportunity. Due to the complexity of frog farming, the reader is reminded that it is good practice to obtain the advice of experts before investing in frog aquaculture.

ACKNOWLEDGMENT

Thanks to Dr. Claudia Maris and Prof. Dos Lantos for general advice on this entry and detailed information about Brazilian frog farming. Dr. A. Flores-Nava provided information on Mexican frog systems.

    Hyphomycetes
Fungal Diseases of Frogs and Alligators
Bibliography

Fungi (mushrooms, yeasts, molds, etc.) are primitive organisms that are characterized by the absence of chlorophyll and the presence of a rigid cell wall. They range in form from a single cell to a mass of branched, filamentous structures. Fungi usually feed saprophytically on dead organic matter (soil, dead plants, and animals), and thus virtually none require a living host to survive. However, some species will infect a living host if its normal defenses are impaired. Therefore, fungi are classical opportunists. Wounds, especially on the skin or cuticle,

but also other body surfaces (gills, gut), due to trauma or other pathogens provide a portal of entry for fungi (1,2). Handling, crowding, heavy feeding rates, and high organic loads also appear to increase the risk of some fungal infections. In other cases, there is no discernible reason for an outbreak.

A fungal infection in a sick animal is usually easily detected using simple microscopic examination of the diseased tissue, as most pathogenic fungi produce long, filamentous structures, known as "hyphae," that are easily identifiable in tissue squashes (see Fig. 1) or histological sections. However, identification of the specific fungus (genus and species) responsible usually requires culture of the agent, in order to stimulate production of reproductive structures, which are needed for taxonomic identification. Gene and antibody tests have been experimentally used in diagnosis, but are not commercially available.

Fungal infections can be extremely difficult to treat, because, unlike bacteria, their metabolism is very similar to that of higher animals (both invertebrates and vertebrates). Thus, drugs that inhibit fungi are often toxic to the host at the levels required for the drugs to be effective. There are no highly useful treatments that are approved for aquaculture species. Thus, prevention of stress, and quarantine, when possible, are the best means for managing fungal problems. For more details on fungal infections, see Hatai (3), Chako (4), and Noga (5–7).

IMPORTANT FUNGAL DISEASES OF FINFISH

Fungal infections of finfish can be artificially divided into two types, based upon whether they cause mainly superficial infections of the skin or gills or penetrate deeply into the body.

Superficial Infections

Typical Water Mold Infections (*Saprolegniosis*). *Saprolegniosis* is the most common fungal infection of freshwater fish. Water molds are distributed worldwide; virtually every freshwater fish is susceptible to at least one species of water mold. Water molds are members of the Class Oomycetes; over 30 species have been isolated from diseased fish. While water molds are classified as animals in the Kingdom Protoctista (8), they look and behave like true fungi and are managed in the same way as the true fungi. The great majority of fish pathogens are in the Family Saprolegniaceae (Order Saprolegniales). Most infections are caused by *Saprolegnia* (which is why the disease is called saprolegniosis), but other Oomycetes cause an identical disease.

Water molds are ubiquitous saprophytes in soil and freshwater. They are appropriately named, reproducing in water or moist soil via formation of swimming spores (sporulation); this mode of reproduction distinguishes them from terrestrial fungi, which produce aerial (airborne) spores. Water molds are transmitted by their swimming spores. Most infections of fish are probably acquired from inanimate sources (i.e., from fungi that produce spores on dead organic matter) rather than from live-fish-to-live-fish transmission. Outbreaks often occur after a drop in temperature (3). This trend may be due to lower immunity of the host (9) and because many Oomycetes are more active in the cooler months of the year (5).

Typical water mold infections appear as a relatively superficial, cottony growth on the skin or gills that can rapidly spread over the body surface. Newly formed infections are white (the color of the hyphae); with time, they often become red, brown, or green as they trap sediment, algae, or debris in the hyphae. When observed on a fish removed from the water, the fungus appears as a slimy, matted mass on the body. (see Fig. 2.) "Winter kill" is a water mold infection of channel catfish (*Ictalurus punctatus*) during winter. The disease typically appears soon after the passage of a cold front, which rapidly drops water temperatures and reduces the resistance of the fish (9).

Although superficial, skin or gill damage from water molds is often fatal, due to loss of body fluids and salts from the open wounds. Mortality increases as the area of affected skin or gill tissue increases. With acute outbreaks, fish usually die within several days or recover within several weeks. Oomycetes are important pathogens of fish eggs. Infections usually begin on dead eggs and can rapidly spread to healthy eggs, eventually resulting in complete loss of the brood.

Figure 1. Wet mount of water mold. (Photo courtesy of A. Colorni.)

Figure 2. Photograph of a water mold infection. Note the slimelike appearance of the infection when viewed out of the water.

Diagnosis of a water mold infection requires that affected fish be alive when examined, because water molds are ubiquitous saprophytes in soil, freshwater, and, to some extent, estuarine environments; dead fish are quickly colonized, resulting in a misdiagnosis. Oomycetes will also invade wounds caused by other pathogens (e.g., bacteria and parasites). Always look for other initiating causes when water molds are identified in a wound.

Water molds are among the most difficult diseases to treat. Except for salt, agents legally approved for foodfish (10) are of limited effectiveness. Malachite green is the most effective agent for treating water mold infections in fish, but it is not approved for use with foodfish in many countries, because it is a teratogen and mutagen. Most water molds that are pathogenic to fish are inhibited even by low salt concentrations (less than 3 ppt), which is probably why most species do not affect marine fish. (However, see the upcoming section on atypical water mold infections.) Salt also helps to counteract osmotic stress due to skin damage and subsequent ion loss, though long-term salt baths are impractical in most commercial production situations. Short-term hydrogen peroxide or formalin baths may be useful for treating some infections (11,12).

Because of the often rapid development of oomycete infections, as well as their resistance to drugs, prophylaxis is the best strategy for treating the infections. Avoid skin damage and predisposing stresses. Salt baths are an effective prophylactic when transporting fish or acclimating them to a new environment. It is probably not possible to eliminate water molds from a culture system.

Deep Infections

Atypical Water Mold Infections. Atypical water mold infections (e.g., epizootic ulcerative syndrome [EUS], red-spot disease [RSD], mycotic granulomatosis [MG], and ulcerative mycosis [UM]) differ from typical water mold infections in that the former cause an extremely deep, penetrating wound. (see Fig. 3.) While atypical water mold infections are less common than typical water mold
Figure 3. Photograph a large, deep skin ulcer (arrow) caused by EUS, also known as RSD. (Photo courtesy of R.B. Callinan.)

infections, they are a serious disease in many parts of the world (13,14).

Atypical water mold infections occur in numerous estuarine and freshwater fish populations, including snakehead, walking catfish (*Clarias* spp.), mullet (*Mugil* spp.), and gouramies. In the Australo−Pacific and southern Asia, they make up one of the most important diseases of cultured fish (13,15). Morbidity and mortality can be very high, and epidemics can develop rapidly. However, once an epidemic has occurred in an area, the prevalence and severity of future outbreaks often subside. The infections are also a problem in wild estuarine fish of the western Atlantic Ocean (7).

Unlike typical water mold infections, atypical water mold infections usually produce reddened, deep wounds (see Fig. 3) that may even penetrate into the body cavity. *Aphanomyces* is most commonly isolated from wounds (7,16). A presumptive diagnosis of atypical water mold infections is based on a microscopic identification of typical hyphae surrounded by many host immune cells in the wound.

While atypical water mold infections can be diagnosed as a disease by confirming that a water mold is present, the primary cause of the ulcers is largely unknown. While the fungi and bacteria present in lesions probably play an important role in killing fish, they are probably not responsible for initiating any of the lesions. There is evidence that skin damage caused by a toxic dinoflagellate, *Pfiesteria*, can lead to atypical water mold infections in Atlantic coast estuarine fish, including hybrid striped bass (17). The cause of the clinically similar RSD and EUS is unknown, although a rapid drop in pH has been suspected to play a role in some cases (18). There is also evidence for the spread of some agent, since EUS and RSD have spread from the Australo−Pacific region to encompass most of southern Asia (13). There is no proven treatment for atypical water mold infections.

Branchiomycosis. Branchiomycosis has sporadically caused acute infection and, often, high mortality rates in several freshwater fish, including cultured American eel (*Anguilla rostrata*), European eel (*A. anguilla*), and centrarchids (19). It has been reported mainly from Europe and Taiwan, but isolated cases have also occurred in the United States. The gills of infected fish are "mottled" in appearance, due to the formation of clots in blood vessels. Wet mounts or histopathology of characteristic branched hyphae causing deep gill infection are diagnostic. There is no known treatment. Reducing organic loading and reducing the temperature below 20 °C (68 °F) might be helpful.

Miscellaneous Deep Fungal Infections. All other deep fungal infections in fish are rare. Most have been encountered as sporadic cases, although some have caused localized epidemics. Virtually all such diseases are chronic infections. Among the most prevalent are *Exophiala* (found in trout, salmon, cod, and flounder) and *Ochroconis* (found in trout and salmon).

IMPORTANT FUNGAL DISEASES OF SHELLFISH

Fungal diseases occur in most major groups of cultured invertebrates, including shrimp, lobster, crabs, clams, oysters, and cephalopods (3,4,6). While they occasionally are localized problems, they are usually much less important than other infectious agents, such as viruses, bacteria, and parasites.

Water Molds

Oomycetes are the most important fungal pathogens of aquatic invertebrates. They usually infect shellfish in the early stages of life, affecting eggs, larvae, and postlarvae. Particular species are restricted to either marine or freshwater environments. This is due mainly to the inability of freshwater species to withstand the osmotic conditions of the marine environment, and vice versa (20).

Crayfish Plague. The most important fungal infection of aquatic invertebrates is *Aphanomyces astaci*, or krebspest, the cause of crayfish plague. All native species of European crayfish are highly susceptible (with usually 100% mortality) to this fungus, and its spread throughout Europe, to which it was introduced from North America with shipments of imported crayfish, has lead to the extinction of many native crayfish populations. Species of North American crayfish, such as *Pacifastacus lenisculus*, are much more resistant and can carry *A. astaci* and transfer it to other crayfish species (21).

A. astaci is transmitted by motile spores that settle on and infect the cuticle, eventually penetrating into deeper tissues. Crayfish may die within two weeks of becoming infected. Infected crayfish are hyperactive at first, but then become lethargic. The tail is extended instead of tucked under the abdomen, and the crayfish may lie on its back and move its legs continuously. The claws hang down when the crayfish is taken out of the water. Normally noctural, the crayfish will begin to move around during the day. Its abdominal muscles may turn white. Infections may be difficult to detect grossly, but hyphae are visible in infected tissue through microscopic examination.

Resistant species of crayfish can also become infected and may become sick, but the infection is usually successfully limited by their host defense, mainly the production of toxic chemicals that melanize the hyphae, turning them black and killing them. It is advisable to avoid moving crayfish from infected areas. Traps and other gear used in areas that have *A. astaci* should be disinfected to kill the fungus. Unlike other Oomycetes, *A. astaci* supposedly requires live crayfish to survive and thus should eventually die out in waters that are free of crayfish (21).

Other Oomycete Infections. Other important water mold pathogens of aquaculture species include *Lagenidium*, which is responsible for larval mycosis of shrimp and crabs, and *Sirolpidium*, which causes larval mycosis of oysters, clams, and shrimp. Many Oomycetes have a broad range of hosts. Examples include *Lagenidium callinectes*, which infects many species of crabs and shrimp, and
Figure 4. *Fusarium* infection causing "black gill" (arrow) in penaeid shrimp. (Photo courtesy of C. Bland.)

Haliphthoros milfordensis, which infects crabs, shrimp, and lobsters (6,22).

Hyphomycetes

With the hyphomycete fungi, there is no true distinction between marine and freshwater pathogens. Unlike the Oomycetes, the Hyphomycetes are not well adapted to survive in water. However, they can still cause serious disease in aquatic animals. Unlike Oomycetes, which infect mostly larval invertebrates, Hyphomycetes usually affect subadult and adult crustaceans. They are weakly pathogenic. Thus, they often cause disease in concert with some stressful event. The most clinically important hyphomycete is *Fusarium*, which is responsible for black gill disease of shrimp (see Fig. 4) and black (burn) spot disease of shrimp, lobsters, and crayfish (22,23). *Fusarium* produces intensely dark (melanized) areas, especially on the appendages and gills. Diagnosis is via wet mount or histology showing characteristic fungal hyphae and spores.

FUNGAL DISEASES OF FROGS AND ALLIGATORS

Water molds have occasionally caused disease outbreaks in immature frogs (i.e., tadpoles). Fungal infections in reptiles such as alligators or turtles are rare, although *Aphanomyces* water mold has recently caused epidemics in softshelled turtles (*Pelodiscus sinensis*) (24).

G

GAS BUBBLE DISEASE

John Colt
Northwest Fisheries Science Center
Seattle, Washington

OUTLINE

Supersaturation of atmospheric gases in water is common due to a number of natural and man-induced processes. The exposure of aquatic animals to gas supersaturation can result in the formation of gas bubbles on body surfaces or within the vascular system and tissues. This condition is called gas-bubble disease or trauma. Gas bubble-disease (GBD) can reduce growth, increase mortality, and result in buoyancy problems in small larval fish and amphibians. The formation of gas bubbles and resultant inflammatory reaction provides an ideal environment for opportunistic secondary bacterial invaders. The variability in sensitivity to GBD within a population is significant and is not fully understood.

WHAT IS GAS SUPERSATURATION?

The potential formation of gas bubbles depends on the difference between the measured barometric pressure and the total gas pressure (TGP) in the water (1), given as:

$$\text{Total gas pressure} = \text{PP}^1_{O_2} + \text{PP}^1_{N_2+Ar} + \text{PP}^1_{CO_2} + \text{PP}_{H_2O} \tag{1}$$

where

$\text{PP}^1_{O_2}$ = partial pressure of oxygen gas in the water (mm Hg),

$\text{PP}^1_{N_2+Ar}$ = partial pressure of nitrogen gas in the water (mm Hg),

$\text{PP}^1_{CO_2}$ = partial pressure of carbon dioxide in the water (mm Hg), and

PP_{H_2O} = vapor pressure of water (mm Hg).

In gas supersaturation work, nitrogen gas and argon gas are generally treated as a single gas ($N_2 + Ar$ or simply N_2) because the two gases are not individually determined (2).

Three conditions may exist:

Total gas pressure = barometric pressure (equilibrium)
Total gas pressure > barometric pressure (supersaturated), and
Total gas pressure < barometric pressure (undersaturated).

The difference between total gas pressure and barometric pressure (TPG-BP) is called the differential pressure and is indicated by the symbol ΔP, which can be measured directly. ΔP is the best predictor of the danger from gas supersaturation. If $\Delta P < 0$, then gas bubbles cannot form, regardless of the degree of supersaturation of a single gas.

Gas supersaturation may also be reported as a percentage of the local barometric pressure BP:

$$\text{TGP\%} = \left[\frac{\text{BP} + \Delta P}{\text{BP}} \right] 100 \tag{2}$$

The actual risk to an individual animal depends on both ΔP and the animal's position in the water column (3). The ΔP an animal experiences is equal to the difference between the total dissolved gas pressure and the local pressure (barometric + hydrostatic pressures). The uncompensated ΔP is equal to

$$\Delta P_{\text{uncomp}} = \Delta P - \rho g Z \tag{3}$$

where

ΔP = measured ΔP (mm Hg),

ρg = hydrostatic pressure of water (mm Hg/meter of submergence),

Z = depth in water column (m).

The value of ρg depends both on temperature and on salinity. At 20 °C and 0 g/kg salinity, the value of ρg is

equal to 74.3 mm Hg/m, and other values can be found in the literature (2).

SOURCES OF GAS SUPERSATURATION

Gas supersaturation can be produced by a variety of physical and biological processes. Eight mechanisms can produce gas supersaturation (4): heating of waters, ice formation, mixing of waters of different temperatures, air entrainment, photosynthesis, pressure changes, physiological process, and bacterial action.

In a specific situation several mechanisms may be involved. Many surface waters, groundwaters, and springs are naturally supersaturated during some part of the year. Gas supersaturation can also be produced within the hatchery or rearing unit. Not all supersaturation problems can be prevented by simple degassing of influent water.

MEASUREMENT OF GAS SUPERSATURATION

The preferred method of gas analysis is the direct-sensing membrane-diffusion method. The instruments for this analysis use a variable length of gas-permeable tubing (e.g., dimethyl silicone rubber) connected to a pressure measuring device (5). Silicone rubber tubing is highly permeable to dissolved gases, including water vapor. At steady state, the gauge pressure inside the tubing is equal to the difference in gas pressure (ΔP) between the total dissolved gas pressure and local barometric pressure. Several types of membrane-diffusion instruments are commercially available. These instruments are field portable, and all data collection is completed in the field.

CLINICAL SIGNS OF GAS-BUBBLE DISEASE IN AQUATIC ANIMALS

General information on the sensitivity of aquatic animals to gas supersaturation is available in published sources (6). The clinical signs of GBD are best described in fish (7–9); less information is available for other aquatic culture animals.

The clinical signs of GBD are very dynamic. The suite of clinical signs observed may depend more on the rapid disappearance of some clinical signs than the exposure levels or exposure time. A hydrostatic pressurization of 5 min to 30.5 m of head resulted in a substantial reduction in clinical signs of GBD in the fins, lateral line, and gills of yearling spring chinook salmon (*Oncorhynchus tshawytscha*). Clinical signs of GBD were lost most rapidly in gills, followed by the lateral line. The rate of bubble loss was much less for the primarily extravascular bubbles found in the fins (10). In work conducted on salmon smolts (*Oncorhynchus* sp.), it was found that gill filaments must be examined within 2 min after the gill arch is excised (11), and care must be exercised to differentiate bubbles from similar-appearing lipid bodies. Examination of moribund or freshly dead fishes for subcutaneous bubbles on fins and body surfaces is easily done in the field, providing representative specimens can be

collected (8). Histopathologic examination of fish from suspected supersaturation kills has often been found to be inconclusive and has offered no specific diagnosis. The major clinical signs of GBD that can cause death or lead to high levels of stress in aquatic animals are discussed next.

Subcutaneous Emphysema on Body Surfaces, Including the Lining of the Mouth

Subcutaneous emphysema (gas bubbles within skin tissues) is commonly found on fins and tail, inside the mouth and operculum, and on the body surface. The formation of gas bubbles and resultant inflammatory reaction provides an ideal environment for opportunistic secondary bacterial invaders. Emphysema of tissue in the mouth may also contribute to the blockage of respiratory water flow and death by asphyxiation (12). Subcutaneous emphysema on the dorsal fin of a chinook salmon is presented in Figure 1a.

Bubble Formation in the Vascular System

Formation of bubbles in the vascular system may result in petechial (pinpoint) hemorrhaging, restricted blood flow, necrosis, and death. Long, tubular bubbles may be observed in the gill vessels of fish and are shown in Figure 1b. Bubbles may be found in the blood vessels, heart, kidney, spleen, and liver. Gill bubbles can be observed with a binocular or compound microscope, but bubbles in internal organs are sometimes difficult to see. In animals exposed to high levels of gas supersaturation, incision of internal organs may produce a significant amount of bubbles (8). *Xenopus laevis* exposed to gas supersaturation accumulate a massive amount of gas under the skin (Fig. 1c); when the skin on legs is cut, the incision can bubble (13). Increased mortality due to secondary bacterial infections such as *Aeromonas hydrophila* and *Vibrio alginolyticus* has been observed (14,15).

Bubble Formation in the Eyes of Fish

Exophthalmia or "popeye" results from the accumulation of gas in the eye. While this clinical sign is quite distinctive, it is not as common as subcutaneous emphysema and may be caused by a variety of other diseases. Exophthalmia in itself does not cause blindness and may be reversible if the animal is transferred to nonsupersaturation conditions (8). Exophthalmia is common in captively held cod (*Gadus morhua*) (16) and rock fish (*Sebastes* spp.) (17). It is thought that this condition is caused by malfunctioning of the choroid gland-pseudobranch complex (16) and may be due to a lack of adequate hydrostatic pressure.

Overinflation and Possible Rupture of the Swim Bladder in Fish

The impact of swim bladder overinflation depends strongly on species and size. Fish can be classified as either physostomes (swim bladder is connected to the gut by the pneumatic duct) or physoclists (closed swim bladder).
Figure 1. Common clinical signs of gas-bubble disease in aquatic animals. (**a**) Subcutaneous emphysema on the dorsal fin of chinook salmon *O. tshawytscha* (11); (**b**) bubbles in gills of chinook salmon, *O. tshawytscha*, (11); (**c**) accumulation of gas in *X. laevis* (29); and (**d**) overinflation of the swim bladder and intestinal bubble in larval striped bass, *Morone saxatilis* (21).

Some fish are physostomes as larvae and lose their pneumatic duct as they grow larger. The ability to actively secrete gas into the swim bladder is better developed in the physoclists (18).

The overinflation of swim bladders of small marine fish such as cod (19), sea bass (*Lates calcarifer*) (20), striped bass (*M. saxatilis*) (21), *Siganus lineatus* (22), and mullet (*Mugil cephalus*) (23) is common in culture. Once the swim bladder is inflated, very little gas supersaturation is needed to overinflate the swim bladder. The ability of small larval fish to regulate the volume of gas in the swim bladder may be limited, and formation of a single bubble may float them to the surface. Because of the significant forces exerted against the swim bladder and the resulting physical damage, survival of floating larval fish may be limited even if the swim bladder can be deflated. An example of an overinflated swim bladder and intestinal bubbles in larval striped bass is presented in Figure 1d.

Swim bladder overinflation is also a problem in salmonids. In rainbow trout (*Oncorhynchus mykiss*), the swim bladder can become overinflated as a result of dissolved gases diffusing from the water to the bladder by way of the gills and vascular system. When this happens, fish may become severely overbuoyant. In small rainbow trout (<10 g), the pressure required to vent air out the swim bladder exceeds the swim bladder rupture

pressure (24). Larger fish are able to expel gas out the pneumatic duct and regulate swim bladder size.

Formation of Bubbles in the Gastrointestinal Tract or in Other Organs

The formation of bubbles in the gut of fish has been observed in herring (*Clupea harengus*) (25), plaice (*Pleuronectes platessa*) (19), *Acanthopagrus cuvieri* (26), channel catfish (*Ictalurus punctatus*) (27), white sturgeon (28), and striped bass (21). The accumulation of gas in the gut of bullfrog tadpoles causes them to float with their left sides elevated or on their backs (14). The accumulation of gas in the body and legs of adult bullfrogs and African clawed frogs (*X. laevis*) has resulted in floating animals (13,29). Flotation problems have been observed in small surf clams (*Spisula solidissima*) (30) and *Daphnia magna* (31).

Formation of Bubbles in the Lateral Line of Fish

In salmonids, one of the more common clinical signs of exposure to gas supersaturation is the formation of bubbles in the scale pockets of the lateral line. The formation of bubbles in the lateral line results in reduced or eliminated ability of the fish to detect near-field water displacements and may decrease the fish's ability to avoid predation (32).

Formation of Bubbles Attached to Body Surfaces or in the Mouth

In aquatic insects, exposure to high levels of gas supersaturation may result in the growth of gas bubbles on external as well as internal surfaces. External bubbles affect the buoyancy of the insect, but can be dislodged if the animal rises to the water surface (31).

In steelhead fry (*O. mykiss*), large bubbles may form in the buccal cavity. While these bubbles are not physically attached to the fish, their presence may result in reduced water flow through the gill, development of opercular deformities, and may force the fish to swim in a heads-up position (33).

LETHAL LEVELS

Acute GBD is associated with bubble formation in the vascular system and tissues. It produces a large array of clinical signs, leads to damage to tissue and vascular occlusions, and results in high rates of mortality (up to 100%) with even short exposures (2 h to 10 days). Lethal concentration information is useful for assessing the potential impact of short-term exposures to high gas supersaturation levels. The lethal tolerance of an animal will decrease as the exposure time increases, although the variability among animals is surprisingly large.

Eggs and newly hatched fry appear to be resistant to high ΔP's. In a study of steelhead trout, ΔP's up to 200 mm Hg had no effect on hatching (34). The lack of sensitivity of eggs is probably due to the fact that pressure within the eggs is higher than 1 atmosphere. After 1,000 h of incubation, pressure inside the eggs of different salmonids species ranged from 51 to 76 mm Hg above barometric pressure (35). This pressure reduces the ΔP_{uncomp} within the egg (Eq. 3). In the incubation of semibuoyant eggs, such as those of striped bass, attachment of bubbles to the external surface of the egg may float the egg out of incubation systems and down the drain.

Newly hatched steelhead trout are resistant to ΔP until about day 16 posthatch (34). According to the study, at day 16 bubbles formed in the mouth, gill cavity, and yolk sac. Accumulation of bubbles in the larvae prevented normal swimming and feeding and eventually trapped the fish at the surface. Over a 90-day exposure, starting with fertilization, a ΔP of approximately 130 mm Hg resulted in 50% mortality.

The 4-day LC_{50} value of juvenile and adult fish ranges from 53 to 230 mm Hg. The 30- to 35-day LC_{50} of fish ranges from 106 to 117 mm Hg. The lethal tolerance of salmonids depends strongly on size or age (Fig. 2). The tolerance of Atlantic salmon (*Salmo salar*) and lake trout (*Salvelinus namaycush*) to gas supersaturation is high for small fish (<50 mm) and decreases for larger fish. For lake trout, the tolerance to gas supersaturation also decreases for larger fish (>150 mm Hg). The tolerance of marine species is highly variable; no quantitative data are available for larval stages of the small marine and estuarine species known to be very sensitive to gas supersaturation. Crustaceans and insects have a wide
Figure 2. Tolerance of Atlantic salmon and lake trout to gas supersaturation as a function of total length (45). The vertical arrow symbol represents exposures levels where mortality was insufficient to allow computation of the LC_{50} value. The 4-d LC_{50} levels is the level of gas supersaturation that will kill 50% of the animals in 4 days.

variation in sensitivity to gas supersaturation, at least over a standard 4-day exposure. Molluscs have a high tolerance to gas supersaturation, some of which may be due to the ability to "clam up" for an extended period of time. Amphibians appear to have a sensitivity to gas supersaturation comparable to that of freshwater fish.

CHRONIC GBD

When aquatic animals are continuously exposed to ΔP's in the range of 20 to 100 mm Hg, a chronic type of GBD develops and is associated with extravascular symptoms such as bubble formation in the gut and buccal cavity, hyperinflation or rupture of the swim bladder, and low-level mortality in juvenile animals over extended periods of time.

In a study of striped bass larvae, gas supersaturation resulted in hyperinflation of the swim bladder and formation of gas in the gut (21). Clinical signs of GBD were observed at ΔP's as low as 22 mm Hg, and mortality was increased at 42 mm Hg. However, mortality may have been due to rupture of the swim bladder, because none of the typical clinical signs of acute GBD were observed. The period of maximum sensitivity appeared to occur near the first filling of the swim bladder and the beginning of feeding. The accumulation of gas in these small larvae commonly floated them to the surface. Flotation problems, overinflation of the swim bladder, and the accumulation of gas in the gut are the most common clinical signs of GBD observed in small marine fish larvae.

Growth is not a good indicator of sublethal impacts of gas supersaturation in some fish. In studies of channel

catfish and rainbow trout, gas supersaturation levels resulting in significant mortality from gas supersaturation had no impact on the growth of survival animals (33,36). In lake trout, corneal swelling was observed at ΔP's greater than 17 mm Hg, although the total incidence of ocular abnormalities did not increase for ΔP's up to 43 mm Hg (37).

ANCILLARY OR MODIFYING FACTORS

Physical and biological factors can significantly modify the effects of a given ΔP. Some of the most important factors in aquatic systems are discussed next.

Depth

The ΔP_{uncomp} decreases approximately 74.3 mm Hg/m (Eq. 3), and a few meters of submergence can protect aquatic animals from high levels of gas supersaturation as long as they remain at this depth. The impact of hydrostatic pressure on an acutely lethal gas supersaturation level of 250 mm Hg is presented in the following table:

Depth (m)	ΔP_{uncomp} (mm Hg)
0	250
1	176
2	101
3	27
4	−47

As long as an aquatic animal remains below the compensation depth of 3.36 m, there is no tendency for gas bubbles to form. However, if this animal is forced to the surface, GBD can develop rapidly.

It does not appear that fish can directly detect gas supersaturation, but they will respond to overinflation of the swim bladder. Work with coho salmon, (*Oncorhynchus kisutch*), shows that fish increased their mean depth to alleviate the symptoms of GBD up to a ΔP of 84 mm Hg (38). Above this ΔP, the fish no longer remained below a depth that compensated for the ΔP, and increased signs of stress were evident. In the laboratory environment, Shrimpton (39) also found that given the opportunity to use water depth to compensate for overbuoyancy, small rainbow trout would spend a significant amount of time at a water depth where they were neutrally buoyant. Furthermore, as ΔP increased, fish would move deeper in the water column to overcome the effects of swim bladder overinflation. Increasing the depth of culture systems can offer passive depth compensation by allowing the fish access to greater hydrostatic pressure (40).

(Nitrogen + Argon): Oxygen Pressure Ratio

Increasing the partial pressure ratio of (nitrogen + argon): oxygen, increases the lethal effects of a given ΔP (41). Regardless of the value of this ratio, the ΔP_{uncomp} inside the animal must be greater than 0 for the formation of gas bubbles.

Feeding and Diet

Fasting appears to increase the impact of a given ΔP (14,21).

Intermittent Exposure

Juvenile salmon and trout can tolerate an acutely lethal ΔP (170 mm Hg) for 16 hours/day if they are returned to saturated water for the other 8 hours (42).

WATER QUALITY CRITERIA FOR GAS SUPERSATURATION

The water criterion for gas supersaturation established by the U.S. Environmental Protection Agency (43) is 110% of barometric pressure or a $\Delta P = 76$ mm Hg. This criterion is inadequate to protect the more sensitive species of nonsalmonid fish or salmonids exposed to chronic gas supersaturation, particularly when water depth is limited.

The following chronic water-quality criteria are proposed for gas supersaturation:

Characteristics	ΔP (mm Hg)
Very sensitive animals and experimental trials	<10
Sensitive animals	<20
Average animals under production conditions	<40

An example of a very sensitive animal is the lake trout if ocular lesions are considered. A sensitive animal would include small marine fish larvae, especially when reared in shallow containers (<0.5 m). Average animals would include most other fish, crustaceans, and mollusks reared under production conditions. Criteria in the range of 10−20 mm Hg are consistent with GBD threshold levels based on bubble formation and growth (44). These criteria should be very protective on a chronic basis, and higher values may be tolerated for shorter periods of time. A criterion of 40 mm Hg may not offer absolute protection for all species and life stages, but is a reasonable goal when economics are a consideration.

PREVENTION OF GAS BUBBLE DISEASE

The prevention of GBD within a hatchery will depend on degassing of influent water and some process waters, the design and operation of aquatic systems to prevent production of gas supersaturation within the hatchery, and possibly changes in facility design and management practices for sensitive animals. The monitoring of ΔP's of influent waters and at key points in the hatchery may help to identify problems and allow correction before major mortality occurs.

Bibliography

Gilthead sea bream, a member of the family Sparida, is found in the Mediterranean and Black Seas and extends into the Atlantic Ocean from the British Isles south to Senegal. Sparidae is represented by approximately

26 species in this region, including two migrants from the Red Sea that have become established in the eastern Mediterranean Sea since the opening of the Suez Canal (1,2). The reported fisheries catch for this family in the Mediterranean and Black Seas during 1996 reached close to 70,000 metric tons (77,000 short tons); the gilthead sea bream contributed almost 7% (3). Farming of sea bream is carried out in seawater ponds and lagoons; the bulk of production occurs in sea cages of various types. Most countries around the Mediterranean culture sea bream; Greece, Turkey, and Spain are the major producers in the region, accounting for over 70% of production. The culturing of sea bream has made impressive strides in much less than two decades, going from an estimated 110 metric tons (121 short tons) of fish in 1985 (4) to 41,900 metric tons (46,200 short tons) in 1998 (5). This success is the result of strong research and development programs in many of the region's countries, fueled by a persistently strong market demand for sea bream.

LIFE HISTORY

The gilthead frequents coastal and lagoonal waters during most of its life, moving into deeper waters during the spawning season in late fall and winter (6). The adults return to the shallower areas after spawning and are later joined by the young fry, which remain in the area until they reach sexual maturity. Sea bream generally feed on shrimp and shellfish, which they find on or in the sandy bottom sediments. Fish can be observed digging their heads into the sand and removing shellfish and crustaceans, which they easily crush with their strong molar-like teeth.

The gilthead sea bream has a typically oval shaped body, which is deep and compressed laterally. Its body color is mainly silver grey, with a large black blotch starting behind the gill cover and extending forward over the upper part of the gill cover. A yellowish area appears below this black blotch, and bright yellow lines both between the eyes and on the stomach, starting behind the pelvic fins. These bright yellow colors are the origin of its Latin species name *aurata*.

REPRODUCTION AND LARVAL CULTURE

Early attempts at sea bream culture started in Italy and France (4), in sea water lagoons and tidal ponds under extensive conditions, with wild-caught fry, juveniles, and growout stage fish of various sizes. The successful reproduction of sea bream in captivity resulted in barely enough production of stockable fry for the initiation of intensification of sea bream culture. The following decades saw the production of stockable fry increase significantly, to 161 million by 1997 (7). This increase was paralleled by the development of feeds specifically formulated for sea bream and by the development of the intensive culture and management techniques that have made sea bream culture a major form of mariculture in the Mediterranean region today. In addition, the gilthead sea bream has established itself as an important model species in the study of fish reproductive physiology and molecular biology (8–16).

The gilthead sea bream, a protandrous hermaphrodite (17), in captivity develops as a functional male by the end of its first year. After the spawning season, the males begin to develop ovaries; this process continues until early fall (September in the eastern Mediterranean region); at this point, a fish either develops as a functional female or absorbs the ovarian tissue and redevelops male gonadal tissue (17). The proportion of males that undergo sex reversal is dependent primarily on the male-to-female ratio in the population (18). Males do not lose their potential for sex-reversal, and can do so at any age if placed in the right social environment in terms of male-to-female ratio.

Sea bream reproduction is controlled by light (or photoperiod), thermal, and social cues. Fish respond primarily to a shortening of the day's length and secondarily to a reduction in water temperature. Spawning in captivity in the eastern Mediterranean region starts at around the shortest day of the year, provided that fish are in a balanced sex ratio — optimally 1 : 2 (male : female) in groups over 9 fish, 1 : 1 in smaller groups. Single-pair matings are difficult to obtain on a reliable basis (19) and should be avoided. Sea bream will spawn in a wide range of tank sizes, from 1 m^3 (264 gal) upward, but their density should not exceed 5 kg/m^3 (11 lb/264 gal). A minimum of 2–3 females, with a similar number of males, provides successful spawnings and a high rate of egg fertilization.

The act of spawning usually takes place in the late afternoon, although some groups can adopt a morning pattern. Prior to spawning, the fish undergo a change in both body coloration and behavior; then, a typical group courting swim occurs, and finally spawning. Sea bream are batch spawners; females undergo daily cycles of final oocyte maturation, ovulation, and spawning during the reproductive season (15,17). The net result is that each female can produce some 1–3 million eggs during the spawning season (20,21).

The strong influence of photoperiod (day : night ratio) on sea bream reproduction makes the fish susceptible to a manipulation favoring the goal of extending its reproductive season. In fact, year-round spawning has been accomplished under artificial lighting, that mimics changes in day length, coupled with the shifting of the shortest day of the year to March, June, or September. This photoperiod shift, coupled with corresponding control of water temperature, can provide three groups of broodstock that will spawn outside of the natural reproductive season and yield year-round egg production.

Parent stock derived from fish bred in captivity for a number of generations usually spawn naturally and do not require spawning induction. This situation has been true for the past four to five years; previously, however, hormonal therapy for spawning induction was essential in order to obtain reliable spawning. The most effective treatment for the sea bream is the use of controlled release gonadotropin releasing hormone (GnRH) devices, administered either as implants or as microspheres (22–24). If it is important that all the females in the broodstock spawn (such as in cases of genetic selection), then it is recommended that the females be treated using one of the methods mentioned.

Extensive research into the influence of environmental and biotic factors on the rearing of gilthead sea bream larvae have resulted in the successful mass rearing that is carried out in many commercial hatcheries throughout the Mediterranean region. The techniques used vary among the different protocols, but most are based on R&D carried out over the past two decades. The following research findings helped in the development of one of these protocols, which will be described later.

Intermediate photoperiods of 15L : 8D (15 hours light and 8 dark) provide better survival than either more or less daylight; however, best larval growth seems to occur under continuous light (25). An intermediate light intensity, 1000–1500 lux at the water's surface, favors better growth and survival than lower (100–250 lux) or higher intensities (10,000 lux) (26,27).

A reduced salinity (25 ppt) also promotes the growth and survival of sea bream larvae, causing up to a 13% improvement in growth and a three-fold increase in survival, to 32 days, as compared with that of larvae reared in 40-ppt seawater (28,29). This inverse relationship between survival and salinity suggests that a portion of the larval population may be predisposed to having insufficient reserves of energy, which would result in reduced survival, and, further, that any environmental factor associated with energy sparing may therefore affect larval survival. In addition, reduced salinity (25 ppt) is associated with an almost 50% improvement in the development of a functional swimbladder (28).

Sea bream larvae demonstrate a size preference in rotifer consumption that is associated with their size. Newly pigmented larvae prefer 180 μm (7.1×10^{-3} in.) rotifers, even avoiding larger, 340 μm (1.34×10^{-2} in.) ones, while six-day-old larvae demonstrate a reverse preference (30). The enrichment of rotifers and Artemia is designed to modify the feed organisms' essential fatty acid composition to better suit the larval sea bream requirements for maximum growth and survival. Sea bream up to 22 days old require rotifers enriched to 4–8 mg *n*-3 highly unsaturated fatty acids (HUFA)/g dry weight ($1.4–2.8 \times 10^{-4}$ oz/3.5×10^{-2} oz dry weight); older fish require 29 mg *n*-3(HUFA)/g dry weight (1×10^{-3} oz/3.5×10^{-2} oz dry weight) of Artemia (31–33).

Management factors in larval rearing — for example, the type of tanks used, larval stocking densities, the water temperature regime, and the species and concentration of microalgae used — all play important roles in the success of a rearing regime. Under conditions of high salinity (40–41 ppt), cylindroconical tanks 400–1700 L (104–442 gal) in volume have provided consistent larval survivals of 25% up to day 32 after hatching. This survival has also been related to rate of water exchange; two to four exchanges per day are commonly used for these tanks (34).

The following rearing protocol, based on the research findings discussed above, was devised and is currently in commercial use. Fertilized eggs are stocked at 100/L (90/qt) in the cylindro-conical tanks, and hatching success is estimated with aliquot measurements. The initial water temperature is set at $19 \pm 0.5\,°C$ ($66.2 \pm 0.9\,°F$); the temperature is raised gradually, to $24.5 \pm 0.5\,°C$ ($76.1 \pm 0.9\,°F$) by the last nine days of the 32 day rearing period. The tanks are supplied continuously with filtered (to 10 μm = 3.9×10^{-4} in.) water, and temperature and salinity are controlled. Seawater is exchanged at a rate of two to four times a day, depending upon larval age. Freshly enriched live food (rotifers and Artemia nauplii) as well as single cell algae (*Nannochloropsis* sp.) are supplied continuously to the rearing tanks through a controlled delivery system designed to maintain rotifers at 10/mL (296/oz), algae at 5×10^5 cells/mL (148×10^5/oz), and nauplii at 1/mL (29.6/oz) during the 15 hours of light. Rearing tanks require only one cleaning during the 32 days to produce 15–35 larvae/L (13.5–31.5 larvae/qt) at the end of the cycle, a 20–40% survival rate.

Although current protocols for the nutrition of larval sea bream are based on live food organisms, there has been emphasis on developing formulated microdiets that can replace live food. The initial work has indicated that microdiets are eaten and assimilated much less than live food (35); however, the addition of exogeneous digestive enzymes promotes a 30% improvement in assimilation (36). The combination of a microdiet with live food promotes the best growth, which may result from the attraction of the live food (35). The addition of attractants (glycine, alanine, arginine or betaine) to the microdiet raises ingestion to the same levels as live feed (37).

Recent work has shown that the phospholipid content of soybean lecithin, in particular phosphatidyl choline (PC), acts as a feeding attractant (38) in sea bream larvae and increases the assimilation rate of dietary lipids into body tissues by almost 50% (39). PC is thought to increase lipoprotein production, the function of which is to carry absorbed lipids to the rest of the body (39). Arachidonic acid has been suggested as playing an important role in promoting growth and survival in young sea bream larvae, through its role as a precursor of different eicosanoids in the body.

Once larvae metamorphose and reach 32 days of age, the problem of cannibalism becomes important and must be dealt with to minimize mortality (40). Homogeneity in the size of the larvae being cultured significantly reduces mortality by reducing the extreme size differences among the individual larvae that facilitate predation. In the above protocol, larvae are routinely graded mechanically into three size groups: 5, 10, and 32 mg wet weight (2, 4, and 12×10^{-4} oz); this segregation by size helps increase the overall survival of the population.

COMMERCIAL CULTURE

Juvenile sea bream weighing 1–5 g ($3.5–17.6 \times 10^{-2}$ oz), when stocked in culture systems, reached commercial sizes of 250–300 g (9–10.5 oz) over a period of 18–24 months during the early years of intensification of sea bream culture. Domestication, improved feeds and feeding techniques, and a limited amount of selective breeding have reduced the growout time for sea bream to 12–14 months, yet yield a larger fish: 400–500 g (14–17.6 oz) average weight. Fish are cultured to sizes of up to 1.5 kg (3.3 lb), but the majority of sea bream are marketed in the 250–800 g (8.8–28 oz) weight range.

The intensive culture of sea bream today is carried out mainly in sea cages, although land-based cement ponds or raceways are also in use where this type of culture is appropriate. Sea-cage culture is usually less costly to initiate and operate: there is no need to pump seawater, to provide aeration, or to undertake costly construction of ponds or raceways. Sea cages do, however, require protection from heavy seas and storms that can wreak havoc upon, even destroy, an established cage farm. The use of sinkable cages, or of cages specifically designed to withstand adverse sea conditions, has afforded some protection to sea bream cage farms. In many cases, however, the lack of sheltered lagoons or of a protected coastline has made establishment of the more expensive land-based systems necessary. Pollution caused by cage farms and the resulting environmental deterioration are another reason for farming sea bream on land. Effluents from ponds and raceways can readily be treated to reduce their effect on the surrounding environment before the water returns to the sea; sea-cage wastes are more difficult to treat. A comparison of the characteristics of cage- and land-based culture systems is presented in Table 1.

NUTRITIONAL REQUIREMENTS

The nutritional requirements of sea bream (Table 2) have been studied over the past 25 years, and the findings have been used to develop optimal feeds for their culture. Commercial feeds have been available to farmers since the 1970s and those feeds have undergone gradual improvement using research findings to refine feed formulations. Feed improvement has been characterized by better feed use by fish (lower feed conversion ratio), faster growth, healthier fish, and lower feed costs to the farmer. The present trend is the development of high-energy extruded feeds that are used more efficiently by the fish, for better growth and less environmental impact. Such feeds encourage the use of lipids as an alternative source of energy for the fish and, in so doing, spare some of the dietary protein for the preferred use: building and maintaining body tissues. Lipid levels approaching 20% are currently being used in commercial diets, and even higher levels are being investigated. The major limitation on the maximum level of lipid that can be incorporated in such diets is its effect on body composition: excessive levels of fat in the fish reduce their consumer appeal and so, ultimately, their price in the marketplace.

DISEASE PROBLEMS

The rapid development of sea bream farming has not been paralleled by adequate progress in the veterinary aspects of its culture. As a result, health management remains one of the major concerns of the aquaculturist, because diseases can cause major losses to commercial crops. The following are the diseases most commonly identified in gilthead sea bream, to date.

Viral Diseases

Lymphocystis. This highly contagious infection is caused by a cytoplasmic-DNA iridovirus. The disease

Table 1. Characteristics of Sea Bream Culture Systems[a]

Type of System Approach	Ponds		Sea Cages (Standard)
	Semi-intensive	Intensive	
Size (m^3)	100–1000 (130–1300 yd^3)	100–500 (130–650 yd^3)	1000–5000+ (1300–6500+ yd^3)
Construction	Earthern — can be plastic/rubber lined	Cement or block — can have liner	Solid or flexible mesh — fish net common
Relative cost[b] ($/$m^3$ are $/1.3 yd^3)	50–100	100–200	20–80
Max. fish culture density (kg/m^3)	10–25 (22–55 lb/264 gal)	>50 (>110 lb/264 gal)	15–20 (33–44 lb/264 gal)
Water exchange (vol/day)	0.5–5 (open system)	10^{+c} (open system)	Function of area's current flow
Supplementary oxygen supply	Aeration by mechanical means	Pure oxygen enrichment	None
Feeding systems	Hand or automatic	Same	Same
Effects on environment	Effluent can be controlled or treated	Same	Little control — no significant treatment of waste
Sensitivity to environmental factors	Water quality and temperature	Reduced sensitivity — water temperature and quality	Vulnerable to sea conditions, water temperature and quality
Routine maintenance	Periodic emptying and treatment of sediments	Periodic emptying and cleaning; removal of organic accumulation	Frequent cage inspection and repair; removal of fouling growth; periodic cage removal for treatment

Table 2. Summary of the Known Nutritional Needs[a] of the Gilthead Sea Bream

	Percentage of Diet Unless Otherwise Indicated
Protein	
Total dietary level	
Larval/juvenile	$50–60^{41}$
Growout	$45–50^{41}$
Amino acids	
Arginine	$<2.6^{42}$ (% of dietary protein)
Lysine	5.0^{42} (% of dietary protein)
Methionine + cysteine	4.0^{42} (% of dietary protein)
Tryptophan	0.6^{42} (% of dietary protein)
Estimates of remaining (IAA)[b,43]	
Histidine	1.7^{43} (% of dietary protein)
Isoleucine	2.6^{43} (% of dietary protein)
Leucine	4.5^{43} (% of dietary protein)
Valine	3.0^{43} (% of dietary protein)
Phenylalanine + tyrosine	2.9^{43} (% of dietary protein)
Threonine	2.8^{43} (% of dietary protein)
Lipid	
Total dietary level	$12–24^{cf}$
(n-3) HUFA (EPA + DHA)	
Larvae: 7–23 mg ($2.5–8.1 \times 10^{-4}$ oz)	2.98^{44} (% dry Artemia)
Juveniles: 1–11 g ($3.52–38.7 \times 10^{-2}$ oz)	$\geq 0.9^{41}$
12–30 g ($4.22–10.6 \times 10^{-1}$ oz)	1^{45}
Growout to commercial size	$1.5–2.7^{cf}$
Broodstock	$0.42^{c,46}$
Energy	
Daily maintenance requirement	55.8 kJ · BW $(kg)^{-0.83(47)}$
Growth requirement	23 MJ/kg live weight gain[d,47]
Carbohydrate[e]	20^{49}
Vitamins mg/kg diet — pyridoxine (B$_6$)	$3–5^{51}$ ($5–8 \times 10^{-5}$ oz/lb)
Biotin	0.37^{52} (5.9×10^{-6} oz/lb)
Nicotinic acid	$63–83^{53}$ ($1–1.33 \times 10^{-3}$ oz/lb)
Thiamin (B$_1$)	$>5.0^{49}$ (8×10^{-5} oz/lb)
Riboflavin, and pantothenic and ascorbic acids	Essential: levels unknown[54,55]
Minerals[f]	Commercial premixes[rv]
P : E ratios	28–19 g digestible protein/MJ dig. Energy[g]

[a]Superscripts on table values indicate: "numbers" = research data from published literature; "rv" = recommended values; "cf" = values found in commercial feeds for sea bream.
[b]Estimates of IAA based on ratios of whole-body IAA to total IAA (43).
[c]Minimum level required to provide 50% viability of spawned eggs.
[d]Calculated from function.
[e]Low digestibility.[48–50]

[g]Calculated range for sea bream from 10–500 g (0.35–17.6 oz) (I. Lupatsch, NCM — unpublished data).

is characterized by tumor-like tissue masses on the body surface. These external growths are clusters of extremely hypertrophied fibroblastic dermal cells. Occasionally, internal organs will become infected (56). The disease follows a chronic course, and, although it is usually nonlethal, it causes an unsightly appearance of the skin that makes the fish unmarketable. Diagnosis of lymphocystis can be confirmed by histological sections and the appropriate staining of the tissue lesions. Extensive infections occur mainly in juveniles, with limited mortalities. Infected fish recover within a few weeks, retaining little or no scar tissue. Although the disease is widespread, affecting at least 30 families of marine fish (57), lymphocystis is a species-specific disease. The virus from one fish species will not infect another fish species, so the disease is most likely caused by a group of different viral strains. No effective therapy is known; reduction in stocking density and the removal of heavily infected individuals are the only measures that can be adopted to reduce the impact of this disease.

Bacterial Diseases

The clinical symptoms of many bacterial diseases are similar; therefore, clear diagnosis requires the isolation and culture of the organism involved in the disease. Subsequent identification is not always simple, especially of aquatic bacteria, because their taxonomy is not well

known. Many aquatic bacteria are opportunistic; they become virulent only when the delicate balance between the fish and its environment is disturbed. This imbalance can result from poor culture conditions due to high stocking densities of fish, to improperly balanced feed, or to deteriorating water quality, from a high load of pathogens, from rough handling, and from a variety of other factors that cause stress. The following diseases are caused by "true" bacterial pathogens.

Epitheliocystis. Epitheliocystis is caused by a *Chlamydia*-like, obligate, intracellular prokaryote that produces a chronic gill infection. The epithelial cells of the gills become packed with minute coccoid organisms, and hyperplasia and fusion of adjacent lamellae soon follow. Affected fish have flared opercula and display fast, shallow breathing. Epitheliocystis infections in juvenile fish tend to be both extensive and lethal. In histological sections, the infected cells, are of dimensions up to $220 \times 100 \, \mu m$ ($8.66 \times 10^{-3} \times 3.9 \times 10^{-3}$ in.), are basophilic, and are uniformly granular in appearance. The disease is highly infectious but species-specific, so different strains of closely related bacteria probably cause these infections. The bacteria cannot be cultured on ordinary laboratory media, and no effective treatment is known. Infections in farmed sea bream have been reported from the Red Sea (58–60).

Vibriosis. Vibriosis is the name given to a disease caused by a large group of bacteria belonging to the family Vibrionaceae. These organisms are gram-negative rods with motile polar flagella; they are noncapsulated and nonspore-producing. They are positive when assayed for oxidase and catalase enzymes. This bacterial family is widespread in marine environments; many of them are facultative pathogens. Their taxonomy is still controversial, in particular as a result of recent phylogenetic studies based on DNA homology among strains. Mortalities of sea bream cultured in the Red Sea have been associated with *V. alginolyticus*, *V. parahaemolyticus*, and *V. anguillarum* (or *V. anguillarum*-like) bacteria.

The disease is characterized by a systemic hemorrhagic septicemia; the clinical symptoms are the appearance of hemorrhages on the surface of the body. Vibrios produce a wide variety of proteases and extracellular enzymes, which are responsible for the extensive tissue damage. As the disease progresses, intestinal hemorrhage, destruction of the tunica mucosa, congestion and hemorrhage of the liver, enlargement and liquefaction of the spleen, the liver, and the kidney are often observed.

The same vibrios that cause vibriosis exist in the aquatic habitat and are often part of the normal intestinal flora of the fish. Good animal husbandry and adequate nutrition are essential to prevent the development of the disease. Treatment of vibriosis with medicated feed can be effective if done at the initial stage of the disease, while the fish are still eating.

Pasteurellosis. Pasteurellosis, a disease widespread in the USA, Japan, and the Mediterranean basin, is caused by *Pasteurella piscicida*, recently renamed *Photobacterium damselae* subsp. *piscicida* (61), another member of the Vibrionaceae. The infection caused by this bacterium develops rapidly into an acute septicemic condition that is characterized by an enlarged spleen containing typical foci of bacterial microcolonies. In advanced infections, these lesions appear as whitish spots and patches on the spleen surface. Sea bream suffer large mortalities from this bacterium, especially during their post-larval and juvenile stages.

Vaccines have been developed against *P. damselae*, but their effectiveness has yet to be proven. Early detection and administration of medicated feeds, while fish are still feeding, seem to offer the best chance of saving infected individuals. *P. damselae* rapidly develops resistance to antibiotics, which gradually become less effective; therefore, it is advisable to perform an antibiogram before treating fish for this disease. This bacterium is highly infectious, so strict measures should be taken to limit its spread.

Protistan Parasites

The protistans associated with fish form a large, heterogeneous group of single-cell organisms; some are ectoparasites, others follow an endoparasitic life cycle. Both types can cause severe damage to intensively cultured sea bream.

Amyloodiniosis. Amyloodiniosis is one of the most devastating parasitic diseases in temperate (62,63) and tropical mariculture (64–67). *Amyloodinium ocellatus*, which causes the disease, is a dinoflagellate that is highly adapted to parasitism. In the wild, damage to the host is limited by the shortness of its parasitic stage. In the confined volume of a tank or pond, however, this organism finds ideal conditions to reproduce and infect the entire population of fish in a matter of days. Its life cycle has three main phases: a parasitic feeding stage (trophont), an encysted reproductive stage (tomont), and a free-swimming infective stage (dinospore) (67).

Copper compounds are effective against *A. ocellatum*, but care must be taken when using them, because of the toxic effects of copper on fish. The concentrations used to kill the pathogen are close to the levels at which copper acts as a membrane poison and harms the gills, the liver, the kidney, and the nervous system. In addition, its immunosuppressive nature is a major drawback to its use in treating fish (68). Despite these drawbacks, treatment of infected fish is carried out over a 12–14 day period by maintaining a concentration of 0.75 mg/L (2.39×10^{-3} oz/qt) of $CuSO_4$ in the water (66), using a slow drip of a concentrated solution and closely monitoring its concentration in the water.

Cryptocaryonosis. Cryptocaryonosis is caused by the ciliate *Cryptocaryon irritans*, class Colpodea (69), which is known to have intraspecific variants (70–72). Although typical of tropical seas, this parasite has a worldwide distribution and extends well into temperate environments. In the Mediterranean sea, it was diagnosed in sea bream from Israel, Italy, and Spain (70).

The ciliate invades the skin, the eyes, and the gills of its host and impairs the functioning of these organs.

External signs of the disease are the appearance of pinhead-size whitish "blisters" on the skin, an increase in mucus production, and, in the case of heavily infested fish, frequent surfacing and gasping for air. Diagnosis of cryptocaryonosis is made by microscopic examination of gill, fin, or skin tissues to determine the presence of the large, revolving ciliate. The ciliate's life cycle consists of four phases. The first is parasitic (trophont); it feeds on the fish's epithelia. After three to seven days of growth, it leaves its host, loses its cilia (protomont), encysts, and starts dividing (tomont), eventually producing up to 200 free-swimming infective organisms (theront). Theronts have a life span of 24 hours, but their ability to infect a host decreases rapidly after 6–8 hours (73,74).

Brooklynellosis. *Brooklynella hostilis* is a ciliate easily recognizable: by its oval, dorsoventrally flattened shape; by its notched oral area; and by its size $36–86 \times 32–50 \ \mu m \ (1.4–3.4 \times 10^{-3} \times 1.26–1.97 \times 10^{-3}$ in.) (75). As a gill pathogen, *B. hostilis* can cause serious skin lesions (76), destroying the host's surface tissue with its cytopharyngeal armature, feeding on tissue debris, ingesting blood cells, and causing hemorrhages in the gills (75). *B. hostilis* was recently diagnosed in cage-cultured sea bream, *Sparus aurata*, in the Red Sea (77).

Myxosporean Infections. Myxosporeans are endoparasites that either can reside in visceral cavities such as the gall bladder, the swim bladder, and the urinary tract (celozoic species) or can settle as inter- or intracellular parasites in the blood, in muscle, or in connective tissue (histozoic species). Spores typical of the genus *Kudoa* [6.4 to 13.6 mm (0.25–0.54 in.) long] were found in the viscera of gilthead sea bream cultured in the Red Sea (78) and, on occasion, reappear in the same species. This parasite causes relatively benign infections, one usually limited to a few individuals.

A debilitating myxosporean disease caused by *Myxidium leei*, a histozoic species, has been described in sea bream (79,80). The parasite settles in the intestinal mucosa; in cases of heavy infections, affected fish have an enlarged abdomen, and the intestinal tract is filled with a foul-smelling liquid. Histological examination of the intestine shows the presence of spores between the epithelial cells of the mucosa lining the entire tract. The same parasite was later discovered in Mediterranean fish (sparids and grey mullet) (81), suggesting that it was imported into the Red Sea with its host. Recent literature has shown that it can be transmitted directly (82).

Metazoan Parasites

Monogenean Infections. The monogeneans form a very diverse group of (mostly ectoparasitic) worms that feed on epithelial cells and mucus. Monogeneans are hermaphroditic, and they do not require an intermediate host to complete their life cycle. A free-swimming ciliated larva emerges from an egg, the shape of which is species-dependent. Most of the marine monogeneans have a long polar filament, for attachment to the substratum (83). This direct life cycle, coupled with the availability of stressed fish in high-density culture systems, facilitates infestation (84–86).

The body of these parasites is relatively large and flat; it has a conspicuous muscular disc haptor at the posterior end and a pair of large disc-like adhesive organs on the anterior end. The intestinal caeca are diverticulate and end blindly. *Neobenedenia melleni* has been detected on the body of sea bream cultured in the Red Sea (87). The active feeding of the monogeneans on mucus and on epithelial cells leads to hemorrhage, inflammation, and the over-production of mucus (88,89). Monogeneans often settle on or around the eyes, damaging the cornea and causing blindness (89,90). Despite their size [up to a few mm (1 m = 0.04 in.)], monogeneans may go unnoticed. A freshwater dip of about five minutes is sufficient to dislodge the parasite from its host and kill it, causing it to turn opaque and become more visible.

Diplectanid monogeneans, which infest only the gills of their host and feed on mucus, are elongated and are characterized by a large flat opisthaptor with squamodiscs at the posterior end. The diplectanid species commonly infect farmed fish of the sea bass and sea bream families. They are host-specific — each species will infect only one particular species of fish, even if other fish are being cultured in the same water.

Texas Sea Grant College Program
Bryan, Texas

OUTLINE

Attributes of Goldfish

Culture Techniques

Bibliography

The goldfish (*Carassius auratus*) is a member of the minnow family (Cyprinidae) and is one of the most widely recognized of all fishes, at least in countries where ornamental species are maintained in homes, restaurants, and other types of business establishments. Goldfish are extremely hardy, so they make excellent aquarium species as well as good laboratory species. They are easy to culture and come in several varieties, some with unusual names, such as the blue shubunkin and the telescopic-eye black goldfish. Their hardiness and ready availability give them scientific value for genetic and physiological research. Fish, such as goldfish, can sometimes be used in place of mammals for research, including biomedical research that may ultimately have implications for human health.

ATTRIBUTES OF GOLDFISH

Selective breeding has produced a wide variety of goldfish, some of which carry unusual names and attributes.

Goldfish come in a number of colors, from red and orange to black, olive-green, and the popular gold. There are goldfish with greatly protruding eyes, odd body shapes, and unusual tail fin configurations. All are extremely hardy, which is one of the reasons that they are very popular as ornamentals.

Goldfish can frequently be found in backyard ponds, pools built in conjunction with restaurants, aquaria located in medical and professional offices and many other types of businesses, and, of course, in the home fish bowl or aquarium. Most children, at least in the United States, have had at least some experience in owning and caring for a goldfish. Being tolerant of degraded water quality and able to survive long periods of abuse, goldfish can survive infrequent feeding, as well as overfeeding, and will often live in unaerated water that has not been changed in months. They can also tolerate temperature extremes.

Goldfish were introduced to the United States in 1878 and have become widely dispersed around the country (1). While many people think primarily of goldfish as ornamentals, they have had some use as forage fish and as bait (1,2), though use of goldfish for bait is not legal in some states. They are also produced as feeder fish for carnivorous aquarium species. Arkansas is now the leading goldfish-producing state in the United States (3). Large numbers of goldfish are also produced in Missouri and a few other states. Various other nations also produce goldfish, including countries in both Europe and Asia.

When confined in a small fish bowl or aquarium, densely crowded, stressed by poor water quality, or not provided with sufficient amounts of food, goldfish tend to grow very slowly and often may not increase much in size, even after one or more years following purchase at a retail outlet. Given sufficient space, good water quality, and a good diet, goldfish will reach nearly a foot (30 cm) in length. Large goldfish are most commonly seen in very large aquaria or in outdoor ponds.

CULTURE TECHNIQUES

The basic techniques for rearing goldfish generally do not differ from those for culturing other freshwater ornamentals and warmwater fish. (See the entries "Carp culture," "Ornamental fish culture, freshwater," and "Tilapia culture," for example.) Goldfish are usually produced in ponds, captured as fingerlings, and shipped throughout the world, usually in oxygen-charged plastic bags packed in insulated boxes. Spawning techniques used in conjunction with goldfish are dissimilar from those used with many other species, though the techniques for goldfish and another member of the minnow family, the golden shiner (*Notemigonus crysoleucas*), are virtually identical (4).

Goldfish can be induced to spawn at any time of the year, through environmental manipulation, but the normal spawning season is in the spring when the water temperature reaches 64 °F (18 °C). Natural spawning is the dominant method used by commercial culturists who rear goldfish in ponds and depends on nature to provide the proper temperature for spawning. A large female may produce from 2,000 to 4,000 eggs (1).

There are three spawning methods employed by the goldfish industry (3,4). One technique, which is an extensive method known as free spawning, involves lowering the water level in spawning ponds during the late winter and early spring, to allow grass to grow along the shoreline. Rye grass may actually be seeded to ensure that plants will become established. As spawning season approaches later in the spring, the ponds are refilled and the grass is used as a spawning substrate.

Induction of spawning and extension of the spawning season can be achieved by flowing cool water into the ponds and rapidly raising the water level. Once the fry reach a size at which they begin to compete for food with the broodfish, the latter may be removed from the spawning ponds. The adult fish may be sold as large baitfish or retained as broodfish for subsequent years.

A second, more intensive form of spawning goldfish, called the egg transfer method, is commonly practiced by large farms and is virtually the same as the method used for spawning golden shiners (4). Rather than encouraging plant growth in spawning ponds, those who employ the egg transfer method diligently manage their ponds to avoid the establishment of vegetation. Instead of plants, spawning mats are placed in the brood ponds. The mats are typically about 1×2 ft (30×60 cm) in area, though other sizes are also used. Mats can be constructed by sandwiching Spanish moss between pieces of welded wire with a mesh size of 4×4 in (10×10 cm). Hog rings are typically used to tie the two pieces of welded wire together. Alternatively, mat material is available in rolls of latex-coated coconut fibers on a polyester net backing. The latter resembles air-conditioning filter material.

The spawning mats are placed on the bottom of the pond when the broodfish approach spawning condition. The mats should be placed on level areas, so that there is 1 in. (2.5 cm) of water above them. This technique requires modification from the standard construction of pond levees. (See the entry "Pond culture.") The mats should be placed end to end, parallel to the shoreline. Once they are uniformly covered with eggs, the mats should be removed and placed in nursery ponds. New mats may be installed as replacements if spawning continues to occur. Allowing too many eggs to accumulate on mats can give rise to fungus problems. Mats can be checked each morning to determine the density of eggs. Goldfish usually spawn just after dawn and stop spawning when sunlight directly strikes the water.

Up to 167 mats/acre (400 mats/ha) can be placed in the nursery ponds. The mats are allowed to remain in the nursery ponds for 10 days, after which they are washed thoroughly and reused for egg collection, if necessary.

A third spawning method used by goldfish producers is known as "fry transfer." This method has some advantages over the other two, in that the number of fish stocked in nursery ponds can be determined with a higher degree of accuracy (it is possible to estimate the number of eggs on a spawning mat, but such estimates are not very accurate in most cases). Fry transfer involves removing fry, instead of broodfish, from spawning ponds; removing both fry and broodfish and separating them; or capturing fry from ponds in which they have been incubated on mats transferred from spawning ponds. The fry are restocked at densities that typically range from about 20,000 to 1,000,000 fry/acre (50,000 to 2,500,000 fry/ha). The density used depends on whether the fish are to be reared quickly for sale (low density) or overwintered for growout to market size the following spring (high density).

Nursery ponds are fertilized to induce algae blooms, which retard, through shading, the development of unwanted aquatic vegetation and to produce natural food for the fry. Liquid inorganic fertilizer, such as 10-34-0, is commonly used and may be used in combination with an organic fertilizer, such as cottonseed meal or manure. Sufficient fertilizer is applied to provide a Secchi disc[1] reading of about 8 in. (20 cm).

When fry are observed swimming freely in the nursery ponds, prepared feed should be provided in the form of finely ground meal. Initially, a 48% protein feed is appropriate, and ponds should receive 1 kg/ha/day (1 lb/acre/day). After a few weeks, the protein level can be reduced to 33%, and the feeding rate can be increased to 2–6 kg/ha/day (2–6 lb/acre/day). When the fish reach about 1 in. (2.5 cm) in length, they can be fed small pellets or crumbles. Goldfish fingerlings are usually fed pellets or crumbles at the rate of 20–60 kg/ha/day (20–60 lb/acre/day). (2). The feeding rate depends on the stocking density, water temperature, and other factors. It is adjusted as needed, based on the basic condition that all feed is consumed in a reasonable period of time (i.e., no more than two hours). Goldfish producers may provide hard-boiled egg yolk filtered through cotton cloth as a first feed, to promote rapid growth. The egg yolk is soon replaced by more conventional prepared feed.

Predators can be a significant problem. Bird predation is a constant threat, and there are a number of kinds of birds that may be involved. In addition, carnivorous fishes, mink, raccoons, frogs, snakes, turtles, insects, and alligators can be problems. Human poachers may also cut into the inventory if proper security is not provided.

Diseases of goldfish include various of the more common bacteria; the protozoans *Trichodina*, *Ichthyobodo*, *Chilodonella*, *Cryptobia*, and *Ichthyophthirius*; the sporozoan parasite *Mitraspora cyprini*; and the crustacean parasite *Argulus*, which is also known as the fish louse (1,4). Viruses have also been reported from goldfish. (For more information on each disease, see the entry "Bacterial disease agents.")

To avoid damage, goldfish should be harvested with soft-mesh seines. Lift nets are also used. Lift nets are pieces of fine-mesh netting suspended from long poles by ropes. They are baited with fish feed and then lowered into the water and allowed to remain for a some time, after which they are lifted and the fish that have been attracted to the feed are removed. The fish may be held unfed in raceways for 24 hours prior to shipment, to allow them to void feces and acclimate to a more confined environment.

---

[1] A Secchi disc is a flat, circular plate, typically painted in pie-shaped wedges of alternating black and white, that is lowered into the water column by a rope. The Secchi disc reading is the depth at which the disc just disappears from sight.

General Comments
Bibliography

Groupers are classified in 14 genera of the subfamily Epinephelinae, which comprises at least half the approximately 449 species in the family Serranidae. Throughout most warm and temperate marine regions, serranids are highly valued for food, and both small and large species are kept in aquariums. Maximum size ranges from 12 cm (4.7 in.) total length (TL) for the Pacific creole-fish (*Paranthias colonus*) to more than 4 m (13 ft) TL (440 kg, 968 lb) for the groper, or brindlebass, (*Epinephelus lanceolatus*). Several grouper species have been raised commercially (mainly in Hong Kong, Taiwan, and the Southeast Asian region), usually by growing out captured wild juveniles. Some species can grow from 15–20 g (0.5–0.7 oz) to 1 kg (2.2 lb) in about a year. Research has been conducted on spawning and rearing of dozens of serranid species (Table 1). The main accomplishments are reviewed here. Additional information can be found in various publications (1–7).

REPRODUCTION

Most groupers studied mature within 2 to 6 yrs (7). Many serranids are protogynous hermaphrodites (8,9). Some species, as a rule, change from female to male with age, while others might change only if there is a shortage of males. In nature, Nassau groupers (*Epinephelus striatus*) spawn in large aggregations (100s to 1,000s of fish) with a sex ratio near 1:1. Gag groupers (*Mycteroperca microlepis*) spawn in harems, with a sex ratio often near 1 male:10 females. For both species, individual spawning events usually involve small numbers of fish (e.g., 2 to 5). Small serranids often spawn in pairs without aggregating. A few species are simultaneous hermaphrodites, but self-fertilization seems to be rare.

Voluntary spawning of captive groupers has occurred mostly with well-fed, uncrowded fish during the natural spawning season under conditions of ambient temperature and partial or total natural light (7,10). Day length seems to be a less important stimulus than temperature. At least 27 serranid species have spawned voluntarily in captivity, with groupers spawning in 1- to 21,200-m^3 tanks or ponds and 26- to 75-m^3 cages. In Kuwait, 40 female and 9 male orangespotted groupers (*Epinephelus coioides*) held in a concrete tank spawned almost continuously for 50 days during April to June (11). In the Philippines, 1 female orangespotted grouper with 2 males held in a 48-m^3 cage spawned 5 to 10 times a month for 4 months (12). In Singapore, during December 1989 to October 1990, 10 female and 10 male brownmarbled groupers held in a 75-m^3 cage spawned 2 to 5 times during each of nine periods of 2 to 6 days, usually starting between the last quarter moon and new moon (13). In Taiwan, 8 female leopard coraltrout held in a pond produced eggs 110 times during May to October (Chen et al., 1991a, cited in 7). In Florida, 3 or 4 female Nassau groupers and 2 males held in a 37-m^3 raceway spawned near the full moon in March and April, with each female spawning as many as 9 times a day for 1 to 4 days (14).

Hormone-induced ovulation of ripe, wild, or captive groupers also is reliable (7,10). At least 31 serranid species have been induced to ovulate. Typically, a female with fully yolked oocytes will ovulate within 24 to 72 hours (usually 36 to 50 hours) after the first of 1 to 3 injections of 500 to 1,000 IU human chorionic gonadotropin/kg body weight. Similar results have been obtained for several species given 1 to 3 injections of 10 to 50 μg gonadotropin releasing hormone analog/kg body weight. GnRH-analogue implants were effective for spawning white groupers (*Epinephelus aeneus*). For six grouper species with egg diameters of 800 to 1,000 μm, the minimum effective oocyte diameter before injection was in the range 41 to 61%. For Nassau groupers, the time from ovulation to overripeness is only 1 to 2 hours at 26 °C.

Nassau groupers at 6 kg can produce about 900,000 eggs per day by natural or hormone-induced ovulation. At the same size, hormone-treated brownmarbled groupers can produce 1.7 million eggs. Hormone-treated 1.5-kg squaretail coraltrout can produce 400,000 eggs. A 1-kg (2.2 lb) redspotted grouper can produce more than

Table 1. Some Characteristics of Representative Groupers Raised Commercially (C) and Experimentally (E)

Species	Type of Culture[a]	Locations	Egg Diameter (μm)	Larval Duration (d)	Source of Juveniles[b]	Market Size (kg)	Maximum Size[c]	Maximum Age (yr)

[a]C = commercial, E = experimental.
[b]H = from a hatchery, W = from wild stocks.
[c]Whole weight or total length.

5 million eggs in a season, and a 6-kg Nassau grouper can produce 3.3 million eggs in a 4-day period.

With good timing and luck, groupers have been caught just before spawning and held in tanks or cages until they ovulate naturally. The eggs are stripped, or rarely, the fish are left in the tank for voluntary or accidental fertilization to occur.

LARVAL FOODS

With the notable exception of *Siniperca* spp., which have large eggs and hatchlings (~5 mm) and are easy to feed and rear, grouper larvae usually are small and fragile and have relatively small mouths at first feeding. Yolk and oil tend to be exhausted quickly (7,15). Typically, the larval period is long, and groupers tend to require live food longer than most marine fishes that have been reared.

Grouper larvae usually are raised in green water (*Nannochloropsis, Tetraselmis, Chlorella* spp.). At first feeding, most species can eat small rotifers, but oyster or clam eggs and trochophore larvae sometimes are used as a supplement. Growth and survival rates tend to increase if copepods or mixed zooplankton are included in the diet, but care must be used to avoid introduction of pathogens or predators. Enriched *Artemia* can be a staple food beginning at 10 to 30 days, but their density should be controlled to minimize gorging. Microfeeds (artificial diets) have been tried as a supplement during the first week, but probably

are not digested well until at least 2 to 4 weeks. Weaning can be completed just before or during transformation into the juvenile stage, which occurs at 35 to 70 days after hatching, depending on species.

COMPOUND FEEDS

In nature, juvenile and adult groupers eat mainly fish, crabs, shrimp, mantis shrimp, lobsters, and molluscs (16). Red groupers (*Epinephelus morio*) seem to prefer crabs first, then shrimp. In Thailand and other areas, groupers have been fed mainly trash fish (with vitamins and minerals) secondarily moist or semimoist pellets, and rarely high-protein dry pellets (17). A suitable starter feed for groupers would contain 50 to 60% high-quality protein, 12 to 16% fat, no more than 15% carbohydrate, less than 3% fiber, and less than 16% ash (7). Groupers larger than 500 g (1.1 lb) can be given a feed with approximately 45% protein, about 9% fat, and no more than 20% carbohydrate, 4% fiber, and 22% ash. Lower quality feeds likely would result in a higher feed conversion ratio and possibly slower growth.

RAISING GROUPERS TO MARKET SIZE

In Indo-Pacific and Middle Eastern regions, several species of grouper are farmed in cages, ponds, and tanks, but

usually they are raised from wild juveniles and are fed trash fish. They sometimes are fed small tilapia (*Oreochromis* spp.) and occasionally are polycultured with them. Typical market size is 500 to 1,000 g (1.1–2.2 lb), which can be reached in 6 to 8 months of grow-out. The minimum size to begin grow-out, 75 to 100 mm, can be obtained in nursery tanks, cages, or ponds. They are stocked up to 60 fish/m^3 (<1 kg/m^3) in cages. In Taiwan, a pond farm typically stocks 60,000–80,000 groupers/ha and harvests 80% of them for a production of 30,000 to 40,000 kg/ha; the groupers are fed mostly trash fish and grow from 46 mm to 600 g in 12 months and 2 kg (4.4 lb) in 19 months (18). When fed pellets only, Nassau groupers can reach at least 450 g (1 lb) at 12 months and 2 kg (4.4 lb) at 24 months of age.

HEALTH

For groupers, snappers, and similar warmwater fish, gram-negative bacteria (*Vibrio, Aeromonas, Pseudomonas, Pasteurella* spp.), *Streptococcus, Mycobacterium*, ectoparasitic protozoans (*Amyloodinium ocellatus*, sporozoans, *Cryptocaryon irritans, Brooklynella* spp.; *Ichthyophthirius* sp.), and monogeneans (*Neobenedenia melleni, Diplectanum* spp.) are among the most important pathogens (19–23). In Singapore, sleepy grouper disease (lethal) probably was caused by a virus introduced with wild juvenile groupers imported for cage farming (24). Other viral pathogens and diseases include golden eye disease, red grouper reovirus, spinning grouper disease, and viral nervous necrosis. Rancid dietary lipids are thought to cause nervous suffering disease of groupers, which could result in gill, blood, gas bladder, liver, heart, brain, and nerve damage (25). In Japan, pasteurellosis has been a major disease of young redspotted groupers (26).

ANNUAL PRODUCTION

In 1996, the Peoples' Republic of China produced 58,437 metric tons (mt) of Chinese perch (mandarin fish), which has been considered a serranid, but has affinities with the centropomids (snooks). Malaysia produced 837 mt of greasy groupers and Hong Kong 360 mt. Hong Kong produced 750 mt of squaretail groupers. Taiwan produced 1,883 mt of miscellaneous groupers, Thailand 600 mt, Philippines 595 mt, Singapore 93 mt, and Republic of Korea 9 mt. In 1995, Hong Kong produced 30 mt of redspotted groupers (27).

GENERAL COMMENTS

Commercial-scale hatcheries for redspotted grouper and kelp grouper (*E. bruneus*) in Japan and Malabar grouper in Taiwan and Thailand have raised large batches of juveniles, with survival as high as 34% from hatchlings (7). The larval period is longer than for most cultured fishes. Some groupers need small rotifers, trochophores, or copepods at first feeding. Proper aeration is critical. Early grouper larvae, especially when stressed, sometimes exude an excess of mucus, which can cause them to stick to each other, to the surface film, or to solid objects. Too little turbulence in larval tanks can allow the water to stratify and zooplankton and fish to aggregate dangerously. With too much turbulence, the fish are battered. Gorging on *Artemia* is another source of mortality, and cannibalism among early juveniles can be a problem. Larvae are fragile, and survival from eggs to juveniles often has been only 0 to 1%, but juveniles and adults are among the hardiest of fish.

Grouper farming fluctuates because of variability in the (mostly decreasing) supply of wild juveniles and lack of sustained hatchery production for most species. Variability in quantity and quality of trash fish and the lack of economical compound feeds also has been a constraint in some areas. Nevertheless, the commercial feasibility of grouper culture has been proven in several countries, including Malaysia, Hong Kong, Taiwan, China, Philippines, Singapore, Japan, and Korea.

OUTLINE

Introduction
Life History
Culture Techniques
Bibliography

INTRODUCTION

The Gulf killifish (*Fundulus grandis*), also commonly known in Texas as the mudfish or mudminnow and in Alabama as the bull minnow, is a widely used baitfish within the marine recreational fishing community along the Florida and northern Gulf of Mexico coasts of the United States. Historically, the species has been captured from nature and sold through retail bait outlets; however, supplies from that source have waned in recent years, and both interest and activity associated with the culture of Gulf killifish have developed in areas to which that fish is native.

Gulf killifish are found in coastal marshland areas. They are common in grassy bays and canals, and even in adjacent freshwater areas, because they have a very wide tolerance for salinity. While their maximum length (1) is reportedly 180 mm (7.1 in.), fish in excess of 15 cm (6 in.) are not commonly seen. Bait dealers prefer fish of 7.5 cm (3 in.) or slightly less. Bait-sized fish can be produced from eggs in a few months. A brief guide to their culture, by Strawn et al., in 1986, continues to be a highly useful publication, which, unless otherwise noted, forms the basis of the following discussion (2).

LIFE HISTORY

Gulf killifish can be found along both the Atlantic and Gulf coasts of Florida, in the Florida Keys, and along the Gulf of Mexico coast to eastern Mexico. The fish is also found in Cuba (1).

Male Gulf killifish are a uniform greenish-silver in color, while the females are darker and have prominent spots on their bodies and fins. Eggs are laid on suitable substrates, such as submerged or emergent vegetation in nature. Spawning can occur over a period of several months, from early spring to early fall. Reproduction has been known to occur in the salinity range of 3–20 parts per thousand (ppt).

Eggs hatch in 10–21 days; the time depends on temperature and salinity. Higher temperatures reduce incubation time, as do lower salinities. Egg hatching has been reported over a salinity range from 0 to 40 ppt with subsequent good fish growth; survival has been reported over a salinity range from 5 to 40 ppt. Fry survival and growth are reduced in freshwater or at salinities in excess of 60 ppt, yet juveniles and adults can tolerate very low salinities (<1 ppt) and near-zero dissolved oxygen concentrations for at least brief periods of time. Anecdotal reports of high mortalities associated with high pH (9.0–9.5) have occurred (Jack Booth, personal communication), but the mortalities may have been related to high percentages of un-ionized ammonia (NH_3). Un-ionized ammonia is the more toxic form. In solution, total ammonia is a combination of ionized (NH_4^+) and un-ionized ammonia. The percentage of un-ionized ammonia in the mixture increases with increased pH. In any case, one desirable feature of Gulf killifish is their ability to survive under the stressful conditions that exist in bait buckets.

CULTURE TECHNIQUES

The recommended stocking rate for Gulf killifish of 5–7.5 cm (2–3 in.) is 30,000/ha (12,000/ac) in a ratio of two females for each male in advance of the spawning season. Commercial minnow feeds have been used successfully, as have floating catfish feeds and agricultural by-products.

In ponds, natural vegetation can provide suitable spawning substrate, but the standard practice is to employ spawning mats that consist of about 1 kg (2.2 lb) of Spanish moss sandwiched at a thickness of 5–7.5 cm (2–3 in.) between pieces of plastic-coated wire mesh. The pieces of wire mesh are typically 0.7 × 1 m (2 × 3 ft) in size, though any convenient size is suitable. Materials other than Spanish moss have been used, but Spanish moss continues to be commonly employed and is locally available along much of the Gulf coast.

Spawning mats should be evenly distributed along the edges of each brood pond at a rate of no less than 125/ha (50/a). In windy areas, the mats should be placed along the upwind side of the ponds. Placement in that less turbid pond region helps avoid silting in of the mats, which would result in smothering of the eggs.

The mats should be fully submerged and should be suspended a few cm (1 cm = 2.5 in.) above the bottom, as the fish will deposit their adhesive eggs on all mat surfaces. If the mats lie on the bottom, access to their undersides is denied and the mud can work up into the mats and cause eggs to die.

It is possible to allow the eggs to hatch in spawning ponds and then to harvest the young fish after a few months for marketing, but that approach requires sorting (which is not difficult) and can result in high mortality due to cannibalism. The preferred method is to remove the mats after about one week and put them in a fertilized, empty pond. Clean spawning mats can be reintroduced to the brood pond after the egg-laden mats are removed so that more eggs can be collected.

Ideally, the culturist should transfer spawning mats on which 1,000 to 2,000 eggs have been deposited. An estimate of the number of eggs present can be obtained by counting the eggs found in several random meshes of the wire and multiplying the average egg count by the total number of meshes on the upper and lower surfaces of the mat. Ponds should be stocked with a goal of producing fry at the rate of 480,000/ha (160,000/ac). To make the calculation, you can assume that the hatching rate will be between 50 and 80%, and that the percentage will increase as the total number of eggs on a particular spawning mat decreases (i.e., 50% hatch when 2,000 eggs are present on a mat, but as much as 80% when the mat contains about 1,000 eggs).

An alternative to the method described earlier is to stock much larger numbers of eggs [up to 3.75 million/ha (1.5 million/ac)]. When the fry reach approximately 1.25 cm (1/2 in.), they should be transferred to growout ponds in which the stocking rate should be no more than 400,000/ha (160,000/ac). A major advantage of this approach is that the farmer can better control the number of fish stocked in growout ponds. In addition, the fish can be graded so they can be stocked at uniform sizes in the receiving growout ponds.

Commercial feeds are available, as previously mentioned. However, it may be possible to improve fish growth rate and shade out unwanted submerged vegetation by fertilizing ponds to stimulate phytoplankton blooms. One study indicated that fertilization of ponds with 45.5 kg/ha (40 lb/ac) of 12-12-12 (N-P-K) fertilizer was effective to meet this goal (3). Fertilizer was added at weekly intervals in amounts that resulted in maintenance of a Secchi disk reading of 30 cm (12 in.).

Harvesting is typically accomplished by placing baited minnow traps in growout ponds, with feed pellets being used as bait. Seines can also be used to harvest marketable fish.

OUTLINE

Reproductive Plasticity
The Process of Gynogenesis
Bibliography

Gynogenesis is the production of viable offspring by a mature female from ova that develop without any paternal contribution to the genome (1,2). Gynogenesis sometimes occurs naturally, and it can be induced artificially in various species through proper manipulation of unfertilized eggs. The offspring, which are all female, may be desirable when a culturist wants to avoid reproduction or when females grow more rapidly than males.

REPRODUCTIVE PLASTICITY

Fish and many invertebrates are particularly diverse with respect to reproductive system function. In fish, one can find nearly every imaginable variation. Included are species that are hermaphroditic (i.e., contain both testes and ovaries), that spend part of their lives as males before becoming females, that spend part of their lives as females before becoming males, and that have distinct sexes throughout their adult lives. In addition, the sex of some fish may not be determined at egg fertilization, or even during embryogenesis. In fact, for many species, it is possible to force the majority of the fish in any population to become either males or females by feeding them hormones for a few weeks at the time of first feeding. (See "Reproduction, fertilization, and selection.")

Aquaculturists often want to produce fish of only one sex, to enable the fish grow more rapidly or to prevent reproduction. For example, female channel catfish tend to grow more rapidly than males, while male tilapia grow more rapidly than females and, in the latter case, often become reproductively active prior to reaching market size. (See the entries "Channel catfish culture" and "Tilapia culture.") Also, all of the fish stocked are of a given sex, they obviously cannot reproduce, which is often a consideration when exotic species are to be stocked.

In addition to using sex reversal to produce animals that cannot reproduce, techniques have been developed that produce sterile polyploid fishes (i.e., fish that have more than two pair of chromosomes in their cells) and gynogenetic fishes.

THE PROCESS OF GYNOGENESIS

In the typical scheme of reproduction for vertebrates, the sexes are separate and diploid; that is, they have two sets of chromosomes in the cells of their bodies. One set of

those chromosomes is obtained from the male parent and the other from the female. Various, but usually constant, numbers of chromosomes are present in every species, with one pair being sex chromosomes. Diploid females, in general, have two X sex chromosomes, while males have an X sex chromosome and a Y sex chromosome. As body (somatic) cells divide through a process known as mitosis, the pairs of chromosomes in the cells are replicated. Eggs and sperm cells are different, however. Those cells divide through a process called meiosis and, at the time of reproduction, have only one set of chromosomes and are known as haploid cells. Each female haploid cell has one X chromosome in its set, while haploid sperm may have an X or a Y chromosome. Offspring produced by the joining of the chromosomes in the two gametes are normally diploid, with the sex of the progeny being determined by the male contribution to the pair of sex chromosomes.

During meiosis, also known as reduction division, one set of the chromosomes produces what are known as polar bodies. The process, simplified for this discussion, involves the production of two polar bodies at different stages, with the second polar body being the one of primary interest. Neither of the polar bodies becomes involved in normal reproduction, but both are a means by which the second set of chromosomes is ultimately eliminated from the gamete. In gynogenetic animals, haploid eggs are produced and development occurs, but without any contribution of genetic material from the male sperm. Gynogenetic fish are, however, diploid, because the second polar body is not ejected; its genetic material is recombined with that in the egg to produce the diploid embryo.

In most cases wherein aquaculturists induce artificial gynogenetic development, they do so by eliminating the ability of sperm from the same species to fertilize the eggs (often through irradiation with radioisotopes or, more commonly, through exposure to ultraviolet light), or they use sperm from a distantly related species (3,4). The sperm penetrates the eggs, but no combination of the genetic material occurs. Instead, the second polar body is induced to recombine within the egg to form a diploid cell that can divide to produce all female offspring. Induction of recombination of the ova and polar body can be achieved by heat shock, cold shock, increased pressure, or exposure of the eggs to certain chemicals.

An optional approach, and one that will create clones of the adult female, involves allowing sufficient time to pass after mock fertilization for the polar body to be ejected. The culturist then applies the proper type of physiological shock to the haploid egg to induce the chromosomes to divide within the egg, producing a diploid cell that will, thereafter, divide normally through mitosis and produce viable embryos. While the technique is relatively simple, details of the process vary from species to species (5,6), and it is not widely used by commercial aquaculturists, because often only small numbers of viable gynogenetic animals are produced from any batch of eggs. Other methods to produce a single-sex set of animals have proven to be more effective and often less difficult to undertake in a commercial culture setting.

Gynogenesis continues to be the subject of researchers interested in understanding sex determination and other aspects of genetics and reproduction (6). Fishes and molluscs have been the primary aquaculture species studied by researchers to date.

OUTLINE

INTRODUCTION

The halibut (*Hippoglossus* spp.) is the largest of the pleuronectid flatfish and, in life spans reported to be as long as 50 years, may reach lengths in excess of 2 m and weights of 300 kg. Two major species have interested farmers: the Atlantic halibut (*H. hippoglossus*) and the Pacific halibut (*H. stenolepis*), although at present only the Atlantic species is the subject of significant commercial production. Consequently, much of this review will concern the Atlantic halibut. However, the two species appear very similar in shape, size, and biology, so much so that over the years at times they have been classified as a single species (see Ref. 1 and the section on "Taxonomy" that follows). Consequently, it is likely that the research carried out on the Atlantic halibut will be directly applicable to any future culture of the Pacific species.

Halibut have been identified as ideal fish for farming at higher latitudes as they maintain good growth rates in relatively cold northern waters (0−14 °C) and can reach a predicted market size for farmed stocks of 3−5 kg, approximately 2−3 years postweaning. The Atlantic halibut is one of the most highly priced fish at retail first-sale, fetching two to three times that of salmon, which is the principal farmed fish in European markets. Reductions in wild fish to less than 3,000 tons per year over the past 15−20 years have only served to strengthen their market value.

High fecundity accompanied by the docile nature of the broodfish, a batch-spawning habit and a large pelagic egg, compared to other marine species have facilitated controlled spawning under farm conditions. Although there is now a fast-developing hatchery production of juveniles in Norway, Scotland, Canada, and more recently in Chile, survival through the long egg and yolk-sac incubation periods, plus the time to first-feeding and metamorphosis up to weaning, is relatively poor. As a consequence, there has been only limited growout of the fish, and up to the present, only small quantities of farmed product have reached the market. A major constraint to the farming of halibut is the length of the production cycle from broodfish to marketable fish. Figure 1 summarizes the different stages of the life cycle and their approximate duration. However, much work still remains to be carried out on (*1*) identifying the optimum conditions and requirements of broodstock, (*2*) establishing a reliable supply of good-quality eggs, (*3*) increasing the number and quality of metamorphosed juveniles, and (*4*) appropriate husbandry for the growout phase of the production cycle.

TAXONOMY

The Atlantic halibut was first described by Linnaeus in 1758 as *Pleuronectes hippoglossus*, at which time all flatfish were placed in the same genus. Following more detailed descriptions of their fin structure in the nineteenth century, Cuvier varied the taxonomic position of flatfish and classified the halibut in a new genus: *Hippoglossus*. Initially, the Atlantic and Pacific halibut were both considered to be the same species, first as *H. vulgaris* and then as *H. hippoglossus*. Subsequently, Schmidt in 1930, using studies of meristic characters and scales, placed the Atlantic and Pacific forms as separate species: *H. hippoglossus* and *H. stenolepis*, respectively, which, despite a series of other studies and genetic analyses, remains the taxonomic position today (1).

BROODSTOCK MAINTENANCE

In the wild, mature halibut gather every year in winter in defined spawning grounds at depths of up to 700 m (2,300 ft). Halibut are batch spawners that produce up to 15 but more usually 5−10 batches of 100−200,000 eggs at 3- to 4-day intervals over a 1- to 2-month spawning period (2); different geographical stocks spawn at different times over the period February through May, usually at water temperatures of 5−7 °C (41−45 °F) or less. Males reach maturity at a younger age or size than females; e.g., Faeroese males mature at 4−5 years of age, 55 cm (22 in.) in length, and 1−3 kg (2.2−6.6 lb) in weight, whereas corresponding females mature at 7−9 years of age, 110+ cm (43 in.) in length, and at weights of >15 kg (33 lb). Most large fish captured in the wild are females, with males rarely exceeding 50 kg (110 lb).
Figure 1. Life cycle of farmed halibut showing approximate times and sizes of the different stages of development.

The physical and environmental requirements of broodstock halibut impose considerable problems on their culture. In order to produce good-quality eggs, temperatures are usually maintained at <6 °C (43 °F) for at least a month before spawning and are continued until all fish in the tank have completed spawning (3). At present, it is not entirely clear whether the necessity for low-temperature water needs to be extended beyond this period. Certainly there is little feeding above 12 °C (54 °F), and higher temperatures should be avoided. In certain locations, either water chilling or heating is necessary in order to achieve a constant temperature of 6 °C (43 °F) or less, which because of the relatively high costs, inevitably has led to investigations of possible water reuse or recirculation (4).

There is also a parallel requirement for full-salinity seawater supplies (32–34 ppt). This has meant that at sites where dilution of seawater has occurred due to freshwater inputs or high rainfall, salinity control is necessary. Most broodstock facilities for halibut rely on pumped seawater supplies, preferably with deep-water inlets because these provide more stable temperature, high-salinity waters, and are less susceptible to the problems of surface water contamination and storm detritus.

Fish are usually held in 5–10 m (16–33 ft) diameter circular tanks at densities of 5–10 kg/m^3, with a tangential inflow, central drain, and water levels of 1–2 m (3–6 ft) depth. Oxygen levels should be at least 6 ppm in the outflow. Flow rates and water exchanges should be as high as is economically possible, with replacement rates of 10–15 water exchanges each day sometimes quoted. Pumping and chilling costs may, however, prove prohibitive and fewer exchanges (2–3/day) or water reuse with biological treatment may be both necessary and feasible (4). Tanks should be covered with netting, for despite their large size, halibut broodstock may jump out. If the tanks are not in a covered building, the netting also serves to protect, in part, against sunburn, which is a particular problem for halibut. Sections of the floors of the tanks are also now commonly covered with a plastic-coated netting which reduces the development of sores that somewhat surprisingly are found on the undersurfaces of fish maintained in smooth-bottomed tanks; the netting is also easier to clean than the gravel previously used.

Generally, halibut are exposed to subdued artificial lighting (approximately 100 lux appears generally suitable), with different broodstock groups exposed to a series of out-of-phase seasonal photoperiod regimes to both advance and delay spawnings (5,6). In this way egg and fry availability are extended beyond that derived from broodstock maintained under simulated natural daylengths.

Broodstock are commonly fed 3–4 times a week to satiation (0.1–0.4% body weight/day) on moist diets containing 60% protein, 17% lipid, and 6–7% moisture. Fresh or frozen wet fish has historically been a major component of broodstock diets. However, because of the variable nutritional composition of this component and the possible inadvertent introduction of pathogens, many operators have switched to using dry ingredients and fully fabricated diets (7,8).

Experience in the United Kingdom has shown that captive halibut are very susceptible to eye damage. Williams et al. (9) described the occurrence of gas-filled cysts and cataracts in captive halibut. There is no clear explanation as to why the eye damage appears, but handling is the most likely reason. The condition frequently progresses until there is a total loss of vision from the affected eye. Some fish become blind in both eyes, with consequent difficulties in feeding and detrimental effects on spawning condition.

A range of parasitic infections is found in broodstock, including the "halibut louse" (*Lepeophtheirus hippoglossi*), *Entobdella hippoglossi*, *Trichodina* spp., and costia (*Ichthyobodo necator*). In captivity, infestations are usually confined to *Entobdella*, which can be treated successfully with either formaldehyde or freshwater baths. Halibut also suffer from *Vibrio* spp., infectious pancreas necrosis (IPN) (10), nodavirus (VNN) (11), and *Cytophaga* spp. (12), all of which can cause mortalities. They may also act as carriers to furunculosis (13,14).

Readers interested in the studies that have been carried out on broodstock and early larval rearing of Pacific halibut should refer to the review of Stickney and Liu (15).

SPAWNING

Historically, broodstock tanks comprise 3–4 pairs of fish. However, much larger groups are now maintained successfully in Norway, Iceland, and Canada. Where possible these groups should be established at least one year before spawning, as it has been suggested that spawning success is influenced by behavioral and social group interactions. Some farms, however, routinely move females from tank to tank, particularly around spawning time, without any apparent ill effects on egg quality.

Impending spawning time can be estimated from the visible abdominal (gonadal) swelling of the females. A more recent development has been the use of ultrasound scanning, which can be used to differentiate the gender of immature fish as well as to monitor maturational state (16).

A major difficulty with spawning marine flatfish is that of predicting the optimal time for stripping of the broodfish (i.e., removal of eggs by gentle hand manipulation) and, in turn, fertilization of the eggs (17,18). Halibut are batch spawners producing a series of egg batches at 70- to 90-hour (often more at lower temperatures, up to 110 hours) intervals (17,18). However, each fish has its own specific ovulatory rhythm, and eggs must be stripped and fertilized within six hours of ovulation at 6–7 °C (43–45 °F); otherwise there is a rapid decline in fertility (17,18). If eggs are kept at 1–3 °C (34–37 °F), they can be kept for up to 12 hours poststripping without noticeable reductions in fertilization rates. Before stripping is attempted one needs to establish the timing of this rhythm. This is achieved by placing some form of egg collector in the outflow water. Eggs are collected from the first 2–3 spawnings of each fish, and the average intervening time between spawnings of that individual broodfish is then used to predict the time interval at which that brood female is monitored and examined for the occurrence of ovulation, over the remainder of her spawnings. Ovulatory periodicity can be disturbed by changes in temperature and handling stress (17). Later egg batches from individual females also tend to occur earlier than might be expected from the recorded periodicity of the first few batches.

Once ovulatory rhythms are established, each broodfish should be examined at the appropriate interval and an attempt made to strip eggs. Eggs have to be stripped from the female fish without coming into contact with seawater, i.e., the fish have to be removed from the water at least until the gonadal pore is visible and out of the water. However, the large size of the brood females and their shape preclude manual lifting, and the following procedure, which requires a minimum of two persons, is commonly adopted. First the tank water level is lowered to approximately 45 cm (18 in.). A table constructed from aluminum, plastic, or other suitable material, free from any sharp edges, is often used to position the broodfish for stripping (Fig. 2). The table, which should be approximately 2 m (6 ft) long, has two fixed and two adjustable legs whose lengths are such that the fixed end of the table is above the water level in the tank while the other adjustable end is submerged. The selected broodfish is gently guided onto the inclined surface of the table, whereupon the submerged end is raised and the adjustable legs lengthened, lifting the fish clear of the water. This procedure is possible with smaller broodstock. With larger fish some farms use a pulley- or winch-operated system to raise the table. After carefully drying the area around the gonopore, eggs are stripped

Figure 2. Stripping of 30 kg (66 lb) halibut female.

from the brood female into 2 to 3-L (∼1–3 qt) graduated jugs by gentle posterior–anterior hand pressure.

In some instances females fail to release eggs, which have been ovulated into the ovarian lumen, even when assisted by stripping. The retention of eggs can cause blockages when this material starts to degenerate inside the fish. Blocked females can be injected intramuscularly with antibiotics (amoxycillin or oxytetracycline), which generally induce the release of the egg debris within three days.

A similar procedure is used to strip male fish. Males generally continue to produce milt for the duration of the spawning seasons of the different females in the same tank. Again the fish must be carefully dried and the milt then stripped into 250 mL (8 oz) graduated containers. The gametes should then be transferred to the hatchery in a light-proof insulated box as temperatures must be maintained below 6 °C (43 °F) and light affects osmolarity and, in turn, the buoyancy and handling of the eggs. Ideally the egg incubation facility should be a purpose-built room whose temperature is maintained at 6 °C (43 °F). Before the eggs are fertilized the milt should be checked for motility under a microscope (400×) after adding a few drops of seawater to a drop of milt. Although generally males continue to produce milt throughout the spawning period of the females, toward the end of the season some males may become spent or their milt becomes viscous and very difficult to handle. Providing the fish are not spent, high spermatocrits can be diluted and hence made more fluid by treating brood males with 25 µg/kg of GnRHa (19). Milt can also be stored in the refrigerator for seven days or an adjustable freezer at −4 °C (25 °F) for 29 days without any loss of viability (20). Once a ready supply of milt is assured, then one can proceed with fertilization.

The eggs are "wet fertilized" in a ratio of 250 : 1 : 250 egg to milt to UV sterilized seawater (we use 1000 : 1 : 1000) by first diluting the milt with the sterilized seawater and then quickly adding the mixture to the eggs. The eggs and diluted milt should be gently stirred by hand and then left undisturbed for 20 minutes. Sperm motility ceases after 2–3 minutes although fertilization is complete in less than a minute. After 20 minutes the eggs should have absorbed water and become fully water-hardened. They are then washed in two further changes of sterile seawater to remove excess milt and any egg debris or ovarian fluid. The fertilized eggs are then stocked in egg incubation systems in a dark room at 6 °C (43 °F). A small sample (about 100 eggs) of each egg batch is retained in full-strength seawater in a screw top jar for assessments of fertilization rate or egg quality, as described in the following section.

EGG QUALITY ASSESSMENT

After 16 hours at 6 °C (43 °F), i.e., 96-degree hours, fertilized eggs will have undergone cleavage and reached the eight-cell stage. At this point an assessment can be made of fertilization rate and the predicted future "quality" of the egg batch (i.e., the potential of the eggs to produce viable fry), thus enabling decisions to be made
Figure 3. Halibut blastomere at the 8-cell stage of development (left) and yolk-sac larva (right).

as to whether to discard the egg batch or to stock the incubation systems. Egg and yolk-sac incubation and early rearing are relatively long processes in halibut (50+ days) compared to other marine species. Informed predictive decisions to discard poor batches of eggs, which are likely to exhibit poor survival later in development, can be of great benefit in the saving of staff time and the optimization of usage of limited rearing facilities. For some marine species, egg buoyancy provides an accurate prediction of subsequent egg quality, whereas for other species fertilization rate alone suffices and shows good correlation with survival rates at hatch and first-feeding. However, neither of these is particularly helpful for halibut, and alternative methods have been sought. In the United Kingdom, a useful assessment has been developed which relies on the morphology of the early cell divisions or blastomeres at the eight-cell stage (21). High viability has been demonstrated in egg batches in which the divided cells are closely adherent to one another, have clear, well-defined margins, and show symmetrical cleavages with few or no vacuolar inclusions or droplets (Fig. 3). In practice fertilization rates of 70% or more of stripped eggs can be readily achieved and hatcheries generally incubate all egg batches with rates above 40%.

EGG AND YOLK-SAC INCUBATION

Procedures for halibut egg incubation and yolk-sac rearing differ considerably from those of many other marine fish and most cultured flatfishes because of the large size of the eggs [3.5 mm (0.14 in.) diameter] and the extended time involved in these periods of development. It takes 85 degree days [15 days at 5–6 °C (41–43 °F)] for the egg to hatch and a further 220–290 degree days to reach first-feeding, with temperatures maintained throughout at 5–6 °C (41–43 °F) (22). Generally, eggs up to hatch are incubated in 100 to 500-L (26–132 gal) cylindroconical tanks in an upwelling current of 1 to 5-µm filtered, UV-sterilized and temperature-controlled seawater. Because of the cost consideration of ensuring a supply of 5–6 °C (41–43 °F) seawater, some hatcheries operate their egg incubation facilities with recirculated water supplies. The eggs are generally neutrally buoyant in full-strength seawater and the aim of the upwelling current is to distribute the eggs evenly throughout the tank; flow rates of 2–5 L (0.5–1.1 gal) per minute are commonly used

with stocking densities of 200–1000 eggs L (760–3800 eggs/gal). Usually, each incubator is stocked with a batch of eggs from a single female. Dead eggs are removed from the incubation system on a regular basis using a technique involving a hypersaline (40 ppm) "salt plug" (23); this procedure relies on the fact that dead eggs are nonbuoyant and will sink rapidly through a salt plug whereas live eggs do not pass into this layer. The salt plug is applied by turning off the upwelling seawater flow and introducing approximately 2–10 L (0.5–2.6 gal) of the hypersaline solution into the conical base of the tank. After a few minutes most of the dead eggs enter the "salt plug" and this layer can be removed and the upwelling seawater inflow restarted. Generally, 40–50% of the stocked eggs are lost from each batch during incubation.

After 65 degree days of incubation at 6 °C (43 °F), the eggs are disinfected by immersion in either gluteraldehyde (200–400 ppm) or peracetic acid (200 ppm), for 10 minutes. Disinfection helps avoid the carryover of bacterial contamination, which has been implicated as a major cause of losses in yolk-sac fry (24). Some hatcheries move eggs directly to a yolk-sac production system after disinfection; others initially move them to a clean egg incubation system and only move to the yolk-sac system after hatching. This has the advantage of not transferring any of the egg debris from hatching to the yolk-sac system.

A wide range of tank sizes has been used for yolk-sac rearing from 400 to 10,000 L (105 to 2630 gal) capacity (23,25). All are cylindroconical and use 5–6 °C, (41–43 °F) filtered, sterile seawater in an upwelling current (Fig. 4). Water inflow rates range from 1 to 5 L (0.25 to 1.3 gal) per minute depending on tank capacity (23). Inlet pipe diameters are critical to the flow characteristics of the upwelling current; generally most hatcheries use 15–25 mm (0.6–1.0 in.) diameter in the smaller-volume tank inlets, but diameters may reach 100 mm in the larger-volume system. All systems should be in the dark.

After disinfection the eggs or larvae are stocked into the yolk-sac tanks at densities 15–40 eggs or larvae/L (57–152/gal). Hatching occurs after 85 degree days (see Fig. 3); it can be synchronized by applying light (20 lux) to the eggs (26) for 24 hours and then switching off the lights; hatching then occurs after a few hours.

After hatching the yolk-sac larvae remain in the system for a further 200 degree days (up to 270 degree days), with any dead larvae being removed daily using the salt plug technique. With use of this procedure, survivals through the yolk-sac stage are usually 40–50%. However, substantial losses have occurred in both Norwegian and Scottish hatcheries approximately 150 degree days after hatching, at which time some of the larvae are seen to collect at the surface and then gradually sink down to the conical base of the tank and die. In an attempt to avoid these losses, many hatcheries are transferring larvae into first-feeding tanks up to 100 degree days before they are expected to take first feed (27). The larvae start to develop a positive phototaxis around 160 degree days posthatch and this behavioral response is used to advantage in helping to draw the larvae to the surface of the tank for collection and subsequent transfer to the first-feeding tanks.

LARVAL REARING

Larval rearing can be usefully divided into two phases. During the first of these the larvae are fed on live feed organisms of which the main ones are the brine shrimp (*Artemia* sp.) and copepods e.g., *Eurytemora* (28). In addition to the live feed, a range of microalgae, including *Nanochloris, Nannochloropsis*, and *Isochrysis* spp., are added to the tanks before stocking the fish. This "green water" approach significantly improves the initiation of start feeding in the larvae probably by its influence on light levels and/or on the behavior of the live feed organisms or the halibut larvae, rather than any effect on nutrient intake. Figure 5 shows larvae at the onset and at a later stage of live feeding.

The second phase of larval rearing involves the weaning of the larvae onto inert dry diets (29). This is carried out after the larvae have completed metamorphosis. Metamorphosis comprises a major developmental reorganization of
Figure 4. Tank system for yolk-sac larvae.
Figure 5. Early (top) and later (bottom) live-feeding larvae.

tissues and physiology in flatfish, during which the larva changes from a bilaterally symmetrical, free-swimming, pelagic form to an asymmetric, flattened, and demersal or bottom-living form (30). This involves the left side of the fish effectively becoming the "ventral" or bottom-facing surface with the left eye having migrated from the left to the right sides so that both eyes are on the upper surface (31). The upper and lower surfaces of the fish also change their pigmentation, becoming darker and lighter, respectively. There are also profound changes in the structure and physiology of the digestive system (32). Metamorphosis is usually completed at about 650 degree days and the larvae are then transferred to purpose-built weaning tanks over the next 15−20 days.

The tanks used for initial feeding with live feeds are usually circular, 1.5−6.0 m (4.5−20 ft) in diameter, 1−2 m (3−6 ft) deep, and flat bottomed with a tangential inflow and central gridded outflow drain. Unlike the earlier egg and yolk-sac stages, the first-feeding larvae require light for feeding (100 lux is commonly used but some hatcheries use brighter light). Tanks are often provided with a peripheral collar, which serves to shade the walls of the tanks from the above-tank lighting (33). The photoperiod is 24 hr continuous light (LL) and the water temperature ideally 6−8 °C (43−46 °F). Light intensity levels are gradually increased during the period of larval rearing up to 1000 lux by day seven post-first feeding. Temperature can also be gradually increased up to 12 °C (54 °F).

Before stocking with larvae, the tanks are "greened" with appropriate microalgae at concentrations up to 10^7 algal cells/L; these concentrations are maintained by further daily additions of algae up to approximately 500 degree days posthatching. Larvae are stocked at 200 degree days posthatch by some hatcheries, although recently there has been a move to delay first-feeding as late as 270 degree days. Stocking densities range from 2 to 7 larvae/L (8−27 gal). Water flow rates are increased from 1 to 5 L/min (0.3−1.3 gal/min) during first-feeding, although some hatcheries also use aeration to maintain an upwelling current and a good dispersal of larvae, live feed organisms, and microalgae within the tank.

By 220−270 degree days posthatch larvae are ready to take first feed. Different hatcheries use a range of different protocols principally because procedures are still being optimized (4,27). Generally, hatcheries that have access to supplies of copepods prefer to use them because it is widely recognized that they provide the ideal nutritional source for halibut (34). However, because of difficulties in culturing or obtaining supplies from the wild, copepods are invariably in short supply. Hence, their use has to be rationed. Most hatcheries start-feed with enriched *Artemia* as halibut larvae at 13−14 mm (0.51−0.55 in.) in length are already larger in size than most marine larvae at start-feeding (4,35). A few units initially use rotifers, although these are generally considered to be too small for halibut to prey upon.

Artemia can only be used successfully as a first-feed for halibut larvae if its nutritional composition is first supplemented with enrichment of additional nutrients, in particular, sources of essential polyunsaturated fatty acids and amino acids (36,37). Enrichment aims, in part, to simulate the nutrition provided by copepods or by the natural zooplankton diet of wild halibut. Enrichment procedures for *Artemia* show considerable variation among hatcheries because the detailed nutrient requirements of first-feeding halibut, and in turn, the appropriate enrichment levels needed to meet those requirements, are not fully known. In a number of hatcheries the *Artemia* are enriched with mixtures of Super Selco (INVE Aquaculture, Belgium) and a marine heterotroph Algamac 2000 (Aquafauna Biomarine Inc., USA). These are then added to the tanks at the rate of 1,000 *Artemia* nauplii/L (3,800/gal) twice a day; this corresponds to a daily ingestion rate for each halibut larva of approximately 2000−3000 prey organisms/day. As the nutrient composition of the enriched *Artemia*, and in particular, the polyunsaturated lipid levels, deteriorate over time, it is essential that the fish eat all the added *Artemia* within a few hours. Accordingly, *Artemia* additions are matched closely to consumption levels. Where possible the *Artemia* are supplemented with 20% copepods. Using such proportions, hatcheries have achieved 30% survival through first-feeding and 95% fully pigmented fish. Most of the mortalities occur during the initial phases of first-feeding, and after 350 degree days, losses are minimal. Tank hygiene can become a problem, so every day dead larvae and debris are removed by siphoning.

By 600−700 degree days, the fish are fully pigmented, metamorphosed, and starting to settle on the bottom of the tanks. They are then ready for transfer to weaning systems. If the fish are in good condition and around 100−130 mg in size, the process of weaning can generally be accomplished in 2−3 weeks (29,38).

Weaning tanks are usually circular 2−4 m (6−12 ft) tanks preferably with a conical sump covered by a perforated grille and a central double-sleeved standpipe, both tank adaptations which aim to improve the self-cleaning properties of the tank, as the inert diets can cause hygiene problems. Water temperature should be 10−15 °C (50−59 °F), with 5 μm filtered, UV sterilized water and continuous 1000 lux white light. Fish are stocked at 2−5 larvae/L (8−19/gal). As fish at this stage rest on the bottom, it is more appropriate to define stock levels in terms of bottom surface area. Fish stocked at 2−5/L (8−19/gal) equates to 1−2,000 fish/m^2.

A wide range of dry feeds is available and these can be fed continuously to satiation via automatic feeders. Over the first week of weaning some live food should be given with the dry feed (1000–3000 *Artemia*/fish/day). As soon as the fish are weaned, they grow rapidly and should reach 500 mg (0.02 oz) in size by 80 days post-first feeding. At 20 g (0.67 oz) in size the fish can be moved into the larger circular tanks [up to 5 m (16.5 ft) in diameter]. Aggression can be a significant problem; consequently, the fish should be regularly graded to avoid disparities in size within single tanks.

GROWOUT

It is considered that much of the initial growout of halibut will occur in sea cages or pens, mainly because many of the operators who have become involved with halibut are salmon farmers wishing to diversify their production. However, there are difficulties in the cage design and construction of cages for halibut because of their bottom-living habit. Hence, tank-based holding systems with solid floors may be more appropriate. This development becomes increasingly likely with the continuing reductions in costs of pump ashore systems and advances in recirculation technology. At present three of the biggest producers of market-size halibut in Norway and Scotland are using land-based pumped seawater facilities. One of those farms has constructed a series of shelves within a deep tank to maximize the stocking capacities of the tanks.

Problems associated with cage culture of halibut have included loss of appetite or mortality following exposure to excessive current speeds and swells; mortalities resulting from high surface water temperatures; sunburn in shallow cages without adequate shading; predation from seals and otters attacking fish lying on cage bottoms; and difficulties with removal of mortalities from cage bottoms covered with other live fish.

Most of the modified salmonid cages used for halibut utilize some form of rigid frame and anchor ropes around the four sides of the cage bottom in order to provide a flat and square floor on which the halibut can settle. There have been trials with cages with solid floors but these are highly subject to tidal damage and movement. Although we might have expected that the halibut would prefer a solid floor, it appears that netted floors are quite acceptable to the fish. It is clear, however, that the cage sites must be in sheltered positions preferably with waves no more than 0.5 m (1.5 ft) in height and currents less than 5 cm/sec (2 in./sec). For this reason some farms have experimented with submersible cages as the surface effects of wind are significantly reduced at only a few meters (yards) of depth.

Fish can be safely transferred to sheltered sea cage sites when they have reached 100 g (3.3 oz) in weight. Initially, stocking densities are 10–15 kg/m^2 with further reductions generally when stock levels reach 40–50 kg/m^2, although some farms have stocked up to 100 kg/m^2 without any problems. Fish continue to feed and grow down to 3–4 °C (37–39 °F), although the optimum temperatures for growth are 13–16 °C up to 25 g; 11–13 °C, 25–100 g; 10–12 °C, 100–500 g; 9–11 °C, 500–1000 g; and 7–11 °C,

1000+ g (38,39). Artificially extended daylength can, however, increase growth at the lower temperatures. Fish up to 500 g and 1–2 kg in weight grow at 0.5–1.0% body weight/day, respectively, and will reach 2 kg (4.4 lb) in size 1.5 years after the transfer to sea cage and market size (3–5 kg) (6.6–11 lb) after 2–2.5 years. Mortalities range from 3 to 9% during growout. FCRs of 1:1 are achievable with a 45–50% protein and 25% oil-extruded pellet offering 22–25 mj kg^{-1} of energy. Work on different dietary formulations and their effects on body composition and sensory assessments for halibut is only just beginning (40).

A major problem with the growout of flatfish, and halibut in particular, is the poorer growth of male fish. Most male halibut fail to reach a market size of 3 kg (6.6 lb) by the time they reach three years of age. This constraint has led to preliminary work on producing all-female or sterile triploid lines of fish (38,41). However, a complication for halibut at present is that it is not clear how gender is controlled and whether the male or the female is the homogametic sex. Clearly, commercial production of gender-manipulated stocks must await clarification of these issues.

OVERALL COMMENT

It is clear that halibut will be the next major cultured species in colder, higher-latitude waters. At present a number of problems still remain. However, significant numbers of weaned larvae are now beginning to appear on the market, and it is likely that world production will approach 1000 tons early in the twenty-first century. The continuing high prices achieved for halibut together with the diminishing wild fishery and the improvements in culture will no doubt ensure the future growth of halibut farming.

Introduction
Harvesting Intensive Culture Systems
Harvesting Extensive Culture System
Specialized Harvesting Techniques
Bibliography

INTRODUCTION

Once an aquatic species has been reared to sufficient size for marketing, the animals must be harvested and, in many instances, hauled some distance for processing or for live sale. At a minimum, harvesting usually involves capturing a significant proportion of the animals within a given culture chamber (pond, raceway, tank, netpen) within a short time period. This can be accomplished by reducing the water volume and netting the animals, seining, trapping, and by other means. For animals that are to be kept alive after harvest, it is important to minimize stress to the extent possible.

Some foodfish aquaculturists incorporate processing into their operations, but many send the live animals to processing plants in water or on ice. Ornamental fish are usually packaged for shipping at the site of production and taken to airports for dispersal to retail dealers. The information presented here is adapted from Stickney (1).

HARVESTING INTENSIVE CULTURE SYSTEMS

One of the primary advantages of intensive culture is the ease with which harvesting can be accomplished, in systems of virtually all types. In closed recirculating water systems, as well as in open systems, utilizing tanks, or raceways, harvesting is often merely a matter of draining the culture chambers and collecting the animals in dip nets. In large raceways and circular tanks, the water may be partially drained and the animals herded into a relatively small volume with the aid of movable screens (Fig. 1). As the number of animals is reduced through dipnetting, the volume confining those remaining can be decreased further by repositioning the screens and lowering the water level.

Some aquaculturists, including those who rear fish in ponds, employ a technique known as continuous harvesting. As the culture animals reach market size, they are removed from the system. Replacement juveniles are added either after each such harvest or less frequently. While no given pond, raceway, or tank is harvested every day (days or weeks may separate harvesting activity in any particular culture chamber), harvesting is conducted almost every day in large facilities.

If continuous harvesting is practiced in intensive culture systems, grader screens can be used in tanks or raceways. This allows submarketable fish to escape while crowding the marketable fish into a small space from which they can be dipnetted, often without requiring raceway draining. Another option is to rapidly drain the culture chamber through a net bag or some type of structure that will retain the animals while allowing the water to flow away.

In most cases, animals harvested from intensive culture systems can be loaded directly into hauling tanks for transport to the processing plant. All such systems, including those located in buildings, should be designed to provide easy access to all culture chambers by hauling vehicles; or some other suitable technique, such as fish pumps, (Fig. 2), should be used to move the fish from the tanks to the hauling truck. A fish pump can remove fish from culture chambers after they have been crowded. Fish pumps can move fish relatively long distances, can sort

Figure 2. A large fish pump (Israel). The fish are sorted by workers who separate them into marketable and submarketable groups. Submarketable fish are returned to a pond for further growout.

the fish in some cases, and when properly designed and operated, will not damage the animals.

Harvesting aquaculture animals from cages can be a relatively simple matter. Cages can be towed to shallow water or to a dock where the fish can be removed with dip nets or fish pumps (Fig. 3). If dip nets are used, the fish are typically placed in baskets and carried by hand or lifted by means of a gantry fitted with a block and tackle to the hauling truck or to a frame attached to the dock. A scale hung between the block and tackle and the basket provides a means of weighing each basket of fish as it is being loaded.

Lifting cages from the water is not generally feasible, since most are not sufficiently strong enough to be removed from the water when filled with harvestable fish. If a cage ruptures during the process, the fish will be lost. An exception is small cages [typically no larger than $1\,\mathrm{m}^3$ $(9\,\mathrm{ft}^3)$] like those used for research (Fig. 4). The small cages are not usually heavily stocked and are commonly constructed of sturdy materials that will accommodate removal from the water while the fish are present.

Netpen harvesting is more involved than harvesting associated with cages, because netpens are much larger in both surface area and depth. Typically, harvesting involves pulling up the netting to reduce the volume of the netpen, dipnetting out some of the fish, pulling up more net to concentrate the remaining fish, dipping more

Figure 1. Workers crowding fish in a raceway (Idaho, USA). The fish are removed from the crowding screen with dip nets.

Figure 3. For harvest, cages can be towed to a dock where the fish are removed with dip nets or by using a fish pump (Arkansas, USA).

Figure 4. Research cages tend to be small enough to allow removal from the water for harvest (Texas, USA).

fish, and so forth, until all the fish have been harvested. It may be necessary to grade the fish during the process. Submarketable individuals can be placed in a different netpen for additional growout. If the facility is attached to the land (e.g., attached to some access structure such as a rigid or floating dock), it may be possible to drive vehicles relatively close to pens that are being harvested. For offshore facilities, the fish are transported to the shore on boats.

HARVESTING EXTENSIVE CULTURE SYSTEM

The harvesting of ponds is easier when they are constructed in regular shapes, with properly sloped banks, proper depth, easy access by vehicles, large drain lines that allow rapid and complete emptying, and the incorporation of a harvest basin near the drain. Many ponds lack one or more of these features. Each is important, but the regularity of pond shape is the least concern. In some instances, it is more convenient to lay out a series of ponds that conform to natural variations in terrain than to greatly alter a site to accommodate square or rectangular ponds. It is important to have smooth and clean pond

bottoms. If culture ponds are not fitted with drains, the water can be pumped out of them at the time of harvest.

It is common practice in the catfish industry to use the continuous harvesting approach previously described. Ponds can be kept in production for a period of three or more years by harvesting marketable fish every few weeks and by restocking with replacement fingerlings a few times a year. Many other species of fish are maintained in ponds through a single growing season and are then harvested *en masse*. Whatever technique is used, at some point it becomes necessary to drain each pond. As time passes, ponds that are used for continuous harvesting accumulate organic matter, impairing water quality and reducing productivity. For example, phosphorus levels increase from year to year in undrained ponds (2). In addition, stunted fish continue to eat but may never reach market size. As their numbers increase (a result of intermittent restocking), the impact on culture economics can become significant. In most cases, even ponds used for continuous harvesting are drained and completely harvested every few years, although some farmers have apparently kept ponds in continuous production for 15 or more years. When ponds are drained, the bottoms are allowed to dry and are disked to promote oxidation of organic matter. The ponds are then placed back in production.

Harvesting should be planned in advance, and precautions should be taken to avoid stress to the extent possible, particularly when the harvested animals are to be live-hauled to market. Feeding should be discontinued at least 24 hours before harvesting. Automatic feeders and other obstacles to seining should be removed, and water quality should be examined to ensure that optimum conditions are maintained. Temperature is of particular importance. To help avoid stress, harvesting should be undertaken during the coolest part of the day (very early in the morning) during warm months.

While seining of full ponds may be undertaken when subsamples of fish are collected or in conjunction with the continuous harvest technique, harvesting is usually conducted with partial draining prior to initial seining, even when harvest basins are present. Typically, the water level is reduced, perhaps by half, and a seine is then passed through the pond to capture a portion of the fish present. The volume of the pond is then further reduced, and depending on the size of the pond, subsequent seine hauls may be made before the final harvest occurs in the harvest basin. In ponds with no harvest basins, seine hauls are made until the pond volume is reduced to 10% or less of the original volume, then the rest of the water is removed, and the remaining fish are harvested by hand.

Small ponds can be seined by hand (Fig. 5). Tractors or trucks are required to pull seines in large ponds. When the fish have been concentrated in a harvest basin, they may be dipnetted into baskets or pumped, eventually ending up in live-hauling trucks.

Harvest seines should be approximately 1.5 times longer then the pond is wide to ensure that they will bow out during harvesting operations. For additional capacity, seines may be equipped with a bag located in the middle. Seine bags provide additional capacity while reducing escapement. The depth of the seine should be

Figure 5. A seining operation (Philippines).

at least twice the depth of the water in the pond being harvested. The mesh size should be small enough to retain harvestable animals but no smaller, since reduction in mesh size increases the resistance of the net in the water making it more difficult to pull. In addition, the cost of netting increases with decreasing mesh size.

The upper rope on a seine (float or head line) typically consists of a rope to which floats made from cork, plastic, Styrofoam, or some other buoyant material are strung at intervals. The bottom rope (lead line) is designed to keep the seine in contact with the sediments. Lead lines may be ropes to which lead weights are attached at intervals or ropes that have a lead core. In ponds with muddy bottoms, traditional lead lines are often not efficient since they tend to burrow into the sediments and dig up mud, which weighs down the seine and causes it to roll up. In soft-bottomed ponds, seines with mud lines tend to be more effective. A mud line is composed of a number of relatively small diameter ropes wound loosely together. The ropes are made from a material that readily absorbs water (e.g., cotton). Mud lines tend to maintain contact with pond bottoms without digging into the sediments. Thus, escapement under seines, so equipped, is reduced. Such lines tend to wear rapidly if used in ponds with firm sediments.

Harvesting is the most labor-intensive activity associated with an aquaculture operation. Several people are required on the typical seine crew, even if trucks or tractors are used to do the bulk of the work. The aquaculturist may be required to live extra help during harvesting, and this added expense should be taken into consideration during business planning.

SPECIALIZED HARVESTING TECHNIQUES

Harvesting sessile marine animals such as oysters and mussels requires techniques different from those used for motile species. Oysters reared on the bottom floor can be harvested manually by picking intertidal oysters up at low tide or by tonging or dredging for subtidal animals. A mechanical oyster harvester developed in South Carolina was described by Collier and McLaughlin (3,4). Oysters grown in trays and on long lines suspended from rafts

or floats are manually harvested. Mussels are grown on the bottom, on poles, and on long lines. The harvesting technique is based on how the mussels are grown, but generally mirrors the methods used for oysters. Clams can be dredged or grown in trays and manually harvested. Scuba divers may also be used for harvesting benthic animals such as abalone.

Crawfish are harvested by trapping, although mechanical harvesting devices are being developed (5). During the harvest season, which extends from 60 to 180 days in Louisiana, traps are set out at intervals over the pond bottom. Various factors influence the efficiency with which crawfish are trapped. The catch can be affected by water quality, the amount of forage present, crawfish density, climate, trap design, the bait being used, and of course, trap density (6). Romaire and Pfister (7) compared catch rates with trap densities of 25, 50, 75, and 100 traps/ha (10, 20, 30, and 40 traps/ac) and found that 3.3 times more crawfish were captured at the highest density as compared to the lowest. The catch rates at 50 and 75 traps/ha (20 and 30 traps/ac) were 2.8 and 1.6 times more than the rate at 25 traps/ha (10 traps/ac). A variety of trap designs have been used in such studies.

Traps are baited with dead fish or commercially manufactured bait and are usually checked once or twice a day. One impetus for developing manufactured baits is the increasing cost of the fresh fish that have traditionally been used, such as gizzard shad (8). Rach and Bills (9) evaluated the effectiveness of three types of commercial crawfish baits, comparing them with dead fish bait. Results showed that commercial baits were easier to handle, did not have noxious odors, and did not require refrigeration — all advantages over dead fish. Meriwether (10) found that commercial crawfish bait containing about 20% protein resulted in the highest crawfish yields.

In small ponds, the culturist may wade through the pond to check traps, but in most instances boats are used. The boat may be operated by one or two people. If two people are involved, one drives the boat while the other handles the traps. As each capture location is approached, a newly baited trap is placed in the water and the trap that has been in the pond is removed, emptied, and rebaited. The newly baited trap is then placed in position at the location of the next trap in the line. With the technique described, it is possible to keep the boat in continuous motion during harvesting.

Following harvest, crawfish are often held in flowing water long enough to allow their digestive tracts to be purged. This process leads to improvement in overall appearance and increases the market value of the animals. Purging in spray systems works as well as flowthrough systems (11). Purging in spray systems requires no more than 40 hours (12). If the proper spray rates and crawfish densities are employed, mortality is less than 5% during the purging period.

Crawfish producers began producing soft-shell crawfish in 1985 (13). The technique involves trapping immature animals, placing them in culture trays at high density, and feeding them. Individuals that are about to molt are identified and removed to molting trays to prevent

cannibalism. Newly molted crawfish are packaged and frozen. Soft-shell crawfish bring a premium price and can be eaten whole, whereas processing for tail meat results in only about a 15% dress-out.

Some ponds have drains that empty into a receiving ditch immediately adjacent to the pond levee. In such ponds, an alternative approach to collecting fish or shrimp in a harvest basin during pond draining is to place a bag of appropriate mesh size over the effluent end of the drain pipe. As water is released from the pond, many of the aquaculture animals are swept into the bag. The technique works fairly well with shrimp and other species that are not particularly strong swimmers in strong current. Workers must still walk the pond bottom to pick up animals left behind when the pond was drained.

HISTORY OF AQUACULTURE

Robert R. Stickney
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

Aquaculture has a history that likely goes back over 4,000 years, possibly beginning in Egypt with tilapias or China with carp. Until the past few decades, aquaculture was conducted almost exclusively in ponds, at relatively low densities. In the United States, aquaculture began in the 19th century, mostly in association with state and federal government hatcheries that produced fish to stock public waters. Little changed until the 1960s, when commercial aquaculture began to grow at an exponential rate, not only in the United States, but around the world. Today, channel catfish is the leading species of fish cultured in the United States, while marine shrimp culture dominates in many tropical nations. Various species of algae, shellfish, and finfish are produced worldwide, with salmonids (trout and salmon) dominating cold-water areas. The public is familiar with cultured finfish (many species), molluscs (clams, oysters, and mussels), and crustaceans (marine and freshwater shrimp), but seaweeds are also widely cultured, as are, to a lesser extent, echinoderms (sea urchins), cephalopods (cuttlefish, squid, and octopus), amphibians (frogs), and reptiles (sea turtles and alligators).

THE FIRST FEW THOUSAND YEARS

The first known written document on aquaculture appeared in China in 475 B.C. (1). That very short volume by Fan Li, called *Fish Breeding*, discussed carp culture, which may have already been going on for centuries when the book was written. History reports that oyster culture was being undertaken during the period the Roman Empire was flourishing. Even earlier, the ancient Egyptians may have been involved in fish culture: Hieroglyphs in the tombs of the pharaohs depict what appear to be tilapia. (See the entry "Tilapia culture.") Whether the fish were being cultured or captured is not known, but pond culture is a distinct possibility. If that was the case, then perhaps both the Egyptians and the Chinese were involved in aquaculture as much as 4,000 years ago.

Early aquaculture was not restricted to the great civilizations of the world: Coastal fishponds were constructed in Hawaii many centuries ago by people thought to have been settlers from Polynesia. The ponds were undoubtedly stocked by the tides; then the inflow channels were closed, and the animals within the ponds were allowed to grow prior to harvesting them.

The Chinese may have grown marine shrimp as early as the eighth century B.C., and the Japanese were referring

to shrimp culture by 730 A.D. (1). The basis for modern shrimp culture was established by Japanese scientists in the 1930s, although the first commercial shrimp farms in Japan were not constructed until the early 1960s. Latin America and various Asian nations quickly adopted shrimp production and now produce the majority of the world's cultured shrimp. Total production exceeded 900,000 tons in 1995 (2).

Polyculture (see the entry "Polyculture") — the rearing of two or more compatible species in the same culture system — appears to have been developed by the Chinese. Various species of carp with different food habits have long been cultured together to take advantage of all the natural food in the pond, in addition to supplemental feeds provided by culturists. (See the entry "Carp culture.") This form of culture has survived for millennia and continues to be pursued in China today.

In Europe, at least primitive forms of aquaculture, including attempts at enhancing existing fish populations, were put in place by the eighteenth century (3). By the late nineteenth century, culture methods as sophisticated as or more sophisticated than, those employed in the United States had been adopted (4).

PUBLIC AQUACULTURE IN THE UNITED STATES

Aquaculture in the United States began as a commercial enterprise. In the 1850s, fish culturists in the eastern part of the nation developed the technology necessary to spawn and rear brook trout. Several became proficient in the technique and found that they could sell their fish for a reasonable profit.

During the latter half of the nineteenth century, it became apparent to at least some individuals that valuable commercially fish species were becoming depleted. One of those concerned about the problem was Spencer F. Baird, who was affiliated with the Smithsonian Institution (Fig. 1). Baird had a vision to create a federal fisheries agency and worked with Congress for its establishment. Ultimately, he was not only successful, but was named

the first commissioner of the US Fish and Fisheries Commission in 1871 (3).

Baird was responsible for the establishment of the Woods Hole Oceanographic Institution, in addition to being the visionary behind the development of the US government's fish hatchery system. He enlisted the assistance of the practicing fish culturists of the day to spawn and distribute species of interest. Among those early culturists were Seth Green and Livingston Stone.

Species that initially received the most attention were the Atlantic salmon and the American shad. Others that held interest were the flounder, largemouth bass, striped bass, and walleye, as well as various species of oysters, and lobsters. Within a few years of the establishment of the commission, large numbers of fishes and invertebrates were being transported across the country on railroad cars.

Livingston Stone (Fig. 2) was dispatched by Baird to California to spawn chinook salmon (then known by their Indian name of Quinnat salmon, Fig. 3), as well as rainbow trout, and to ship eggs and fry to the east coast. Since Atlantic salmon were declining, it was thought that Pacific

Figure 1. Spencer F. Baird as he appeared as a young man.

salmon might be successfully introduced to create a new fishery. At the same time, efforts to reestablish Atlantic salmon on the east coast were being pursued. Over the years, Atlantic salmon were also shipped to the west coast in attempts to establish the species there. While those attempts failed, rainbow trout were successfully introduced well outside of their west-coast range. In addition, spawning populations of striped bass and a few other Atlantic coast species were successfully introduced to the Pacific coast of the United States.

Soon after the US Fish and Fisheries Commission was established, it became involved in shipping fish to, and receiving them from, various foreign nations. Brown trout were imported from Europe, while rainbow trout and Pacific salmon were shipped to Europe and New Zealand. Baird, a strong proponent of establishing the common carp in US waters, was not the first to bring carp into the United States, but he was the first to launch a campaign to establish the species on a massive scale. Initially, he arranged to have carp shipped in from Europe, and then he established hatcheries for the production of the species and saw to it that carp were widely distributed throughout the country. His praise of carp resulted in orders from numerous states and territories. Trains were kept busy for several years trying to meet the demand for a fish that ultimately fell into disrepute.

The commission expanded over the years and, early in 1904, became the US Bureau of Fisheries, which was housed within the Department of Commerce. Things remained the same until 1950, when the Bureau of Fisheries was divided into the Bureau of Commercial Fisheries (BCF) and the Bureau of Sport Fisheries and Wildlife (BSFW), which later became the US Fish and Wildlife Service (USFWS). The BSFW was placed in the Department of the Interior, while the BCF remained in the Department of Commerce. In 1971, the BCF was renamed the National Marine Fisheries Service (NMFS), a division within the National Oceanic and Atmospheric Administration, still within the Department of Commerce. Basically, the NMFS has responsibility (including regulatory responsibility) for marine commercial fisheries, while the USFWS is primarily involved with freshwater fishes, whose use is chiefly recreational. The two agencies share responsibility for anadromous fishes, some species of which (e.g., chinook and coho salmon) are of interest to both recreational anglers and commercial fishermen.

Throughout the years, the various federal fisheries agencies have established hatcheries across the nation. Fish have been produced in the hundreds of billions for stocking both coastal and inland waters. During that time, state fish and game commissions also actively constructed hatcheries and distributed fish. Indeed, some state hatchery programs preceded federal efforts.

Both state governments and the federal government also established research facilities that made many contributions to advancing the art of fish culture in the United States. Among them were the USFWS laboratories in Hagerman, Idaho, and Cortland, New York, which concentrated on fish nutrition and dietary considerations; the Western Fish Disease Laboratory in Seattle, Washington; and the Stuttgart, Arkansas,

laboratory, established in 1958, with a satellite facility in Marion, Alabama, established in 1959. The latter two laboratories initially conducted research to assist in the development of the then fledgling commercial channel catfish industry. Later, their activities were expanded to other species. The Marion laboratory was closed in 1995, and the Stuttgart facility was transferred to the US Department of Agriculture, although its basic mission did not change. Aquaculture research has also been, and continues to be, conducted at various NMFS laboratories located along the east and west coasts of the United States, as well as the coast of the Gulf of Mexico.

Agency hatcheries produced fish of many species. Easily reared species like trout, salmon, and, eventually, catfish could be grown to fingerling size and released. Those species had a relatively good chance of survival after they were liberated into streams, lakes, or reservoirs. The technology was also developed to rear largemouth bass and sunfishes for stocking as fingerlings. Many other species were successfully spawned, but rearing beyond hatching was difficult or impossible given the technology available in the late nineteenth and early twentieth centuries.

A major problem was associated with the fact that many important commercial and recreational species have very small eggs and, as a result, similarly small larvae. Feeding fish and invertebrates that are nearly microscopic was beyond the ability of the early fish culturists and, in fact, continues to be a major impediment to the commercial culture of many species today. The approach was to release newly hatched fry into inland and coastal waters. It is unlikely that many of the billions of walleye, shad, lobsters, and various other species of fishes and invertebrates released into these waters survived. The majority undoubtedly served as food for predators or entered the food chain as detritus. There is no evidence that stocking US waters with such larvae ever increased the numbers of animals that were entering the commercial or recreational fisheries.

State fish hatcheries, some of which were established prior to the formation of the US Fish and Fisheries Commission, were also actively producing fish and stocking their local waters with them. Among the many major achievements of the state public hatchery system were advances in the development of prepared feeds, the identification of diseases and the development of treatment protocols for them, engineering advances associated with water systems, and the identification of methods to measure and control water quality.

Fish production continues in both state and federal hatcheries, although the number of facilities, particularly in the federal hatchery system, has declined in recent years. An exception is the Columbia River basin, where federal hatcheries continue to produce hundreds of millions of salmon in Washington, Oregon, and Idaho in an attempt to mitigate the loss of natural spawning habitat caused by the construction of dams, agricultural practices, and industrial development. Each of the states mentioned operates hatcheries in the Columbia River basin.

State hatcheries throughout the nation produce fish for stocking waters within their jurisdiction. At one time, nearly any landowner in the country who had a farm pond

could obtain free fish from the state, but that activity is increasingly being turned over to the private sector. Streams, lakes, and reservoirs within the various states continue to receive hatchery fish, however.

Pacific salmon (coho and chinook) were successfully introduced into the Great Lakes during the 1980s to replace top predators that had been decimated for a variety of reasons. A multibillion-dollar recreational fishing industry resulted, and a number of hatcheries were established to maintain the fisheries that developed.

DEVELOPMENT OF COMMERCIAL AQUACULTURE IN THE UNITED STATES

Academic Programs

Around 1960, commercial foodfish production, largely restricted to trout prior to that time, began to grow in the United States. The trout industry, centered in Idaho, expanded rapidly, and interest developed in foodfish production with warmwater species in the southern states. First among the warmwater fishes to be evaluated were buffalo (*Ictiobus* sp.), and a modest amount of production resulted. The warmwater fish farmers quickly turned to catfish, however, and buffalo culture waned.

Dr. H.S. Swingle was an entomologist with a passion for fishing that ultimately caused him to refocus his research activities on fish culture. In 1957 and 1958, he presented information which demonstrated that channel catfish could be reared profitably in ponds (5,6). Within a few years, the catfish industry, helped by research at Auburn and a few other universities, as well as the Stuttgart and Marion federal laboratories, began to develop and expand.

Commercial aquaculture caught the attention of researchers in several universities, particularly in the southern and western states. The University of Washington, which had been involved in salmon culture for decades, expanded its program significantly. Dr. Lauren Donaldson, who began his pioneering and universally recognized research on trout and salmon at that university in 1930, had established a salmon run that returned salmon to a pond adjacent to the campus hatchery. The fish, thus, literally returned to the classroom. Dozens of graduate students received advanced training and hundreds of thousands of children were introduced to the unique life cycle of Pacific salmon at that university's facility. Expertise in nutrition was provided by John Halver, who had been a leader in the development of prepared salmonid feeds during his tenure with the US Fish and Wildlife Service. William Hershberger was retained to run the hatchery after Donaldson's retirement in 1973 and to conduct research in fish genetics. Ken Chew, a world-renowned expert on molluses, conducted research and trained students in the culture of oysters, mussels, and geoducks.

While the University of Washington had already developed a powerful program in aquaculture even prior the growth of the catfish industry, Auburn University, with a slower start, made up ground rapidly. Swingle got the Department of Fisheries and Allied Aquacultures established and became its head. Wayne Shell assumed

that position when Swingle retired. Between them, they created a program with a highly respected faculty and pond facilities that were not paralleled anywhere in the country. An international program was established too, and it obtained numerous grants and contracts to assist in the creation or expansion of aquaculture programs and facilities in developing nations and to train personnel to manage those programs and facilities.

Auburn's faculty has been unique in that its core membership remained constant until the 1990s, when several faculty members retired. Among those who were active in the department for more than 20 years were Wilmer Rogers and John Plumb (fish diseases), R. Thomas Lovell (nutrition), Claude Boyd (water quality), and R. O'Neal Smitherman (reproduction). A number of other aquaculturists with backgrounds in complementary disciplines were added over the years, so that the core faculty not only failed to decline in numbers, but actually rose significantly.

During the 1970s, other universities expanded their faculties' expertise and research activities in the discipline of commercial aquaculture. In the west, Oregon State University became a leader, along with the University of Washington, in conducting research that led to the development of ocean ranching and salmon net-pen culture. The National Marine Fisheries Service in Washington, which collaborated with the University of Washington, was also heavily involved in net-pen culture development at the federal level. In California, the most visible program was developed at the University of California at Davis, where various warmwater species were subjects of research. In recent years, paddlefish and sturgeon culture have been studied in detail as well. The University of Idaho made numerous contributions, and further west, the University of Hawaii developed a program involving the culture of tropical fishes and invertebrates. The University of Arizona houses the world's leading program in shrimp viral diseases, despite the fact that the state had neither a seacoast nor, until recently, any commercial shrimp culture! Still, Donald Lightner's program is recognized throughout the world, and his expertise is in great demand.

William Lewis at Southern Illinois University (SIU) established the Cooperative Fisheries Research Laboratory at about the same time that Swingle was forging the Auburn program. Lewis retained Roy Heidinger as his assistant director, and together they conducted a large number of studies in fisheries and aquaculture and taught numerous students who went to other universities and became well known in their own right. SIU was among the leading universities involved in striped-bass and walleye culture research.

In the north central United States, the University of Wisconsin became a leader in yellow-perch culture. Purdue University in Indiana and Michigan State University developed active aquaculture programs. Schools in Minnesota became involved in research on what turned out to be an abortive attempt to develop aquaculture facilities in association with lakes created in abandoned iron mines in that state. The program was terminated due to complaints that nutrients added to the lakes from fish feed and waste products were entering the region's groundwater.

In the south, a strong program was developed at Mississippi State University, both on the main campus in Starkville and at the school's Stoneville research station. Robert Wilson developed a widely recognized catfish nutrition research program in the biochemistry department on the main campus of Mississippi State during the 1970s. H. Randall Robinette and Louis d'Abramo of the agriculture college were among the faculty who conducted research on fish and crustaceans. Craig Tucker, joined later by Edwin Robinson, led the program in Stoneville.

Active aquaculture programs were also established at the University of Tennessee, North Carolina State University, Clemson University in South Carolina, the University of Georgia, and the University of Florida. The University of Arkansas was engaged in aquaculture for a few years, but much of the activity in that state ultimately was centered at the branch campus at Pine Bluff rather than at the main Fayetteville, campus. Texas A&M University and the University of Texas, particularly at its Marine Science Institute in Port Aransas, developed aquaculture programs in the 1970s that remain active today.

With the development of technology for producing Atlantic salmon in net pens and the collapse of New England cod fishery in the 1990s, interest in aquaculture has been increasing in portions of the region. Universities in Maine and New Hampshire, in particular, have become increasingly active in aquaculture research and education.

In the mid-1980s, the US Department of Agriculture (USDA) created six regional aquaculture centers: a tropical center in Hawaii and US territories in the Pacific, and five others that represent the western, midwestern, central, southern, and north Atlantic regions, respectively. Several hundred thousands of dollars are allocated annually to each region to support university research. Partnerships with state and federal agencies provide additional input into the system.

The Department of Commerce operates the Sea Grant College Program, with 29 participants in the coastal and Great Lakes states. Over its more than 30-year history, Sea Grant has provided millions of dollars in aquaculture research at universities, and today it even operates (as does the USDA) a Small Business Innovative Research Program that provides funding on a competitive basis to promising private enterprises involved in aquaculture development.

Many other universities and colleges have programs in aquaculture research. In some states junior colleges and trade schools offer certificates in aquaculture.

Parallel with the development of academic programs at universities and colleges was that of professional aquaculture associations. On December 20, 1870, the American Fish Culturists' Association was formed. In 1878 it changed its name to the American Fish Cultural Association and in 1884 the American Fisheries Society (AFS).

The Fish Culture Section of the AFS was established in 1973. The World Mariculture Society was founded in 1969 and became the World Aquaculture Society in 1986. Both societies enable scientists to present their research findings at annual meetings, and both publish respected scientific journals in which scientists can communicate their findings.

Agricultural research in the United States developed in response to pleas from farmers for more information that could be provided only through a scientific approach. The result, the creation of the land-grant college system, revolutionized agriculture. When foodfish aquaculture was beginning to grow in the United States, the scientists tended to be somewhat ahead of the practitioners. Research results often demonstrated the feasibility of an approach before the industry even asked the appropriate questions about it. That state of affairs quickly turned around with the growth of the commercial aquaculture industry.

As the 1980s waned, opposition to aquaculture development began to be voiced. Discharge water was blamed for degrading the quality of receiving waters, while marine culture systems were seen to interfere with navigation, access to fishing grounds, and the views of property owners. Various other issues, including the use of exotics and excessive noise, have also been raised. It is clear that future aquaculture development will have to be environmentally sensitive. With heavy competition for coastal lands and increasing demands on the nation's surface and ground waters, many feel that the future of commercial aquaculture rests in the use of recirculating water systems on land and offshore systems at sea.

Trout Culture

Brook trout culture in the United States was commercial in nature as far back as the 1850s (4). However, while a modest amount of commercial fish culture took place during the intervening decades, including some development of rainbow trout farming in the Pacific Northwest, it was not until the 1960s that foodfish aquaculture became visible to the general public.

The so-called Magic Valley of Idaho on the Snake River is also famous as the Thousand Springs region. Pure, cold water flows freely into the Snake River in the vicinity of Twin Falls, Idaho, from a number of subterranean rivers that originate far to the north in Canada. By harnessing some of that water, fish farmers in Idaho monopolized the commercial rainbow trout farming industry for many years. The water was essentially funneled through raceways and then released into the river. While the trout culture industry has become more dispersed in recent years, at one time over 90% of all cultured trout produced in the United States came from the Magic Valley. A relatively small number of producers was responsible for developing the industry. Vertically integrated, those producers not only spawned and grew trout, but even processed the fish and delivered them to the marketplace.

Catfish Culture

Three species of catfish can be readily reared in aquaculture: the channel catfish (*Ictalurus punctatus*), white catfish (*I. catus*), and blue catfish (*I. furcatus*). Research was conducted on each of these species and on crosses among them by the BSFW and, later, the USFWS at its Stuttgart, Arkansas, laboratory, and in Marion, Alabama. John Guidice in Stuttgart and Kermit Sneed in

Marion were the main researchers on the project. While each of the species was adaptable to culture, it quickly became clear that the channel catfish was the species of choice.

The Stuttgart laboratory was established by Congress in 1958 to conduct research in support of the fledgling catfish industry. During its early development, the industry was centered in Arkansas in rice country where water was plentiful and it was relatively easy for rice farmers to convert all or part of their land to catfish farming. By the early 1970s, it became clear from falling water tables that the potential for expanding catfish farming in Arkansas was limited.

In their search for new locations, catfish farmers discovered the Mississippi Delta region, a flat area dominated by cotton production and featuring a relatively shallow water table that seemed to be inexhaustible. The industry soon became centered in the state. Production continued to expand in Arkansas, however, and other states also became involved. While Mississippi dominates production today, channel catfish are produced in all the southern states, including Texas. Limited commercial catfish production occurs in many other states as well, including California and Idaho. (The latter state has geothermal water, which allows year-round production.)

Research in federal, state, and university laboratories, together with studies conducted within commercial facilities, led to the technology upon which the industry depends today. Surprisingly, when in 1958, Swingle demonstrated the feasibility of producing catfish profitably (5,6), he placed the pond-bank market price at $0.50/lb ($1.10/kg). In 1997, the pond-bank value of catfish, was less than $0.80/lb ($1.76/kg) after 40 years and significant inflation. The fact that catfish farmers continue to make a profit relates to the fact that production was much more efficient in 1997 than in 1958. In 1997, sales of catfish were in excess of $350 million. The total number of operations in the United States (the only nation that produces channel catfish to any extent) was in excess of 1200. Catfish were being produced on over 170,000 acres (68,000 ha), of which some 100,000 acres (40,000 ha) were in Mississippi.

Catfish were once of interest as food only in the southern states. Through aggressive marketing and the production of a high-quality product, the catfish farming industry has developed a national market and is expanding on the international front as well.

Other Freshwater Species

In addition to trout and catfish, various other freshwater foodfishes and invertebrates have been reared commercially in the United States since the 1960s. Among the most widely cultured are various species of tilapia (in particular, *Oreochromis aureus* and *O. niloticus*) and crayfish (see the entries "Tilapia culture" and "Crawfish culture").

Tilapias, exotic tropical fishes from Africa and the Middle East, were introduced into the United States in the 1960s and are being reared in ponds in locations where they can survive during winter (Hawaii, south Florida, and, during most years, extreme south Texas), in outdoor facilities supplied by geothermal water and in indoor facilities where the water can be kept warm enough

for their survival with electrical or fossil-fuel heaters. While not widely recognized in the United States even a few years ago, tilapias (sometimes called St. Peter's fish) are highly marketable and increasingly in demand for their excellent flavor and texture.

Crawfish have long been consumed in large numbers in Louisiana, but in recent years they have come to be accepted in markets throughout the United States. Most of the crawfish that enter the American market come from the Atchafalaya River basin in Louisiana and are captured from nature. That supply is augmented by a significant level of production in shallow ponds (often converted rice ponds) in the state. Additional crawfish production has come from adjacent states, but is minor in comparison with the activity in Louisiana.

A considerable amount of interest, but limited production, has been associated with such fishes as walleye, yellow perch, and sturgeon. All three are marketed, but because of difficulties associated with their culture or limited popularity, no major industries have developed around them. That situation could change, however, as appropriate technology is developed and the fish are more widely and aggressively marketed.

During the 1970s, a great deal of interest arose in the culture of freshwater shrimp (in particular, *Macrobrachium rosenbergii*, the so-called Malaysian giant prawn). Several commercial operations were established in Hawaii and a few other states. Ultimately, nearly all of those ventures, which were augmented by a significant amount of university research, failed. Freshwater shrimp did not keep well when frozen and had to be reared to very large sizes if premium prices were to be obtained. When marine fish culture came on the scene in the 1980s, interest in freshwater shrimp culture waned, not only in the United States, but worldwide. Currently, little or no commercial freshwater shrimp is cultured in the United States.

Other species that have received attention by researchers and commercial aquaculturists are recreationally important fishes, such as largemouth bass, sunfish, and crappies, and species that are of interest primarily as bait — for example, minnows and goldfish.

The ornamental fish industry in the United Stated is centered in Florida, where well over 100 species of freshwater ornamentals are routinely produced in a number of commercial operations. Cultured ornamental fishes entering the aquarium trade are indistinct from fishes imported from abroad.

Finally, at least some level of plant culture is taking place in the United States. Decorative plants for aquariums, water lilies, and plants used in restoring or creating wetlands are produced commercially, although the industry is not large compared with various other freshwater aquaculture enterprises.

Anadromous Fishes

Interest in the commercial culture of salmon arose in the Pacific Northwest during the 1970s. Net-pen technology had been developed, and a large facility was put in place in Puget Sound, Washington, in which pansized coho salmon were produced. Research conducted in government and university laboratories first focused on coho and chinook

salmon. In the meantime, the NMFS was charged with the task of maintaining and spawning threatened stocks of Atlantic salmon that were shipped from Maine to the Puget Sound region of Washington where the work was conducted. The researchers learned that Atlantic salmon were better able to adapt to being reared in captivity than their Pacific counterparts were, and by the mid-1980s, several net-pen facilities were in place in Puget Sound.

Interest in Atlantic salmon culture also developed in Maine. In Washington, opposition to net-pen culture by property owners and environmentalists became very strong and led to long delays in permitting as prospective fish farmers attempted to address the claims that they were responsible for pollution, excessive noise, the transmission of disease to wild populations, and various other unacceptable consequences. As a result, the industry remained small. Opposition led by environmentalists also existed in Maine, but with the collapse of the cod fishery and the desire to retrain fishermen, salmon aquaculture quickly became an accepted practice, and those who were willing to become farmers of salmon or other aquatic species became eligible for federal assistance. Today, salmon culture continues to grow in Maine, while it is virtually stagnant or declining in Washington.

Spawning and rearing of Atlantic salmon for the first year are conducted in land-based facilities using freshwater. Smolts weighing about $1\frac{1}{3}$ ounces (40 g) are introduced into net pens, which they grow out of in approximately two years.

Net-pen salmon culture is illegal in Oregon and Alaska, but salmon ranching can be practiced in both states. Salmon ranching involves the spawning and rearing of the fish (Pacific salmon) up to the smolt stage, after which they are released to grow to adulthood at sea. When the fish return to spawn, they come back to the hatchery of their origin, where they can be captured and marketed (with a portion being retained as brood stock for the next generation).

In Oregon, for-profit salmon ranching has been attempted, but with only limited success, in part because commercial and recreational fishermen have access to the returning fish. Thus, there are often insufficient numbers coming back to the hatcheries to afford a profit once the required numbers of brood fish are collected. The quality of the flesh of fish that are allowed to reach full maturity is poor, so those fish have little value as human food.

In Alaska, not-for-profit ocean ranching is practiced. Hatcheries contract with commercial fishermen to capture the returning fish (less the number needed for brood stock). Ocean-ranching hatcheries utilize species not historically found in the rivers on which the hatcheries are located, so fish returning to the immediate vicinity of a hatchery represent those that were produced in that hatchery. In Oregon, ocean-ranched fish mix freely with wild and government hatchery fish, so there is no easy way to sort them out or charge a fee for the ocean-ranched fish.

Another anadromous fish that has been the subject of a considerable amount of research and commercialization is the striped bass. There is also culture of hybrids between striped bass and white bass. While it is possible to rear brood stock, most hatcheries depend on wild stock as brood animals.

Striped-bass and hybrid striped-bass farming in ponds is concentrated in the southeastern United States, although the fish can be reared virtually anywhere in recirculating water systems. Such systems have been established in many states, with modest production following. Rearing can be in either freshwater or saltwater.

Marine Species

Commercial marine fish culture in the United States is a fledgling industry. A few commercial operations produce red drum (primarily in Texas), and opportunities for expansion of that industry seem good, particularly in ponds. High-intensity systems may not be profitable, and the cost of rearing red drum in offshore facilities seems much too high, given the current value of the fish.

There is considerable interest in flounder culture, particularly in the northeastern and southeastern United States, but also along portions of the Gulf coast. The technology for spawning and rearing flounders, primarily the summer flounder and the southern flounder, has been developed, and a few commercial enterprises have been established.

American eels have been cultured, and at least one commercial producer grows Japanese eels. Since eels cannot currently be spawned and reared to the elver stage in captivity, elvers are collected from nature and introduced into culture facilities for growout. There is a limited, though significant, market for eels in the United States, and extensive markets for eels exist in Europe and Asia.

Tuna have been spawned in captivity, and early rearing has been successfully achieved, although the technology has yet to reach the commercial aquaculture sector. Tuna can bring very high prices in the marketplace, so there is interest in their culture. Current commercial culture depends on capturing juvenile tuna and rearing them in net pens, although that will change with time as hatchery technology improves.

Similarly, the basic information required for rearing dolphins (mahimahi) is now known, and the species sustains some commercial activity in Hawaii. Milkfish, Japanese flounder, and other species are also being reared or evaluated as candidates for culture in Hawaii. Other marine fishes that are being studied and that hold potential as commercial species are the Atlantic halibut, the Pacific halibut, various members of the snapper family, and the pompano.

Among the invertebrates, oysters have long been cultured in the United States. Much of the culture has been extremely extensive in nature, often involving little more than control of predators on leased beds. Oyster hatcheries do exist, however, and are responsible for supplying many of the oysters that are grown on the west coast of the United States. Triploid oysters—those carrying an extra pair of chromosomes—were developed several years ago and are now being stocked in many areas. Triploids do not become sexually mature, so they do not divert energy into gonad development, thereby maintaining excellent eating quality throughout the year.

Diseases have devastated oyster production along the east and Gulf coasts of the United States. Research has resulted in disease-resistant oysters that could

eventually lead to explosive expansion of production of these molluses. Offsetting the demand is public fears of transmission of disease from oysters that become contaminated in coastal regions where sewage pollution occurs. Enhanced inspection, successful efforts to reduce or eliminate sewage runoff into coastal waters, and the recent introduction of pasteurized (pathogen-free) oysters into the marketplace should help overcome the negative attitudes.

Other molluscs that are reared commercially in the United States include mussels, clams, and, to a lesser extent, scallops and abalone. Those molluscs, as well as oysters, can be reared on the sea bottom or suspended from ropes or rafts.

Marine shrimp culture is a major industry in portions of Latin America and Asia, and while much of the research that led to successful shrimp culture was developed at the Galveston, Texas, laboratory of the National Marine Fisheries Service in the 1960s and 1970s, the US commercial industry is small. Commercial growout efforts began during the 1960s, with much of the activity centered in Florida. Many operations came and went, but success with domestic species was elusive. When the Latin American industry achieved success by using species native to that part of the world, US shrimp farmers shifted from Gulf of Mexico species (white shrimp, *Litopenaeus setiferus*; brown shrimp, *Farfantepenaeus aztecus*; and pink shrimp, *Farfantepenaeus duorarum*) to exotic Latin American species (whiteleg shrimp, *Litopenaeus vannamei*; and blue shrimp, *L. stylirostris*) and, in a few cases, species from Asia (primarily the giant tiger prawn, *Penaeus monodon*).

Interest in shrimp culture has remained high in the United States, but strict permitting regulations, viral diseases, and problems associated with nutrients and levels of suspended solids in effluents from shrimp farms have been major issues in some areas where shrimp are reared. Another problem is the inability of pond shrimp farmers to produce two or more crops a year in most of North America because of low water temperatures over several months in the late fall through early spring. Some interest has developed in rearing shrimp in closed water systems, and a few commercial facilities have been established, but production remains at the pilot-scale level. Pond facilities for rearing shrimp can be found in South Carolina, Texas, and Hawaii; all of those farms use exotic species as the primary culture organism, but interest is once again turning to domestic species, although a considerable amount of research may be required before domestic shrimp can supplant exotics in the US shrimp-farming industry.

There is some seaweed culture in the United States, although it is not a large or very visible industry. Additional information on culture techniques for most of the species discussed in this article can be found elsewhere in the volume.

GLOBAL AQUACULTURE

In 1995, global aquaculture production exceeded 27,750,000 tons. (See Table 1.) Of that amount, 52.8%

Table 1. Top 20 Aquaculture Nations in Terms of Production in 1995[a]

Nation	Production (tons)
People's Republic of China	17,600,000
India	1,609,000
Japan	1,405,500
South Korea	1,017,250
Philippines	812,300
Indonesia	719,400
Thailand	464,200
United States	413,400
Bangladesh	321,500
Taiwan	286,200
Norway	282,500
France	280,800
Italy	224,900
Vietnam	219,400
North Korea	216,000
Chile	206,300
Spain	138,300
Malaysia	132,700
United Kingdom	93,800
Ecuador	91,200

Table 2. Top 15 Aquatic Animals Produced in Aquaculture During 1995[a]

Species	Production (tons)
Silver carp (*Hypopthalmichthys molitrix*)	2,555,000
Grass carp (*Ctenopharyngodon idella*)	2,102,700
Common carp (*Cyprinus carpio*)	1,783,400
Bighead carp (*Aristichthys nobilis*)	1,256,900
Crucian carp (*Carassius carassius*)	537,500
Giant tiger prawn (*P. monodon*)	502,700
Nile tilapia (*O. niloticus*)	473,600
Atlantic salmon (*Salmo salar*)	471,800
Roho labeo (*Labeo rohita*)	458,800
Catla (*Catla catla*)	381,400
Mrigal (*Cirrhinus mrigala*)	373,000
Rainbow trout (*Oncorhynchus mykiss*)	358,500
Milkfish (*Chanos chanos*)	358,100
White amur bream (*Parabramis pekinensis*)	335,900
Channel catfish (*I. punctatus*)	206,100

[a]From (2).

was finfish, 24.5% aquatic plants, 18.3% molluscs, and 4.1% crustaceans. Minor species made up the remaining 0.3% (2). The leading species produced are listed in Table 2.

As with the United States, the beginnings of modern aquaculture everywhere can be placed in the 1960s. The Chinese, who were responsible for the creation of aquaculture, did not begin to adopt modern technology until several years after most other nations had done so.

Tracing the development of aquaculture throughout the world would require hundreds of pages, and much of that history can be found in the contributions on various species that are included in this encyclopedia. Only a brief summary is given here.

Europe and the Middle East

Among the freshwater species that are of commercial aquaculture interest in Europe are trout, walking catfish, and crayfish. Trout (including rainbow trout introduced to Europe from the United States) have long been popular in many European nations. Walking catfish were introduced from Africa and Asia. Most of the activity associated with walking catfish culture is in the Netherlands. Crayfish culture has been plagued by disease in recent years.

In the Middle East, the tilapia is the dominant freshwater species cultured in many countries, although a significant level of carp production takes place in Israel, a leading aquaculture nation in the Middle East. Northern Israel also has at least one trout farm. Tilapias are native to north Africa and the Middle East, so they are naturally of interest to aquaculturists in that part of the world. Interest has also been sparked in freshwater shrimp in Saudi Arabia, Israel, and other Middle Eastern nations.

Marine aquaculture in Europe is quite well developed. Norway and Scotland both produce Atlantic salmon, of whose culture Norway is the world's leading nation. The same two countries also produce Atlantic halibut. The United Kingdom pioneered the development of culture technology associated with plaice, sole, and turbot. Each of those fishes is being reared commercially, with considerable prospects for increasing production dramatically. France has also been involved in flatfish culture, though not with halibut, as that species cannot tolerate the warm waters off the coast of France. Sea bass and sea bream have been of interest in Europe, and some production of those fishes occurs.

Mussels and other shellfishes are grown commercially in Europe, with Spain being a leader in their production. Raft culture of mussels is particularly well developed in Spain, while mussels are grown on poles in France.

Sea bream and, to a lesser extent, sea bass have been of interest in Israel. Much of the early research that led to the commercial sea bream industry was conducted there. Sea bream and sea bass could also be commercially grown in other Middle Eastern nations, in which some commercial marine shrimp culture is already being conducted.

Africa

Tilapias and walking catfish are the primary fish species being cultured throughout much of Africa. A large part of the continent is involved primarily with aquaculture at a subsistence level. Notable exceptions are Egypt and South Africa, each of which has developed commercial culture. In Egypt, interest is strong in the culture of tilapias, various species of carp, walking catfish, freshwater shrimp, and frogs. There is also a potential for culturing various marine species, including sea bream, mullet, sea bass, rabbitfish, flatfish, groupers, snappers, molluscs, and shrimp (7).

Rainbow trout were introduced to South Africa in the late 19th century to support recreational fisheries. The first trout farm was established there in 1945 (8). Today, in addition to trout, freshwater culture species include catfish, ornamentals, tilapias, and carp. Marine culture involves mussels, oysters, clams, shrimp, and redbait (a species of tunicate sold as bait).

Latin America and the Caribbean

The most visible and lucrative aquaculture activity in Latin America is the production of marine shrimp. Shrimp farming in Latin America started on a banana plantation in Ecuador in the 1960s and spread from there. The explosion in Latin American shrimp farming began in the 1980s, led by Ecuador, which was later joined by several other nations, including Mexico, Costa Rica, and Panama. Other marine organisms of interest in Ecuador include molluscs, flatfishes, red drum, snook, pompano, and yellowtail (9). Freshwater species that are of interest in Latin America include tilapias, carp of various species, rainbow trout, walking catfish, and a number of native species (10).

Peru and Chile have a considerable involvement in conjunction with the rearing of molluscs. In southern Chile, the emphasis has been on salmonid culture, with both the commercial trout and the commercial salmon industries having grown to the point that their production has a major impact on world markets for those commodities. Indeed, Chile is now second only to Norway in the production of cultured salmon.

In the Caribbean, a limited amount of aquaculture production occurs on various islands. Puerto Rico produces shrimp and tilapias, and the Bahamas have experimented with rearing tilapias in seawater and at one time had some interest in shrimp culture. A considerable amount of the tilapia that enters US markets comes from Jamaica. A small amount of subsistence-level aquaculture takes place in Haiti, where there is also a professed interest in commercial culture. Haiti's neighbor, the Dominican Republic, on the island of Hispañola, raises tilapias and marine shrimp. Attempts to raise local crabs, queen conchs, and various species of fishes have not led to significant production to date.

Asia

The majority of the world's aquaculture production comes from Asia. Far and away in the lead in terms of total fish production is China (Fig. 4), although in terms of employing technology, nations like Japan and Taiwan have assumed leadership roles. China is associated primarily with an enormous production of freshwater fish,

Figure 4. Carp culture pond in China.

including some seven million tons of various species of carp annually. Tilapias and other freshwater species are produced, too, but pale in comparison with carp production. In recent years, China has become a major nation in the culture of marine shrimp, and the Chinese also produce other marine species.

In India, several native carp species are produced, as are other freshwater fishes, including tilapias and freshwater shrimp. By 1985, marine shrimp culture had become an important industry in India. Important marine finfish and shellfish that are cultured are mullet, milkfish, pearl and edible oysters, and clams. (11). Seaweed is cultured as well.

Throughout Southeast Asia (Figs. 5 and 6), aquaculture has become an important activity. Thailand is the world's leading marine shrimp-producing nation, and Indonesia, Malaysia, and the Philippines are also major producers of shrimp. Milkfish are important in most Southeast Asian nations, as are tilapias, exotics first introduced in the 1930s. Seaweed culture also is important in various southeast Asian countries.

Korean aquaculture is varied and includes species from seaweeds to finfish. Russia and other countries that made up the former USSR also produce significant amounts of cultured products, mainly finfish. Carp is a popular culture

Figure 5. Shrimp farm in the Philippines (photo by Victor Mancebo).

Figure 8. Nets for attachment and growth of seaweed in Japan. The nets ride up and down the poles with the tide.

species in some regions, sturgeon in others. Eastern Russia is much involved in salmon culture.

Japan is perhaps the world's most advanced nation with respect to aquaculture. Relying heavily on protein from the sea to feed its people, Japan has long been a nation of fishermen and aquaculturists. From the southern part of that nation, where yellowtail, sea bream, and warm-water molluscs are reared, to the north, where salmon and cold-water mussels predominate, aquaculture is an important aspect of food production. Mussels, clams, scallops, oysters (including pearl oysters), abalones, shrimp, echinoderms, and a wide variety of finfish are produced by Japanese aquaculturists (Fig. 7). Japan is also a world leader in seaweed culture, with large areas of certain bays employed exclusively for that purpose (Fig. 8).

Australia and New Zealand have active aquaculture programs. Native species are of primary interest in both nations, although in New Zealand the introduced chinook (Quinnat) salmon and rainbow trout are still produced, primarily for recreation. A number of different fishes and shellfishes are receiving attention in both nations.

HORMONES IN FINFISH AQUACULTURE

Edward M. Donaldson
Aquaculture and Fisheries Consultant
West Vancouver, Canada

OUTLINE

INTRODUCTION

The word *hormone* is derived from a Greek word meaning "to rouse or set in motion." Hormones are organic compounds that are synthesized by the endocrine glands and are typically transported in the blood to other tissues or organs where they interact with hormone receptors to alter cell function. Key functions such as growth, reproduction, osmoregulation, metabolism, and the stress response are all regulated by hormones. Some hormones are involved in the maintenance of homeostasis while others are involved in developmental processes such as the coordination of gametogenesis. Many hormones are controlled by the central nervous system (CNS). The hypothalamus produces releasing hormones and release-inhibiting factors that interact at the pituitary level to regulate the synthesis and release of individual pituitary hormones. These pituitary hormones in turn target specific endocrine organs regulating the synthesis of the hormones that they produce. For information on early studies on hormones in fish, refer to the treatise by Pickford and Atz (1).

The structure of peptide and protein hormones such as those produced in the hypothalamus and pituitary gland has evolved over time. Many piscine hormones of this type are biologically active in fish but not in mammals. On the other hand, mammalian peptide and protein hormones are often active in fish, although not necessarily as active as the native piscine hormone. In the case of steroid hormones, the key steroids may be identical to those found in mammals. Thus, the stress hormone cortisol and the estrogen estradiol 17 are present in both fish and many mammals while the male-specific androgen in many fish is 11-ketotestosterone rather than testosterone. The steroids mainly responsible for final maturation in fish are either 17,20-dihydroxy-4-pregnen-3-one or 17,20,21-trihydroxy-4-pregnen-3-one (2).

Of all the hormones that are known to exist in finfish, relatively few are used in aquaculture at the present time. However, those that are used have a major impact on the overall success of aquaculture production systems and within appropriate regulatory frameworks, the use of hormones in a safe and sustainable manner can be expected to increase in the future. We focus attention here on those hormones that are currently used in aquaculture to regulate reproduction and sex differentiation and hormones that may be used in the future to regulate growth.

FINAL MATURATION, OVULATION, AND SPERMIATION

The first and, at present, perhaps still the major application of hormones in aquaculture is in the induction of sexual maturity in captive finfish. There are several objectives, including the induction of ovulation and spermiation in fish which do not undergo final maturation in captivity, the acceleration of spawning date in fish that do mature in captivity, the synchronization of spawning in fish that would otherwise spawn over an extended period, and the synchronization of spawning dates between related species that are being hybridized. In species where culture was previously based on the capture of wild juveniles, the development of induced spawning technologies has contributed to the sustainability of wild stocks.

Hormones were first used in aquaculture in Brazil in the 1930s when von Ihering (3) injected fish pituitary homogenates to induce spawning. The use of pituitary homogenates has continued to the present day. However, the process has some drawbacks, including the lack of

standardization of most pituitary preparations, the presence of other hormones in addition to the gonadotropins, the high cost of fish pituitaries, and, in some cases, poor quality control in the production of dried pituitary preparations. Pituitaries are preferably collected from mature fish when gonadotropin content is maximal and either used immediately, frozen directly on dry ice, or processed through several changes of cold acetone to remove all water before drying. Pituitary donor species that have proved successful include common and other carps and several salmon species. Owing to the phenomenon of species specificity in piscine gonadotropins, the use of pituitaries from homologous or closely related species is recommended.

Partially purified and purified gonadotropins have been prepared from fish pituitaries, especially gonadotropin II, which is homologous with mammalian LH (luteinizing hormone). However, the use of these has been mainly restricted for economic reasons to research and development. Human chorionic gonadotropin HCG, which is extracted from pregnant human urine, is effective in several finfish species including carps, mullet, and sea bream. See Refs. 4–8 for reviews on induced spawning in fish.

GnRH AND LHRH ANALOGS IN INDUCED SPAWNING

The most important development in the advancement of induced spawning technologies in finfish has been the application of gonadotropin releasing hormone (GnRH) analogs over the past two decades. These hormones stimulate the synthesis and release of the endogenous piscine gonadotropins and are therefore believed to mimic more closely the natural maturation process. The natural gonadotropin releasing hormones are decapeptides, i.e., they contain ten amino acids. Several natural forms have been identified, which vary in one or more amino acids. In some fish species, two or three different forms have been found within the same species. Thus, the sea bream contains sea bream GnRH, salmon GnRH, and chicken GnRH II (9). The separate functions of these several forms have not been elucidated. The natural GnRHs have relatively weak activity when administered to fish however; potent synthetic analogs have been produced which have greater receptor affinity (10) and greater resistance to enzymatic degradation (11). Typically, the analogs are substituted in position 6 with an appropriate D-amino acid, such as D-Ala or D-Arg, and the terminal glycine in position 10 is deleted and replaced with an ethylamide group (5). GnRH analogs that have seen considerable use in aquaculture include [D-Ala6, des-Gly10] mammalian GnRH (otherwise known as [D-Ala6, des-Gly10] LHRH) and [D-Arg6, des-Gly10] salmon GnRH. Several of the potent analogs are effective in fish *in vivo*, providing that they are from a reliable source and are of high peptide purity. Typical dosages range between 5 and 100 g/kg, depending on species, the maturity of the broodstock, the nature and purity of the GnRH analog, and, in species where dopamine inhibition occurs, whether a dopamine antagonist has been administered.

Modes of Administration

A variety of modes of administration has been developed for GnRH analogs (12). These include intraperitoneal or intramuscular injection in aqueous solution, injection in a slow release form, e.g., microencapsulated, implantation of GnRH incorporated into a cholesterol or polymer pellet, oral administration in solution or in the diet, and immersion in a solution of GnRH with or without exposure to ultrasound. Injection is effective in many fish, especially warm water species. Implantation is useful for cold water species, such as salmonids, as it removes the requirement for two spaced injections and for repeat spawners such as sea bream. Oral administration and immersion offer possibilities to regulate spawning in species that are stressed by handling (13,14).

Dopamine Antagonists

A number of fish species especially carps respond poorly to GnRH/LHRH injection as a result of the effect of dopaminergic inhibition of gonadotropin release (15). This inhibition can be overcome by the co-administration of a dopamine antagonist with the GnRH analog (16). Dopamine antagonists that have been used successfully for this purpose in fish include domperidone (7), pimozide (15), metoclopramide (17) and sulpiride (18). Appropriate dosages are in the 5–20 mg/kg range depending on the antagonist, the species, the maturity of the broodstock and the dose of GnRH. Domperidone (Motilium), which is not water-soluble is injected in aqueous suspension or dissolved in propylene glycol or other suitable solvent (19). Oral administration in conjunction with GnRH is also possible (14).

Antiestrogens and Aromatase Inhibitors

It has been known for some time that ovulation can be induced by manipulation of the feedback mechanisms that control endogenous GnRH and gonadotropin release. Thus, it is possible to use antiestrogens such as tamoxifen to induce ovulation (19a). Recently, we have demonstrated induction of both ovulation (20) and spermiation in Pacific salmon using the aromatase inhibitor fadrozole that is capable of inhibiting estrogen biosynthesis (21,22). However, further research will be required to determine whether this can be developed into a practical technique.

CONTROLLED SEX DIFFERENTIATION

Hormones, specifically androgens and estrogens, have played an important role in the development of technologies for the production of monosex and sterile fish stocks. In several species, one sex is more valuable than the other, e.g., where the roe is valued. In other species monosex culture facilitates the implementation of a more efficient production system, e.g., where one sex grows to market size faster than the other or where one sex is prone to precocious maturation before reaching full market size. The production of monosex or sterile stocks also provides a means of reproductive containment for exotic species or genetically modified stocks (23–27).

Species where monosex production has been implemented on a production scale include chinook salmon, a species where all commercial culture in Canada has been monosex female for over a decade, and rainbow trout where much of the production in several countries is now monosex female or monosex female triploid. Monosex male tilapia are also widely grown in several countries. Species where monosex technology may be applied in the future include other salmonids, such as Atlantic salmon (27) and coho salmon, flatfish, such as the turbot and halibut where the female grows faster than the male, and the carps, mullets, sea bass, and catfishes. There are two distinct approaches to sex control, direct and indirect (28). In the direct method, production fish are treated with an appropriate androgen or estrogen, usually during early development, to induce gonadal differentiation into the desired sex. This method is widely used for the production of monosex male tilapia (29,30). However, it is being gradually replaced by the newly developed indirect methods for tilapia (31). In the indirect method, hormone treatment occurs in the previous generation and not on production fish. The method depends on the production of monosex sperm which, when used to fertilize normal eggs, results in the production of monosex fish. Thus in the salmonids, which are female homogametic, genetic females are treated by immersion in the alevin stage and in some cases by diet in the early feeding stage to produce phenotypic males that are genetically female. When these fish mature, they produce monosex female sperm which, when used to fertilize normal eggs, results in the production of monosex female offspring. The development of new monosex female salmonid stocks requires the separation of masculinized females from normal males. This has traditionally been accomplished by progeny testing; however, the development of Y-specific DNA probes has facilitated this process in a number of salmonids (32,33). The indirect production of monosex male stocks in female homogametic species requires more steps than the production of monosex female stocks as it depends on the production of YY supermales (31,34). In catfish, this can be accomplished by dietary treatment of genetic males with estrogen (or androgen) to produce XY phenotypic females. When mature, these XY females are mated with normal XY males. The offspring have a 3 : 1 male–female ratio. One-third of these males would be YY males (identified by progeny testing) which, when mature, produce monosex male sperm. When used to fertilize normal ova the result is a monosex male population. Reviews on sex control technology in fish include Hunter and Donaldson (35), Shelton (36), Pandian and Sheela (37), Donaldson et al. (38), Donaldson (6), and Piferrer (39).

CRITICAL VARIABLES IN CONTROLLED SEX DIFFERENTIATION

Choice of Androgen or Estrogen

A number of factors influence the success of hormonal sex control. The choice of a suitable androgen or estrogen is important. In the case of androgens testosterone is only weakly androgenic, while the natural nonaromatizable androgen 11-ketotestosterone is effective (40) but costly

to use. The synthetic androgen 17-methyltestosterone is cost-effective in many species. However, it can lead to paradoxical feminization when administered at higher dosages. The term *paradoxical feminization* refers to the appearance of increasing proportions of females as the dose of androgen increases. This phenomenon has been suggested to occur when the administered androgen is aromatized to estrogen *in vivo*. The nonaromatizable synthetic androgen 17-methyldihydrotestosterone is an effective masculinizing agent in both salmonids (40) and tilapia (41). In some species, such as the channel catfish, masculinization is not possible with any androgen tested to date; however, feminization poses no problem (34,42). In the case of estrogens, the natural estrogen estradiol 17 is effective and the synthetic estrogen 17-ethynylestradiol is also effective and more potent (43).

Dosage and Timing

The dose varies according to species, steroid used, and mode of administration. Treatment must occur during the labile period, i.e., the period during which the fish is responsive to exogenous androgen or estrogen treatment (28). In new species the first step is to determine through histological studies the time of morphological sex differentiation. For species treated by immersion before first feeding, androgen dosages in the range of 400–2000 g/L in the immersion water are effective in, for example, salmonids. Typically, the androgen is dissolved in ethanol or other suitable solvent before mixing with the water. It is important that the immersion water be circulated over the eggs or larvae by aeration or recirculation pump and that the number of eggs or larvae per liter is not excessive. A typical immersion duration is 2 hours; however, isotope studies indicate that uptake is still underway at this time (44). Success has also been achieved with longer immersion periods at low temperatures. Some fish species respond to a single immersion during the labile period while others require repeated treatments during the labile period or a combination of immersion and dietary treatment (45).

Dietary dosages for masculinization vary from 1 to 3 mg/kg diet in salmonids (46) to up to 60 mg/kg diet in tilapia (30). In species such as the Mediterranean sea bass sex differentiation occurs late. Success has been achieved in this species with dietary administration of 17-methyltestosterone at 10 mg/kg initiated 126 days after fertilization and continued for 100 days (47). Androgen dosages higher than those used for masculinization can result in sterility (48–50).

Health and Environmental Issues

Androgens and estrogens utilized in aquaculture are potent steroids that must be treated with great respect. Persons working with these compounds should avoid skin contact or inhalation. The use of hormone mimics such as diethylstilbestrol, which is a known carcinogen of the human reproductive system, should be avoided. Effluent water containing androgens or estrogens should be disposed into a large volume or flow of water where it will be diluted to an insignificant concentration or disposed

to ground well away from domestic water supplies. The use of androgens or estrogens in closed water systems where untreated fish are on the same water supply can lead to unexpected effects on "untreated" fish (51).

GROWTH

The average production cycle for cultured finfish greatly exceeds the production cycle for avian and mammalian species. This results in capital facilities being occupied for longer periods and exposes the fish in each production cycle to greater risk from loss due to a variety of factors, including storm damage, predation, disease, and harmful algal blooms. Progress in reducing production cycles has been achieved through selective breeding, improved nutrition, and improved husbandry. However, it remains of considerable interest to determine whether further reductions in the production cycle can be achieved on a practical and sustainable basis by using our knowledge of the endocrine system. The hormone that has received the most attention in these studies and to date the most effective in stimulating growth has been pituitary growth hormone or somatotropin (52,53) and related hormones such as bovine placental lactogen (54). Somatotropin is a protein with a molecular weight in the region of 20,000 Daltons. Mammalian growth hormones are effective when administered to fish, while fish growth hormones are ineffective in mammals. In addition to stimulating growth, somatotropin facilitates the smoltification process in salmonids (55,56) and may improve feed conversion (54). Its production and secretion from the pituitary gland is under both stimulatory (somatocrinin or growth hormone releasing hormone) and inhibitory control (somatostatin) (57) by the hypothalamus. The actions of growth hormone are believed to be mediated through insulin-like growth factor (IGF I) (somatomedin). However, the effects of growth hormone on growth in fish have not yet been fully replicated by treatment with IGF I (58), suggesting that growth hormone may also act though other mechanisms or that it has not yet been possible to administer IGF I in a fully effective manner for growth stimulation without causing physiological problems normally associated with high levels of insulin (59). Other hormones that have been investigated for their effects on growth include the androgens and thyroid hormones (59a). There are two methods by which growth hormone can be administered to fish. Exogenous hormone can be administered during appropriate periods of the production cycle or the fish itself can be engineered to produce a greater amount of growth hormone, which is not under hypothalamic control, throughout the production cycle (60).

Administration of Exogenous Growth Hormone

There are several means by which growth hormone is administered to fish. It can be given by weekly or biweekly intraperitoneal injection in aqueous form or at much longer intervals in a slow-release formulation (56,61). It can also be supplied as an intraperitoneal or intramuscular slow-release implant such as a cholesterol- (62) or polymer-coated pellet (63,64) or a mini-osmotic pump (62,65).

Immersion in a solution of growth hormone has also been tested (66). Probably the most feasible means of providing growth hormone is either by dietary administration (67,68) or by injection of a slow-release formulation. Finfish are able to absorb intact proteins and peptides from the digestive tract (69,70) and means for protecting the hormones during gut transit and enhancing uptake have been investigated (70a).

Advantages of administration of exogenous growth hormone versus growth hormone transgenic fish include the following: application is possible at a specific life stage; a withdrawal period is possible; reproductive or physical containment is not required; and there is no need to sterilize production fish and no need to maintain a specific broodstock in quarantine. Disadvantages include the following: performance enhancement is not yet as impressive as the transgenics; cost of the growth hormone; treatment requires handling (except the oral route); repeat treatment may be required; regulatory issues, especially with non-homologous proteins; and potential concern over residues in the product and in the environment.

Development of Fish with Enhanced Endogenous Growth Hormone

The development of transgenic fish with enhanced ability to synthesize growth hormone provides another means of increasing growth rate. Success has been achieved with DNA constructs containing homologous or closely related growth hormone genes driven by piscine promoters such as the ocean pout antifreeze promoter (70b,71), and the sockeye salmon metallothionein-B promoter (60). In some fast-growing transgenic fish the increased level of growth hormone has been sufficient to induce deformities in the head region (71); however, fish with moderate acceleration are normal in appearance. Transgenic technology offers the possibility of enhancing or suppressing other parts of the endocrine system (72).

Advantages of growth-enhanced transgenic fish include the following: exceptional growth performance; peptide production is endogenous; the peptides used can be homologous; no fish handling is required; performance enhancement is continuous; performance traits are inherited; and there is the future possibility of controlling growth hormone expression at specific life stages.

Disadvantages of growth enhanced transgenic fish include the following: development of a true breeding stock takes several generations; control over level of expression is only possible through selection and timing of expression is not yet possible; public perception of genetic engineering in export markets; possible concerns over use of nonhomologous constructs; public concern over risk to ecosystem associated with possible escape of genetically modified aquatic organisms; need for broodstock quarantine; and reliable sterilization of production fish.

Many of the possible problems associated with the use of either exogenous growth hormones or transgenic fish do have solutions, and it is probable that both of these technologies will be implemented in the not too distant future.

CONCLUSIONS

This brief review of the use of hormones if fish has focused on those hormones that are actually used or are close to being used in aquaculture. It is important to note that the ability to simply measure hormone levels in wild, hatchery-supported, and aquacultured fish provides powerful tools to assess, for example, the stress and reproductive status of fish.

INGREDIENT AND FEED EVALUATION

J.P. Lazo
D.A. Davis
Marine Science Institute
Port Aransas, Texas

OUTLINE

INTRODUCTION

The development of satisfactory diets for the production of farmed fish and shrimp demands a comprehensive understanding of nutritional requirements, feed processing, and methods to assess the quality of the ingredients that comprise a feed. In the framework of this article, ingredient quality mainly refers to the ability of the ingredient to allow optimum growth and health of the animals in culture. No single feed ingredient can supply all the nutrients and energy required for optimal growth; therefore, a mixture of feed ingredients is combined to produce a diet with the desired nutrient profile. Unfortunately, feed quality can vary considerably even for species for which nutritional requirements and commercial processing techniques are well established. In most cases, variability of the feed can be traced back to ingredient quality and/or quality control at the mill. Consequently, it is essential that the quality of feed ingredients, as well as the final product, are well defined.

Feed and ingredient evaluations can be approached as a stepwise process in which ingredients are analyzed by a series of simple physical and chemical tests, blended to produce a product with the desired nutrient profile, and then evaluated with the target species. A variety of tests that aid in the evaluation of the nutritional quality of ingredients and feeds are currently available. No single test will provide the necessary data for adequate feed evaluation. Hence, a variety of physical, chemical, and biological methods of evaluation are utilized to provide the information required to assess quality and nutritional value of single ingredients and feeds.

Physical and chemical tests include a variety of practical methods that provide a fast and simple way of screening ingredients. Physical methods rely on the characteristics of the feedstuff in question, such as particle size, density, and stability in water. Physical examinations, particularly microscopic evaluations, serve to evaluate the purity or composition of a particular ingredient, but provide little information on the nutritional value of the ingredient. Chemical methods are utilized to further characterize or define the chemical composition of the test substance and can give a very precise chemical definition of nutrients that are present. However, it is important to realize that both types of evaluations do not measure the real nutritional value of the feed or feed ingredient to aquatic animals, but provide only an estimate of its quality and gross composition.

Biological tests do not provide any information about the chemical composition, but offer a more accurate estimate of nutritional value and efficiency to produce growth and maintain a healthy organism. Live organisms are utilized to conduct well-designed feeding trials to evaluate the specific effect of a particular ingredient, nutrient, or feed formulation. Therefore, biological methods provide information that ascertains the true value of the feedstuff to the organism. Although biological tests are the preferred method and the ultimate test of performance, they have the disadvantages of being time-consuming, expensive to conduct, and require specialized facilities for holding live animals.

Physical, chemical, and biological methods will be discussed in the context of evaluating the quality of ingredients. The majority of methods described are equally applicable for the determination of nutritional requirements and the evaluation of prepared feeds.

PHYSICAL EVALUATION

The first step in assessing the quality of ingredients and/or a processed feed is to examine or inspect its physical characteristics. With the aid of a microscope one can confirm the purity of the ingredients (identify foreign contaminants or adulterants) or the variety of ingredients in a feed (1). In addition, some of the common physical characteristics to evaluate are (*1*) particle size and distribution, (*2*) density, (*3*) water stability, (*4*) texture, (*5*) feed shape and pellet quality, (*6*) homogeneity of ingredients, (*7*) color and contrast, and (*8*) smell (e.g., rancidity of oil or ammonia).

The optimal (desired) characteristics to look for will depend on the species of interest, the type of diet, and the size of the organisms in culture. For aquatic feeds, evaluation of pellet stability, shape, and density is very important because these properties will greatly influence the extent of feed utilization. Detection of any possible contaminants present in the ingredient or feed is desirable. Examples are feathers in meat and bone meals, large quantities of sand in fish meals, or toxin-producing models in grains. Physical evaluations can be conducted relatively quickly and represent an easy method to help ensure the purity of ingredients and hence minimize adulteration of the final product.

CHEMICAL EVALUATION

Chemical evaluation assays are those completed *in vitro*. The most common method used to analyze the nutrient composition of feeds or feedstuffs is known as the Proximate Analysis System or Weende Method. Developed in Germany over 100 years ago, proximate analysis is applied routinely in laboratories throughout the world. Although this system provides a general overview of the chemical composition, other chemical methods of evaluation provide more specific nutrient analysis of the ingredients and feed such as amino acid profiles, fatty acid composition, and essential vitamins and minerals.

Proximate Composition

Proximate analysis is based on simple assays that separate the feed or feed ingredients in question into different classes of nutrients such as moisture, protein, lipid, ash, crude fiber, and N-free extract. Detailed descriptions of the following assays are presented in *Official Methods of Analysis of the American Association of Analytical Chemists* (1). These nutrient groups can then be further defined by specific analytical techniques.

A brief description of each method follows, and a flowchart of the sequential procedure can be found in Figure 1.

Dry Matter. Estimates of dry matter (expressed as a percentage of total wet weight) allow for comparison of ingredient composition without the potentially confounding effects caused by differences in moisture content. Dry matter content is determined by heating a sample to a constant weight at temperatures above the boiling point of water (100 to 105 °C). Other methods for determination of water in feeds include toluene distillation, drying under vacuum, and freeze drying. Although estimates of dry matter tend to be simple and accurate, this technique can be a potential source of error for the stepwise procedure of proximate analysis. For example, if heated at temperatures that are too high, some fatty acids or fermented products such as silage can be volatilized, thereby resulting in an underestimate of actual dry weight (2). Conversely, the dry weight of a sample can be overestimated because some liquids do not volatilize when they become oxidized upon heating, and therefore become part of the dry weight of the sample. Since this overestimate can be a source of error that will be amplified in the next steps of the proximate analysis, care must be taken to optimize drying procedures relative to the type of sample being analyzed.

Crude Protein. The standard method used to determine crude protein content is the Kjeldahl technique. This method destroys organic matter, and all forms of nitrogen are then reduced to ammonium sulfate in the presence of sulfuric acid and various catalysts. After addition of excess alkali, ammonia is liberated and subsequently distilled and trapped in boric acid. The boric acid is then titrated with standard acid solution to determine the total nitrogen content (3). Crude protein is calculated by multiplying the amount of nitrogen by the empirically derived conversion factor of 6.25, which is based on the assumption that protein contains 16% nitrogen. Although this value is a good estimate, the actual range of nitrogen content in different proteins is between 12 and 19% (2,4). The calculated protein content can then be normalized to the wet or dry weight (dry matter) of the sample to obtain the percentage of protein content.

The Kjeldahl method does not distinguish between nitrogen originating from protein (amino acids) in the sample and that originating from either single-cell protein sources (bacteria, algae, and yeast) or nonprotein sources (amines and urea). In general, fish do not efficiently utilize single-cell protein sources and cannot utilize nonprotein sources of nitrogen. Consequently, the actual protein available for growth may be overestimated.
Figure 1. Diagram flow of proximate analysis.

Lipid Content. Lipid content is determined by extracting lipids from a sample with organic solvents. The solvent can be ether (1) or other mixtures of organic solvents, such as chloroform and methanol, in a ratio of 2 : 1, vol/vol, respectively (5), or hexane : methanol 4 : 1, vol/vol (6). Once lipids are extracted, the solvent is evaporated under nitrogen and the remaining amount of lipid is determined gravimetrically. The lipid weight can then be normalized to either the wet or dry weight of the ingredient to determine a percentage of lipid content.

Some potential sources of error exist for lipid extraction techniques. Any ether-soluble or chloroform : methanol-soluble compounds will be included in the estimate. Many of these compounds (e.g., chlorophyll, volatile oils, resins, pigments, and plant waxes) are of limited nutritional value to animals. In some cases, as much as 50% of the extract can be composed of these compounds (4). Alternately, lipids in some single-celled protein sources and processed feeds are bound to compounds (i.e., polysaccharide structures of bacterial cell walls) by covalent association and cannot be extracted with organic solvents. Such samples require a pretreatment with 4-N-HCl before extraction (acid hydrolysis) to cleave the lipid−polysaccharide complex (7).

Crude Fiber. Crude fiber is generally regarded as the indigestible part of the carbohydrates, having no nutritional value. To estimate crude fiber, a lipid-free sample is first digested by boiling in weak acid (0.255 N H_2SO_4) followed by boiling in a weak alkali (0.312 N NaOH) solution. This stepwise procedure removes the proteins, sugars, and starches from the sample. The sample is then dried and weighed, burned in a furnace at 600 °C, and reweighed. The material (weight) lost during the oxidation or burning corresponds to the content of crude fiber. This fraction consists primarily of hemicellulose, cellulose, and some insoluble lignin.

Some components of crude fiber, such as hemicellulose, can be partially dissolved by the acid/base treatment and lost from the sample, thereby resulting in an underestimate of crude fiber content. An overestimate of the fiber content can occur if protein is bound to lignin or other insoluble chemical forms, because the protein will remain in the sample and its weight will be included in the crude fiber estimate (4).

Ash. The material remaining after a sample is burned by combustion at 600 °C represents the inorganic or mineral content (8). The combustive process oxidizes all organic material, volatilizing and removing it from the sample. Because some minerals such as chlorine, zinc, selenium, and iodine can be lost through volatilization during combustion (9), caution must be exercised if the ash sample is to be analyzed subsequently for mineral determinations.

Nitrogen-Free Extract (NFE). Once the moisture, protein, lipid, fiber, and ash contents of an ingredient have been determined, the carbohydrate content or NFE can be estimated as the difference between the weight of the whole dry sample and the sum of the protein, lipid, fiber, and ash content. NFE primarily consists of available carbohydrates, such as sugars and starches, but can also contain some hemicellulose and lignin. The levels of specific carbohydrates can be determined by following the techniques described in the AOAC (1).

Energy Content

The gross energy content of a feed or an ingredient can be estimated indirectly from its chemical composition or directly by oxidizing all organic materials and measuring the heat produced (10,11). The direct method is performed with an instrument called an adiabatic bomb calorimeter, which measures heat released during combustion. Using this technique, the average energy values for the major nutrients have been estimated to be 5.6 kcal/g (23.4 kJ/g) for proteins, 9.5 kcal/g (39.8 kJ/g) for lipids, and 4.1 kcal/g (17.2 kJ/g) for carbohydrates (12).

In the indirect method, the estimated proximate composition of the feed or feed ingredient (i.e., protein, lipid, and carbohydrate) is used to determine the gross energy content by multiplying the appropriate average energy conversion factor for each nutrient by the amount of each nutrient and summing them. Both techniques assume that all the dietary energy is available to the organism.

Specific Nutrient Content

Proximate analysis separates general nutrient classes. It does not separately identify nutrients that cannot be utilized by the animal, compounds that have a low nutritive value, or ingredients with an inadequate balance of specific nutrients. Hence, more specific analyses are often warranted. Nutrients such as protein, lipids, carbohydrates, vitamins, and minerals can be analyzed by identifying and quantifying their respective components. Although chemical analyses of specific nutrients provide useful compositional information, such methods do not quantify actual nutrient availability to the animals themselves.

Amino Acid Analysis. Proteins are the principal components of the organs and soft structures of an animal's body. They are large molecules which differ widely in chemical composition, physical properties, solubility, and biological function. All proteins have one common property: their basic structure is composed of repeating units of amino acids. There are 22 amino acids that are commonly found in proteins. Some amino acids (nonessential or dispensable) can be synthesized and hence may not be required in the diet, whereas other amino acids (essential or indispensable) cannot be synthesized or synthesized in sufficient quantities to meet physiological demands.

Since amino acids are the building blocks of proteins, the amino acid profile (identification and quantification of amino acids) of a particular ingredient must be determined to formulate a feed that will meet essential amino acid requirements of the target species. Methods for determining the amino acid composition of ingredients and diets can be found in AOAC (1), and include microbial methods, column chromatography, and HPLC techniques.

However, these methods do not provide information about the chemical form of the amino acids, i.e., free, bound in proteins, or the degree of availability to the organisms.

Chemical Scores, Indispensable Amino Acids Index (*IAAI*), and Essential Amino Acid Index (*EAAI*). Several chemically based methods have been developed to assess the nutritional and potential biological value of feed ingredients to organisms in lieu of the use of live feeding trials. Chemical scores, *IAAI*, and the *EAAI* are based on a comparison of the amino acid content of the ingredient to that of a complete protein or reference protein such as whole egg (chicken) or tissue samples (muscle) of the target species (2).

The chemical score is the simplest and least accurate method and is calculated as follows:

$$\text{Chemical score} = \frac{\text{g amino acid in test ingredient}}{\text{g amino acid in reference protein}} \times 100$$

A score of 100 means that the quantity of the amino acid is equal to that present in the reference protein source. The lowest chemical score of those essential amino acids examined in an ingredient determines the final chemical score. This method measures the potential nutritive value of the protein based on the most limiting essential amino acid (4).

When quantitative data on the essential amino acid requirements of a fish or shrimp species of interest have not been determined, a helpful initial approach is to utilize feed ingredients that approximate the amino acid profile of either the carcass of the animal or a good protein source. For example, the *IAAI* is determined by adding the ratios of the level of each indispensable amino acid present in the ingredient to the level of the same indispensable amino acid in whole egg (2) or a reference protein (*RP*). The higher the *IAAI* value of the ingredient, the greater potential biological value it represents. *IAAI* is calculated as follows:

$$IAAI = \frac{\text{Arg(ing)}}{\text{Arg(RP)}} + \frac{\text{His(ing)}}{\text{His(RP)}} + \frac{\text{Iso(ing)}}{\text{Iso(RP)}} + \cdots \times 100$$

In addition, the *EAAI* (13) can be used to estimate the potential nutritive value of protein sources by calculating the ratio of essential amino acid (*aa*) content in the ingredient to the content in the animal carcass (*AA*) as follows:

$$EAAI = \sqrt[n]{\frac{aa_1}{AA_1} \times \frac{aa_2}{AA_2} \times \frac{aa_3}{AA_3} \cdots \frac{aa_n}{AA_n}}$$

The closer the *EAAI* is to 1.0, the higher the potential nutritive value of the ingredient. In general, ingredients scoring 0.9 are considered good quality, 0.8 are medium quality, and less than 0.7 are considered poor quality (14). This technique is especially useful for the development of diets for larval stages of marine fish and shrimp, for which essential *AA* requirements are very difficult to determine. These methods have in some cases led to a better understanding of the requirement of essential *AA* for some fish species. Significant correlation has been found between the essential *AA* requirements of fish and the *AA* profiles of fish carcass.

All of these methods assume that the amino acids determined by chemical analyses are totally available to the animal and that this ingredient is the exclusive source of amino acids. In the case of formulated feeds, multiple sources of proteins (amino acids) are combined to produce a final amino acid profile for the feed. Consequently, two protein sources that independently have poor *AA* profiles may, when combined, produce high-quality dietary protein. Additionally, the digestibility of proteins and amino acids can vary considerably; therefore, a portion of the amino acids determined by chemical analyses will not be available to the animal.

Fatty Acids. Triglycerides are the most common form of lipids in animals and plants. They are esters of fatty acids and glycerol and serve as a source of energy for many physiological functions in organisms. In addition, fatty acids are an essential component of the membrane structure of cells and have important metabolic functions (i.e., as precursors of hormones and prostaglandins). Fish and shrimp have limited or no capabilities to synthesize certain highly unsaturated fatty acids (HUFA) and thus have an essential dietary requirement for them. Knowledge of the fatty acid composition of an ingredient is important to the formulation of a diet that will provide the required level of HUFA for the species being cultured. As with the crude protein content, the total lipid content of a diet or ingredient does not provide information on fatty acid composition. Methods for the determination of the fatty acid composition of feedstuffs can be found in the *Official Methods of Analysis* (1). For example, once the lipid is extracted with an organic solvent, polar and neutral lipids are separated by column chromatography (i.e., using silicic acid columns; 15). Polar and neutral lipids are then esterified with boron trifluoride. The resulting fatty acid methyl esters are then determined qualitatively and quantitatively by gas chromatography against known standards. In general, digestibility values for lipids are very high and do not vary widely between sources; hence, the lipid content and fatty acid profile are generally true indicators of the nutritional values.

Vitamins. A variety of nutrients, which do no include proteins, lipids, and carbohydrates, are required by animals in small amounts for normal health and growth. These organic micronutrients are referred to as vitamins. Since animals are not capable or have limited capabilities for synthesizing these compounds, they must be obtained from the diet.

The vitamins may be classified according to their solubility in water as water-soluble (e.g., thiamine, riboflavin, pyridoxine, and ascorbic acid) or fat-soluble (e.g., retinol, cholecalciferol, and tocopherol; 11,16). Although the amount of vitamins included in dietary formulations usually comprises a relatively small fraction of the bulk diet, vitamins significantly add to the cost of complete feed formulations. The high cost and potential loss of vitamins during the manufacturing process renders determination of the final vitamin content essential. Due

to the uncertainty in vitamin content and bioavailability in ingredients, as well as the potential interactions of vitamins with ingredients in a diet, vitamin requirements are usually met by supplementation with a fortified vitamin premix. A vitamin deficiency may cause several pathological signs (e.g., for vitamin C, reduced growth, impaired collagen formation, scoliosis, and lordosis; 17). The level of individual vitamins can be determined by several chemical and biological techniques. For a detailed explanation of the methods, see Methods AOAC (1).

Minerals. The inorganic or ash component is composed of minerals. There are about 22 mineral elements that have been found to be essential in at least one species. They are classified according to the level of their requirement; those required in large quantities are termed macro or major, and those required in trace amounts are termed minor or micro (4,11). Some examples of the macrominerals are calcium, phosphorus, magnesium, sodium, potassium, chlorine, and sulfur. Iron, iodine, manganese, copper, cobalt, and zinc are examples of trace minerals. There are marked differences in mineral requirements for fresh and saltwater fish. Differences are primarily attributed to those minerals that play a major role in osmoregulation, but differences are also due to the relative amounts of minerals in the water and the relative ability of the animals to absorb minerals directly from the water. Additionally, all mineral elements, whether essential or nonessential, can adversely affect an animal if included in the diet at excessively high levels (18). Consequently, determining the mineral profile of the feeds and feed ingredients is essential. Prior to analyses, the feed ingredient is either oxidized by a strong acid (acid digestion) or combusted in a muffle furnace, thus removing the organic component. The minerals are then dissolved in a weak acid for analyses. The two most common methods for mineral analyses utilize an atomic absorption spectrophotometer or an inductively coupled plasma spectrophotometer. Additionally, there are colorimetric methods (e.g., phosphorus) and fluorometric (e.g., selenium) methods for determination of specific minerals.

Antinutrients

When evaluating a feed or feedstuffs, in addition to knowledge about the nutritional value, one must be concerned about the possible presence of antinutrients. These substances can affect the health and normal performance of the test animal. Antinutrients include substances that are either toxic to the organism or inhibit metabolic reactions that are catalyzed by enzymes. Antinutrients may be classified as endogenous if they are a natural component of the ingredient or exogenous if they are the result of external contamination. Examples of endogenous antinutrients are urease, gossypol, trypsin inhibitors, and thiaminase. Exogenous contaminants may be aflatoxins, pesticides, heavy metals, and others. Most pesticides are lipid-soluble and bioaccumulate in the lipids of different organisms. Therefore, ingredients with high lipid content should be routinely monitored for pesticides. Antinutrients within the feedstuffs can be determined by

several chemical methods. For example, trypsin inhibitors can be detected by adding commercial trypsin and measuring the decrease in enzyme activity (19). Aflatoxins can be measured by thin layer chromatography and pesticides can be detected by gas chromatography. For a detailed explanation of the analytical methods, the reader is referred to Refs. 8, 20, and 21.

Other Methods for Feedstuff Evaluation

Near-Infrared Analysis. Near-infrared spectroscopy (NIRS) is a new instrumental method that uses light of a near-infrared wavelength to determine the composition and quality of ingredients without causing any physical or chemical damage. This rapid and simple method screens a large number of samples without the need for time-consuming chemical assays. This technique is based on the principle that every organic compound has a unique absorbance spectrum in the near-infrared range. In the analysis, a light source consisting of different wavelengths is directed at the sample and the resulting spectra are collected, registered, and compared to known standards (22). This method of analysis is currently being utilized to determine moisture, protein, and lipid content as well as fatty acid composition of various feedstuffs (23,24).

BIOLOGICAL EVALUATION

For biological evaluation feeding trials are conducted to determine the performance of a complete diet or a particular ingredient of interest. Some measure of performance, such as growth, survival, or feed utilization, is used to evaluate the adequacy of an ingredient or diet. In most cases, other, more specific measures of performance such as the retention or loss of a specific nutrient in the body of the organism, shifts in enzyme activity, or the ability of the organism to survive a specific environmental challenge (i.e., shifts in temperature or salinity and exposure to pathogenic organisms) are needed. Feeding trials should be conducted under strict experimental conditions, which include environmental monitoring, adequate replication, and the manipulation of only one or a few variables at a time. To minimize any nutritional contribution from external sources such as primary production or bacteria, the design of an experimental system must include a means to remove external sources of nutrients from the water prior to entering the culture containers.

Measurements of Performance

Given adequate survival, the two most common measures of response to a particular ingredient or diet are growth and feed utilization. Growth can be measured as function of weight, length, or specific nutrient gain (e.g., protein). One of the goals of the aquaculturist is to maximize production in terms of biomass; hence, biomass increase is a common measure of performance. A distinction should be made between gains in weight or length and true growth. Increases in weight gain can be achieved through the growth of muscle, bone, organs, and the deposition of specific biochemical components such as proteins or

lipids. However, some diets result in a gain in weight caused by the excessive deposition of lipid reserves in the adipose tissue. In fish, this type of lipid deposition is generally undesirable because it decreases dress-out percentage (fillet yield) and may adversely influence shelf life, resulting in human health concerns. Therefore, when a diet is evaluated by means of a growth trial, the performance parameter measured (e.g., growth as weight gain) should be complemented by an analysis of the proximate composition of the carcass of the organism prior to and following feed administration.

The second indicator of performance in feeding trials is feed utilization. Feed utilization describes to what extent food eaten by the organism is actually converted into growth. This information is particularly critical when comparing the economic cost of feeds and their potential for polluting the culture environment. Since the method of feeding will influence the degree of feed utilization, the type of feeding strategy should be well documented in terms of ration size (restricted vs. excess) as well as the number of feedings per day. Several indices are used to express feed utilization and will be described later.

Survival is often another indicator of nutritional status of the animal and should always be high (e.g., >90%) for a positive control or reference diet. In some experimental designs reductions in survival are unavoidable and are a clear indicator of poor nutrition. However, reductions in survival introduce variability into an experiment and thereby can create problems in interpreting the experimental results. This variability may be due to a number of factors which include reductions in density, unequal distribution of feed rations due to the dominance of healthy animals, and secondary sources of nutrients (i.e., cannibalism).

The following calculations are used to derive the indicated indices for weight gain or growth, feed utilization, and survival:

Weight Gain or Growth

Absolute growth or weight gain:

$$\text{Weight gain} = W_f - W_i$$

Percentage weight gain (relative growth):

$$\% \text{ Weight gain} = \frac{W_f - W_i}{W_i} \times 100$$

Absolute growth rate (AGR):

$$AGR = \frac{(W_f - W_i)}{(t_f - t_i)}$$

Relative growth rate (RGR):

$$RGR = \frac{(W_f - W_i)}{[W_i \times (t_f - t_i)]}$$

Instantaneous growth rate (g):

$$g = \frac{(\ln W_f - \ln W_i)}{(t_f - t_i)}$$

Specific growth rate (G):

$$G = g \times 100$$

where W_i is initial weight; W_f is final weight; t_i is initial time (in days); and t_f is final time (in days).

Feed Utilization

Feed conversion ratio (FCR):

$$FCR = \frac{\text{Weight of feed fed}}{\text{Weight gain}}$$

Feed efficiency ratio (FE):

$$FE = \frac{\text{Weight gain}}{\text{Weight of feed fed}}$$

Survival

Percentage survival:

$$\% \text{ Survival} = \frac{\left(\begin{array}{c} \text{Initial number fish} \\ - \text{ Final number fish} \end{array} \right)}{\text{Initial number fish}} \times 100$$

Digestibility

In a strict sense, digestion is the breakdown of feeds in the gut by mechanical, chemical, and enzymatic processes into its constituents parts, rendering them soluble and available for absorption by the gut. Absorption is the process by which molecules and ions are absorbed by the cells lining the gut. Digestibility is therefore a measure of biological availability of the nutrients or energy in the ingredient (i.e., how much is available for absorption), whereas absorption refers to actual uptake. The methods commonly used to measure digestibility, including apparent digestibility and true digestibility, are in fact measures of combined digestion and absorption.

Apparent Digestibility. The most direct method to estimate digestibility involves feeding a specific amount of an experimental diet and carefully recording the quantity of feed consumed and feces produced. The amount of a particular nutrient remaining in the feces is then subtracted from the initial quantity in the test feed; the difference represents the amount of nutrient absorbed by the animal (11).

$$AD = 100 \times \frac{(\text{Nutrient in diet} - \text{Nutrient in feces})}{\text{Nutrient in diet}}$$

This method is termed apparent digestibility (AD) because the feces also contain endogenous fecal excretion (i.e., about 3% for trout; 25) in addition to unabsorbed feed. Hence, the digestibility estimate can be an underestimate because some of the nutrients present in the feces could have originated from endogenously produced waste.

True Digestibility. To obtain a true estimate of digestibility (TD), an accounting of the amount of endogenous fecal excretion is needed. Estimates of endogenous

fecal excretion can be obtained by feeding a diet that does not contain the nutrient being tested and then determining the amount of the nutrient in the feces.

$$TD = 100 \times \frac{\left(\begin{array}{c}\text{Nutrient in diet} - (\text{Nutrient in feces} \\ - \text{Nonfeed nutrient in feces})\end{array}\right)}{\text{Nutrient in diet}}$$

Determination with Inert Markers. It is often difficult to determine feed intake accurately and/or to collect all fecal material produced by aquatic animals. A number of techniques, utilizing inert markers, have been developed to avoid tracking all feed consumed and all feces produced (26,27). This method is less time-consuming for obtaining estimates of digestibility. Animals are fed a diet that contains an inert indigestible marker such as chromic oxide (0.5 to 1%) for several days. The quantity of the nutrient of interest relative to the inert marker can be determined in the feed and feces. Therefore, percentage digestibility can be calculated as follows:

$$AD = 100 - 100 \times \frac{\text{Marker in feed}}{\text{Marker in feces}} \times \frac{\text{Nutrient in feces}}{\text{Nutrient in feed}}$$

Problems and Sources of Error with Digestibility Measurements. Many problems are associated with the determination of digestibility coefficients. Digestibility values can vary relative to many factors such as size and age of the animal, type of feed processing and processing conditions, environmental parameters, interactions with other ingredients and/or nutrients in the diets, method of collecting the feces, type of inert marker used, as well as leaching of nutrients from feed and feces (28,29). Although many technical problems are associated with the use of inert markers, this method remains one of the easiest and best to determine the apparent digestibility of an ingredient and its associated nutrients quickly.

Tracer Studies. Many researchers have utilized radio and stable isotopes as tracers of either ingestion, digestion, and assimilation of dietary nutrients, as well as their metabolism (30–34). Radio (i.e., ^{14}C) or stable (i.e., ^{15}N) isotope-labeled nutrient can be added to the diet and utilized as tracer by determining the amount deposited in the animal tissue. In addition, if an appropriate labeled substrate is utilized, metabolic pathways can also be determined by tracing the incorporation of the labeled substrate into those compounds that the organism can synthesize. Many difficulties such as the possible loss and recycling of the tracer through metabolism are associated with these techniques. Once the tracer is absorbed, it can be utilized for synthesis of new tissue or metabolized and excreted as waste. One possible solution to these problems is to account for labeled nutrient losses through metabolism by using a twin tracer (^{51}Cr–^{14}C) technique (35).

***In Vitro* Digestibility.** Recently developed assays to measure protein quality, such as *in vitro* methods, are simple, rapid, and inexpensive techniques to screen potentially useful ingredients. These techniques rely on the use of digestive enzymes extracted from the organism under study or those readily available commercial enzymes (i.e., extracted from pig, sheep, or bacteria). The enzymes are added to a sample of the ingredient being tested and digestion is measured *in vitro* by one of the following analytical methods:

1. pH-drop method: As proteolytic enzymes attack the peptide bonds of proteins, hydrogen is released and the pH of the protein solution reduced. The pH reduction is highly and positively correlated with the degree of protein digestion (36).
2. pH-stat method: To keep digestive enzymes close to their optimal pH, pH can be maintained by adding NaOH. The amount of NaOH consumed is proportional to the degree of protein hydrolysis and is highly correlated to *in vivo* apparent protein digestibility (37).

Other methods based on *in vitro* digestibility have been developed to measure the degree of digestion in several ways and include the release of free amino acids after digestion (38), the percentage of soluble nitrogen (39), or the absorbance at 280 nm of the soluble fraction after precipitation with trichloroacetic acid (40). Dimes and Haard have reviewed the various methods (41). The accuracy of *in vitro* digestibility methods can be affected by several factors. The source of enzymes (e.g., mammalian vs. fish) can give different digestibility values. In general, *in vitro* assays utilizing enzymes from the animal under study are better correlated to *in vivo* digestion (37,40,42). Due to differences in enzyme concentration, environment, and duration of digestion, *in vitro* assays can overestimate protein digestion of some ingredients that are actually poorly digested *in vivo* (36). In addition, the buffering capacity of the protein source itself may influence the change in pH and thus affect the measurement of pH decline or change. Biological methods to evaluate ingredient digestibility still provide the most accurate nutritional value, but are time consuming and expensive to perform.

Nutrient Retention or Deposition

The daily deposition of a nutrient or its components in the animal carcass can be another useful way of evaluating the availability of a specific nutrient such as the proper proportions of dietary amino acids and fatty acids (43,44). The following derives apparent nutrient retention:

$$\text{Apparent retention} = \frac{\left(\begin{array}{c}\text{Nutrient content in} \\ \text{fish at } T_f - \text{Nutrient} \\ \text{content in fish at } T_i\end{array}\right)}{\text{Nutrient intake}} \times 100$$

where T_i is initial time, and T_f is final time.

Electrical Conductivity

When working with specimens for which physical samples cannot be removed (e.g., intermittent samples, brood stock evaluations, or evaluations of endangered species), traditional chemical methods for measuring lipids and

water content of animals are not suitable. An alternative method based on the different electrical properties of lipids and water can be used. Fat tissue has approximately 20 times less electrical conductivity than lean tissue. By applying an electromagnetic field and measuring the different electrical conductivity the amount of lipid and water in a live organism can be estimated (45). This approach has been successfully used to measure body composition of several aquatic species such as red drum (46) and catfish (47).

Protein Quality

In addition to the previously mentioned chemical assays for evaluating protein and amino acid content, a frequently utilized procedure assesses the quality of proteins by comparing different protein sources in terms of fish weight gain per unit of protein fed. The following calculations are based on this concept.

Protein Efficiency Ratio (*PER*):

$$PER = \frac{\text{Weight gain}}{\text{Protein intake}}$$

Protein Conversion Efficiency (*PCE*):

$$PCE = \frac{PC_f - PC_i}{\text{Protein fed}} \times 100$$

where PC_f is final carcass protein, and PC_i is initial carcass protein.

Apparent Net Protein Utilization (*ANPU*):

Measurements of the protein content of the test animal at the start and end of the experiment, combined with an estimate of the digestibility value of the protein of interest (digestibility coefficient), can be used to estimate *ANPU* (2):

$$ANPU = \frac{(PC_f - PC_i)}{(\text{Protein fed} \times \text{Digestibility coefficient})}$$

To determine true net protein utilization (*TNPU*), endogenous protein changes must also be accounted for by feeding a protein-free diet for the same length of time and then determining the change in carcass protein. True net protein utilization is calculated by subtracting the change in protein carcass of fish fed the protein-free diet from the change in carcass protein of the fish fed the protein diet as follows (2):

$$TNPU = \frac{(PC_f - PC_i) - (PCF_f - PCF_i)}{(\text{Protein fed} \times \text{Digestibility coefficient})}$$

where PC_f is final carcass protein; PC_i is initial carcass protein; PCF_f is final carcass protein of protein-free dietary treatment; and PCF_i is initial carcass protein of protein-free dietary treatment.

Biological Value (*BV*):

Instead of measuring nutrient deposition as in the comparative carcass methods, nutrient excretion during a period of time can be measured. For example, all nitrogen excreted in the feces, urine, and gills is measured and compared to the total nitrogen fed (2):

$$\text{Apparent } BV = \frac{(NF - FN - UN - GN)}{NF} \times 100$$

As with the digestibility method, to obtain a "true" biological value (*TBV*), we have to estimate the endogenous loss of the nutrient in question by feeding a nitrogen-free diet:

$$TBV = \frac{\begin{pmatrix} NF - (FN - \text{endogenous } FN) \\ -(UN - \text{endogenous } UN) \\ -(GN - \text{endogenous } GN) \end{pmatrix}}{NF} \times 100$$

where *NF* is nitrogen fed; *FN* is fecal nitrogen; *UN* is urinary nitrogen; and *GN* is gill nitrogen.

Other Condition Measurements

For some stages of development, such as the larval period, many measurements of performance cannot be easily conducted due to the small size of the organism and the difficulties in measuring feed consumption or feces produced. Consequently, alternative measurements are critical for the determination of the nutritional status of the test animal. For a review of some measurements of larval condition, see Ferron and Leggett (48).

RNA/DNA Ratio. The quantity of deoxyribonucleic acid (DNA), the compound responsible for carrying genetic information, is relatively constant in somatic tissues and has been shown to reflect cell number (49). The quantity of ribonucleic acid (RNA), the transcriptor and translator of genetic information, is directly proportional to protein synthesis inside the cell. Consequently, the ratio of RNA to DNA has been found to correlate well with recent growth (i.e., protein synthesis) and, therefore, the nutritional status of several species of fish (50–52). High RNA/DNA ratios indicate adequate growth and nutritional status while low ratios indicate poor nutritional condition. For a review of the use of this index see Clemmensen (53) and Bergeron (54). For detailed information on analytical techniques, the reader is referred to Buckley (50) and Clemmensen (55).

Challenge Tests for Larvae. Several tests to evaluate the physiological condition of fish larvae in nutritional studies have been proposed (56,57). In these tests, fish larvae are exposed to stressful conditions, such as removing them from the water for a few seconds or exposing them to high or low salinity for a period of time. Thereafter, the cumulative mortality through time is determined. These tests assume that weak fish larvae (poor nutritional condition) will not be able to survive extreme conditions as well as healthy fish larvae (good nutritional status). This approach has been used in the study of the quantitative requirements of fatty acids in marine fish larvae (55,58). In the latter study, Brinkmeyer and Holt (58) used the stress index and detected significantly different responses among red drum larvae fed diets containing different DHA to EPA

ratios. These differences were not detected by comparing larval growth and survival.

FEEDING EXPERIMENTS

Feeding experiments are conducted to evaluate objectively the response of the culture animal to different dietary formulations. Experiments must be conducted under conditions in which biotic (i.e., size, weight) and abiotic (i.e., temperature, light, and water quality) variables are controlled and suitable replication is employed. Such conditions minimize the confounding effect of variables other than those that are being studied while providing the test animal with optimal conditions for growth. Many possible sources of error can arise when conducting and interpreting data from nutrient requirement experiments. Interpretation of nutrient requirements must be conducted within the specific context of the experimental design, including stage of development, size of the animals, sex, and previous nutritional condition. For a detailed critical review of the problems that are often encountered, the reader is referred to Baker (59) and Jobling (60). Additionally, when considering the design of larval feeding experiments, one must recognize that the nutritional status and condition of the broodstock will influence the quality of eggs and larvae (61). In an attempt to standardize larval quality, several egg quality tests that can be performed prior to conducting a larval feeding experiment have been suggested. For example, the percentage of fertilized eggs, buoyancy, appearance of the chorion, distribution of oil globules, transparency, microbial colonization, size, consistency, and shape have been used to determine egg quality. For a review see Kjorsvik et al. (62) and Bromage (63).

The ultimate test of a practical diet is its successful use by commercial growers; thus, evaluation of diets under less stringent conditions may ultimately be necessary. For such purposes, experimental conditions should simulate those found in commercial aquaculture enterprises, such as ponds, as much as possible. In all cases, control should be exercised over as many variables as possible.

Controlled Environments

Unless one of the variables of interest is environmental (e.g., temperature), it is of paramount importance to maintain complete consistency among the environmental parameters within treatments and vary only the specific nutrient of interest. In general, the basic aspects to consider when conducting a feeding trial are the experimental animals, the rearing facilities, and the experimental diets. The appropriate methods can vary considerably between species; hence, the following descriptions should be viewed as basic guidelines for conducting feeding experiments that will require modification relative to the species of interest or specific life stage.

Animals. Same generation animals of similar nutritional history should be used in feeding trials and should be graded to a uniform size before stocking into rearing tanks. Each replicate should be stocked at equal densities with a sufficiently large number of animals to minimize any effects of biased sex ratios (sex-related growth rate) or dominance feeding patterns (hierarchical behavior) and to provide an adequate tissue sample if biochemical analyses are planned. The number of replicates required will vary depending on the expected coefficient of variation for the response(s) to be measured but should never fall below three. In most situations the test population should be allowed to acclimate to the culture system and the basal diet over a 1 to 2-week period. The need for an acclimation period will depend on the species and size of the test animal. This preconditioning practice will be best served by initially stocking an excess of animals and then feeding them a basal diet similar to that which will be used in the experiment. To avoid any confounding effects related to health and disease, the health of the animals should be monitored prior to and during all experiments. If possible, periodic sampling should be conducted to determine growth rates and inspect the animals for signs of disease or stress.

Rearing Facilities and Culture Period. Holding facilities should be of equal characteristics (size and material) and large enough to allow normal growth throughout the experimental period, thereby minimizing any density-dependent effects. The culture system must be suitably designed to allow maximum growth and provide adequate water quality throughout the experiment. Assurance of suitable water quality is particularly important near the end of an experiment when nutrient loading is highest. The system should be isolated or shielded from outside disturbances. Water entering the tanks should come from the same source and be of equal temperature, chemical composition, and flow rate. The system can be designed as a single-pass, flow-through system or as a semiclosed recirculating system. Regardless of the type of system used, uneaten food and fecal material should be removed from the culture chambers daily and no alternate food sources should be available. Additionally, water quality conditions must be maintained within the suitable ranges for the species being tested. Maintaining well-characterized and suitable water quality parameters is critical to the design of any experiment. Therefore, water quality parameters should be monitored either intermittently (e.g., biweekly measurements for ammonia, nitrite, and nitrate) or daily (e.g., dissolved oxygen, temperature, and salinity). Fluctuations in temperature and salinity should be minimized and photoperiod should be kept constant throughout the experiment.

The length of time required to conduct a given study is dependent on a variety of factors that include the objectives of the experiment, species utilized, and the age of the test animal. In general, the growth trial should be of sufficient duration to produce relatively large increases in growth and statistically significant differences between some of the dietary treatments. Examples of experimental periods for different life stages include 14–28 days for larvae, 6–8 weeks for juveniles, and 14–18 weeks for larger fish. Although purified diets often produce slower growth, in general growth rates in

the laboratory should be comparable to those achieved under more natural conditions (e.g., pond) where both high-quality feeds and natural productivity are available as food sources.

Diets. Ingredients for making the experimental diets should be as pure and well characterized as possible so that composition is well defined. Diets prepared for the different treatments should be as close to the same physical (texture, size, water stability), chemical (attractants and taste), and nutritional characteristics as possible. The only differences among the diets should be the amount of nutrient or feedstuff of interest. It should be noted that if a response curve is to be determined, a minimum of four and preferably six dietary levels should be tested. If less than four levels are utilized, fitting the data to a response curve cannot be conducted accurately.

When preparing a diet, all dry ingredients (sources of proteins, carbohydrates, vitamins, and minerals) should be mixed thoroughly before adding and mixing in the lipid ingredients and water. Once the feed has been thoroughly homogenized, it is shaped (spray-dried, microencapsulated, flaked, or pelleted) and then, if desired, dried to a moisture content of 8–10%. The final product should be of a suitable size and texture for the animals to consume easily. Once the diet is made, it can be temporarily stored under refrigeration or frozen until used.

Animals should be fed according to a well-defined feeding rate (ration size) which must be adjusted as the animal grows. Types of feeding include (1) restrictive ration, i.e., feed is offered based on a fixed rate of the animal body weight that is below satiation; (2) in excess, i.e., feed is offered at a fixed rate that is in excess of what the animals will consume; and, (3) to apparent satiation, in which case the food is offered during a specified period of time until the test animals stop consuming feed. The number of feedings and time of day the animals are fed should also be appropriate for the species and size of the animal. Generally, food should be offered on a semicontinuous basis to larvae, 4 times a day for small juveniles, twice daily for large juveniles, and once daily to subadults.

Practical Environments

Nutritional requirements can only be determined when all nutrient sources are quantified. This is quite difficult to accomplish when an animal is exposed to natural food sources. However, under commercial production conditions prepared feeds are not the only source of nutrients. Quite often natural productivity contributes a significant portion of the daily intake of nutrients. Consequently, it is often desirable to evaluate the influence of changes in practical diet formulations when natural productivity is present. The relative contributions of natural productivity and prepared feed can be estimated with the use of stable isotopes of biologically important elements such as carbon, nitrogen, and sulfur. Anderson et al. (64) fed Pacific white shrimp (*Litopenaeus vannamei*) diets that were isotopically different from those of natural pond organisms and were able to determine the relative

contribution of each carbon source. However, natural productivity varies considerably within and between sites, with time of year, and from year to year. Hence, results derived from such studies must be interpreted with caution. From a commercial point of view, the testing of practical diets under actual commercial conditions is desirable. However, replication of commercial production systems is very expensive besides being unrealistic. Therefore, several techniques are used to approximate these conditions. Examples of such systems include (1) tank studies where outdoor tanks, in which natural productivity is allowed to become established, are used as replicates; (2) cage studies where cages are either floated in a pond or affixed to the pond bottom and used as replicates; and (3) pond studies where small ponds are used as replicates (11). When conducting such an experiment, one must realize that a number of variables cannot be controlled in an outdoor situation; hence, appropriate statistical design becomes crucial. To account for high variation, the number of replicates per treatment is often increased. When conducting an outdoor experiment, the stocking and feeding procedures should be similar to those previously described. Additionally, methods to quantify the type and quantity of natural food sources should be considered as part of the experimental design.

Seattle, Washington

OUTLINE

INTRODUCTION

Feeding microparticulate feeds to species with small larvae will aid in the development of reliable, economically sustainable fingerling production industries. However, the culture of larval fish with formulated feeds requires rearing methods different from those used for feeding live feeds. Factors under the control of the larval fish culturist include water flow, lighting, tank color, tank shape, feeding rate, and environmental factors. The effect of feed processing on feed quality, nutrient availability, and feed consumption must also be considered for a larval production program to be effective.

LIVE OR FORMULATED?

Because of the inherent differences between formulated and live diets, use of the same rearing techniques that are adequate for live foods with formulated feeds will likely result in a loss of livestock. Simple modifications in tank design, water flow rate, feeding method and rate, and water flow pattern can result in a much enhanced response of the fish to formulated feeds. Live feeds can be fed less often, at lower rates, and uneaten feed does not deteriorate as rapidly as formulated feeds. Even with these differences, there are several reasons to strive for a

production program that utilizes formulated feeds instead of live foods.

Rearing organisms to feed production species has its own inherent problems. If the live feed culture fails for any reason (i.e., power outage, low hatch rate of cysts, etc.), the production of the target species will suffer. Collection of wild feed for larval fish is susceptible to availability due to weather or other factors that limit zooplankton production. Conversely, formulated feeds can be purchased in advance of the hatch of the larval animals and can be stored for relatively long periods of time, ensuring an adequate supply of feed. Also, wild food supplies may introduce predators, toxins, and/or diseases to the larvae. Feeding formulated feeds avoids that risk. The cost of live foods can also be much greater than with formulated feeds when evaluated on a dry matter basis. Although there are still numerous species of fishes where culture with formulated feeds has been unsuccessful, there have also been many improvements in larval feed manufacturing methods that appear to be increasing survival, growth, and quality of larvae fed formulated feeds (see the entries "Microbound feeds," "Microparticulate feeds, complex microparticles," and "Microparticulate feeds, micro encapsulated particles"). These technological improvements in feed manufacturing should alleviate some of the problems observed with feeding formulated feeds in the past.

FORMULATED FEED AND FEEDING

By evaluating the characteristics of formulated feeds and the larval fish's ability to ingest these feeds, the reasons for modifying rearing techniques becomes clear. Many factors affect feeding in larval fish. Development of culture systems that utilize microparticulate feeds for new species will require attention to both the feed and the response of the larval fish to feed before and after it is ingested. Modifying feed characteristics and culture system design so that fish response is optimized will improve the chances for success. Figure 1 presents factors to consider when feeding larval fish. Some factors are best addressed in the diet formulation and manufacture process, while others need to be addressed by management of the culture system in which the diets are fed. Factors to be addressed in diet manufacture include appearance, attractiveness, texture, formulation, and physical properties. Manufacturing and formulation changes can be used to address problems associated with ingestion, nutrient requirements, digestibility, and leaching. Factors affected by culture system design and management include: feed availability, larval distribution, sensory acuity, and environmental quality. Husbandry and system design changes can improve larval feed consumption, lower cannibalism, reduce deformities, and maintain high water quality. Optimal conditions established for one species or feeding strategy (live vs. formulated) for a given factor may not be optimal for

other species. Likewise, a microparticulate diet that works well for one species may or may not work well for other species.

FACTORS AFFECTING NUTRIENT AVAILABILITY

Digestibility

Rust and co-workers determined how nutrient assimilation was influenced by the structural complexity of nutrients (1,2). The studies specifically investigated the assimilation of protein and lipid in various chemical forms by larvae of different species. The rationale behind the trials was to increase understanding of larval fish digestion so that future formulated larval feeds can be produced which deliver nutrients to the gut in a form that is easily assimilated by the developing digestive system.

Differences in nutrient assimilation efficiencies were found among species and among developmental stages within the same species. For species that start feeding prior to the development of gastric digestion, small molecular weight nutrients were initially assimilated more efficiently than complex forms of the same nutrients, with differences becoming less pronounced as the larvae reached metamorphosis. For example, amino acids were assimilated at higher efficiencies than polypeptides and polypeptides higher than proteins during the first-feeding stage. In striped bass (*Morone saxatilis*), assimilation of protein- and polypeptide-bound methionine increased (from 30 to 62% and 49 to 82%, respectively) over the period from first feeding to metamorphosis. At metamorphosis, all structural forms were assimilated at similar efficiencies. This pattern held for striped bass, walleye (*Stizostedion vitreum vitreum*), and zebrafish (*Brachydanio rerio*) but not for goldfish (*Carassius auratus*) (which do not develop gastric digestion) or salmon (*Oncorhynchus* spp.) (which start feeding after gastric digestion is developed). It is likely that assimilation efficiency of complex nutrients correlates with the presence, location, and amount of key digestive enzymes in the larval gut. Larval microparticulate diets that can deliver simple forms of nutrients to the gut during developmental stages (that lack some of the digestive processes of adults) may improve larval growth and survival because of greater assimilation efficiencies during the critical first-feeding stage.

Nutrient Requirements

No quantitative requirement for any nutrient has yet been determined for the larvae of any species of fish. This is partly due to the difficulty of working with such small animals that typically have high and variable mortality during this life stage. Feeds have been formulated based upon the composition of the fish larvae or the composition of zooplankton. Cowey and Tacon (3) observed that in many juvenile and adult fish, there is good correlation between dietary amino acid requirements and the pattern of amino acids in the muscle tissue of the consuming animal. This approach assumes that the bioavailability of dietary nutrients is equal, an assumption that does not hold for larvae (1). Other scientists have preferred to base

diet formulations on the composition of zooplankton, the natural prey of most larval fish (4,5). That can also lead to misleading formulations because typically only nutrient composition is taken into consideration and not nutrient form.

FACTORS AFFECTING FEEDING

Our understanding of factors that control larval feeding behavior is limited. Before nutrient digestion can occur, the feed must first be ingested by the larval fish. A key research area with formulated feeds is to increase the palatability of the microparticle so the larval fish will identify it as food and ingest it. Physical properties of the feed, such as color and size, along with chemical properties, such as flavor and odor, may be key attributes that stimulate the larvae to approach and ingest the diet in sufficient quantities to sustain growth. In order for microparticulate feeds to be ingested, they must be attractive and visible to the larvae and must be presented under the proper environmental conditions. Many species of fish larvae are visual feeders, though taste buds and olfaction are often also functional at this time (6). This makes vision and chemoreception two of the most important sensory systems used by first-feeding larvae to locate and ingest feed (6,7).

Vision

Physical properties of the diet and rearing environment, such as color, intensity, and wavelength of light, and degree of polarization and contrast, may be key attributes that stimulate the larvae to approach and ingest feed. Three or four cones in the eye may be operational in fish larvae, each with a different light wavelength of maximum sensitivity (8–15). As the larvae develop, visual acuity increases (6,7). Specialized retinal structures such as a tapetum lucidum and macroreceptors (which are adaptations to low-light environments) often do not develop until much later (8).

A heart rate conditioning technique used by Hawryshyn and co-workers (9) has led to the identification of up to four cones in rainbow trout that have different regions of maximal photosensitivity. In addition to the normal blue (400–450 nm), green (500–550 nm), and red (600–650 nm) sensitive cones, a transient UV-sensitive (340–370 nm) cone was also identified. The UV cone was only found in larval and early juvenile fish and was completely absent in adults. This cone has been identified in a number of planktivorous fish (10–15). The ecological significance of this cone is unknown for most fish, but it appears to be involved in prey identification and feeding in fish which feed on zooplankton (15–17). The chitonous exoskeleton of zooplankton is highly reflective to UV light (15). Ultraviolet vision may greatly increase the larval fish's ability to see "Zooplankton culture". If this is the case, then microparticulate feeds that also reflect UV may be advantageous. Tank lighting that lacks UV may be problematic for feeding. For example, lingcod (*Ophiodon elongatus*) larvae reared outdoors under full-strength sunlight feed and behave much differently from larvae reared indoors under incandescent or fluorescent light. These artificial light sources are lacking in the near UV ranges and are strong in the yellow bands. Fish reared indoors under these lights feed poorly and display "nosing" behavior typical of stressed larvae. In several trials, all larvae reared indoors died within three weeks of first feeding (living only slightly longer than starved larvae), while larvae reared outdoors fed normally and survived beyond the juvenile stage (Ken Massee, personal communication).

Chemosensory Systems

Fish have two major chemosensory systems: olfaction and gustation (18). Olfaction is involved in diverse teleost behaviors, including migration, reproduction, fright reactions, and feeding. Gustation is involved primarily in feeding. The olfactory receptors develop early — usually before hatching — from an ectodermal anlagen, while gustatory receptors develop later and are endodermal in origin (18).

Both olfaction and gustation are likely involved in feeding, although the integrated functioning of these two systems remains ambiguous. A likely pattern is that olfactory receptors and external taste buds serve to locate feed at a distance and to trigger the feeding response (19). Internal taste buds serve to screen for palatability and control swallowing (19).

Hara and Zielinski (18), working with rainbow trout, showed that the olfactory mucosa could be stimulated by amino acids in embryos as young as 20 days postfertilization (well before first feeding). At that stage, ciliated receptor cells are sparse and only have 1–3 short cilia, yet are functional. The detection thresholds for amino acids decrease (from 10^{-3} to 10^{-9} M) as the embryos develop until just before first feeding where they remain through adulthood (18). The first immature taste buds (gustatory system) develop later than the olfactory mucosa (20), however, most species have functional taste buds by first feeding (20).

Chemical feeding stimulants have proven effective in feeds for young fish which are being trained to eat formulated feeds after being reared on live foods (21). Stimulants have also been shown to be advantageous for microparticulate feeds used for first feeding carp (*Cyprinus carpio*) larvae (22). Several chemicals have been identified as feeding stimulants in fish, including L-amino acids, betaine, nucleotides, and others (23–31). The specific chemical or combination of these chemicals which is most effective for a given species is often related to the type of prey item (and the content of those chemicals in the prey items) that the given species consumes in nature (26). Betaine plus amino acids tend to be more effective with species consuming invertebrates (worms, molluscs, and crustaceans), and nucleotides plus amino acids are more effective with species consuming vertebrates (26). In most cases, these substances exhibit synergistic effects when used in combination. Because most fish larvae eat similar diets (i.e., zooplankton), it is reasonable to expect fish larvae to exhibit similar preferences for gustatory stimulants.

REARING SYSTEMS

Culture methods such as tank design, effluent screen size and area, lighting, feed distribution, and other factors combine to produce a rearing system. Analyzing the effect on fish performance that each of these factors has with specific types of formulated feed is a key to successful larval culture. Even though specific variations in a rearing system can be important for a given species, a system developed by Barrows and co-workers for larval walleye has also been effective with other species (32).

Feeding System

One of the most important aspects of larval culture is providing large quantities of high-quality feed that is available at all times. Live feeds may swim in the water column for long periods of time, remaining available as a feed source to the larvae. Most formulated feeds will sink, though at different rates, and will not be eaten by most fish once on the bottom of the tank. Different feed manufacturing technologies can produce feeds with vastly different sinking rates. A feed with an appropriate sinking rate should be chosen for each species (see the entries "Microbound feeds" and "Microparticulate feeds, micro encapsulated particles"). The sinking nature of formulated feeds requires several culture technique modifications. The first modification is the use of automatic feeders to provide a steady introduction of feed into the tank. Since the feed is constantly settling out of the feeding area, more feed must be introduced to assure availability of the feed to the fish. The second modification is the use of extremely high feeding rates relative to juvenile fish culture or with live foods. Since the formulated feed does not move like live feeds, attraction of the fish to the formulated feed is presumed to be reduced compared to live feed. To make up for this, a higher feeding rate is used, thus increasing feeding opportunities. The high feeding rate will, over time, deposit significant quantities of uneaten feed on the bottom of the tank, which necessitates several other changes in rearing techniques. A rule of thumb for the early larval rearing stages is to feed as much feed as water quality conditions will allow. Different types of larval feeds break down and foul the water at different rates (33), so feeding rate will be somewhat dependent on feed type and exchange rate.

Water Flow and Effluent Screens

The water flow rate and the design of the effluent screen need to be optimized when feeding formulated feeds. High water flow rates will help reduce water quality degradation caused by uneaten feed on the bottom of the tank. High water flow into the tank may also sweep some of the uneaten feed out of the tank. To facilitate the removal of uneaten feed from the tank, the effluent screen can be modified in two ways. First, openings in the mesh should be as large as possible and still retain the larvae. Simple studies can be conducted to determine the optimal size for a particular species and

stage (34). Second, to avoid impingement of fry upon the effluent screen, the surface area of the screen should be maximized. For example, a circular tank with an interior standpipe can be covered with a larger pipe that has mesh from the top to the bottom of the tank. In this case, flow rate through each mesh opening will be minimized while allowing for a high overall flow rate through the tank.

Gas Bladder Inflation

Feeding formulated feeds can create problems for species that inflate their gas bladders after initiation of feeding (35), even though lack of a gas bladder has also been observed in walleye reared in ponds feeding on natural foods (36). Gas bladder inflation problems have been reported for intensively reared walleye (37), red sea bream (*Pagrus major*) (38), northern anchovies (*Engraulis mordax*) (39), and striped bass (40,41). Several of these species were found to require unobstructed access to the surface or bubbles for initial inflation of the gas bladder. Colesante et al. (35) compared larval walleye fed live foods to fish fed formulated feeds and observed little inflation with the formulated feeds and high levels of gas bladder inflation in the tanks fed live food. To one degree or another all formulated feeds create a surface film when introduced to the rearing container. Feed formulation and manufacturing method will affect the film created when formulated feeds are placed in water. Several methods have been developed to reduce or eliminate the surface film caused by the formulated feed (32,37). The most practical and effective method involves a simple water spray on the surface to disperse the film (32) or the provision of a slight fine bubble stream (41). Selecting a feed that produces a minimal film is also beneficial. A combination of feed selection and modified rearing method can result in high levels of gas bladder inflation when feeding formulated feeds.

Tank Maintenance

Once excess feed accumulates on the bottom of the tank, it should be removed as frequently as possible. Siphoning excess feed from the bottom of the tank two or three times per day during the early stages of rearing is recommended. The type of larval feed used will also impact the frequency of siphoning required. As the particle size of the feed is increased, the need for frequent siphoning decreases. Higher water temperatures, however, will increase the need for siphoning. Siphoning can be facilitated by using a strong circular water flow pattern in the tank. This will cause the feed to accumulate in a circle next to the center. This feed can be quickly siphoned off compared with having feed scattered equally across the bottom of the tank. Siphoning feed and feces from a tank is difficult when larval fish are near the bottom. If the fish are photopositive, use of a deep tank (>60 cm or 24 in. deep) will separate the fish from the excess feed (32). The photopositive fry are attracted to the upper portions of the tank and are not removed during siphoning. Some larval tank designs have incorporated an upwelling water

flow in order to suspend the feed in the water column. The desired effects with this tank design is to increase feed consumption and decrease feeding rate. A problem with this approach is that most larval feeds will lose significant portions of the water-soluble nutrients over a relatively short time period. It is counterproductive to have fish eating feed that has been in the tank for long periods of time. A system designed to separate uneaten feed from the fish, even though feed cost may increase, will in many cases result in higher quality larvae.

Not all of these suggestions will work or are appropriate for all species in every situation. The fish culturist should be aware, however, that the rearing conditions (tank configuration, water flow rate, feeding rate, etc.) can determine the success of a larval rearing program when using formulated feeds. No matter how much technology is employed in manufacturing a larval feed, poor culture techniques can make even the best formulated feed appear ineffective.

OUTLINE

INTRODUCTION

Lipid oxidation is a multistep chemical process by which double bonds on fatty acids become single bonds, thereby converting unsaturated fatty acids to saturated ones. This process is similar to hydrogenation which is used to manufacture margarine from corn oil, soybean oil, safflower oil, and other oils. Hydrogenation introduces hydrogen atoms at carbon double bonds, making them single bonds. The melting point is higher for saturated lipids than for unsaturated ones, and hydrogenation makes margarine produced from liquid plant or fish oils become solid at room temperature but melt when slightly heated. Oxidation involves the addition of oxygen to carbon double bonds but in the process converts them to other compounds. In addition, the oxidation process creates free radicals as a by-product, and these free radicals steal hydrogen atoms from other carbon double bonds on fatty acids, making the double bonds unstable and open for oxygen to attach. Oxidation can occur in any unsaturated lipid if free radicals are available to initiate the oxidation process. Once oxidation reaches a certain stage, it becomes a self-sustaining process, called autoxidation, and proceeds very rapidly, especially in fish oils that typically contain high proportions of polyunsaturated fatty acids having numerous carbon double bonds.

Oxidation of plant and fish oils used in animal and fish feeds is undesirable for a number of reasons. First, oxidation destroys vitamins C and E in the feed unless they are supplemented in chemically protected forms. Second, oxidation produces toxic compounds which cause specific pathological changes in animals and fish. Third, when animal and fish consume feed containing oxidizing lipids, it places a burden on detoxifying mechanisms in tissues and membranes, causing further pathological changes. Finally, oxidation generates heat, sometimes sufficient to cause feed ingredients or feeds to catch fire. Fish oils are highly unsaturated lipids and particularly susceptible to autoxidation. Fish oils are also important ingredients in fish feeds, supplying essential fatty acids and energy. Oxidation must be detected in fish oils before they are used in feeds to maintain feed quality and to ensure fish health. Preventing fish oil oxidation is the most sensible approach in fish feed production, and strategies to prevent oxidation begin with fish oil production and end when fish consume fish feeds.

LIPID OXIDATION

Lipid oxidation is so named because it involves the addition of oxygen along the carbon chains that form all fatty acids at the point where there are double bonds between carbon atoms. Fatty acids differ in the number of carbon atoms and the number of double bonds along their carbon chains. These differences give each fatty acid its unique chemical and physical properties. Fatty acids in plants, animals, and fish generally range from 14 to 22 carbons in length, with a carboxyl group (COOH) at one end and a methyl group (CH_3) at the other. Shorthand notation for fatty acids identifies the number of carbons and double bonds and also the number of the first carbon from the methyl end where a double bond occurs. For example, a saturated fatty acid containing 16 carbons would be noted as C : 16, while an unsaturated fatty acid containing 18 carbons and two double bonds, with the first double bond appearing at carbon number 6 from the methyl end, would be noted as C : 18 : 2,n-6. Typically, lipids from terrestrial animals are highly saturated (few double bonds), making them solid at room temperature and relatively resistant to oxidation. Plant oils are typically liquid at room temperature because they contain fairly high levels of fatty acids having one or two double bonds. Fish oils, particularly from temperate water marine species, tend to have high proportions of long-chain, polyunsaturated fatty acids (PUFAs), of which 20 to 25% have three to six double bonds (1). Thus, of the lipids used in feeds, fish oils are generally the most unsaturated, have the lowest melting point, and are the most susceptible to lipid oxidation (Table 1).

The process of lipid oxidation involves three general stages: initiation, propagation, and termination (Fig. 1). Initiation of oxidation involves the creation of free radicals; without free radical formation, oxidation cannot occur. Oxygen by itself cannot start the process of lipid oxidation

Table 1. Major Fatty Acids Groups (%) in Lipid Sources Used in Fish Feeds

Lipid Source	Sats[a]	Mono[a]	Dienes[a]	PUFAs[a]
Sardine	26	30	2	27
Menhaden	29	23	2	22
Herring	23	42	2	11
Anchovy	28	29	2	26
Mackerel	26	30	2	23
Soybean	15	23	51	7
Corn	15	36	48	1
Tallow	55	41	3	<1

because the activation energy required to create free radicals from oxygen is very high. Rather, free radical formation begins with hydroperoxide decomposition by metal catalysis or by exposure to light (2). Iron from heme is thought to react with oxygen, converting it from Fe^{2+} to Fe^{3+}, the active form of iron, forming superoxide in the process. Superoxide reacts with two hydrogen atoms to form hydrogen peroxide and oxygen. Fe^{2+} reacts with hydrogen peroxide to form Fe^{3+} and a hydroxy (free) radical ($-OH$). This free radical then reacts with double bonds between carbon atoms along fatty acids, changing the double bond to a single bond in a series of steps that result in formation of various chemical products and more free radicals. Until the oxidation process begins to generate more free radicals than it consumes, the process is still in the initiation stage. The initiation stage can be a short or very long period, depending upon temperature, the presence of metal catalysts, and the concentration of antioxidants in an oil (3). One category of antioxidants works by converting free radicals to stable compounds, thus limiting the level of free radicals in a lipid and keeping oxidation in check. However, once the antioxidants in the oil are used up, free radicals accumulate rapidly and lipid oxidation enters the propagation stage.

As mentioned, hydroxy (free) radicals remove hydrogen atoms from carbons adjacent to double bonds on fatty acids, creating instability at the double bond and an opportunity for oxygen to attach to the carbons (2). The resulting compound is also unstable, and, depending upon the particular fatty acid and which double bond is destabilized, further reactions occur which create peroxides, aldehydes, ketones, furans, numerous alcohols, and epoxides from the fatty acid. More importantly, the breakdown of fatty acids into other compounds creates more free radicals. At this point, lipid oxidation has reached the propagation stage, meaning that free radicals are being propagated by the oxidation process itself rather than by other mechanisms. Oxidation now resembles a nuclear reaction in that it is self-sustaining, proceeds rapidly, and releases heat. The number of free radicals formed during breakdown of peroxides increases with the number of double bonds in a given fatty acid. Linoleic acid (C18:2n-6), the most common unsaturated fatty acid in soybean oil, forms one free radical as it oxidizes. Thus, oxidation of linoleic acid is self-sustaining once it starts. Oxidation of linolenic acid (C18:3n-3), the most common fatty acid in linseed oil, forms two free radicals as it oxidizes, thus accelerating the rate of lipid oxidation. This explains why linseed oil has always been an

important component of paints and varnishes; it oxidizes rapidly, especially after it has been boiled to destroy naturally present antioxidants, forming polymers that coat and protect wood. Eicosapentanoic (EPA, C20:5n-3) and docosahexanoic acids (DHA, C22:6n-3) in fish oils can form four or five free radicals for every fatty acid undergoing oxidative breakdown, making the rate of peroxide formation and oxidation extremely rapid in fish oils during the propagation stage. Termination, the last step of oxidation, occurs when breakdown products combine to form stable end products, and the rate of free radical formation slows as the number of double bonds not yet oxidized on fatty acids decreases.

When fatty acid oxidation is in the propagation stage, the levels of free radicals and intermediate breakdown products of fatty acid oxidation are high. When an oil becomes completely oxidized in the termination stage, the level of free radicals declines, as does the concentration of intermediate by-products. Saturated fatty acids, some unsaturated fatty acids, and final end products of oxidation are left. The end products of oxidation vary depending upon the fatty acids present in the oil and the temperature at which oxidation takes place. In pure lipids, the end products are somewhat predictable. For example, oleic acid (C18:1) breaks down via a relatively simple mechanism to four hydroperoxides, the proportion of which depends upon temperature (4). Linoleic acid (C18:2) breakdown is more complicated because it has two double bonds. Thus it can break down into a variety of final products ranging in size from two or three carbon compounds to longer molecules, including dimers, polymers, cyclic peroxides, hydroperoxides, aldehydes, ketones, alcohols, acids, and epoxides. Crude fish oils contain up to 50 different fatty acids, cholesterol and oxysterols, protein, and other reactive compounds, making the list of possible breakdown products almost infinite.

DETECTING OXIDATION IN FISH OILS

As described, oxidation of fish oils involves the addition of oxygen to double bonds on fatty acids and the production of breakdown products such as aldehydes and peroxides from fatty acids. The chemical tests for detecting oxidation and quantifying the extent of oxidation of fish oils are based upon these changes. One approach to detect oxidative status of lipids involves measuring oxygen uptake while a lipid sample undergoes accelerated oxidation at elevated temperature, using a Warburg apparatus (5) or by measuring small changes in weight of a lipid sample (6). When weight gain is measured, the number of hours needed to achieve a 0.6% gain in weight is the usual unit of measurement. Common laboratory tests for oxidation in lipid samples measure the concentration of intermediate products of lipid oxidation (e.g., aldehydes or peroxides). Aldehyde concentrations are measured by thiobarbaturic acid reactive compound concentration (TBARs) or anisidine value (7). TBARs measure malonaldehyde, a breakdown product of polyunsaturated fatty acids (PUFAs) found in relatively high concentrations in fish oils. Anisidine value is similar to TBARs in that it measures both malonaldehye

concentration and other secondary oxidation products of unsaturated aldehydes. Both anisidine and TBARs are quantitative, highly reproducible, relatively inexpensive, and rapid. However, TBAR values go up during the initial phase of the propagation stage and go down in the termination stage as intermediate products are converted to final products of oxidation (8). Thus, it is difficult to determine exactly where a lipid sample is on the continuum between the propagation stage and the termination stage based upon a single TBAR value, in that a given value could mean that the oxidation is increasing or decreasing, depending on the stage. Another chemical test, peroxide value (POV), measures the concentration of peroxides in an oil sample. As is the case with the TBARs test, POVs go up during the propagation stage and down again during the termination stage. The POV is a highly reproducible, inexpensive, and rapid test and is particularly suited to lipid samples. Lipids are sometimes characterized with respect to their oxidation status by the Totox number, which is simply the anisidine value plus 2X the peroxide value.

Other chemical tests to gauge the oxidative status of lipid samples measure the change in numbers of double bonds in fatty acids. The traditional test for this is to measure iodine number. The method involves exposing oils to iodine vapor in a closed chamber and determining the amount taken up by double bonds (7). High iodine numbers are characteristic of polyunsaturated fatty acids, typical of fish oils. Thus, fish oils will have iodine numbers of 120 to 160, depending on the type of fish oil. As oils oxidize, iodine numbers decrease (fewer double bonds). Changes in fatty acid profiles also occur as oxygen is taken up by double bonds along fatty acid chains. Thus, unsaturated fatty acid concentrations decrease as a consequence of oxidation, and this decrease can be measured using a gas chromatograph. Values for some of these measurements in fish oil indicate a wide range of acceptable values (Table 2).

Based upon a single POV or TBAR value, it is impossible to know if an oil is in the early or later stages of initiation or propagation, which is critical information for a fish feed manufacturer. The amount of time required to reach the propagation stage is called the induction time. Without additional information, one does not know if an oil will be stable for a suitable period, if antioxidants should be added to extend the induction time, or if it is about to enter the propagation stage and rapidly oxidize. To overcome this problem and determine the induction time remaining

before an oil oxidizes, the oil must be subjected to an accelerated oxidation test by exposing a sample to air and heat for a specified period of time and testing again. If the POV or TBAR value after stress testing is substantially higher than the initial value, then the oil is near the end of the initiation stage. The Schaal oven test is the best choice for such measurements (8). After an initial POV or TBAR measurement, the oil is placed in an oven at 40 to 45 °C and tested again at daily intervals (Fig. 2). This method is very useful to judge how much longer the oil will remain in the initiation stage during storage. It is not uncommon for an oil to yield a relatively low POV value upon arrival at a fish feed manufacturing plant and be used in production of fish feed, only to have the oil in the fish feed oxidize shortly after it is manufactured. Conducting a Schaal oven test on the oil at arrival will clearly show the quality of the oil with respect to resistance to oxidation provided by natural or added antioxidants. POV values should be less than 20 after five days of the Schall oven test for the oil to resist oxidation through the storage, pelleting, and shipping stages and until used at a fish farm. If the oil is close to entering the propagation stage, antioxidants must be added to extend the initiation stage and thus prevent oxidation.

The chemical tests used to measure oxidation status of fish oils are less accurate when they are used to measure the oxidation status of fish feeds. This is due in part to the difficulty of extracting lipids from fish feeds, particularly feeds that have been pelleted by cooking extrusion. The temperature and pressure used to extrude fish feeds causes some of the lipid in the feed mixture to become bound, making it necessary to subject the feed sample to acid hydrolysis before organic solvents are used to extract the lipid. Feeds for some species of fish (e.g., salmon, trout, and yellowtail) are sprayed (top-dressed) with fish oil after pelleting, but some of the lipid in pellets is present in the mixture before pelleting. It is the latter that is difficult to extract. Another potential problem associated with measuring the oxidation status of fish feeds is that the conditions of pelleting may destroy the intermediate products of oxidation, leading to low TBAR or POV values that underestimate the true oxidation status. A final problem is that the POV test is based upon a titration which causes a color change in the oil sample. This color change is relatively easy to observe in samples

Table 2. Typical Crude Fish Oil Specifications[a]

Measurement	Range of Values
Free fatty acids, %	2–5
Moisture and impurities, %	0.5–1.0
Peroxide value, Meq/kg	3–20
Anisidine number	4–60
Iron, mg/kg	0.5–7.0
Iodine value	
Capelin	95–160
Herring	115–160
Anchovy	180–220

[a]From Ref. 16.
Figure 2. Schaal oven test with various fish oils.

taken from fish oils, but samples from feeds sometimes contain pigments that mask the distinctive end point (color change) during titration.

Based upon studies in which oil of a known POV value was added to a poultry feed, the POV value of the feed after pelleting was significantly lower than the theoretical calculated value (9). A single petroleum ether extraction removed only 60% of the oil in the feed; but after acid hydrolysis and three extractions, 90% of the oil was recovered. In spite of this more complete extraction, the POV value of the oil in the feed remained significantly below theoretical values, most likely because of peroxide destruction during pelleting (9). TBAR values are not affected by factors that make the color change in POV testing difficult to measure accurately, but they are affected by malonaldehyde destruction during pelleting and incomplete lipid extraction from pellets. The safest approach to ascertain the oxidation status of lipids in fish feeds is to conduct thorough extraction, test the oil, heat the pellets in an oven, and conduct repeated testing to determine if AV, POV, or TBAR values increase. This approach will yield information on induction time and status regarding propagation and termination stages of oxidation.

ANTIOXIDANTS

Antioxidants are compounds that interfere with or interrupt the process of oxidation in lipids. There are three categories of antioxidants: preventative antioxidants, sacrificial antioxidants, and peroxide destroyers, and these antioxidants exert their protective effects by affecting oxidation at different stages. Preventative antioxidants operate by chelating or tying up metals (e.g., iron and copper) that initiate free radical formation, thus removing them from circulation. Examples of preventative antioxidants are citric acid, phosphoric acid, ascorbic acid, phytic acid, and EDTA (10). Preventative antioxidants influence the initiation stage of lipid oxidation, acting to extend this stage. Once lipid oxidation moves into the propagation stage, preventative antioxidants do not influence the rate or extent of oxidation because free radical generation is independent of reactions involving copper or iron.

Sacrificial antioxidants interrupt the propagation stage of oxidation by donating a hydrogen to free radicals, converting them to stable and nonreactive forms. Thus, they operate by catching free radicals before they can react with double bonds on fatty acid chains or by donating a hydrogen atom to the double bond after it has lost one to a free radical, thus returning the double bond to its original state and preventing further oxidation reactions. Each molecule of antioxidant can donate two hydrogens, after which it is out of extra hydrogen atoms and no longer able to interrupt oxidation. Thus, it has sacrificed its hydrogens and been altered in the process; hence the name sacrificial antioxidants. In natural oils from plants and fish, tocopherols (various forms of vitamin E) are the sacrificial antioxidants that protect the oils from oxidation.

The third type of antioxidants (peroxide destroyers) operate by reducing peroxides formed in the propagation stage. Their antioxidant properties are associated with removing peroxides, which helps limit the generation of new free radicals and reduces the extent to which oxidation remains a self-sustaining process. Peroxide destroyers are not normally used to protect fish oils and fish feeds because they react with other feed compounds, altering the nutritional value of the feed.

If conditions in a fish oil are such that free radicals are being formed during the initiation stage, oxidation will be limited as long as there are sacrificial antioxidants available. When the antioxidants in fish oil have donated all of their hydrogen atoms to free radicals, there is nothing to stop propagation from proceeding to the propagation stage and the oil from oxidizing. If a batch of fish oil has entered the propagation stage of oxidation and antioxidants are added, propagation will stop until the added antioxidants are used up, at which time propagation will begin again.

Fish and plant oils contain tocopherols and other naturally occurring compounds that protect oils against oxidation (Table 3). In fish oils, alpha-tocopherol is the primary antioxidant, although carotenoid pigments, primarily astaxanthin, are hypothesized to offer some protection against oxidation. The tocopherol content of fish oils varies with fish species, conditions of manufacture, and length of storage of the oil. The alpha-tocopherol content of crude menhaden oil ranges from 20 to 70 mg/kg, while herring and tuna oil are reported to contain 140 to 160 mg alpha-tocopherol/kg (10). Plant oils contain alpha, beta, delta, and gamma tocopherols, plus tocotrienes (11). Soybean oil contains 1,078 mg total tocopherols/kg oil, of which alpha tocopherol accounts for only 93 mg/kg. Gamma-tocopherol accounts for 695 mg and delta-tocopherol for 277 mg/kg oil. These tocopherols are potent antioxidants, but their vitamin E activity is relatively low for animals compared to alpha-tocopherol (12).

There are a number of synthetic, sacrificial antioxidants that are used to protect fish oil and other foods from oxidation. These include ethoxyquin (1,2-dihydro-6-ethoxy-2,-2,4-trimethyl quinoline), BHA (butylated hydroxyanisole), BHT (butylated hydroxytoluene), propyl gallate, TBHQ (tertiary-butyl-hydroquinone), and ascorbyl palmitate (12). Ethoxyquin is not permitted in human food but is approved for use in animal feeds not to exceed 150 mg/kg. BHA and BHT are approved for use in human food and are occasionally used in animal feeds to a maximum level of 0.02% of the lipid content of the food

Table 3. Tocopherol Levels (mg/kg) in Fish Oil and Soybean Oil

Oil Source	Tocopherol Content
Sardine	40
Menhaden	20–70
Herring	140
Tuna	160
Soybean	1,078[a]

[a] Alpha, 93; beta, 12; delta, 277; gamma, 695.

Table 4. Oxidative Uptake to 0.6% Weight Gain of Capelin Oil with Added Antioxidants (6)

Treatment	TBAR (mg malonaldehye/kg oil)	Duration (hr)	Efficiency
None	10	30	1.0
Tocopherol acetate, 0.03%	19	34	1.1
Ascorbyl palmitate, 0.02%	20	42	1.4
BHT, 0.02%	11	55	1.8
Ethoxyquin, 0.02%	10	56	1.9
BHA, 0.02%	9	67	2.2
TBHQ, 0.01%	9	119	4.0

or feed. Propyl gallate and ascorbyl palmitate are used in human foods.

Antioxidants are not equally effective at preventing oxidation of fish oils. Several antioxidants were added to fish oil from capelin, and the oil samples were subjected to an accelerated oxidation test until the oil had gained 0.6% weight (Table 4). Unsupplemented oil reached this gain in weight after 30 hours, at which time it had a TBAR value of 10, a relatively low value. Ethoxyquin extended protection of the oil to 56 hours, longer than tocopherol acetate or ascorbyl palmitate (34 and 42 hours, respectively). BHT offered nearly identical protection to ethoxyquin, but BHA extended protection to 67 hours. TBHQ was the most effective antioxidant, extending protection to the oil for 119 hours. Similar but less dramatic findings are reported for fish feeds to which various antioxidants have been added (13).

Blends of natural antioxidants effectively extend the shelf life (induction time) of fish oils (14). Combinations of tocopherol, lecithin, ascorbic acid, and a small percentage of water to help disperse ascorbic acid increased storage time of fish oil by 22X compared to the storage time of fish oil supplemented with tocopherol alone. Commercial blends of natural antioxidants are available for protecting fish oil and add about US$0.11/kg to the price of the oil, increasing the cost of the oil by about 20%. Because plant oils are rich sources of various tocopherols, mixing plant and fish oils plus adding ascorbic acid (a synergist with tocopherol) and water may be a promising option for protecting fish oils against oxidation without using synthetic antioxidants.

PREVENTING OXIDATION IN FISH OIL

Fish oil is the second largest source of edible and feed-grade oil produced in the world, and currently 25% of world production is used in fish feeds. Of the amount used in fish feeds (380,000 MT), half is used in salmon feeds, with trout the second largest aquaculture user (15). A decade from now, estimates are that nearly 500,000 MT will be used in salmon feeds alone, with carp, shrimp, and yellowtail aquaculture feeds also predicted to increase dramatically (15). Given these predictions, it is clear that fish oil will continue to be a key constituent of fish feeds and that preventing oxidation of fish oils will require a better understanding of the critical points between fish oil

production and its use in fish feeds where the potential for oxidation is enhanced.

Oxidation of fish oil requires the production of free radicals and the presence of oxygen. Free radicals are formed as a consequence of enzymatic breakdown of fish tissue, mainly through release of iron from hemoglobin and from contamination of oil with iron and copper from equipment used to manufacture, pump, store, and transport the oil. Therefore, minimizing tissue damage of fish used to produce oil and avoiding iron and copper contamination from storage tanks, processing equipment, and especially valves used to pump oil between tanks and trucks or railcars, are key factors to produce stable fish oil.

Most fish oil and fish meal is produced using the wet reduction process (16,17). The wet reduction process is a continuous process involving cooking, pressing, decanting, separating, and polishing. Cooking and pressing do not enhance oxidation, but the decanting, separating, and polishing steps, which separate and clean the fish oil, can influence oxidative stability of the oil. Crude fish oil is not a pure substance. Insoluble impurities and free fatty acids are commonly present, as are small amounts of water and water-soluble proteins, trace metals, oxidation products, pigments, and tocopherols. Fish oil is then stored in large tanks where antioxidants may or may not be added, depending on the final use of the oil. Approximately 75% of the fish oil produced in the world is used to make edible products, such as margarine, and addition of antioxidants to oil that will be used to make edible products would interfere with their manufacture. Consequently, bulk fish oil often does not have antioxidants added to it until an order is placed from a feed manufacturer, and it is shipped. Certain conditions in storage tanks can accelerate the oxidation process. These conditions include a large head space containing air, contamination with iron or copper, and direct sunlight on the storage tank, which causes thermal convection and turnover of oil in the tank. Circulation of oil within a tank brings more oil into contact with the surface, thereby exposing more of the oil to oxygen in the air in the head space. Further, entrapment of air into the oil can occur as a consequence of thermal convection. Lastly, tanks should contain a sump in which water and insoluble impurities settle. The sumps should contain drains through which these materials can be regularly removed as they collect. If this mixture of water and protein is not removed, it can act as a substrate for bacteria that generate acid, thus hydrolyzing triglycerides to free fatty acids, which are more susceptible to oxidation.

The consequence of poor oil storage conditions is that they reduce the concentration of natural antioxidants present in the oil, thereby shortening the induction time of the oil once it reaches a feed plant. The same conditions that are stressful to fish oil in storage can occur when the oil is transported to distribution facilities and to the feed plant. In addition, oil is sometimes transported in rail cars or trucks that have previously contained other materials, thereby potentially contaminating the oil. Cleaning rail cars and tanks between shipments is important, even if the tank is only used to ship fish oil; because after oil is drained from a tank, the inside of the tank remains coated. This coating is fully exposed to air and is very likely to oxidize, thus contaminating new shipments with oxidizing oil.

Once fish oil reaches a fish feed plant, it is stored in tanks where oxidation can be enhanced by the same conditions already described. In particular, it is critical to clean out storage tanks when they are emptied before a new shipment of oil is added. Oil tanks should have conical bottoms to eliminate dead spaces and ensure that all the oil in the tank can be drained out. The stearine fraction of fish oil, which is rich in saturated fatty acids and thus solid at temperatures where fish oil is liquid, tends to make a relatively solid coating on the insides of fish oil storage tanks. This material is less susceptible to oxidation than fish oil, but because it coats the inside of tanks and is thus exposed to air when oil tanks are emptied, it can oxidize. Stearines must be removed from the inside surfaces of storage tanks and pipes by pressure washing with water, detergents, or biodegradable solvents to reduce the chance of contaminating new shipments of oil with oxidizing oil. Other practices that can be employed to reduce the rate of lipid oxidation in storage tanks include coating the inside of iron or steel tanks with epoxy and injecting nitrogen into the oil. Injecting nitrogen strips air from the oil and displaces air in the headspace as the oil in the tank is used.

Fish feed pelleting involves heat, moisture, and pressure, all of which one would think would likely accelerate destruction of antioxidants that protect fish oils from oxidation. However, most damage to lipids in fish feeds is associated with overdrying the pellets after they are produced. Heat is less of a contributor to oxidation than is drying to a moisture content of <8.5% moisture. After pellet drying, fish oil is sometimes added by top-dressing. Oxidizing oil present in pipes and top-dressing equipment can contaminate clean oil as it is used to coat pellets. Thus, this equipment should be cleaned regularly.

After pellets are manufactured, oxidation can be accelerated by several factors. These include abusive storage conditions (primarily high-temperature storage), the presence of pro-oxidants (e.g., iron and copper) coming from pelleting equipment and mineral supplements, and, especially, freezing of dry pellets. Most freezers at fish farms are not cold enough to freeze all of the water in pellets. Thus, pure water is frozen, but water containing pro-oxidants remains a liquid and is concentrated in parts of pellets. Besides concentrating water-soluble pro-oxidants, freezing allows oxygen to penetrate more freely into the pellets. Thus, dry fish feed should never be frozen; rather it should be stored in a cool, dry place.

HEALTH EFFECTS OF FEEDING DIETS CONTAINING OXIDIZING FISH OIL

Oxidation of lipids is one of the more common problems in fish feeds. The trend is toward high-energy (high-lipid) feeds, especially in salmon farming, and periodic dips in global fish oil production, which causes feed manufacturers to seek fish oil of any quality. This combination of factors increases the likelihood that fish feeds will contain oxidizing oil. Feeds containing oxidizing lipids can cause nutritional disease by depleting tissue antioxidant levels, producing toxic compounds and destroying essential fatty acids (18). The levels of tissue and membrane antioxidants (e.g., tocopherol and vitamin C) are reduced when feeds containing oxidizing lipid are fed because they are used to control free radical levels in tissues faster than they can be regenerated. This results in biomembrane changes, mainly alterations in membrane permeability and fragility. In addition, the free radicals, peroxides, aldehydes, and ketones produced during lipid oxidation are all toxic to fish and capable of reacting with other dietary components. While essential fatty acids (PUFAs) are destroyed in feeds as a consequence of oxidation, the health problems associated with feeding oxidizing lipids are most often the result of depleted tissue antioxidants and the toxic products named previously.

The primary health effects associated with feeding oxidizing fish oils in feeds to fish are liver degeneration, anemia, and spleen abnormalities (19–22). The most serious problem associated with rancidity is lipoid liver disease. As mentioned, rancid lipids are toxic per se, but they also have a deleterious effect on tissue levels of vitamins E and C. Consequently, the features of lipoid liver disease often vary from outbreak to outbreak, depending on the contribution of each of the components to the degeneration. Fish suffering from lipoid liver disease have extreme anemia (manifested by pallor of the gills and erythrocyte fragility), a bronzed, rounded heart, and a swollen liver with rounded edges (19). Histologically, the main feature is the extreme infiltration of hepatocytes by lipid, which causes loss of cytoplasmic staining and distortion of hepatic muralia. There is degeneration of splenic and renal haemopoietic tissue with high levels of pale-staining pigment in melanomacrophage centers. There is also often auxiliary haemopoiesis in the subepicardial tissues and the periportal areas. Depending on the length of time the condition has been extant, the degree of oxidation, and the type of fat in the diet, there is a varying degree of infiltration of the liver by macrophages containing ceroid, a pigmented breakdown product of phospholipid metabolism (23).

All salmonids are susceptible to lipoid liver degeneration, but it is a particularly significant problem in rainbow trout culture (23). Slightly affected fish are usually capable of complete recovery, but once there is severe anemia and hepatic ceroidosis has developed, the fish is rarely capable of satisfactory recovery to its previous efficiency of feed conversion. Other conditions reported to be associated with the feeding of rancid lipids include exophthalmia, steatitis, darkening, splenic hemosiderosis, and skeletal myopathy (21,24–26).

Because one of the primary health effects of feeding oxidizing fish oil is depletion of tissue vitamins C and E, it is logical to conclude that elevating the dietary intake of these vitamins might alleviate the condition. In fact, in catfish and trout, many of the pathological effects associated with feeding oxidizing fish oil can be prevented by increasing the dietary intake of tocopherol (21,25). However, acute toxicity is not always prevented by increasing dietary tocopherol intake, especially in small fish which have not yet accumulated substantial tissue stores of ascorbic acid and tocopherol. Growth rates of Atlantic and coho salmon fry are reported to be inversely proportional to the level of oxidation in starter feeds, with reduced growth being observed at levels of oxidation that do not reduce growth in larger fish (20,27). There is also some suggestion in the literature that there may be species differences in sensitivity to oxidizing feeds (27). The link between tocopherol deficiency signs and those associated with consumption of oxidizing lipids is weak. If oxidizing lipids caused pathological problems in fish solely by reducing tissue tocopherol levels, one might expect that signs of tocopherol deficiency (e.g., muscular dystrophy), exudative diathesis, and depigmentation, would be prevalent in fish consuming feeds containing oxidizing lipids. However, this does not occur.

A very distinctive syndrome closely resembling diabetes has been described in carp fed diets containing high levels of silkworm pupae (28). This syndrome, called Sekoke disease, is characterized by destruction of the endocrine pancreatic islets of Langerhans, concomitant lipid infiltration of parenchymatous organs, bilateral cataracts, and degenerative alterations to the extrinsic eye muscles, the retina, and the choroid (23). Sekoke disease was found to be caused by oxidation of lipids in the silk worm pupae and can be prevented by increasing the dietary intake of vitamin E.

Influence of Dietary Lipid Composition on Fish Health
Marine and Nonmarine Lipid Sources in Feeds for Finfish
    Lipid Sources

Lipids and their constituent fatty acids, as well as the metabolic derivatives of some of the latter that are termed eicosanoids and other associated compounds, play central and dynamic roles in the maintenance of optimum growth, the reproduction, the health, and the flesh quality (market size) of finfish species. In this review, our first intent is to introduce the reader to the various types of lipids and fatty acids that are present in the diet and the bodies of finfish species and to the general functions of those compounds. Thereafter, we describe how finfish species digest, absorb, transport, and store lipids in their bodies, emphasizing some interspecific differences in this regard. Then, we highlight the extent to which the various species differ in their requirements for dietary lipids and fatty acids, taking into consideration the lipid compositions of their natural diets in the freshwater and marine environments and at each life history stage — larvae or fry, juveniles, post-juveniles, and adults (nonmature or maturing). Next, we describe in general terms the effects that dietary fatty acids have on finfish reproduction and health (cardiovascular function and immunocompetence). Lastly, we consider their impacts on the chemical composition and sensory attributes of the flesh, especially when non-marine sources are used as partial replacements for marine lipids during times when the latter are of high price and low quality.

TYPES, CLASSIFICATION, GENERAL FUNCTIONS

Lipids

"Lipids" refers to compounds that are relatively insoluble in water but are soluble in organic solvents such as chloroform, ether, hexane, and benzene. There are many types of lipids, and their classification has been undertaken in several ways. For instance, they have been differentiated either by the presence or absence of fatty acids or of the alcohol glycerol in their basic structure or according to their polarity. With respect to the latter, some lipids such as triacylglycerols, wax esters, alkyl diacylglycerols, and sterol (e.g., cholesterol) esters are insoluble in water because of nonpolar hydrocarbon groups. Consequently, they are called nonpolar lipids. By contrast, other lipids such as phosphatidyl choline (PC), phosphatidyl ethanolamine (PE), phosphatidyl serine (PS), and phosphatidyl inositol (PI) — collectively called phosphoglycerides — along with plasmologens, shingomyelin, cerebrosides, and gangliosides, contain polar groups as part of their basic structure. Accordingly, these are referred to as polar lipids, and they are essential components of biological membranes. Many finfish species such as salmonids

(salmon, trout, and charr) derive most of their dietary non-protein energy from triacylglycerols and, in the case of wild salmon in the ocean and marine species, also from wax esters that are present in several marine prey species.

The basic structures of the preceding compounds differ considerably from each other. Triacylglycerols, for instance, consist of three fatty acids esterified to the alcohol glycerol. The three different fatty acid hydrocarbon chains vary in the number of carbon atoms, the degree of unsaturation and, where applicable, the position of the first double bond in relation to the methyl end of the molecule. Numerous combinations of fatty acids are possible within the triacylglycerol structure, because more than 40 different fatty acids are known to occur in nature (1). This variety results in differences in such chemical and physical properties as melting point, dependent upon which fatty acids are affixed to the glycerol moiety. For example, the melting points of the saturated (no double bonds in the carbon chain) fatty acids $14:0$ (myristic acid), $16:0$ (palmitic acid), and $18:0$ (stearic acid) are respectively 54, 63, and $70\,^{\circ}$C. The corresponding value for a typical monounsaturated (possessing one double bond) fatty acid, $18:1n$-9 (oleic acid), is lower: $16.3\,^{\circ}$C. Moreover, those for polyunsaturated (two or more double bonds) fatty acids, such as $18:2n$-6 (linoleic acid), $18:3n$-3 (linolenic acid), $20:4n$-6 (arachidonic acid), $20:5n$-3 (eicosapentaenoic acid), and $22:6n$-3 (docosahexaenoic acid) are even lower, being (respectively) -5, -10, -49.5, -54.4, and $-44.5\,^{\circ}$C (2).

At this point, it is necessary to provide some background information about fatty acids before proceeding further. In this regard, it should be mentioned that fatty acids differ from each other not only in their degree of unsaturation but also with respect to the number of carbon atoms in the chain and the family or series of fatty acids to which they belong. The products of fatty acid synthetase are saturated fatty acids. However, fish lipids contain high levels of unsaturated fatty acids, derived in part from food ingestion. The polyunsaturated fatty acids belong to one of three major families or series, namely, the oleic or n-9, the linoleic or n-6, and the linolenic or n-3 series. The majority of members of the two most important ones from a nutritional standpoint are depicted in Figure 1. The individual members of each of the families can therefore be differentiated by the number of carbon atoms and double bonds in the chain and by the position of the first double bond, counting from the terminal methyl (CH_3) group carbon to the carbon atom of the first double bond. Thus, for example, the complete structure of $18:3n$-3 is as follows:

$$CH_3CH_2CH{=}CHCH_2CH{=}CHCH_2CH{=}CH(CH_2)_7COOH.$$

With reference to Figure 1, it should be noted that finfish, like other vertebrates, but unlike plants, do not possess the $\Delta12$ and $\Delta15$ desaturase enzymes required for the synthesis of $18:2n$-6, the parent acid of the n-6 series, and $18:3n$-3, the precursor of the n-3 series (3). Consequently, these fatty acids (or their metabolic derivatives) must be of dietary origin. Also, depending upon the finfish species, the parent acid of the

Figure 1. Probable pathways involved in the desaturation and elongation of the *n*-6 and *n*-3 series of fatty acids in freshwater fish. The parent acids of each family, as well as their respective nutritionally important highly unsaturated fatty acids and series of cyclooxygenase and lipoxygenase-derived prostanoids (prostaglandins and thromboxanes), leukotrienes, and lipoxins (collectively termed eicosanoid compounds) are indicated. The production of $22:5n\text{-}6$ and $22:6n\text{-}3$ is now believed to occur as shown rather than through Δ4 desaturation of $22:4n\text{-}6$ to yield $22:5n\text{-}6$ and $22:5n\text{-}3$ to produce $22:6n\text{-}3$ (148,149). There is some evidence that eicosanoids are formed from DHA (e.g., 14-hydroxydocosahexaenoic acid), through the action of 12-lipoxygenase (150).

n-3 series, the proper levels and proportions of some of the highly unsaturated members of the *n*-3 series, and the counterparts of the *n*-6 series of fatty acids are considered to be essential for normal growth, food utilization, health, and reproductive viability (refer to the later section on lipid and fatty acid requirements). The members of each of the families of fatty acids are created from their respective parent acids by a common enzyme system of alternating desaturases and elongases that yield series of fatty acids of increasing unsaturation and length. Further, the members of one family are not interconvertible with those of another. The highly unsaturated fatty acids (HUFAs) of the *n*-9, *n*-6 and *n*-3 families of nutritional significance are (respectively) eicosatrienoic acid ($20:3n$-9), dihomo-γ-linolenic acid ($20:3n$-6), arachidonic acid ($20:4n$-6; AA), eicosapentaenoic acid ($20:5n$-3; EPA), and docosahexaenoic acid ($22:6n$-3; DHA). The latter four fatty acids are progenitors of a series of compounds (collectively

called eicosanoids) that are essential for the regulation of many physiological processes in the body. The last two of them are frequently referred to as *n*-3 HUFAs (EPA + DHA), although this term can also include other C20 members of the *n*-3 family.

With this background information, it is now possible to continue the discussion of triacylglycerols. In addition to differences in the melting points of the individual fatty acids affixed to the glycerol moiety, the fatty acids also show differences with respect to their positional distribution. This distinction has been reviewed thoroughly by Polvi 1989 (4), who observed that the *n*-3 fatty acids in the triacylglycerols of Atlantic salmon (*Salmo salar*) were divided almost equally between positions 2 and 3. Thus, depending upon their fatty acid composition, triacylglycerols may exist in either a liquid or a semisolid state at room temperature, in which cases they are called oils and fats, respectively.

The wax esters present in the prey — for example, calanoid copepods, bathypelagic mysids, some euphausiid species, deep-sea squid and myctophids — of wild salmon in sea water and of marine species are unlike triacylglycerols, because they are primary esters of long-chain fatty alcohols (not glycerol) and long-chain fatty acids. Furthermore, the alcohols are rich in 20:1n-9 and 22:1n-11, and the fatty acids can be represented well by n-3 polyunsaturated fatty acids and 14:0 (5).

Cholesterol and cholesteryl esters (cholesterol esterified to a fatty acid) are the third group of nonpolar lipids that should be considered before discussing the essential fatty acid needs of some of the finfish species and the influence of lipids on their cardiovascular health. Cholesterol is ubiquitous within the body of fish and other animals. It is an essential component, along with phospholipids (discussed later) and proteins, of all cellular and subcellular membranes (6). In addition, cholesterol is involved in lipid transport, because both free and esterified cholesterol are constituents of lipoproteins (as discussed in the lipid transport section). Moreover, cholesterol is a precursor of adrenal and reproductive hormones (androgens and estrogens), of vitamin D_3, and of bile acids that facilitate dietary lipid digestion and absorption.

The basic structure of polar lipids consists of a glycerol or sphingosine (an amino alcohol) moiety coupled with one or two fatty acids and a polar head group. All polar lipids except glycolipids (cerebrosides and gangliosides) contain a phosphate group and generally a nitrogenous base; they are therefore referred to as phospholipids (7). Phospholipids contain two fatty acids esterified to glycerol. Usually the fatty acids in position 1 are saturated or monounsaturated (e.g., C16:0 or C18:1, present in marine poikilotherms) (8). By contrast, polyunsaturated fatty acids, especially of the n-3 series, are generally found in position 2 (4). Because of the high occurrence of C_{20} and C_{22} polyunsaturated fatty acids, such as EPA and DHA at position 2, the fatty acids of phospholipids are more unsaturated than those of triacylglycerols. Phospholipids are classified according to the nitrogenous base moiety attached to phosphoric acid. Lecithins, for example, have choline (phosphatidylcholine; PC) as their nitrogenous base, whereas cephalins have ethanolamine (phosphatidylethanolamine; PE). Other cephalins have serine (phosphatidylserine; PS) or inositol (phosphatidylinositol; PI) (6).

Phospholipids have hydrophilic (because of the polar phosphoric acid and the nitrogenous base region) and hydrophobic (because of the nonpolar fatty acid chain) properties. Together with proteins and cholesterol, they form the basic structures of cellular and subcellular membranes. Within the membranes, the polar lipids are organized in the form of a bilayer, with the hydrocarbon chains providing a hydrophobic environment in the interior of the bilayer and the lipid polar head groups encountering the outer aqueous phase. The proteins within the membranes are bound to the bilayer surface, or they are integrated into the lipid bilayer, with hydrophobic amino acids in the interior and charged amino acids on the exterior. The lipid bilayer region is generally well ordered, and only a small region is liquidlike (9).

The physical and functional properties of the membranes are determined by the following: (1) the levels and types of the constituent phospholipids; (2) the fatty acid compositions of the phospholipids, especially at position 2 of the glycerol backbone; (3) the interactions of the phospholipids with cholesterol and either enzymatic or structural proteins; and (4) the specific pairing of long-chain polyunsaturated fatty acids with Δ9 (18:1) monounsaturated fatty acids in the sn-1 position, especially in PE (8,10–12). Biomembrane fluidity, for example, largely reflects the balance between polyunsaturated fatty acids on position 2 and saturated fatty acids or monounsaturated fatty acids on position 1 of the glycerol backbones of the phospholipids (8). In this regard, there is in the livers of winter (cold)-acclimated carp (*Cyprinus carpio*) a decrease in the level of 18:0/22:6 species and an attendant increase in the levels of 1-monounsaturated, 2-polyunsaturated (18:1/22:6, 18:1/20:4) species in PC and PE. The accumulation of 18:1/22:6 and to some degree 18:1/20:5 PE has also been demonstrated in marine fish inhabiting cold waters and in the brains of fresh water fish adapted to reduced temperatures (12). The elevation of PE and the concomitant decrease of PC in membranes may facilitate membrane fluidity at low temperatures, because PE does not readily form compact lamellae (3). Water temperature is a very important factor influencing the growth and physiology of poikilothermic finfish species, and it is important that the biomembranes exist in a liquid-crystalline state at body temperature. Indeed, the cells of the body must adapt to establish a new equilibrium between the environment and the physicochemical properties of their membranous structures in order to survive the new conditions. This process is known as homeoviscous adaptation (12).

Cellular function and metabolism in mammals can be influenced by alterations in the composition of the membrane constituents in several ways. First, the activities of membrane-bound enzymes such as Na^+,K^+ATPase, adenylate cyclase, and Ca^{2+}-ATPase can be changed (9,11). Second, the extent of hormone binding to membrane receptor sites, such as insulin to adipocyte membranes and triiodothyronine to hepatic nuclear membrane sites, can be varied (11). Third, there may be modification of the control and expression of cell nucleus activity (11). Lastly, there may be modulation of the types and levels of cyclooxygenase and lipoxygenase eicosanoid products (Fig. 1) produced in response to the levels of non-esterified AA, EPA, and DHA. All of the foregoing mechanisms appear to operate in fish, and disruption of their normal synchrony in cellular metabolism can lead to adverse physiological consequences.

For instance, overproduction of the highly bioactive n-6 polyunsaturated (PUFA)-derived eicosanoids may be involved in the induction of cardiac myopathy in Atlantic salmon postsmolts that ingest a diet rich in n-6 fatty acids (13,14). Also, suboptimal levels of di-22:6n-3 species in the retinal membranes of herring (*Clupea harengus*) are known to reduce their visual acuity at low light intensities, where retinal rods normally function (15). Further, reduced levels of di-22:6n-3 species in brain phospholipids of fish probably adversely influence their brain function, a phenomenon that has been demonstrated in mammals

(including man) (16). In addition, dietary deficiencies of DHA and AA impair pigmentation in the Japanese flounder (*Paralichthys olivaceus*) (17). Kidney and gill function (osmoregulatory ability) in Atlantic salmon post-smolts can likely be influenced positively or negatively by the dietary balance between n-6 and n-3 fatty acids and by the ratios between their respective prostaglandins derived from AA (2-series) and EPA (3-series) (18). Likewise, pineal organ function in salmon probably is influenced by dietary levels of n-6 and n-3 fatty acids and by suboptimal ratios of 2- and 3-series prostaglandins that occur in response to varying nonesterified levels of AA in relation to EPA (19). As Clandinin et al. (1991) (11) pointed out, biological membranes should be viewed as dynamic and highly responsive structures whose constituents (and consequently functions) vary according to both intrinsic factors (e.g., fatty acid desaturation and elongation; phospholipid biosynthesis; types and levels of eicosanoid compounds elaborated) and extrinsic factors (e.g., dietary lipid composition). The interrelationship between these factors will be considered further in the next section.

DIGESTION, ABSORPTION, TRANSPORT, AND STORAGE

The hydrolysis of lipids in the intestinal lumen appears to be accomplished mainly by nonspecific and bile-salt dependent lipase, with perhaps some involvement of 1,3 specific pancreatic lipase (20). In many teleosts, lipid digestion and absorption take place in the anterior intestine, where the pyloric caecae are located and the pancreatic enzymes are secreted into the intestinal lumen. In some species, however, like the turbot (*Scophthalmus maximus*), there is evidence that these processes occur mainly in the hindgut and rectum (20). The process of lipid digestion yields free fatty acids, fatty alcohols from wax esters (marine species), glycerol, 2-mono-acylglycerol, sterols, and lysophospholipids. As a general trend, the absorption of the various fatty acid groups in the intestinal region of finfish shows the following sequence: saturates < monoenenes < polyunsaturates. Moreover, fatty acid digestibility (bioavailability) is known to decrease with increasing chain length. The bioavailability of marine lipids (rich in n-3 HUFAs) in most fish species appears to be ≥90% (21–23) using reliable digestibility procedures. (Refer to (24,25).)

The aforementioned products of lipid digestion are metabolized further in the intestinal mucosa enterocytes. Most of the lysophospholipids are re-esterified with fatty acids to phospholipids, and glycerol and 2-monoacylglycerol are re-esterified with free fatty acids into triacylglycerols (3).

Some of the exogenous fatty acids may also undergo desaturation and elongation in the intestinal enterocytes (26). The lipids are then transported to the liver as chylomicrons (lipoprotein complexes comprised of triacylglycerols and of minor amounts of cholesterol, cholesteryl esters, phospholipids, and protein components, termed apoproteins) and as very low density lipoproteins (VLDL), via the blood or the lymphatic system. Also, a significant quantity of free fatty acid may be transported as albumin complexes, via the portal blood (5). Within the liver,

fatty acids synthesized endogenously—saturated and/or monounsaturated fatty acids—are combined with those of exogenous (dietary) origin in the form of VLDL. The liver is the main site for endogenous synthesis in fish. This organ is also highly active in modifying fatty acids of both endogenous and exogenous origin, through desaturation and elongation enzymes located in the microsomes (27). Dietary lipid composition, as well as such other factors as water temperature, influences the types of fatty acid derivatives that are elaborated.

In regard to dietary lipid composition, the substrate preference for $\Delta 6$ desaturase (Fig. 1) in fresh water salmonids is $18:3n$-3 > $18:2n$-6 > $18:1n$-9. Also, a surfeit of one series of dietary fatty acids (for example, high levels of n-6 versus n-3 fatty acids) may, depending upon the species, competitively inhibit the formation of the long chain highly unsaturated members of the series in lower concentration. Further, high dietary levels of n-3 HUFAs in rainbow trout (*Oncorhynchus mykiss*) are known to inhibit the hepatic bioconversion of $18:3n$-3 and $18:2n$-6 (27). Lastly, a deficit of n-3 and n-6 fatty acids in the diet of salmonids leads to the bioconversion of $18:1n$-9 to $20:3n$-9, and this situation indicates essential fatty acid deficiency (3). Hence, the character of the lipids composing hepatic VLDL can vary considerably. VLDL transports lipids of exogenous and endogenous origin from the liver to the extrahepatic tissues. Here, the VLDL triacylglycerols are hydrolyzed by lipoprotein lipase, with the consequent uptake of fatty acids into the cells and with the formation of cholesterol-rich low-density lipoprotein, which is specialized for transport of the esterified cholesterol to the extrahepatic tissues (28).

Within the cells, the new fatty acids supplied by VLDL can be esterified into triacylglycerols or incorporated into membrane lipids by *de novo* phospholipid synthesis and by acyl group turnover in the membrane phospholipids (11). Some metabolically active extrahepatic tissues such as the heart, gonad cells, and leukocytes may also be able to desaturate the fatty acids derived from VLDL. Other possible pathways for the nonesterified fatty acids originating from VLDL or from membrane phospholipids by the action of phospholipase A_2 include the formation of eicosanoid compounds, because of the action of cyclooxygenase and lipoxygenase enzymes (Fig. 1), and of acylcarnitine for mitochondrial β-oxidation (energy provision).

Two other lipoproteins that are also involved in lipid transport also require mention. These are high-density lipoprotein (HDL) and vitellogenin (VTG). HDL is derived from LDL and is rich in phospholipids and cholesterol (5). HDL is specialized for transport of cholesterol that has been taken up from the extrahepatic tissues to the liver (29). VTG is a specific female lipoprotein that is present in oviparous fish. VTG (as well as VLDL) is secreted by the liver in response to estrogen stimulation; these lipoproteins play a central role in gonadal development (30,31). HDL is generally the main lipoprotein in fish (5,32,33), although not always. For instance, in the Japanese eel (*Anguilla japonica*), a species that is known to accumulate considerably more lipid in its muscle than in the liver, VLDL was identified as the

main plasma lipoprotein (31). As a general trend, plasma VLDL levels in fish are directly related to their ability to store lipid in the muscle as opposed to the liver. Thus, Ando and Mori (1993) (33) observed that the striped jack (*Caranx delicatissimus*), which has a high level of muscle lipid, had a high level of plasma VLDL, whereas pufferfish (*Takifugu rubripes*), which have high hepatic lipid stores, were noted to have low plasma VLDL levels. Nevertheless, as mentioned, HDL still remained the dominant plasma lipoprotein in these species.

Besides liver and muscle (red and white), lipid can be stored along the intestine and its mesentery. In *Oncorhynchus* species (Pacific salmon and rainbow trout), the stores of lipid in the preceding locations vary widely, especially seasonally. Most of this variation is due to the following factors: (*1*) the species and its size and sex; (*2*) the level of food (digestible energy) intake; (*3*) the proportions of total available dietary energy originating from protein and lipid; (*4*) the smoltification and reproductive status of the fish; (*5*) water temperature; (*6*) salinity; (*7*) the level of physical activity; (*8*) the extent of hepatic fatty acid synthesis; or (*9*) a combination of these factors (25).

LIPID AND FATTY ACID REQUIREMENTS

The known dietary lipid and fatty acid requirements for most species of fish of commercial importance are provided in Table 1. In regard to the needs of finfish for dietary lipid, it first should be stressed that these requirements were estimated in general, by using optimal dietary concentrations and sources of the other energy-yielding nutrients (protein and carbohydrate) and lipid sources of high digestibility ($\geq 90\%$).

The information presented in Table 1 reveals that there are wide differences in dietary lipid requirements within and between species. Salmonids, for example, often have high requirements for dietary lipid (usually ≥ 150 g/kg diet) relative to most fresh water non-salmonid species and many marine species, to spare dietary protein for growth, to enhance the efficiency of energy retention, and to meet the required dietary amounts of digestible energy. Lipid is the preferred dietary non-protein energy source in salmonids, because of their limited ability to utilize digestible carbohydrate as an energy source. This bias likely stems from the fact that salmonids in the wild derive most of their energy needs from the high levels of protein and lipid in their prey (25). Indeed, the needs of wild salmonids for glucose are met largely through the process of gluconeogenesis, which uses the glucogenic amino acids derived from the digestion of dietary protein or tissue proteolysis (e.g., alanine, serine, and glycine) plus lactate and glycerol as the substrates. Salmonids also have other metabolic deficiencies that restrict the utilization of high dietary levels of digestible carbohydrate [reviewed by (25)], and it is generally recommended that the dietary level of digestible carbohydrate should not exceed 150 g/kg and should, in some cases, be even lower. Other finfish species, such as channel catfish (*Ictalurus punctatus*), common carp (*C. carpio*), and tilapia (*Tilapia zillii* and *Oreochromis niloticus*), have greater ability than

do salmonids to utilize digestible carbohydrate as a non-protein energy source (34–36); accordingly, they place less emphasis on digestible lipid to meet their non-protein energy demands.

The data in Table 1 also suggest that the dietary lipid needs of finfish may vary in relation to the stage of life history. This effect is clearly evident in the Atlantic salmon (*S. salar*), where it has been found that very high-energy (~ 330 g lipid/kg) diets support maximum performance (growth and feed efficiency) of post-juvenile salmon (> 200 g) in sea water, whereas the dietary lipid needs of the juvenile salmon in fresh water are lower (240 g/kg).

The dietary essential fatty acid needs of finfish shown in Table 1 largely reflect the lipid compositions of their respective natural prey. *Oncorhynchus* species in fresh water, for example, ingest prey that contain substantial amounts of *n*-3 and *n*-6 fatty acids, mostly in the form of the parent acids and highly unsaturated members of each series (i.e., AA, EPA, and DHA, with EPA often greater than DHA). The levels of *n*-3 series fatty acids in the freshwater prey items always exceed the levels of the *n*-6 fatty acids. In the marine prey of these species, the levels of *n*-3 and *n*-6 fatty acids are respectively much higher and lower than those found in the fresh water prey. Also, the fatty acids of the *n*-3 series are largely represented by EPA and DHA, and frequently the level of DHA is equivalent to or greater than that of EPA (25). Accordingly, the essential fatty acid needs of salmonids in freshwater are mostly satisfied by 18:3*n*-3 alone, and in one instance (chum salmon, *Oncorhynchus keta*), by a combination of 18:3*n*-3 and 18:2*n*-6 or by *n*-3 HUFAs alone (present at $\geq 10\%$ of the dietary lipid level). All of the species in freshwater appear to have good ability to convert 18:3*n*-3 to *n*-3 HUFAs, and, depending upon the speed of the bioconversion in each species, *n*-3 HUFAs may have greater essential fatty acid activity than 18:3*n*-3 (e.g., in rainbow trout) or equivalent essential fatty acid activity (e.g., in coho salmon, *Oncorhynchus kisutch*). The essential fatty acid needs of *Oncorhynchus* species in sea water have been studied only in chum salmon, and they did not differ from those established for this species in fresh water (i.e., 10% of the dietary lipid level as *n*-3 HUFAs). It is assumed that this similarity is also the case for the essential fatty acid requirement of the other *Oncorhynchus* species in the marine environment.

The natural diet of nonsalmonid freshwater fish (e.g., carps, tilapias, and eels) is comprised of terrestrial and aquatic plants and insects. Consequently, these species in the wild, like the anadromous salmon described above, consume considerable amounts of 18:3*n*-3 and 18:2*n*-6 and lower levels of 22:6*n*-3. In response, these species, like the salmonids, generally convert 18:3*n*-3 and 18:2*n*-6 readily to 22:6*n*-3 and 20:4*n*-6, respectively (37). Hence, the essential fatty acid needs of the freshwater species are generally satisfied by 18:3*n*-3 or 18:2*n*-6 alone or in combination. In some instances, however, the requirements are satisfied by a combination of 18:2*n*-6 and *n*-3 HUFAs, or by 20:4*n*-6 alone, or by *n*-3 HUFAs alone (Table 1).

Many marine species eat fish in the wild; others ingest zooplankton, and a small number consume unicellular

Table 1. Recommended Dietary Levels (g/kg dry weight basis and percentage of dietary lipid where established) of Lipid and Fatty Acids for Maximum Growth and Feed Efficiency, as well as for Reproductive Performance, in Finfish Species*

Species/ Life History Stage	Lipid (g/kg)	Fatty Acid 18:3n-3 (g/kg)	18:3n-3 (%)	18:2n-6 (g/kg)	18:2n-6 (%)	n-3 HUFAs (g/kg)	n-3 HUFAs (%)	20:4n-6 (g/kg)	Source

*It is assumed that the dietary levels and sources of the other energy-yielding nutrients, viz., protein and carbohydrate, are optimal and that the digestibility of lipid is ≥90%. In many studies, "n-3 HUFAs" refers to 20:5n-3 (EPA) and 22:6n-3 (DHA); in others, this term also includes small amounts of 20:4n-3 and 22:5n-3, and sometimes 20:3n-3.

[a]The rainbow trout requires 20% of the dietary lipid content as C18:3n-3 or 10% as n-3 HUFAs. This provision appears to satisfy all needs for growth and reproduction, although there may be a small need for 20:4n-6 for optimal reproductive performance.

[b]Required.

[c]Maturing coho salmon in freshwater need ≥10 g of n-3 fatty acids/kg diet for optimal reproductive performance. It is unknown whether there is a small requirement for 20:4n-6.

[d]O. keta require either 1% 18:3n-3 and 1% 18:2n-6 or 10% of dietary lipid as n-3 HUFAs.

[e]O. masou need 1% 18:3n-3 or 0.5% n-3 HUFAs in their diet.

[f]I. punctatus require 1.0–2.0% 18:3n-3 or 0.5–0.75% n-3 HUFAs in their diet.

[g]C. idella require 1.0% 18:n-3 and 1.0% 18:2n-6 or 1.0% 18:2n-6 and 0.5% n-3 HUFAs in their diet.

[h]T. zillii need 1.0% of 18:2n-6 or 1.0% 20:4n-6 in the diet.

[i]P. altivelis require 1.0% 18:3n-3 or 1.0% 20:5n-3 in the diet.

[j]P. dentex require 1.7% n-3 HUFAs or 1.7% 22:6n-3 in their diet. (DHA has higher essential fatty acid activity than does EPA).

[k]The ratio of EPA to DHA in the dietary lipids was 2:1.

[l]The ratio of EPA to DHA in the dietary (rotifer) lipids was 0.77 or the ratio of DHA to EPA was 1.3.

[m]This dietary level is recommended for optimum egg quality. The ratio of DHA to EPA in the dietary lipids was 2.8.

[n]This dietary level is recommended for highest fecundity, hatching, and larval survival. The ratio of DHA to EPA in dietary lipids was 0.66.

[o]Deduced requirement for DHA and 20:4n-6, considering the results of this study in relation to those of previous ones on turbot.

[p]C. chanos required 1% 18:3n-3 and 0.5% EPA + 0.5% DHA in their diet.

[q]The ratio of DHA to EPA should exceed 2.5.

[r]S. schlegeli needs about 1% of EPA and/or DHA in the diet. DHA has higher essential fatty acid activity than does EPA, and the optimum dietary ratio of EPA to DHA is less than 1.

algae. In all cases, they consume large amounts of EPA and DHA and little 18:3n-3 in their natural diets (37). Consequently, these species have little or no requirement to biotransform 18:3n-3 to EPA, and they therefore have little or no Δ5 fatty acid desaturase activity. Hence, there is insufficient conversion of EPA to DHA to meet the requirements of these species for growth. In the diet, then, DHA must be supplied preformed (37). The dietary essential fatty acid needs of the marine species shown in Table 1 support the preceding scenario, and they clearly show that all species require n-3 HUFAs and generally optimal ratios of DHA and EPA in their diet for maximum growth and for optimal feed utilization. In some species, DHA has been shown to have higher essential fatty acid activity than EPA. Also, in the turbot (*Scophthalmus quinqueradiata*), it is noteworthy that a small requirement for AA has been found, in addition to that for DHA, for optimal performance.

The quantitative essential fatty acid requirements of finfish species undergoing gonadal maturation are not extensive. In salmonids, Hardy et al. (1989) (38) reported that maturing coho salmon in fresh water require ≥10 g of n-3 fatty acids/kg diet for optimal reproductive performance. In nonsalmonids, Harel et al. (1994) (39)

reported that gilthead seabream (*S. aurata*) require ≥4.2 g of n-3 HUFAs/kg diet (ratio of DHA to EPA in dietary lipids, 2.8) for optimum egg quality. Further, Fernández-Palacios et al. (1995) (40) found that 16 g of n-3 HUFAs/kg of diet (ratio of DHA to EPA in the dietary lipids, 0.66) was necessary for highest fecundity, hatching, and larval survival of gilthead seabream.

As a general observation, larval marine fish species require high dietary levels of n-3 HUFAs [by most estimates, between 9 and 39 g/kg dry diet (41)], as well as optimal dietary ratios between DHA, EPA, and AA, for maximum growth and survival (42,43).

DIETARY LIPID COMPOSITION AND FISH REPRODUCTION

In fish, environmental signals mainly trigger oocyte growth; these signals are converted from electrical to chemical in the hypothalamus. Gonadotrophin releasing hormone is then released from the hypothalamus, and this stimulates the secretion of gonadotrophins (GtH 1 and GtH 11) from the anterior pituitary. GtH 1 stimulates the oocytes to produce estrogen (estradiol-17β), which subsequently promotes the production of yolk-protein

precursors and egg-shell protein by the liver. GtH 1 also stimulates uptake of VTG into trout oocytes. GtH 11 functions later in oocyte development and acts in the follicle cells to promote the synthesis of progesterones, which, in turn, control termination of oocyte growth and ovulation of the egg (44).

Egg lipids are derived from nonpolar lipid stores in the body and from dietary (exogenous) sources. The latter are particularly important in species such as gilthead sea bream, which continue to eat during sexual maturation and throughout the spawning season. Triacylglycerols from body lipid stores (e.g., visceral and muscle lipid in rainbow trout and Pacific salmon), together with free amino acids originating from muscle-protein breakdown, are carried in the blood to the liver. Here, the free fatty acids are incorporated mainly into phospholipids that are rich in n-3 HUFAs, especially DHA, and to a lesser degree into triacylglycerols. The amino acids are used for hepatic synthesis of egg-specific apoproteins that are then combined with the newly synthesized lipids to form VTG. VTG is then transported to the developing oocytes via the blood. Thereafter, VTG is sequestered by the oocytes by a process of pinocytosis, and then it is cloven in the egg to generate the egg-yolk proteins, namely, lipovitellin and phosvitin. Most of the n-3 HUFA-rich phospholipids are located in the former protein (45). Eggs with short and long incubation times accumulate low and high levels of triacylglycerols, respectively, and both phospholipids and triacylglycerols are catabolized to provide metabolic energy during egg development and early larval rearing. The principle role of the n-3 HUFAs, particularly DHA, is in the elaboration of cellular membranes of neural tissues (e.g., brain and eyes). Low levels of AA are also present in (primarily) PI, and it is believed that this fatty acid has a specific role in eicosanoid formation (45).

Most studies that have assessed the influence of dietary lipid composition on the reproductive performance of finfish have found dramatic effects when marine species such as red (*Pagrus major*) and gilthead sea bream have been employed as the test fish (Table 2). These species rely extensively on exogenous lipid for oocyte development. Consequently, the lipid composition of the developing oocytes can be changed rapidly to reflect the dietary lipid composition (within 15 days in gilthead sea bream). Further, there can be an attendant decline in egg viability within 10 days in gilthead sea bream ingesting a diet deficient in n-3 HUFAs (39). In another study on this species, Fernández-Palacios et al. (1995) (40) reported improved spawning quality (fecundity, hatching, and larval quality) after only 3 weeks of feeding a diet containing an optimal concentration of n-3 HUFAs. Marine species generally require high dietary levels of n-3 HUFAs, especially DHA, relative to salmonids; consequently, suboptimal dietary levels and suboptimal ratios of these fatty acids to one another and to AA (46); (Table 2) appear to affect their reproductive success negatively to a greater extent than is noted in most studies on salmonids (Table 2). If all of the studies on marine species shown in Table 2 are viewed collectively, it is apparent that dietary deficiencies or excesses of n-3 HUFAs or suboptimal ratios of EPA and DHA themselves or with AA

can markedly influence almost all aspects of reproductive performance. By contrast, the reproductive performance of salmonids appears to be affected adversely mainly in cases of extreme dietary deficiencies of n-3 fatty acids over a 3- to 12-month period. Moreover, there is little indication that wide variations in dietary levels of n-6 fatty acids (such as $18:2n$-6) depress their reproductive performance, provided that their dietary needs for n-3 fatty acids are met (Table 2). Other consequences of feeding diets to broodstock fish that contain inappropriate lipid composition may include reduced sperm quality (47,48), depressed levels of serum VTG (49), decreased testicular steroidogenesis and development (50), and suboptimal levels of 2-series and 3-series prostaglandins (derived from AA and EPA, respectively) (40,51).

INFLUENCE OF DIETARY LIPID COMPOSITION ON FISH HEALTH

As mentioned previously, our intent here is to restrict our focus concerning the effects of dietary lipid composition on fish health to those effects concerned with cardiovascular function and disease resistance (immunocompetence). There is an extensive literature in the latter area, and only some of the highlights will be mentioned below. The purpose is to provide the reader with some appreciation of the possible consequences of using lipids other than of marine origin in fish diets.

In humans and other animals, high dietary intake of lipid (especially saturated fatty acids) and cholesterol, coupled with a diet rich in n-6 fatty acids (relative to the proportion of n-3 fatty acids), is known to increase the likelihood of atherosclerosis, heart attacks, strokes, and various inflammatory conditions. The etiology of atherosclerosis is believed to result from overproduction of eicosanoid compounds derived from AA via the cyclooxygenase and lipoxygenase enzymes. For instance, thromboxane A_2, which is produced from the blood platelet membranes, is a potent blood platelet aggregator and constrictor, and 4-series leukotrienes are proinflammatory. By contrast, depressed levels of unesterified AA in the tissues and elevation of EPA lead to the production of thromboxane A_3 and prostacyclin I_3 which reduce blood platelet aggregation and enhance vasodilation. Also, 5-series leukotrienes from EPA are antiinflammatory, and they attenuate the response of neutrophils and monocytes to inflammatory stimuli (25).

Studies on post-smolt Atlantic salmon suggest that metabolic and cardiovascular events similar to those described above for mammals occur in fish. Thus, Bell et al. (1991) (13) and Bell et al. (1993) (14) have shown that Atlantic salmon fed diets containing excessive quantities of n-6 fatty acids (but still adequate in dietary levels of n-3 fatty acids for growth) develop severe cardiomyopathy. This effect caused extensive thinning of the ventricular muscle and active necrosis in the atrium and ventricle. These pathological responses, in turn, were accompanied by elevation of AA in tissue phospholipids at the expense of EPA and by increases of the levels of 2-prostanoids (prostaglandins and thromboxane B_2, a stable metabolite of thromboxane A_2 derived from AA).

Table 2. Influence of Dietary Fatty Acid Composition on the Reproductive Performance of Finfish*

Species	Duration	Test Lipid or Fatty Acid Source	Dietary Level (g/kg)				Reproductive Performance					Source

*The symbols 0, +, and − signify respectively, that the dietary treatment either had no effect (normal response), or enhanced or depressed the reproductive performance parameter.

[a]Refers to the sum of 20:5n-3 and 22:6n-3.

[b]Total numbers of eggs produced, relative to body weight.

[c]Egg volume, weight, or diameter.

[d]Percentages of fertilized eggs, eyed eggs, or buoyant eggs (sea bream) or egg development.

[e]Percentages of total eggs, eyed eggs, or buoyant (viable) eggs (sea bream and sea bass) that hatched into viable fry or larvae.

[f]Fry or larval size, growth, survival, and/or morphology.

[g]Essential-fatty-acid-sufficient diet.

[h]Essential-fatty-acid-deficient diet.

[i]Diet enriched with 18:2n-6.

[j]Noted when fish at 18°C but not at 8°C.

[k]Noted within 10 days of feeding a diet deficient in n-3 HUFAs and when the egg n-3 HUFA content was <17 mg/g dry weight.

[l]Results examined /kg female. Egg composition and spawning quality were affected by dietary essential fatty acid levels after 3 weeks of feeding.

[m]Diet also rich in 18:1n-9.

[n]Number of buoyant eggs significantly decreased from day 80 onwards. The hatching percentages decreased from day 70 onwards (response not significant). High negative correlations between 18:3n-3, 18:1n-9, and the 18:1n-9/(n-3 HUFA) ratio of polar lipids and the percentages of buoyant eggs were observed.

[o]Optimal levels and ratios of 20:5n-3, 22:6n-3, and 20:4n-6 are required to maximize reproductive performance.

In relation to immunocompetence, fish possess both non-specific and specific defence mechanisms. The specific defence system involves T and B (specific antibodies) lymphocytes; non-specific defence mechanisms include phagocytes or natural killing cells and several humoral components (e.g., lysozymes and complement) that facilitate the activity of phagocytes (52).

The results of three studies, two on catfish (*I. punctatus*) and one on Atlantic salmon (*S. salar*), serve to illustrate the importance of this area to the investigation of alternate lipid sources. In the studies on catfish, which are known to require either 1.0–2.0% 18:3*n*-3 or 0.5–0.75% *n*-3 HUFAs in their diet to meet their requirements for growth (Table 1), Fracalossi and Lovell (1994) (53) and Li et al. (1994) (54) found that excessive dietary levels of *n*-3 fatty acids, either from 18:3*n*-3 (from linseed oil) or from *n*-3 HUFAs (from menhaden oil), increased the mortality of the fish that were challenged with *Edwardsiella ictaluri*. The adverse response was found to be dependent upon the prevailing water temperature, and no differences in circulating antibody titers were observed in the former study. Interestingly, the fish ingesting the diets enriched in *n*-3 exhibited growth equivalent to or better than that of the fish fed the diets based on animal or plant lipid sources. In the study on Atlantic salmon parr, Thompson et al. (1996) (55) observed that salmon fed diets adequate in *n*-3 content, but containing a low ratio of *n*-3 to *n*-6 fatty acids, were less resistant to infection (when challenged with *Aeromonas salmonicida* and *Vibrio anguillarum*) than salmon fed diets with a high ratio of *n*-3 to *n*-6 fatty acids. Further, they found that vaccinated salmon fed the latter diet also exhibited higher numbers of B cells in the kidney and spleen following an *A. salmonicida* challenge.

Hence, there appears to be a need to carefully balance the dietary levels and ratios of *n*-3 and *n*-6 fatty acids in fish diets (specifically EPA, DHA, and AA) to ensure optimal growth and immunological performance, as well as freedom from pathology.

MARINE AND NONMARINE LIPID SOURCES IN FEEDS FOR FINFISH

Lipid Sources

Fish oil is the traditional source of lipid for fish feeds, because it is a rich source of the dietary essential fatty acids needed by fish and is a by-product of fish meal production. However, the challenge of finding environmentally and economically sustainable sources of fish-feed ingredients raises questions about the future suitability and availability of fish oil. As the demand for fish oil increases relative to supply, the price increases, making other lipid sources economically competitive. In addition, there has been a trend toward increasing the percentage of lipid in feeds for some species, such as salmon and trout (Fig. 2), and it is clear that lipid ingredients are a major part of and major expense item in fish feeds. The trend toward an increasing demand for fish oil in a market of static or dwindling supply (Fig. 3) further supports the need to investigate the suitability of
Figure 2. Changes in protein and lipid levels in trout feeds (% of feed).
Figure 3. Predictions of future fish oil needs in aqua feeds versus global fish oil supply.

non-fish sources of lipid ingredients. In general, when the price of fish oil exceeds that of soybean oil, the use of plant oils offers an advantage. Animal fats are favorably priced relative to fish oil most of the time.

While both menhaden oil and herring oil currently are commonly used ingredients, other oils are already being included in feeds for some aquatic species (Fig. 4). Increased attention has been given to studying the nutritional value of other, more sustainable, animal lipid
Figure 4. Use of fish oil in fish feeds (in 1000 mt).

resources and processing by-products, such as rendered fat from hogs (lard), from chickens (yellow grease), and from cattle and sheep (tallow) and the oil that comes with fish silages (38,56–65). Sustainable vegetable sources have also been studied, such as soybean oil, canola oil, soybean lecithin, corn oil, safflower oil, and linseed oil (13,38,59,61,63,64,66–73) (Table 3). Whether each of these oils, or a combination thereof, constitutes a suitable replacement for fish oils depends on whether the feed and lipid ingredients meet the requirements of the fish for essential fatty acids, on the oxidative stability of the lipids, on the extent of breakdown before and after incorporation into feed, on the cost of the ingredient, and on the effect, if any, of the lipid source on the fatty acid composition of the fillet and on the lipid deposition pattern in the whole fish.

Fish health concerns, such as susceptibility to disease, also need to be considered.

Because marine oils are rich sources of the essential fatty acids (EFA) (Fig. 5) and almost all plant oils are not, some marine oil has to be blended with other lipid ingredients and added to the feeds. The fatty acid profiles and the cholesterol and phytosterol concentrations in lipids from plant sources are shown in Table 4, those from animal sources in Table 5. Both animal and plant lipid sources can vary in fatty acid profiles and in the extent of fatty acid hydrolysis and oxidation. Animal sources have effectors such as diet, species, and age; plant sources have variables such as variety, growing location, and harvesting time. Both animal and plant lipid sources can be affected by initial product quality,

by conditions of storage before lipid extraction, and by level of antioxidant present (naturally occurring or added). Also, during feed manufacture, the formulation of the feed, time/temperature treatments, and post-processing storage can significantly affect the fatty acid profile. For a discussion of the main contributors to lipid oxidation and of the effects on fish of feeding oxidized lipid, the reader is referred to the entry by Hardy and Roley on "Lipid Oxidation and Antioxidants" in this book.

The fatty acid profile of fish fillets largely reflects the dietary lipid composition, and that, in turn, is influenced by the fatty acid compositions of the dietary lipid sources. Thus, diet can potentially affect fillet storage quality, with fillets having high levels of highly unsaturated fatty acids being more susceptible to oxidation than those containing increased proportions of monounsaturated fatty acids. The fatty acid profile in the fillet can also affect the sensory properties of the fillet, in both the raw and the cooked

form, and thus can affect consumer acceptability of the food fish product.

Numerous researchers have incorporated alternate lipid sources into fish feeds to determine a variety of outcomes most importantly the following: how well the feed sustained body weight gain; the effects on the fatty acid composition of the carcass, the muscle, the viscera, visceral fat, eggs at spawning, the liver, the heart, the brain, and the retina and on the fatty acid composition of triacylglycerols versus phospholipids; the effects on fillet quality in terms of sensory attributes; the degree of lipid oxidation during refrigerated and/or frozen storage; and the effects of dietary antioxidants. There has been particular interest in identifying lipid ingredients from plant-based sources that are cheaper than fish oils or that may help to extend the shelf life of the food fish product. Because, however, of the reports of lower levels of n-3 HUFAs in cultured fish compared to those in wild fish (74), there has also been interest in discovering the levels of marine oils in fish feeds that can help to enhance the n-3 fatty acid content of the fish fillets (75).

Effects on Growth and Body Composition

The most consistent findings in all of the reports in the literature are (a) that, in general, the various substitution levels of plant or animal-based lipid for fish oil were successful in supporting normal weight gain as long as the dietary levels of essential fatty acids were maintained and (b) that the fatty acid composition of the muscle and of the whole body often nearly reflected the composition of the diet, but usually within limits. Reports on salmonids and on other cold water fishes, such as sturgeon and ayu, have focused on such plant sources as sunflower oil (regular and

Table 6. Percentage of Oleic Acid (C18:1) in Regular Versus in High-Oleic Varieties of Selected Oils

Seed	Regular Seed	High-Oleic Seed
Corn	33	65–80
Peanut	59	75–80

Safflower	13	75–80
Sunflower	24	80–90

high-oleic; Table 6), soybean oil, canola oil, soy lecithin, low- and high-erucic acid, rapeseed oil, linseed oil, and coconut oil (supplemented with specific fatty acids) and on such animal sources as chicken fat, beef tallow, fish silage, beef and swine fat, hide fleshings, and capelin oil (Table 3). The control diets typically have had menhaden oil, herring oil, or sardine oil for comparison. In warmwater fishes, such as catfish, red drum, hybrid striped bass, goldfish, and mackerel, plant lipid sources such as coconut oil, corn oil, canola oil, soybean lecithin, soybean oil, sunflower oil, high-oleic corn oil, and linseed oil and animal sources such as beef tallow, cod liver oil, and lard have been tested (Table 3). The majority of these studies determined the fatty acid composition of the whole body or of muscle after feeding of the different lipid sources for anywhere from 6 weeks to 10 months.

In both coldwater and warmwater species, there have been reports that, although the composition of the flesh usually reflected the composition of the diet, the triacylglycerol fraction was more responsive than the phospholipid fraction to the lipid composition of the diet. Increases in the n-3 HUFAS tended to be in

the phospholipid fraction, and the accumulations of *n*-3 HUFAS and saturated lipids were limited.

Mugrditchian et al. (1981) (61) fed juvenile chinook salmon feeds containing salmon oil, linseed oil, and beef suet in diets where EFA needs were met, and they reported no significant differences in weight after 16 weeks. The fish maintained a constant level of saturated fatty acids regardless of the amount in the diet. The fatty acid composition of nonpolar lipids generally reflected the composition of the diets, whereas the polar lipids selected for the more unsaturated fatty acids of the *n*-3 series. Although Mugrditchian et al. (1981) (61) reported that dietary 18:3*n*-3 was not deposited in body lipids as such, but instead was apparently converted to 22:6*n*-3, significant activity of this pathway could not be confirmed by Polvi et al. (1992) (70) in Atlantic salmon fed diets including canola oil.

In a study with sturgeon, Xu et al. (1996) (64) fed diets containing 15% of either canola oil, corn oil, cod liver oil, lard, linseed oil, soybean oil, or safflower oil and measured the phospholipids and triacylglycerols of muscle, liver, and brain. Like other researchers, they found that tissue triacylglycerol fatty acid composition ranged widely, in step with the dietary lipid composition, while phospholipid changes were more conservative. In particular, the brain phospholipid fatty acid composition was less responsive (more nearly conserved) than that in muscle and liver. Considerable amounts of *n*-6 and *n*-3 long chain PUFAS were found in the triacylglycerol and phospholipid fractions in fish fed all diets, showing that white sturgeon can desaturate and elongate linoleic and linolenic acids. The highest EPA and DHA levels in muscle triacylglycerol were found in fish fed the diet with fish oil rather than in those fed the diet with linseed oil. Therefore, it was concluded that the best dietary enhancement is with preformed EPA and DHA.

Hardy et al. (1989) (38) fed diets to coho salmon in which approximately 40% of the dietary lipid source was either herring oil, soybean oil, or beef tallow (or combinations thereof). Fatty acid profiles of the fish muscle and developing eggs reflected dietary fatty acid profiles after two months of feeding and at spawning for monoenoic, dienoic and *n*-3 fatty acids. Saturated fatty acid profiles of the muscle and the eggs did not reflect dietary levels and were similar among groups. Again, among dietary groups, the ranges in the fatty acid categories were larger in the nonpolar lipid fraction than in the polar lipid fraction. They observed no differences in fecundity, egg viability, or egg size among the dietary treatment groups.

When Greene and Selivonchick (1990) (58) fed diets to rainbow trout containing either salmon oil, soybean oil, linseed oil, chicken fat, pork lard, or beef tallow, they found that the dietary treatments supported similar growth rates and feed conversions during a 20-week trial. Although some of the diets provided 18:3*n*-3 that could be desaturated and elongated to EPA and DHA, there appeared to be a physiologically optimum level of long-chain fatty acids maintained in the muscle.

Dosanjh et al. (1984) (76) reported that coho salmon fed diets with either canola oil, pork lard, or herring oil had body lipids that generally reflected that of the diet, except that the levels of saturated and unsaturated fatty acids were less variable in the body lipids than in the dietary lipids. Dosanjh et al. (1988) (77) confirmed the findings of this study, using chinook salmon, and observed that, although body lipid generally reflected that of the diet, the percentage of DHA was higher in the body than in the diet. They also reported that the range for percentages of saturated fatty acids in body lipids was narrower (15.7–22.8%) than for the dietary lipids (12.5–29.5%).

Craig and Gatlin (1995) (57) reported that red drum (*Sciaenops ocellatus*) could not efficiently use tricaprylin (caprylic acid, 8:0), a medium-chain triacylglycerol, as an energy source and that consequently there were significantly lower weight gains, lower *n*-3, and greater *n*-6 fatty acid levels in the nonpolar lipid fraction of muscle tissue than in fish fed no tricaprylin. However, the dietary inclusion of coconut oil and beef tallow resulted in normal weight gain as long as the requirements for essential fatty acids were provided.

Alternate lipid ingredients have also been used to help determine the essential fatty acid requirements of particular species. Mukhopadhyay et al. (1998) (68) suggested the essential nature of both *n*-3 and *n*-6 in fingerling and fry catfish using cod liver oil, sunflower oil, a mixture of these, and hydrogenated vegetable oil. There were significant differences in weight gain, feed efficiency, and tissue fatty acid profiles, and the deposition of fatty acids in the carcass very closely followed the fatty acid composition of the diet. They concluded that a combination of *n*-3 and *n*-6 fatty acids resulted in best growth, best feed efficiency, and increased deposition of HUFAS.

After feeding Arctic charr diets with 1% coconut oil plus different PUFAs, Olsen et al. (1991) (78) suggested that charr require *n*-3 fatty acids, and they noted that these were used in preference to *n*-6 fatty acids for desaturation, elongation, and incorporation into phospholipid. They also reported that muscle phospholipids were less influenced by diet than those in the liver, where phopholipid PUFAS were significantly influenced by diet composition.

Effects of Soy Lecithin

The inclusion of soy lecithin in the feed has been reported to improve weight gain and feed efficiency of some species of warmwater and coldwater fishes. Lochmann and Brown (1997) (67) reported that, in goldfish, weight gain and feed-efficiency ratio were significantly higher with soybean lecithin than without. They hypothesized that lecithin provided myoinositol or phophatidylcholine to support rapid membrane proliferation, increased absorption of dietary lipid, and enhanced lipid transport.

Craig and Gatlin (1997) (79), using red drum, also reported that lecithin increased weight gain and feed efficiency and also increased liver lipid concentration. Choline alone increased muscle lipid as well as intraperitoneal fat content and decreased liver lipid concentrations.

Poston (1990a) (80) reported that rainbow trout needed at least 4% soy lecithin, either with or without choline, for maximum growth. With Atlantic salmon, Poston (1990b) (81) examined the effect of the initial size of the

fish on response to food-grade soy lecithin and to feed-grade lecithin (corn–soy mix). He reported that dietary lecithin enhanced survival when the fish were small (0.18 and 1.0 g) but not large (7.5 g).

Effects on Food Fish Product Quality

In some studies, the inclusion of alternate lipid sources has been reported to result in significant differences in sensory analysis tests of the fillets. The usual difference was that feeding a non-fish-oil ingredient resulted in a less fishy aroma or flavor than was found in fillets from fish fed fish oil.

Fowler et al. (1994) (82) reported that hybrid striped bass fed diets supplemented with EPA and DHA and containing at least 0.5% EPA and 0.24% DHA in the fillets had a more fishy flavor in the cooked fillets compared to that in the fillets from unsupplemented controls. Skonberg et al. (1993) (71) reported that substituting high-oleic sunflower oil for herring oil in feeds for rainbow trout and coho salmon for 6–8 weeks resulted in significant differences in triangle tests, with the sunflower-oil fillets having less fishy aroma than the herring-oil fillets. Using Atlantic salmon, Thomassen and Røsjø (1989) (73) replaced up to 68% of the capelin oil in feeds with either soybean oil, low-erucic acid rapeseed oil (LERO), or high-erucic acid rapeseed oil (HERO). Although the heart and muscle lipids and the n-3 to n-6 ratio were affected, there was no difference in growth or mortality. Fillets from fish given the soybean treatment were reported to have less salmon taste than those from fish receiving the LERO treatment. Also, the fillets from fish given the rapeseed oil treatments had less salmon odor than those from the capelin-oil control fish, and, by sensory and instrumental analyses, the HERO fillets were less red than other groups.

Waagbø et al. (1993) (83) assessed the influence of varying dietary n-3 PUFA content (low, medium, or high PUFA content was achieved by blending soybean oil, capelin oil, and sardine oil), as well as that of two supplemental levels of vitamin E (0 and 300 mg alpha-tocopherol/kg), on the flesh quality of Atlantic salmon. They found that the total lipid fatty acid composition and the vitamin E content in the fillets reflected the diet composition; however, the vitamin E content of fillets did not influence the fatty acid composition. Sensory analysis was performed on cooked fillets from fresh, 4-day frozen, 5-week frozen ($-18\,°C$), and traditionally smoked never-frozen fish. Rancid flavor, fattiness, juiciness, and taste intensity were significantly higher in fish raised on the diet with high n-3 PUFA content and on the low vitamin E diets, than in the controls.

There have also been studies indicating no significant differences in sensory qualities when alternate lipid ingredients have been given compared to fish oil controls: Boggio et al. (1985) (56), for example, when rainbow trout were fed diets with swine fat; Cowey et al. (1979) (84), when rainbow trout were fed diets with rendered hide fleshings that contained saturated fat; Guillou et al. (1995) (66), when brook trout were fed diets with soya or canola oils; Hardy et al. (1987) (59), when Atlantic salmon were fed diets containing soybean oil or tallow; Koshio et al. (1994) (85), when Atlantic salmon received

diets either with canola oil or with herring oil or with these same oils submitted to oxidation treatments; Morris et al. (1995) (86), when catfish were fed diets supplemented with menhaden oil; and Sugiura and Lovell (1996) (87), when catfish were fed diets with high-oleic corn oil. The possible reasons for the discrepant sensory-analysis results are many, viz., differences in the lipid concentrations and/or protein/lipid ratios in the feeds, dissimilar diet formulations and lipid quality, and differences either in the types of sensory tests performed or the methods used to prepare the samples.

Effects of Dietary Antioxidants on Storage Quality of Cultured Fish

Gatlin et al. (1992) (88) examined the storage quality and body composition of catfish fed natural and synthetic antioxidants (AO) in the diet. They used a semipurified casein/gelatin diet, with either 60 or 240 mg dl-alpha-tocopherol and either with no synthetic AO, with ethoxyquin (150 mg/kg), with BHT (10 mg/kg), with BHA (10 mg/kg), or with Endox (125 mg/kg). None of the AO significantly affected growth, feed efficiency, proximate composition of whole body and fillets, or tissue levels of alpha-tocopherol. In forced-oxidation tests, however, fillets from fish ingesting the higher level of alpha-tocopherol had lower thiobarbituric acid reacting substances (one index of lipid oxidation), but the synthetic AO's did not reduce oxidation.

Ackman et al. (1997) (89) reported that gamma-tocopherol may potentially replace alpha-tocopherol to reduce autooxidation of fillets during storage of Atlantic salmon. Atlantic salmon have a requirement for dietary EPA and DHA for subcellular membrane lipids; the fish also deposits them in the muscle depot fats. Ackman et al. (1997) (89) showed that if both alpha- and gamma-tocopherol were fed, alpha-tocopherol was found in phospholipid-rich organ tissues and gamma-tocopherol was found in the lipid stores of the muscle. There may thus be a potential to feed gamma-tocopherol to reduce autooxidation of fillets during storage, so one approach would be to use natural mixtures of alpha- and gamma-tocopherol as a low-cost alternative to 100% alpha-tocopherol. They hypothesized that highly oxidized herring or canola oil was not toxic to salmonids as long as alpha-tocopherol was present, although feed intake may be reduced. Others have shown that flavors of farmed Atlantic salmon were not altered by different tocopherol types, by dietary fats and oil, or by the oxidation status of those fats/oils.

Concluding Remarks

Considerable research is still required to establish optimal dietary concentrations of n-3 and n-6 fatty acids in cultured finfish species and, in particular, the desirable levels and ratios of EPA, DHA, and AA for their growth, health, and reproductive viability. Research should concurrently involve assessments of how much the dietary treatments influence the types and levels of eicosanoid compounds elaborated from AA, EPA, DHA, and $20:3n$-6 and whether these in turn adversely affect fish physiology, biochemistry, endocrine status, and histopathology. This

information is required to facilitate establishment of acceptable dietary levels of various blends of alternate animal and plant lipid sources with marine lipids at different stages of the life history.

The global supply of marine lipids will be insufficient to meet the demands for aquafeeds at some point in the next 15 to 20 years, unless suitable alternate lipid sources are identified and/or developed. Additional studies are also required to assess whether diets containing various mixtures of alternate lipid sources with marine lipids negatively affect the sensory attributes and chemical composition of the flesh from market-size fish.

College Station, Texas

OUTLINE

Conventional Sealed Containers

Humid Containers

Tanks

Farm Distribution and Transport

Live Transport of Particular Animal Groups

Bibliography

Live transport is a method that is essential to all of the animal industries. The great diversity of aquatic livestock originates from aquacultural and natural systems. In the realm of international traffic, the total number of aquatic livestock probably exceeds that of terrestrial livestock. The size of aquatic animals makes their live transport practical. The volume of a chicken egg, for example, is roughly equivalent to that of 7,000 trout eggs or to the volume of a shipment of water containing 6,000 crustacean nauplii. Although fishes are carried alive in different stages, most fry and fingerling stages and many adults

are smaller than the smallest stage at which terrestrial vertebrates are stocked.

Hatcheries ship eggs and larvae long distances to other hatcheries and nurseries, where they will grow to a stockable size. International commerce in juveniles for the purpose of stocking production units is feasible because a multitude of individuals may travel inside packages that weigh little have a small and volume. Local and regional commerce of many cultured fishes typically involves the sale of fingerlings.

Live transport serves other purposes as well. Ornamental, bait, and forage products have market value only as live animals. The sale of certain live food species brings more revenue than does the sale of a freshly killed or refrigerated product of the same species. Indeed, some processors require that the product arrive alive at their plant.

CONVENTIONAL SEALED CONTAINERS

Boxes of sizes suitable for hand loading are useful means of transporting the eggs and young of most species and adults of smaller species. The method is also sometimes convenient for distributing small lots of moderately sized adults intended for use as broodstock or for sale in specialty markets.

The typical unit consists of a corrugated shipping carton enclosing walls of Styrofoam™ insulation and sealable plastic bags. The Styrofoam may itself be a molded box for use within shipping cartons or, if it is of a more durable design, as the sole container. More sophisticated designs are commercially available, but the conventional box that contains sealed bags remains the norm for delivering small swimming animals by air.

Bags may be built to fit the dimensions of their container. Those with square bottoms prevent folds that could entrap smaller animals from forming. Bags are one to four mils in thickness and are often doubled; the thicker ones are the more widely used. Shippers of ornamentals pack several smaller bags within a box, each containing a preestablished count of a particular species. US wholesalers of minnows for bait commonly use a cylindrical bag of 46×81 cm (18×32 inches) in size.

Bags typically contain 25% water, but packers sometimes use up to 40%. A shallower level of water that barely covers the fish can be successful in some cases. The temperature of the bag water is adjusted prior to loading. A rubber band or other binding device seals the bag. Oxygen gas overlaying the water is preferable to air, but air is sufficient in certain applications. Frozen gel packets placed inside the box, but out of contact with the water, control the temperature while a package is en route. Heat packs prevent tropical species from over chilling in packages traveling to or through cold climates.

Lower water temperatures slow many biological processes and reduce the animals' release of waste in confinement. Lower temperatures also cause more oxygen to become saturated in the water and reduce the animals' need for oxygen. Consequently, many shippers pack boxes in a way that maintains the temperature near the lowest suitable temperature for a species.

The addition of pure oxygen to sealed bags supersaturates the transport water.

Other than oxygen, additives for bag transport are mostly meant to arrest microbial reproduction and give the animals that are being shipped an osmoregulatory advantage. At levels that are not toxic to the animals, antibacterials give only a modest benefit: Their effectiveness is soon overcome by resistant bacteria that flourish in the presence of the rising levels of organic compounds. The addition of calcium chloride or sodium chloride to the water medium usually provides an osmoregulatory benefit to freshwater species. The more equal internal and external osmotic states reduce the physiological adjustments that must be made to control waste and salt exchanges. In sufficient concentrations the sodium chloride has the additional advantage of blocking the reproduction of ectoparasitic protozoans. Marine- or brackish-water species benefit from salinity adjustments when the water at the destination differs sharply from that at the source. The adjustment is usually downward and is accomplished by the addition of freshwater.

Waste from animals accumulates in sealed containers. By not feeding the animals for an appropriate period prior to transport, shippers give them time to discharge solid waste that would otherwise foul the transport medium. Pond fishes of fingerling size are normally brought to holding facilities immediately after harvest. A further period without feeding enhances the survivability of the fishes. In the meantime, other operational chores, such as grading for size, culling, sorting for sale, and determining weights or volumes are performed. The outcome of the fasting process is better for species with shorter intestines than for species with longer ones.

During transport, the bag water retains considerable quantities of carbon dioxide, whose otherwise toxic effect is greatly offset by the ample quantity of dissolved oxygen. The accumulation of carbon dioxide causes an increased concentration of hydrogen ions and, hence, a lower pH. Accordingly, freshwater aquaculturists occasionally add buffering compounds to bag water to help stabilize the pH. Supplying the bags with relatively hard groundwater, however, is usually adequate. Still, species that are particularly intolerant of low pH may especially benefit from one of the widely available buffering compounds. Of course, the normal lowering of pH by dissolved carbon dioxide abates some of the harmful effect of increasing nitrogen waste by shifting the ionic state of ammonia (unionized) to a less harmful ammonium (ionized).

Ammonia is the most harmful waste. As the primary nitrogenous waste for marine and freshwater species, its accumulation proceeds almost unchecked in bag water. Controlling the travel temperature and selecting loading rates greatly determine the amount of ammonia released. In freshwater transport, packets of ion exchange media may be helpful for binding ammoniated nitrogen, but the presence of sodium chloride, so often a packaging additive, can interfere with the binding and diminish its benefit.

The conversion of ammonium nitrogen into nitrite by bacteria is usually not a problem, due to both efforts to keep ammonia production and bacterial development in check and the insufficient time for meaningful conversion

to occur. Chloride competitively inhibits nitrite uptake by fishes. Enough chloride is present in transport water that is suitable for marine species and in freshwater that contains additional salt to negate nitrite effects. Some further benefit may result from the bacterial seeding of saline water, the intention of which is to convert accumulations of ammonia to nitrite, any harm from which is offset by the presence of chloride ions.

Bag water with an overlay of oxygen requires no special aeration prior to loading if the bag is closed immediately after fish are added. Depending on the circumstances, adjusting the temperature of the water or the fish prior to loading may be helpful. Within a known safe range, the sudden introduction of most animals into cooler water calms them and reduces injury due to handling.

Sharp points on certain animals' bodies, such as the rostra of large shrimps or the spines of some fishes, may puncture a bag. For protection, a hard, lightweight canister may be used to contain spiny fishes within their bags. Also, stuffing of suitable thickness may be utilized between the inner and outer bags. Crustaceans may be shipped within physical constraints that can prevent punctures, as well as injury from aggressive movements. In some cases, inserting the animals' sharp points into protective tubes or other coverings also helps to avoid damage.

Knowledge of the behavioral and physiological characteristics of transport animals is useful in predicting their response during loading and delivery. For example, the size of the animals during early growth may determine the rate of accumulation of nitrogenous waste in their containers (Table 1). If the shipper knows the characteristics and tolerances of a particular species and its developmental stages, he or she may anticipate the transport conditions and the length of time the animals will be in transport and, on the basis of these parameters, choose an appropriate loading rate. Predicting carbon dioxide and total ammonia concentrations may also help (Table 2). A conventional application of this knowledge according to the type of species shipped, provides a good starting point for selecting a loading rate (Table 3).

Boxes containing sealed packages usually move to their destinations in airplanes and a variety of land vehicles. If the shipment is by air, certain standards may be set by commercial carriers, particularly with respect to international shipments. Once packages (bags) are sealed and boxes closed, delivery may be directly to the airport. There the bags and boxes may sit in storerooms or outside on concrete until they are loaded into special airfreight containers.

Table 1. Production of Total Ammonia, in mg/L (ppm), by Fingerling Channel Catfish of Three Sizes at 21 °C (70 °F) in 24 Hours[a]

g/L of Fish	Group I (13–27 mm, mean 21 mm)	Group II (24–43 mm, mean 32.5 mm)	Group III (62–107 mm, mean 88.6 mm)
3.0	3.16 (2.63–3.50)	2.63 (2.61–2.66)	1.02 (0.91–1.11)

[a]From (1).

Table 2. Water Chemistry of Sealed Transport Bags (with water volume one-third of total volume) Maintained at 17 °C (63 °F) for 24 Hours and Containing Various Weights of 7.6-cm (3-in.) Channel Catfish[a]

Amounts of Fish (g/L)	Total Ammoniated Nitrogen (mg/L)	Carbon Dioxide (mg/L)
25	5	5
75	14	30
150	21	55

[a]From (1).

Table 3. Capacity (normal) Load, in Grams per Liter of Water or Number of Animals per Liter of Water, for Conventional Bag-Oxygen Method of Transporting Aquatic Animals in Good Condition at 18 °C (65 °F)[a]

	Duration of Transport (hr)		
Size or Stage of Animal	12	24	48
Fish fry with yolk sac (large)	4,000	3,000	2,500
Fish fry yolk with sac (small)	—	10,000	8,000
Fish fry, no yolk sac (large)	2,500	2,000	1,500
Fish fry, no yolk sac (small)	—	5,000	4,000
Fish fingerling, 1.25 cm (0.5 in.)	[50]	[40]	—
Fish fingerling, 2.5 cm (1.0 in.)	[75]	[50]	[25]
Fish fingerling, 5.0 cm (2.0 in.)	[75]	[50]	[25]
Fish fingerling, 10.0 cm (4.0 in.)	[100]	[75]	[50]
Fish fingerling, 20.0 cm (8.0 in.)	[200]	[150]	[75]
Adult fish	[200]	[150]	[75]
Crustacea nauplii	200,000	100,000	—
Crustacea, 1 week old, as postlarvae	2,500	2,000	—
Macrobrachium postlarvae	1,000	150	—

[a]From (1).

Some boxes may be opened for inspection by customs, either at the departure point or at the destination. In international or interjurisdictional transfers, inspectors who open boxes may seek to discover contraband, confirm the contents or determine of a shipment, whether the items that are shipped conform to packaging standards. Incomplete documentation — for example, with health certificates or official permits missing — may block deliveries.

Upon arrival of the shipment at the destination, unloading proceeds. First, attention is given to the state of the package and the condition of the animals in it. Then the animals must be transferred into water of good quality and of a type that is close enough to that of the package water to avoid shock. Important differences could exist in temperature, gas saturation, salinity, and pH.

Delays in transferring animals to receiving units can be highly detrimental. When sealed containers are opened, the benefit of a high level of saturated oxygen soon disappears. Unnecessary risk to animals may also be posed when bags are floated in receiving units for the purpose of equalizing temperatures. Once the temperature rises in a bag, a delay in removing the animals that are inside may result in serious damage to the animals due to the high content of waste toxins.

Whenever possible, new arrivals should not be placed directly into systems that already contain resident populations. Mixing the two populations runs the risk of inoculating the residents with disease agents.

HUMID CONTAINERS

Humid containers, airtight or not, allow sufficient oxygen to reach the animals inside, while preventing an undesirable absorption of heat. There is no "standard" humid container. Airtight boxes commonly contain a supply of pure oxygen and some form of water-soaked material to sustain a moist interior. The distribution of the animals is usually critical, and the use of trays makes greater loading possible. Reducing the temperature prior to transport and maintaining the lower temperature throughout the duration of shipment of the animals is usually beneficial.

Some fish species that are tolerant of cold do very well in this form of packaging. The most useful means of transporting salmonids over long distances is to send "eyed" eggs in humid boxes under ice. Salmonid eggs hatch after weeks of incubation, rather than the period of several days that is typical of many other fish species of interest to aquaculturists. This slow rate of development contributes to the successful transport of salmonids.

Though sometimes sent in conventional sealed bags, crabs, crawfish, and freshwater shrimp can be suitably transported in open, but humid, boxes, baskets, or bags. Sufficient ventilation must be present to allow moist air to reach all the animals inside. Transport is generally successful if the packages remain cool and the fragile animals withstand crushing from clumsy handling. Chilled humid boxes are used to ship cold-tolerant species of marine shrimp and lobsters to restaurants for display in live tanks. Molluscs from young to adult stages also transfer well in humid boxes.

TANKS

Tanks are a popular means of delivering fish that are to be transported within a reasonable driving range. The capacity of a typical transport tank is suitable for the delivery of large numbers of fingerling to adult-sized animals. Tanks are sometimes also useful for the delivery of very large numbers of small organisms, such as shrimp postlarvae. It is usually cheaper to haul aquatic animals for short distances than it is to package them for delivery within sealed containers.

Transport tanks are typically loaded and fastened to the back of a pickup or flatbed truck. Tanks that are made of wood, fiberglass, or aluminum are more common than those made of stainless steel or plastic. Some tanks contain urethane foam or some other insulating material for temperature control. Bottoms may be false, slanting toward the gate to make it easy to remove animals. An inside sliding gate controls the flow of water better and allows an outside gate to be removed without releasing the contents of the tank. Smooth surfaces on the interiors of tanks reduce abrasions that result

from rubbing. Wide doors at the tops of tanks aid in netting transported animals. Vents at the top prevent the buildup of carbon dioxide. Agitators that run off the vehicle's electrical system enhance water circulation and gas exchange. Larger tanks may contain inside baffles to prevent sloshing, especially if the driver loses control of the vehicle when braking. Some larger tanks have compartments with individual gates. Tanks with double levels or floors are sometime used to carry bottom-hugging species.

For long transfers, bottles, cylinders, tanks, or dewars supply oxygen to replenish that consumed by the animal load. The oxygen originates from the container and feeds through lines bottom to the of the tank, where diffusers deliver the gas as fine bubbles. Flowmeters may be used to discover the gas delivery rate. A small tank or compartment typically receives a flow of two to five liters per minute.

Haulers that regularly transport large volumes of water and animals use liquid oxygen, one advantage of which is a lengthy duration of flow. With the gas flowing at more than 5 liters per minute, a standard-sized oxygen cylinder lasts less than one day. In contrast, a 160-liter liquid-oxygen dewar would flow for more than two weeks at a rate of 5 liters per minute. The cost of liquid oxygen is approximately one-third that of gaseous oxygen and requires less loading weight per unit of volume. The cost equation changes, however, according to frequency of use and leasing arrangements made for the container.

Lights mounted on the rear of the cab of the truck help at night. When salt is regularly used as a freshwater additive, or when marine species are being transported, truck or trailer beds might best be constructed of aluminum to reduce the corrosive effects of the salt. Local regulations may require that transport tanks or trucks be specially marked.

Smaller, shorter transfers in tanks require less sophistication. Common equipment consists of easily removable units in the backs of small trucks. Agitators provide aeration during delivery of the cargo. Cylinders containing compressed oxygen gas are kept on board for emergency use. In addition to custom made hauling tanks, aquaculturists use a variety of sturdy, light, and well-insulated containers for the shipment of produce and chilled animal products.

Water-displacement tests determine the total volume of the animals to be shipped, from which their numbers or weight may be derived by simple algebra. Tank windows, outside tubes, or interior markings are useful in determining the animals' volume. Scales are also useful; some trucks have a hinged boom that supports a scale and a basket for on-the-spot weighing when the animals are unloaded.

The air temperature can become a factor to be reckoned with if it differs considerably from that of the water in the tank. The latter may become too warm if its circulation by agitators promotes the uptake of heat. In contrast, the constant delivery of fine bubbles from a liquid-oxygen dewar promotes cooler-than-ambient water. Ice is widely used to chill tank water to a suitable temperature; refrigeration or heating units in connection with transport

tanks or the airspace in which tanks travel are uncommon in aquaculture.

Water-quality constraints for transfers of aquatic animals in tanks are almost the same as those for transfer of the animals in bags. Tanks are not sealed, however, and carbon dioxide does not appreciably accumulate in tanks that receive normal aeration. Ammonia accumulates in tank water according to its output by the animals.

Sedatives have the potential for slowing the animals' activity, but in practice, they have relatively little application. In freshwater fishtanks equipped with agitators, mucus and organic matter will froth at the water surface and can interfere with gas exchange. The application of "defoaming" agents, and to some extent sodium chloride, resolves the problem. Sodium chloride and calcium chloride are widely used in conjunction with tank transport of freshwater species.

Tank water may be supersaturated with oxygen bubbles prior to loading fishes. Supersaturation satisfies the initial demand for oxygen by excited fish. Salts appropriate to the circumstances of transport may also be added prior to loading.

Nighttime and early morning are preferable delivery times during hot seasons. The driver of a delivery truck may monitor the dissolved-oxygen content of tanks on the truck bed if the cab is equipped with a meter that connects to a probe of suitable length. Accurate knowledge of the water quality upon arrival at the destination is helpful. When differences in important water parameters are great, adjustments must be made en route or at the destination to prevent harm to the animal load. Adjustments at the destination usually involve a slow blending of the receiving water with the delivery water. In some cases, adjustments to the receiving water are made prior to arrival of the load.

Many variables influence the selection of the animal load for tank transport. Table 4 gives some customary loading rates for several species of fish.

Careful attention must be paid to the selection of a transport temperature when atmospheric temperatures are extreme and deliveries are long. A water temperature suitable for cold-season transport is likely to be too low for summer transport. In either season, the temperature of the transport water should not differ by more than $10\,^{\circ}C$ ($20\,^{\circ}F$) from the ambient temperature. The lowest suitable transport temperature for tropical species is higher than that for temperate species. Tilapia, for example, should travel above $16\,^{\circ}C$ ($60\,^{\circ}F$).

Fish displace a certain amount of water when they are loaded. Interpreting the amount of displacement is easier when one uses metric units rather than English units. A pound of fish displaces roughly 0.12 gallon of water (one kilogram displaces one liter of water). If one knows the total weight requirement for a delivery of fish, a converting to gallons gives the volume of water displaced by the fish. This conversion helps to determine tank capacity requirements and load limitations according to an acceptable loading rate for a particular species.

Fish are sold according to their weight or number, and type or size. A common means of determining the number of weight of small animals is to estimate the volume

Table 4. Customary Loading Rates (proportion of fish in tank load as a percent fish) for Several Fish Stages in Transport Tank Water at 18 °C (65 °F) Aerated with Air

Fish and Stage	Duration (hr)	Percent Fish[a]
Catfish		
13 cm (5 in.)	8,16	26,18
23 cm (9 in.)	8,16	32,23
40 cm (16 in., 1.3 lb)	8,16	38,32
Sunfish		
2.5 cm (1 in.)	16	4
7.5 cm (3 in.)	16	7
13 cm (5 in.)	16	15
Carp		
<15 cm (<6 in.)	16	11
>15 cm (<6 in.)	16	15
Tilapias		
5 cm (2 in.)	12	23
>7.5 cm (>3 in.)	12	32

5 cm (2 in.)	8	4
Drums		
5 cm (2 in.)	8	4

[a]Percent fish is given to avoid confusion that might otherwise arise from differing expressions of volume composition. Generally, the fish load (weight) increases 25% if a tank is supplied with liquid oxygen. The weight decreases or increases 25% if the water temperature is $5\,^{\circ}C$ ($10\,^{\circ}F$) warmer or cooler, respectively, than $18\,^{\circ}C$ ($65\,^{\circ}F$) for these species listed.

of animals at the time of loading. Estimates of volumes for particular products are established with experience and, perhaps, the help of length–weight tables that are available for many species.

FARM DISTRIBUTION AND TRANSPORT

On farms, live animals are frequently transported and distributed to nearby sites. The conditions for this short transport of live animals differ considerably from those discussed in previous sections. The brief time involved does not allow to accumulate significantly metabolic wastes, in the transport units if reasonable loads are carried. Attention is paid primarily to providing adequate oxygen. Many variations, of course, exist, and a usual application is to replenish oxygen to a loaded container by bubbling oxygen from a sparger that is connected to a bottle of oxygen gas. Shallow water may also be useful in quick transfers. Water of a depth that barely covers fishes permits enough air to diffuse through the water to match that consumed by the fishes. The number of animals a sealed container is able to hold is greater for short deliveries.

Conditions in some areas cause the transport time to extend for several days. Adjusting the density of animals to account for the buildup of waste is not economical, so water must be exchanged at intervals during transport. Similarly, intercontinental transfers are often too long without the benefit of repacking. In either case, handlers may profit from planning and foresight regarding the conditions at key points of the delivery route.

LIVE TRANSPORT OF PARTICULAR ANIMAL GROUPS

Commercial traffic in live marine shrimp consists primarily of nauplii, postlarvae, and adults. Long-distance shipments use sealed containers. The destinations of nauplii and adults are other hatcheries. There, the nauplii are grown into postlarvae. The destination of postlarvae is a nursery or a growout system.

Sellers prefer to ship postlarvae of small size (5 to 12 days in the postlarvae stage), because more can be safely sent per container. Nauplii are even smaller and do not feed during the first day after hatching. Feeding peculiarities of larval stages other than nauplii discourage their transport.

Crawfish ponds are stocked with adults. The source is another farm where they are packed for delivery in sacks similar to those used to transport onions for marketing. When the animals are not allowed to dry out in the back of a vehicle or to overheat in sunlight, delivery is generally successful.

Like crawfish, adult freshwater shrimp may be carried to destinations in a moist container such as a covered basket. The young are shipped in a manner similar to the way young marine shrimp are shipped. Brine shrimp are important as food for many young aquaculture animals, particularly those of marine species. Following harvest of the buoyant eggs, a dehydration process makes the eggs suitable for distribution as a living dry product in a variety of types of packages. Crabs and lobsters are transported to the market primarily as adults.

Live molluscs are transported between aquaculture facilities mostly as larvae and juveniles. Edible market animals are shipped according to industry standards. In the United States, the Interstate Shellfish Sanitation Conference was instrumental in the development of the National Shellfish Sanitation Program's manual of operations. A manual also is available from the U.S. Food and Drug Administration.

Juvenile molluscs (postset) with shells 1 mm (0.04 in.) in length are often shipped in 500-mL (0.13 gal) volumes. Size is determined by screening. The handler spreads the animals on moist paper or food wrap and sprays them with a mist of cool saltwater. When the paper or wrap reaches 18 to 20 °C (65 to 68 °F), it is folded and placed into insulated containers with or without small chill packs. Delivery is by routine service of a courier.

Mature larvae (preset) are sometimes transported in a damp cloth in insulated boxes. Another means of transport, sometimes also used with oysters, is to allow the larvae to set individually on particles of ground shell prior to packaging. Smaller preset and postset animals have a nursery as their destination. Larger postsets (0.5 to 1.0 in. length) (1.25 to 2.5 cm length) are packaged in boxes as balls or layers. Transport is successful if temperature and moisture meet the requirements for the species.

All stages of fish are subject to live transport. Eggs are shipped in humid boxes and in water in sealed or open containers. Eggs should be able to be transported to their destinations without hatching. Some fish species are deliverable as fry during the period prior to absorption of the yolk sack. At that stage, the fish have not yet begun to feed. Large adults of some species are apt to become too aggressive in transport and may consequently be given individual space in tanks or sealed containers of a suitable size. Shippers normally pack only one fish per plastic bag if the fish are valuable and are to travel over a long distance or by air.

Tadpoles and aquatic stages of salamanders are transported in tanks or plastic bags. Adult frogs transfer well in vented boxes that retain reasonable humidity and temperature. Because of cannibalistic tendencies, they are shipped in uniform sizes. Turtles and alligators are packaged so as to reduce harm from aggressive behavior.

Shippers are mindful of local, national, and international regulations that may affect live-animal shipments. Differences in government strictures provide a complexity of often interrelated regulatory applications. Air shipment will normally include a shipper's certificate, an air waybill, a health certificate, and the necessary export–import permits or licenses. The package will likely have to conform to packaging standards. A couple of organizations produce helpful documentation (2,3) that explains the legalities of transport by air and road. Regulations in some areas may require that a bill of lading and special permits and licenses be on board a road vehicle.

Bibliography

The American lobster, *Homarus americanus*, is a highly sought-after seafood, and there has been considerable research on lobster aquaculture for seafood markets and fisheries stock enhancement. Lobsters were not always so highly appreciated, and, in colonial times in North America, indentured servants in Massachusetts insisted

on a clause in their contracts that they be fed lobster no more than three times per week (1). Today, there is a thriving North American lobster fishery centered in New England and the Canadian Maritimes, with 90% of the landings occurring from the Gulf of Maine and coastal waters around Nova Scotia and New Brunswick. A similar fishery exists for the European lobster, *Homarus gammarus*, throughout its range in the Eastern Atlantic Ocean, the Mediterranean, and the North Sea. These fisheries respond to a strong market demand that piqued the interest of aquaculturists. As a result of this, in the 1970s, significant research in Canada, Europe, and the United States successfully refined techniques for the controlled reproduction and growth of both American and European lobsters for aquaculture.

Efforts to reproduce lobsters began early in this century, when government hatcheries were built in Canada, France, Norway, the UK, and the US. Hatchery managers held gravid broodstock until eggs hatched and then released these early larval stages, in an attempt to enhance the commercial fishery. This was a massive effort, and Atlantic Canada alone had 15 hatcheries that released around 900 million larvae between 1891 and 1917 (2). The Massachusetts State Lobster Hatchery also released millions of lobster larvae subsequent to opening in 1939 on Martha's Vineyard and is still a center of lobster culture and research.

In the 1970s, concerns about the lobster fishery, coupled with the lobster's high value, encouraged institutions in Europe and North America to develop research programs to close the life cycle of lobsters in captivity. This included research on lobster reproduction, nutrition, disease, larval rearing and grow-out. Researchers at the Ministry of Agriculture, Forestry and Fisheries Laboratory (MAFF) in Conway, North Wales succeeded in developing techniques to culture the European lobster to a market size of 350 g (~3/4 lb.) in 2 1/2 to 3 years (2).

During this same time, scientists at the University of California's Bodega Marine Laboratory, with funding from the California Sea Grant Program, embarked on a similar research program aimed at refining techniques for captive reproduction, larval rearing, and grow-out of the American lobster. This research was also successful and contributed significantly toward defining nutritional requirements and techniques for broodstock management, larval rearing, and commercial production of the American lobster (3–5).

While successful at closing the life cycle and demonstrating techniques for controlled production of lobsters in captivity, this research has not led to large-scale development of lobster aquaculture. Reasons given for this are a lack of comprehensive information on nutrition, disease control, and viable grow out systems (6,7). Computer modelling of a commercial lobster production facility suggested an economically viable production level to be just shy of one million animals per year or 450 metric tons of product annually (8,9). There have been no attempts at large-scale lobster culture that might validate this model. The greatest constraint to large-scale commercial production is the need to isolate animals in order to protect them from cannibalistic tank mates while molting. The labor and capital costs associated with the care, holding, and feeding of isolated animals will have to be overcome to allow economically viable commercialization of lobster aquaculture as a food product. There is, however, a strong interest in stock enhancement using cultured juveniles, and projects are currently underway, primarily in the United Kingdom.

CLASSIFICATION AND DISTRIBUTION

Clawed lobsters belong in the phylum Arthropoda and are members of the class Crustacea, which they share with the other crabs and shrimp. They belong in the order Decapoda and the suborder Reptantia. Two species have been the primary focus of aquaculturists, and these are the American lobster, *H. americanus*, and the European lobster, *H. gammarus*. Some interest has developed recently in culturing the clawless spiny lobsters of the genus *Panulirus*; however, due to the extremely long larval cycle, it is likely that this will involve capturing wild late-stage larvae or juveniles for further growout in order to be economically viable.

LOBSTER ANATOMY

Lobsters have a hard jointed exoskeleton covering their bodies that provide sites for muscle attachment and protection from predators. The pigmented exoskeleton is a mottled dark greenish-black on the dorsal surface and orange on the ventral surface. It is comprised primarily of chitin and minerals absorbed from the surrounding seawater. Three main body parts are the head, thorax, and abdomen, with the first two being fused into a cephalothorax that is covered by a hard-shelled carapace. The jointed abdomen houses the large abdominal muscle sometimes referred to as the tail. This is attached to the cephalothorax with a soft tissue suture. For growth to occur, lobsters must shed their rigid exoskeleton in a process called molting, and it is at this suture that the lobster withdraws from the old exoskeleton. Rapid absorption of water then increases the animal's size by as much as 20%, and the new exoskeleton hardens around this enlarged body. Lobsters are extremely vulnerable to predation after molting and must seek shelter from predators.

As decapod crustaceans, lobsters have ten appendages on their thorax: the conspicuous paired claws, and four pairs of walking legs or pereiopods (Fig. 1). The large crushing claw is used to crush shellfish and other prey, while the tearing claw rips soft tissue. Lobsters are primarily benthic organisms and use their eight walking legs to move around. When alarmed, however, they will propel themselves rapidly backwards through the water with powerful contractions of the abdominal muscle. Attached to the ventral surface of the abdominal segments are the paired pleopods or swimmerets (Fig. 2). These are used to help maintain position and swim when animals are in the water column but more importantly serve as a site for egg attachment. An egg bearing or "berried" female will constantly fan the egg laden pleopods back and forth to keep clean water circulating around the eggs (Fig. 1).
Figure 1. Lobster, ventral view (9).

Figure 2. Lobster anatomy, lateral view (9).

It is important for lobsters to have a well developed sensory system that allows them to find food and seek out a mate when they become reproductively mature. The compound eyes located on anterior eyestalks allow lobsters to see motion and respond to different light intensities, but the chemosensory system is far more important as an aid in finding food and escaping predation. The long antennae are sensitive to touch and can detect slight changes in water pressure. The antennae and similarly sensitive hairs along most of the ventral surface of the body provide information on currents and potential predators and prey. The branched antennules are extremely sensitive chemoreceptors that aid in locating food, warn of predators, and help to locate mates (Fig. 1). Additional sensory hairs lining the feeding appendages allow animals to identify food items selectively.

Lobsters feed primarily at night and are opportunistic predators, consuming a wide variety of prey items as they are available. These include other crabs and shrimp, shellfish, polychaetes, urchins, and starfish. Juvenile lobsters generally seek refuge amidst rock crevasses and feed on drifting particles, animals growing on rock surfaces within the burrow, and other small prey found nearby. Adult lobsters will forage away from sites of refuge. When feeding, lobsters use their large claws to crush and tear apart prey but rely more on their first two pairs of clawed walking legs and accessory mouth parts to select and manipulate food to the mouth. These mouth parts include the paired mandibles, the first and second maxillae, and the first, second, and third maxillipeds. Ingested food passes from the mouth into the first (cardiac) stomach, where it is mechanically ground by three hardened chitinous teeth referred to as the gastric mill. Further tissue breakdown results from digestive enzymes. The ground particles then pass into the pyloric stomach and
from there to the digestive gland or hepatopancreas, which is the principle site for nutrient absorption. The hepatopancreas is the large green organ known and loved by lobster aficionados as tomalley. Undigested material and waste passes into the intestine and leaves via the anus at the tip of the tail (Fig. 2).

LIFE HISTORY AND BROODSTOCK MANAGEMENT

Mature female lobsters can mate only following molting, and, in the wild, pre-molt females typically seek out a male's den the summer this occurs. The male cues in on sex pheromones and becomes less aggressive, allowing the female to enter the den with him for a few days until she molts. The male then transfers a sperm packet into a receptacle on the female's ventral surface, using a modified first pair of pleopods. The male provides protection until the female's shell hardens, and within about one week the female will depart, retaining the sperm packet for the next 9 to 12 months. The following summer, primarily in July and August, the female will roll on her back and cup her tail before extruding 10,000 to 20,000 eggs, which are fertilized as they pass over the sperm receptacle (9). These eggs attach to the pleopods, where they are kept clean and maintained by the female until they hatch into an early larval stage the following summer.

It is desirable in aquaculture to have healthy gravid lobsters and complete control over the reproductive cycle, so that larvae are consistently available. Fortunately, this can be accomplished through the control of temperature and photoperiod. Hedgecock and co-workers at the Bodega Marine Lab describe a technique for managing broodstock that consists of holding three separate broodstock populations under different photoperiod and temperature regimes and is summarized here (3). A reserve population is held in System I at 10 to 15 °C under a short-day photoperiod of 8hL : 16hD. This temperature promotes egg development and vitellogenesis, while the short day length inhibits extrusion of eggs. Females are placed in this tank after they have completed a nuptial molt and have been mated. Four months in this system allows eggs to develop fully, and the females are then transferred to System II, which is at the same temperature with a long-day photoperiod of 15hL : 9hD that promotes extrusion of eggs. The egg-bearing females are then transferred to

System III, which uses a long-day photoperiod and an elevated temperature of 20 °C. This elevated temperature accelerates embryo development, such that the eggs hatch in four months rather than the 9 to 10 months observed at 10 °C.

While this system can consistently produce lobster larvae, there are areas in which additional research could greatly improve the economics and efficiency of larval production. Only 64% of the females held in System I extruded eggs, and less than half were able to carry the eggs until hatch (3). In those females that carried eggs to hatch, clutch sizes were often greatly reduced. Areas for investigation to improve larval production include low mating success, poor sperm and egg quality, and inadequate nutrition. Other stresses in captivity could interfere with mating or female care and cleaning of eggs during brooding.

To alleviate stress, culturists must insure that broodstock holding tanks have excellent water quality and are in quiet locations, so normal brooding behavior is not disrupted. Dissolved oxygen levels should be at saturation, and the salinity and pH should be around 32 ppt and 8, respectively. Ammonia levels should be kept below 0.2 mg/L (13). Broodstock nutrition is critical to high health and egg production, and animals should be fed to satiation using a mixed diet of chopped squid, fish, mussels, and shrimp at 2% of body weight per day (3).

LARVAL HUSBANDRY

The relatively short larval cycle of American and European lobsters is an attractive life history characteristic for aquaculturists. Lobster larvae have four planktonic stages, and at 20 °C they will complete their larval cycle in 10 days (5) (Fig. 3). The final larval molt involves a metamorphosis into a postlarva, which closely resembles the adult form, and, at this time, the small lobsters will settle to the bottom and seek shelter to avoid predation (Fig. 4). As with the culture of any larval crustacean, it is important to have ready availability of high-quality food and maintain excellent water quality during the larval cycle.

To obtain newly hatched larvae, "berried" females are moved two weeks before the eggs are ready to hatch and held in individual mesh containers in hatching tanks (4). These tanks receive UV-sterilized, 50 μm-filtered seawater

at 20 °C provided with light aeration. Flow rates should be sufficient to maintain ammonia levels below 0.2 mg/L. Outflow from the hatching tanks enters a 1-mm-screen-bottomed container floating partially submerged in a larger tank fitted with an overflow pipe, so that the larvae are retained in the screened container. It is recommended that larvae for culture be collected over at most a 24-hour period, so that they are all approximately the same age and size, in order to reduce cannibalism. When sufficient larvae have been collected, they are transferred to the larval rearing tanks.

A variety of tank configurations can be successfully used for larval rearing, provided the water can be uniformly mixed. Some tanks use a "Kreisel" system, where incoming seawater enters from jets in the bottom that maintain a pattern of upwelling. This helps to keep the larvae uniformly distributed (10). Conical-bottomed tanks work well, and aeration can be used to generate an upwelling that serves the same purpose as the "Kreisel" jets. Rectangular flat-bottomed tanks have also been used, and strategic placement of aeration can accomplish uniform mixing in these tanks. This even mixing keeps larvae and feed organisms uniformly distributed and insures ready access to food for larvae, while minimizing cannibalism. Larval rearing tanks are stocked at densities ranging from 50 to 100/1, and the highest survivals, of 70%, are achieved at the lower end of the range (4,11).

Water quality in larval rearing containers is critical and can be maintained by using either flow-through systems or static systems with batch exchanges of water. Water

quality parameters are similar to those required for the hatchery tanks, with flow rates or frequency of water exchanges set to maintain low ammonia levels. Mild aeration is used to insure oxygen saturation and provide mixing. Outlets are screened at 1 mm to retain larvae.

Nutrition is extremely important for larval organisms, to provide the energy necessary for successive molting and the protein and essential fatty acids for proper development. Newly hatched and adult Artemia provide an excellent source of feed. Citations in the literature recommend maintaining an Artemia ratio of four per lobster larva or providing eight Artemia/larva/day (4,12). The important thing to address in feeding larval crustaceans is availability of feed, and for this reason it is recommended that a particular prey density be maintained. Feeding levels from 0.5 to 1 Artemia/mL will provide enough food at a density that ensures it is readily available to the larvae. An additional benefit of live Artemia is that they will not decompose as rapidly as previously frozen Artemia or other prepared foods. Although survival is usually reduced, other feeds that have been successfully used are mixes of finely chopped fish, squid, other molluscs, and frozen Artemia. There are a number of larval diets that have been developed for use in penaeid shrimp hatcheries that should also work well for lobster larvae and should be evaluated. If not using live feeds, it is important to monitor water quality closely, and any build-up of uneaten food should be removed with a siphon.

Cultured algae such as *Isochrysis galbana* or *Chaetoceros gracilis* can also be added to the rearing tank, at densities from 10 to 100 cells/mL. While this algae will not be consumed directly by the carnivorous larval lobsters, it is eaten by the Artemia and will help to maintain their nutritional value. Algae will also contribute oxygen to the system through photosynthesis and will utilize nutrients that might otherwise be available to other bacteria and protozoans.

LOBSTER GROWOUT

Lobsters can be grown from postlarvae to six-month-old juveniles either communally or in separate containers. If they are grown communally, it is essential to provide complex habitat for individuals to seek shelter and avoid predation, especially after molting. A variety of materials can be used to provide this cover, including oyster shell, pieces of white fluorescent light baffling, or an assortment of biofilter media. While these materials provide adequate shelter, they complicate tank cleaning, and the decision for communal or individual rearing should be based on relative costs of materials and labor. Densities used in communal culture range from 100 to 200 per square meter. Other techniques to reduce cannibalism in communal rearing units include sorting to maintain a uniform size and immobilization of the claws or removal of the dactyls, all of which require considerable labor.

Tanks used for individual lobster grow-out are generally shallow and often situated in tiers to maximize utilization of floor space. Individual compartments are fashioned with plastic mesh, slotted PVC, or acrylic plastic
Figure 5. Individual lobster enclosures used in growout.

(Fig. 5). A slotted false bottom is sometimes employed, to facilitate cleaning the tank and removing uneaten food. Container size is important, or growth will be reduced. A 25-mm-carapace-length (CL) lobster should be held in a space of at least 310 cm^2, while a 40-mm-CL animal requires a 620-cm^2 container (5).

Water needs to be uniformly distributed to each rearing unit, and this can be accomplished by using overhead rotating spray bars (or submerged rotating slotted bars, in tanks with false bottoms). Sprinkler heads can also be used to distribute water over the surface. Water quality should be maintained as for broodstock, except that ammonia levels should be kept below 2 mg/L in growout systems. Water temperatures of 20 °C have been found to promote optimal growth, and a market-size lobster can be grown in 2 to 3 years under these conditions (2,5).

There are currently no commercial rations known to support growth in larval and juvenile lobsters comparable to that achieved using fresh and frozen Artemia. A similar situation exists for older animals, which exhibit the best growth rates on diets of fresh and frozen foods. This highlights the need for research and development to produce economically viable lobster diets. A feeding rate of 2% of body weight/day produces the best food conversion, but 4%/day maximizes growth (14). Given the difficulty of handling large volumes of fresh feeds and their impact on water quality, it is unlikely that a large venture will develop until a suitable prepared diet is commercially available.

FUTURE PROSPECTS

There is considerable recent interest in operating lobster hatcheries and nurseries to augment fishery stocks. In the U.K., there are government hatcheries, fisherman's associations, and supermarkets conducting outplantings of tens of thousands of juvenile lobsters for subsequent recapture in the fishery. In initial trials, five-year survival of outplanted juveniles was found to be 38%. Eight percent of these survivors were subsequently recaptured in the fishery (2). These results are encouraging, and, as the economics of juvenile production improve, this may become a viable technique to enhance the commercial fishery.

Lobster aquaculture from egg to market remains an elusive goal. The difficulties of raising a highly carnivorous crustacean in individual compartments and the resulting labor costs have, to date, precluded any successful business development. As long as the fishery remains stable and prices do not escalate significantly, it is unlikely a commercial industry will develop. Even so, the basic information to culture lobsters is available, and, if prices increase sufficiently to allow economically viable culture, a ready market is there to purchase the product.

M

MARKET ISSUES IN THE UNITED STATES AQUACULTURE INDUSTRY

Upton Hatch
Terry Hanson
Auburn University
Auburn, Alabama

OUTLINE

Aquaculture has grown dramatically worldwide in the past two decades. Although there have been culture systems developed for a wide array of aquatic species, the dominant species have been shrimp, salmon, catfish, carp, and tilapia. Southeast Asia has been the leading production area. The catfish industry in the south central United States has grown rapidly, while other production areas in the United States have experienced some success and some emerging species. New production areas may prove to be important in the near future.

Cultured fish and seafood products have established important market niches in the U.S. food supply. In only a few decades, production systems have been developed that provide a standardized product with availability extended across geography and seasons. Farm-raised shrimp, catfish, and trout, and pen-raised salmon are available virtually anywhere in the United States, any time of year. In addition, several emerging species (tilapia, molluscs, crawfish, and scallops) may reach this level of market development in the very near future.

The consumer image of fish and seafood supplies will have an important impact on the U.S. aquaculture industry. Although producers of cultured fish assert the relative quality and safety advantage their product has over wild-caught species, the general public may not perceive the difference. In addition, public perceptions of negative externalities through environmental or aesthetic degradation could play an important role in U.S. aquaculture production growth.

Nonetheless, the growth of aquaculture appears assured. Growing population, changing nutritional habits, increasing income, relatively constant catch from capture sources, and water pollution all suggest that the share of fish and seafood coming from culture sources will increase. In fact, if enhancement of wild populations is included as an aquaculture enterprise, the world fish and seafood market will be dominated by supplies dependent on culture sources in the near future. This entry focuses on the market issues that will largely determine the future growth of the U.S. aquaculture industry. The emphasis is placed on demand factors; however, related supply issues are also discussed. Comparative advantage underlies interregional and international competition for market share and profits. Market development and demand characteristics are intertwined with comparative advantage in complex ways that do not generally allow for a clean distinction between marketing and production influences on growth.

INDUSTRY TRENDS

Major Species

Wild-caught seafood dominates production from the ocean, however, in fresh and brackish water, aquaculture is a major source of commercial fish and seafood production. Even recreational catch is based on frequent restocking from aquaculture operations of private, state, or federal hatcheries.

For U.S. aquaculture to continue to grow, there must be an expanding demand for its products. Consumers have indicated that they consider seafood to be a healthy product, yet seafood consumption has remained steady over the past decade (Fig. 1a) (1); compared to other meat and poultry products, seafood is a distant fourth to poultry, beef, and pork (Fig. 1b). The 10 most important fish and seafood species consumed in the United States are presented in Figure 1c. Because most aquaculture products tend to be in the middle-to-high end of the price range for seafood products, the state of the economy plays a large role in their demand. The sales values A for the major culture species in the United States (catfish, trout, and salmon) are depicted in Figure 2, where catfish has dramatically increased and salmon has reached the level of trout production.

Catfish. The top 10 catfish-producing states are (in order of production) Mississippi, Alabama, Arkansas, Louisiana, California, South Carolina, Missouri, North Carolina, Kentucky, and Texas. Some production also occurs in Tennessee, Oklahoma, Kansas, and Florida; however, catfish production is dominated by the first four states in the first list. Dramatic growth in catfish production has occurred in the past two decades (Fig. 3a).

Catfish farm prices have ranged from $1.32 to 1.74/kg ($0.60 to 0.79/lb) in the 1990s, with an average price of $1.58/kg ($0.72/lb). On a real-price basis, the long-term trend for catfish farm prices has been downward (Fig. 3b). The number of catfish producers peaked in 1991 and

has since declined, with 955 operations in 1981, to 1,943 operations in 1991, and 1,250 operations in 1998 (Fig. 3c). Average farm size doubled, increasing from 165 ha (66 ac) in 1981 to 330 ha (132 ac) in 1998.

Exports of catfish products have been seen as a source of future market growth for the catfish industry. To develop foreign markets for catfish, The Catfish Institute has used grants from the U.S. Department of Agriculture's (USDA) Foreign Agricultural Service to determine how best to promote its product in places such as the European Community and Japan. In 1992, U.S. exports of catfish products totaled 111,360 kg (245,000 lb) and were valued at $561,000. Currently, the United Kingdom is the largest buyer of U.S. catfish products, with small amounts going to other European countries, Japan, and Singapore.

Imports peaked in 1980 at 6.75 million kg (15 million lb) and have since declined steadily as a percentage of domestic production. Catfish imports fell 44% from 1991 to 1992 to 1.3 million kg (2.9 million lb), the lowest in

13 years. The drop in 1992 imports can be attributed to low farm prices in the United States. Imports of catfish were up in 1993, aided by higher catfish prices at the farm and processor levels. Brazil was again the largest supplier of catfish imports, accounting for 90%. Mexico has been the second largest supplier of catfish to the United States. In 1998, catfish imports were 625,500 kg (1.39 million lb) with Vietnam and Guyana becoming important suppliers.

Trout. Idaho dominates trout production in the United States, comprising 75% of the market. The growth of trout culture has been somewhat variable during the 1990s but has averaged 25.2 million kg (56 million lb) and $71 million in sales annually, and the number of operations has remained steady during the 1990s. The primary states involved are Idaho, North Carolina, California, Pennsylvania, Washington, and Virginia. Trout farming requires colder water temperatures and flowing water with a high oxygen content (>5 ppm). The predominant trout species raised is the rainbow trout (*Oncorhynchus mykiss*), which is considered a hardier variety compared to other species such as brown, (*Salmo trutta*) and cutthroat trout (*Salmo clarki*). The United States has been a net importer of trout during the 1991 to 1997 period.

Salmon. Commercial landings of salmon in the United States are enormous (Fig. 4) and dwarf farm-raised salmon production in the U.S. (Fig. 2). Estimates of farm-raised Atlantic salmon (*Salmo salar*) production in the United States were 3.15 million kg (7 million lb) in 1988 and increased to 13.95 million kg (31 million lb) in 1996. Virtually all U.S. production is in Maine and Washington.
Figure 3. (**a**) Production of food-sized catfish in United States (1969–1998). (**b**) Real and nominal price of catfish 1970–1997, lb. (**c**) Number of catfish operations and processors, 1981–1998. *Source*: Economic Research Service, U.S. Department of Agriculture.

Maine's seafood industry ranks the contribution of 9 million kg (20 million lb) of farm-raised Atlantic salmon, valued at $55 million annually, second only to wild-caught lobster. This is remarkable considering that the industry only successfully experimented with Atlantic salmon in the early 1980s and expanded rapidly from 1987 to 1991.

While the domestic farm-raised salmon industry is expected to expand, its rate of growth in coming years will likely be much slower (in both Maine and Washington), due to the lack of high-quality sites and cost of obtaining new farming permits. Almost all of the increase in production in the last several years has been at existing leases, not
Figure 4. Commercial landings of shrimp and salmon in the United States (1980–1997). *Source*: Economic Research Service, U.S. Department of Agriculture.

through additional lease sites. Another major factor in the slowdown is increasing foreign competition in the salmon market. Canada is currently the largest supplier of farm-raised product, but imports from Chile have also expanded rapidly during the past few years. While Norway is not a large supplier in the fresh market, it remains the world's leading producer of farmed Atlantic salmon. Production in Norway has not been growing rapidly, but innovations in production practices promise to lower production costs. Production in Chile has expanded very rapidly over the last several years so that Chile is now probably the lowest cost salmon producer.

From 1993 to 1997, U.S. salmon exports (wild-caught Pacific salmon plus farm-raised Atlantic salmon) fell from $700 million to $436. The 1993 total included 1.8 million kg (4 million lb) of fresh cultured Atlantic salmon valued at $11 million; exports of fresh Pacific salmon, all wild caught, were 10.35 million kg (23 million lb), valued at $34.8 million. The majority of salmon exports were frozen Pacific salmon, 115.65 million kg (257 million lb), valued at $484 million.

Shrimp. In 1993, U.S. culture of shrimp was approximately 3 million kg (6.6 million lb), which is about 2% of the U.S. wild-caught shrimp quantity. Imports of shrimp were estimated to be $3.0 billion in 1997, and historically imports have always exceeded exports. Approximately 60% of the imported shrimp are thought to be farm raised. Expansion of U.S. shrimp aquaculture is limited because of the low cost of production in foreign countries and the large U.S. wild catch. Asian and Latin American countries that produce farm-raised shrimp have developed Western markets through the steady supply of consistently high-quality and uniformly sized shrimp at competitive prices. It has been suggested that the comparative U.S. advantage may lie in the technical aspects of producing disease-free postlarvae for the foreign shrimp industries or in providing hatchery technology for production of postlarvae.

Emerging Species

Molluscs. Culture of oysters, mussels, and clams is small compared to the wild catch, but aquaculture is growing because of reduction in available oyster and clam stocks and aquaculture's ability to supply a steady high-quality product that can command a premium price. U.S. production data for most molluscs are not available on any comprehensive basis that separates the species or distinguishes between wild and cultured. In 1993, total oyster sales in the United States were approximately 14.4 million kg (32 million lb), valued at $98 million. Mollusc imports ranged from 1.8 to 4.5 million kg (4 to 10 million lb) from 1989 to 1993, with value ranging from $52 to $64 million. Mollusc exports averaged approximately 2 million kg (4.4 million lb), valued at approximately $11 million during the 1990–1993 period; however, in recent years, this trade imbalance has grown dramatically (Fig. 5). In 1997, scallop imports exceeded $200 million, and the other three emerging species approached $50 million each. As these new species imports grow in combination with existing shrimp and other fish and seafood imports, it is clear that these sources are becoming an important element in the U.S. trade imbalance.
Figure 5. Net import–export of emerging species in the United States (1989–1997). *Source*: Economic Research Service, U.S. Department of Agriculture.

The outlook for mollusc culture is mixed. Advances continue in efficient culturing methods for some species such as abalone and oysters, while for other species such as soft clams, surf clams, and scallops, culture techniques are still in the experimental stages. The two greatest constraints to expansion of mollusc culture are the limited number of suitable sites and food safety related to consumption of raw molluscs, particularly oysters and clams.

Tilapia (*Oreochromis* sp.). The outlook for tilapia production in the United States is good for several reasons. First, tilapia can be polycultured (cultured in the same pond with other fish species) with no adverse effects. Second, it can eat many types of feed, and, of special importance, it can be grown profitably using diets of less expensive vegetable protein. Third, it can be bred easily and quickly. Last, the flesh is mild and can be substituted for a number of other traditional seafood species. However, there are limitations to U.S. culture of tilapia, foremost being its intolerance to water temperatures below 7 °C (45 °F) and reduced growth below 21 °C (70 °F). Geothermal water sources and recirculating systems using heated water are being used to circumvent the temperature constraint. Tilapia production is not concentrated in one region or area and is presently being undertaken in Arizona, California, Florida, Idaho, New Jersey, and Texas. Promotional efforts to make consumers more aware of the product and its quality are attempting to expand the market for tilapia. Some consumers prefer the lighter color of the golden hybrid to the darker color of the more common tilapia species. Consumer tests also indicate a preference for a larger size, such as the fillet from a 340 g (0.75 lb) fish.

Future growth of the industry will require expansion of the market, lowering of production costs to be competitive with other fish species, and development of cost-efficient water recycling production systems. Imports of tilapia have grown dramatically from $13 million in 1992 to $49 million in 1997 (Fig. 5). Most of the tilapia imported from Asian countries are cultured, while fresh fish imports from Mexico are primarily wild caught.

Ornamental Fish (Tropical Fish). The ornamental fish industry is centered in Florida, particularly in the Tampa and Miami areas. These products are considered luxury items and may decline during recessions, as in 1992, when imports were down 12%. Producers are concerned about the Food and Drug Administration applying the same rules for therapeutic chemical use in food fish production to the ornamental fish industry.

The forecast for U.S. exports of ornamental fish indicates continued expansion, but net trade will continue to be negative (Fig. 5). Export markets to the European Community (EC) are increasing but American producers must compete with Asian producers for this market. There are concerns about recent EC directives covering the importation of fish, which require U.S. exports to the EC to be certified by a U.S. agency that the product complies with EC regulations. Imports of ornamental fish have ranged from $12 to $53 million from 1988 to 1997, while exports have ranged from $6 to $41 million over this same period.

Crawfish. Crawfish culture is probably the U.S. aquaculture activity most heavily affected by wild production of the same species. Wild production occurs during the same season as aquaculture production. Wild harvests are dependent on water temperature and the volume of water moving through the swamp areas of Louisiana. Because of the variability of these factors, wild crawfish production has experienced wide year-to-year swings 8.1 million kg from (18 million lb) in 1991 to 31 million kg (69 million lb) in 1993. This supply fluctuation is a serious limitation to crawfish market development because the food industry wants a product that is in constant supply, has good quality, and has a relatively stable price. Crawfish are not available year round, which makes it difficult to build a steady market. Seasonal harvesting patterns, along with a considerable wild catch, means there are huge swings in prices throughout the season.

The advantages of crawfish culture are the relatively low fixed costs of production, natural reproduction, and the ability to be double-cropped with rice. United States consumer demand is still relatively restricted to the states where crawfish are found naturally and those areas where they are farmed. Large crawfish are exported to Sweden at a premium price, medium crawfish are sold to restaurants, and small crawfish are peeled for tail meat. Recent exports from China during the off-season for U.S. crawfish production may allow for a more continuous year-round supply. United States culture may actually expand as a result.

COMPARATIVE ADVANTAGE

Industry growth is largely determined by comparative advantage, with both production and marketing factors involved. Aquaculture competes for resources with other potential or existing production activities and competes in the marketplace with fish and seafood products from capture sources. On the production side, fish culture systems may often be able to use, and even thrive, on land resources that are not suitable for other agricultural enterprises. Examples include salt flats for shrimp, highly erosive watersheds for catfish, and pens for salmon.

The relative net returns to land, water, labor, management, and capital in one location versus other locations will ultimately determine aquacultural viability. It is not simply a matter of relative production costs. As long as the returns in a location provide an incentive, culture will continue. If the opportunity cost of resources is lower in a given area, the cost of production can be higher, allowing the industry to still maintain competitiveness. Returns to alternative uses of land, water, and other resources may be higher as a result of agricultural commodity programs or potential urban-industrial uses. Thus, the ability to compete with production from other areas will depend on relative input costs, including opportunity cost. For example, 0.4 ha (1 ac) of delta land in Arkansas may have a lower cost of production

in catfish than the same area in the Black Belt of Alabama; but if the land in Arkansas can produce rice and receive a subsidized price, it will probably not be put in catfish while land in Alabama is available for catfish production because net returns to alternative enterprises is low.

The quantity that can be produced from a given area using a given technology will be limited by the availability of the resource. Often this will be land and water of a certain quality. Once the low-cost alternative reaches its capacity, the next more expensive technology and resource combination will come into production. New technology can increase the capacity by decreasing dependence on the most limiting resource. If water availability or quality were constraining the production acreage of catfish in the Mississippi delta region, then new techniques to conserve or re-use water could increase the area's capacity. Where the availability of postlarvae (PL) for shrimp production has become limiting, hatchery technology has been improved to decrease dependence on wild-caught PL. Waste assimilation in salmon culture has been an important constraint that has limited growth and has resulted in greater public and private scrutiny of location and intensity of pen culture.

Aquaculture is closely linked to capture fisheries. The development of aquaculture is greatly enhanced by selecting a species with a strong history of consumption. The shrimp and salmon aquaculture industries have grown in response to a deficit in the supply of these species from capture sources that allowed the cost of production to be competitive with the cost of capture. The consistent quality and quantity that can be made available to the market through culture is a further advantage. Catfish production has been hindered by the lack of a history of consumption in many areas of the United States. Catfish promotion and advertising programs have been needed to improve its image. Aquaculture is able to break the seasonal and geographical limits historically imposed by capture sources.

Culture industries that are favored by a ban or moratorium on a capture fishery are vulnerable to the possibility that the capture fishery could recover before the cost of culture has decreased sufficiently to compete with capture sources. Such bans on striped bass, salmon, and cod may provide opportunities for the culture of these species; but they may also prove to be either temporary opportunities or an opportunity better filled by other species that the consumer is willing to switch to. Consumer loyalty to a species is probably limited. At some point, higher prices, low quality, and relative lack of availability of the traditionally consumed but restricted species will lead the consumer to try alternatives. Thus, a restriction on the capture of a particular species does not necessarily imply a long-lasting opportunity for the culture of that species.

Externalities

Aquaculture generates and is affected by a number of externalities that could have profound impacts on the sustainability of the industry. Environmental pollution associated with pond effluent, discharge from processing plants, and sedimentation in coastal areas is a pressing issue that has to be resolved. There is some evidence that catfish aquaculture is lowering the water table in the Mississippi Delta. This raises pumping costs for current producers and threatens the long-term viability of the industry. Communities and other producers in the region that depend upon the water table are also affected.

Aesthetic objections represent another class of problems for U.S. aquaculture, especially in connection with salmon farming and the raft culture of shellfish in the Pacific Northwest. Coastal residents find rafts, pens, and other facilities unsightly. Zoning, licensing, and other restrictions have been placed on the industries. Although aesthetics represent a legitimate concern, there are tradeoffs involved in terms of reduced employment in the affected communities, reduced local tax revenues, and higher seafood prices. Economic research is needed to shed light on the magnitude of these tradeoffs so that all parties and costs are adequately represented in the debate.

Environmental quality problems experienced by overseas producers may improve the competitive position of U.S. aquaculture. For example, the shrimp culture industry in Taiwan was decimated by environmental and disease problems in the early 1990s. Shrimp production areas in Indonesia, the Philippines, Ecuador, and Thailand have experienced some of the same problems. Much of the problem is rooted in overexploitation of the resource base through intensive production practices located in highly exploited watersheds. Aquaculturists have espoused the advantages of culture relative to capture based on the notion that capture fisheries have reached their carrying capacity, but watersheds also have carrying capacities. Ill-advised intensity and density of production operations have led to conflicts with other users of the resources in the watershed and degradation in the quality of the pond environment. Not only has this overexploitation led to declining yields and profits, in some cases the intensive production practices, especially the use of some chemicals, have raised issues of consumer health concerns. If U.S. producers are better able to deal with environmental and food safety concerns, they may gain an important advantage relative to international competitors.

Common property resources such as wild-caught postlarval shrimp represent another class of externalities. Postlarval shrimp obtained from the oceans are used by shrimp farmers in many parts of the world to stock their ponds. Increased harvests of the postlarvae reduce the wild catch of adult shrimp. Thus, cost savings from using the wild postlarvae for aquaculture come at some expense to those involved in the ocean capture industry. There is growing concern that shrimp aquaculture is causing a rapid depletion of natural shrimp populations.

The importance of postlarval shrimp in the food chain of many marine fish species raises additional concerns. Reduced shrimp populations may adversely affect fish populations of important commercial, ecological, recreational, or aesthetic value. Increased development of shrimp hatcheries can reduce dependence on an uncertain seed supply and eliminate the threat to the regeneration of wild stocks.

Aquaculture may be adversely affected by externalities generated by other enterprises. Fish health, growth rate, and human safety may all be compromised by pesticides, fertilizers, and industrial pollutants in streams and groundwater. Catfish farms are often in close proximity to chemical-intensive row crop operations such as cotton, soybeans, and peanuts. In fact, much of the land converted to catfish ponds in Mississippi is former cotton and soybean land. Agricultural runoff, crop-dusting, chemical leaching into the groundwater, and chemical residues from former crops are all potential vectors of contamination.

Major problems for molluscs are generated by their dependence on water quality, because they are filter feeders that concentrate toxins. Dinoflagellate blooms produce toxins that are harmful to humans, for example, paralytic shellfish poisoning (PSP). Mollusc beds are continually monitored by state and federal agencies for dinoflagellates, and producers must tag all bags of molluscs for identification purposes. A solution commonly used in Europe is depuration facilities. They remove most harmful substances, including infectious bacteria, but not viruses or heavy metals. Such facilities will become more commonly used in the future as concerns increase about the safety of seafood products.

Growers must sometimes deal with restrictions concerning obstructions that interfere with navigable waters. In addition, in most states, growers will be faced with a long and elaborate process of leasing the rights to farm-specific areas of the bay or ocean bottom. Not owning the property may increase risks, limit planning horizons, and lower the amount of total capital invested. These limitations are also faced by salmon netpen culturists. Leasing ocean bottoms may cause potential conflict among aquaculture operators and fishermen, regulatory agencies, and recreational fishermen. Leasing arrangements may be even more of a problem for off-bottom operations, such as raft culture, as operators lease the water column as well as the bottom.

Infrastructure

Infrastructure facilitates the flow of aquacultural products between buyers and sellers. Specialized research facilities, industry trade associations, extension services, physical facilities such as feed mills, fish disease diagnostic laboratories, supply firms specializing in aquacultural inputs, live-haul and other transportation services, and processing plants are all important elements of the infrastructure supporting aquaculture. For example, growth in the shrimp aquaculture industry in South Carolina has been impeded occasionally due to limited stock availability from wild sources and hence, a lack of suitable infrastructure. Because aquaculture in the United States is relatively new, many of the components of infrastructure that are taken for granted in other industries (e.g., extension expertise and specialized research facilities) either do not exist or are still in developmental stages.

Market growth has permitted increased specialization and improved scale economies in production and processing (2). Processors are a pivotal link in the marketing chain that enables aquacultural production units to thrive in a particular locale.

Vertical integration, production and marketing contracts, and cooperatives can be implemented as a means of lowering costs or enhancing price. The chicken broiler industry may serve as a model for the catfish industry, suggesting its eventual evolution into a fully integrated production system. There are many situations in which contracts or integration are cost-saving alternatives to market exchange. For example, processing is an industrial activity that achieves lowest cost by operating at a steady rate throughout the year. Contracts or integration offer a mechanism for assuring a continuous supply of the size and type of fish desired by the processor. Farmers gain through year-round markets at known prices. Cooperatives and bargaining associations permit fish farmers to exert greater control over the pricing and marketing of their products.

Supply Response and "Boom and Bust" Cycles

Aquaculture has been described as simply another form of livestock production and, as such, should receive the same treatment as the more traditional forms of agriculture. Livestock development evolved from hunting to domestication of animals, and the fishing industry is following a similar path. The fishing industry is basically involved in the tracking and harvesting of wild populations. However, modern fishing fleets have the capacity to harvest fish faster than the animals can reproduce. In conjunction with the problems inherent in common property resources, the depletion of ocean fish populations is occurring. Farming trials to evaluate wild fish species to determine their suitability for aquaculture have been conducted over the past few millennia in China, and in the past few decades in many Western countries. Even though a number of fish species are now farmed, in many cases the genetic stock is still basically that of a wild population. Using the same type of genetic selection that has increased the efficiency of livestock and poultry production, aquaculture operations should be able to increase their efficiency.

Another comparison often made between aquaculture and livestock production involves cyclical or "boom and bust" production cycles. This type of cyclical production may be developing now in the catfish industry. That industry has gone through a series of slower and faster growth periods, but they have been overshadowed by the overall growth of the industry (Fig. 3a, b). Over the 1991 to 1993 period, the catfish industry saw production increase very rapidly, resulting in farm prices falling below production costs for many producers. In response to this, producers cut back on their stocking rates and some growers were forced out of the industry. The end result was that, after a period of time, stocks of available fish were reduced and farm prices rose. As prices improve, the growers remaining in the industry will gradually increase their production. If prices remain above the average cost of production for an extended period of time, new growers will enter the industry. With new growers entering the industry and established growers expanding production,

prices will begin to fall and the cycle will start all over again.

Now that the aquaculture industry has gotten past the initial phase of working out basic production techniques, it seems to be following the type of development seen in the livestock and poultry industries. For the major livestock species, some of the trends have been for larger units of production, greater concentration of production, and vertical integration of production. Many of these trends are also evident in the growth of the shrimp industry in other countries and the catfish, trout, and salmon industries domestically. If the major aquaculture species follow the development path of traditional livestock and poultry industries, the outlook will be for larger production units, higher concentration of production, more vertical integration, rising production efficiencies, and declining real costs.

In the long term, real prices for livestock and poultry products have declined. This trend has also occurred in the catfish industry (Fig. 3b). As a result, growers will continue to be pressured to adopt or develop new methods of increasing their production efficiency. On the positive side, this long-term decline in real prices will likely mean that the price of farmed products will become more competitive with the wild harvest and that aquaculture production will become a major factor in those markets.

However, aquaculture may develop differently from the livestock and poultry industries because of its wider range of species. In this sense, aquaculture could be more closely compared with the fruit and vegetable industries. Some aquaculture species appear to be developing into major industries, such as catfish and trout, and they will likely follow the path taken by the livestock and poultry industries. For many other aquaculture species, production will remain much lower, and they will be marketed more as specialty products (3).

The response of aquacultural supplies to changes in price is a critical factor affecting the ability to understand and predict the economic consequences of technical change. Similarly, the effects of competing fish supplies, feed costs, industry advertising, and governmental regulation and policies are difficult to analyze without this information. While an increasing body of evidence is becoming available on the demand elasticities for fish and seafood products (See the section "Demand Characteristics"), including aquacultural products (4,5), relatively little is known about the size of supply elasticities for aquacultural products. Branch and Tilley (6) estimate harvest response elasticity for catfish of about 0.60. Zidack, Kinnucan, and Hatch (7) estimated the short-run supply elasticity for catfish over the 1980–1989 period to range from 0.15 to 0.72. Beyond those studies, little is known about supply response for major aquacultural products, such as shrimp and salmon.

Knowledge of supply is complicated greatly by the problem of monitoring on-farm inventories. At any given time, there is a large "floating inventory" of fish in ponds that often cannot be measured with much precision (8). The lags that are prevalent with the growout of land animals are also important in aquaculture supply. In addition, the rapid growth of an infant industry, such as aquaculture, can result in misallocation of resources and price instability.

MARKET DEVELOPMENT

The main tools of market development are price, product, place, and promotion. The demand for fish in general, and aquacultural products in particular, is price elastic, meaning that consumers are price sensitive. On the one hand, price increases for nonaquacultural fish products associated with the depletion of natural fisheries enhance market development efforts of aquaculture. At the same time, however, increased production costs are difficult to pass along to consumers without loss in market share for aquaculture. Product differentiation is one means for decreasing the price sensitivity of consumers.

"Product" refers to the physical attributes of aquacultural commodities in terms of the characteristics that consumers desire. Convenience, freshness, flavor, texture, product form, safety, and nutrient content are all characteristics of aquacultural products that have relevance to the consumer. Consumers place a value on each relevant product attribute. Knowledge of the implicit prices consumers attach to fish characteristics can be used to position aquacultural products against competing fish and non-fish food items. Consumer taste tests (9) delineate differences between captured and cultured fish and provide valuable information for developing marketing strategies.

Spatial dimension of marketing are referred to as "place." Areas or locations are identified where the product commands a premium price net of transportation costs. Although shrimp is a universal favorite, regional differences exist in consumer preferences for fish and seafood. For example, salmon, halibut, catfish, perch, haddock, and flounder are the most preferred finfish in the United States depending on the census region (10). The identification of regional preference patterns aid market development by pinpointing areas in which aquacultural products may be introduced with the least consumer resistance and, therefore, the highest probability of success.

In some cases, overseas markets are easier to penetrate than domestic markets. For example, in 1991, over 10% of the cash value of U.S. crawfish was exported, primarily to Sweden and Finland (11). Although export markets in general may be a less economical way to expand the demand for aquacultural products than domestic market development, subsidies available through federal export promotion programs may encourage foreign market development in some instances.

"Promotion" is an especially important market development tool in infant industries where little is known about the product. Classical product life-cycle curves consisting of introductory, growth, and maturity phases characterize the development of many aquaculture industries (8). Technical constraints, production costs, and competing products are fundamental factors governing how rapidly a particular industry moves through phases. Product promotion, however, plays a key role.

Consumers must be informed about the product's existence and unique characteristics if an industry is to

gain a competitive edge in a complex market such as the United States. The mass media, both electronic and print, offer an efficient vehicle for communicating the merits of fish to a large potential market. In the case of catfish, print media advertising increased consumer awareness of farm-raised catfish, which in turn significantly increased the ability of the industry to expand markets both within and outside the traditional consuming areas (12).

Market development will be an important source of growth as the aquaculture industry matures. In general, there will be a continuous attempt to increase supply in order to take advantage of larger market opportunities. Individual growers, groups of growers, and processors will be in a constant struggle to expand to the next level of market size; however, there is "lumpiness" in the technologies and markets related to the additional size needed to exploit economies of size. Expansion must take place within the context of the minimum flow of product required in the larger market and of maintaining profitability.

In cases where the species is well established, infrastructure investment will be needed to augment the consistent quality and flow of product. When the cultured species is relatively new to the consumer, infrastructure development will have to be augmented with strategies to increase consumer awareness. Several studies have found that consumers are more likely to experiment with new food purchases in a restaurant than in a grocery store. Restaurant managers are often looking for new products to add to their menus, and new "exotic" entrees attract consumers.

Grocery store managers are more likely to select well-established products due to the competition for space in the store and consumer tendency to purchase products with which they are familiar in terms of taste, difficulty of home preparation, and safety. Managers of grocery stores that have specialized seafood sections may be more like restaurant managers in that they will desire diversity. Prepackaged, value-added cultured species may be located in the meat section along with beef, pork, and poultry as opposed to the fish and seafood section.

Market development can target two segments: domestic and foreign. Because the United States is a major market, it makes sense first to exploit the latent demand for aquacultural products within the United States before investing significant resources to expand foreign markets. The long-term trend of rising U.S. per capita fish consumption appears to have ceased in the early 1990s, based largely on safety and quality concerns. Since most, if not all the world's major fisheries are being exploited at or beyond sustainable yields, the opportunity for aquaculture to expand its market share is obvious, especially if renewed consumer confidence can result in a continuance of the long-term upward trend in per capita fish consumption.

Aquaculture's ability to provide a consistent, high-quality, standardized product for large commercial markets has made it attractive for institutional markets. Restaurants and retail supermarkets have had problems with the inconsistent quality and quantity of fish and seafood from capture sources (13,14). As a competitor with other sources of protein (principally beef, pork, and chicken), fish contains less fat (15).

Processors dominate the marketing of aquacultural products. Due to economies of size and the expense of transporting live fish, many aquaculturists are served by few processors (16,17) (Fig. 3c). Alternative marketing channels have been profitable for small numbers of producers; however, the limited market represented by direct sales to restaurants, live-haul, and fish-out creates a dependence on the processor for moving large quantities of product (18). The development of these smaller markets may be an appropriate transitional strategy to build up sufficient acreage in an area to attract a processor.

Because of the large number of fish species available in the market, the demand for any particular aquacultural product is likely to be price elastic (19). Price increases are resisted by consumers, who simply purchase a close substitute. This high substitutability also implies that increases in production or marketing efficiency that lower price offer an important avenue for accelerating the rate of aquaculture growth. If a capture species becomes more expensive, consumers are likely to switch to the cheaper cultured product.

Information dissemination and consumer education programs can play a vital role in expanding the demand for aquacultural products. Aquaculture's ability to control environmental factors that may affect the safety and nutritional quality of fish may not be perceived by the consumer unless the information is effectively communicated. The negative product image associated with some fish or mollusc species may be overcome with appropriately designed generic advertising campaigns (12). In other cases, product differentiation and market segmentation can be facilitated through the development of consumer information programs tailored to specific target groups, for example, Pacific coast versus Gulf coast oysters.

Aquacultural products are similar to other new products in that they are subject to the same S-shaped diffusion paths (8). Whether the diffusion proceeds slowly or rapidly is determined to a significant degree by the marketing effort to support the product. Although industry advertising offers an efficient mechanism for stepping up the rate of consumer acceptance of aquacultural products, the collective action required to obtain the funding and the attendant free-rider problems pose a challenge for the diverse and fragmented aquacultural industry (20).

Product Differentiation

Product differentiation is an especially important aspect of U.S. aquaculture that has received inadequate attention. The ability to convince consumers of the superior qualities of fish and seafood products in general, and aquacultural products in particular, is crucial to the industry's long-term growth prospects. Although being farm raised may not ensure a better-tasting product (9), consumers may find the farm-raised product appealing in other respects. For example, feeding farm-raised fish carefully formulated feeds may allay fears about the safety of eating fish. Kummer (21) stated that chefs find penned fish flesh flaccid because of lack of exercise and flavorless because of the fish's packaged feed diet. A bland taste, however, is what most U.S. consumers appear to want

in fish. Kummer (21) attributed catfish's rapid growth in popularity to the "perfect blandness" of the farm-raised product.

Health-conscious consumers want a diet with less fat and cholesterol. The leanness of fish could be a targeted message of promotion campaigns. Better understanding of consumer perceptions of aquacultural versus nonaquacultural fish products will assist in identifying misconceptions and enhance the ability to educate consumers about aquaculture's contribution to a healthy and satisfying diet.

Food Safety

Food safety is one of the key consumer issues of the 1990s. Media attention given to contamination incidents (e.g., vegetables, fruits, milk, and meats) has sensitized consumers to food quality and safety. The perishability of fish, coupled with their tendency to absorb and concentrate some pollutants, make the issue of food safety especially germane to aquaculture. Brooks (22) found that 38% of consumers had seen or heard news stories on some negative aspect of seafood. Actual risks have been measured to be substantially less than consumer perceptions. Greater control over the culture process as compared with the total lack of control over the capture process should be emphasized to allay consumer safety concerns. Water quality in ponds is monitored daily and nutrient intake is controlled through diet. Fish is a highly nutritious food and has been associated with a lower risk of heart disease (23).

Consumers often weigh negative information more heavily in their decision-making than equal quantities of positive information (24). The knowledge that catfish is farm raised (and presumably safe) was found to be the single most important factor influencing consumer perceptions of product quality and, therefore, purchase behavior (12). However, advertising must try to project the positive attributes of cultured species without creating strong negatives concerning capture products. The concerns associated with the latter message could lead consumers to bypass fish and seafood altogether, even if they are convinced that cultured fish and seafood are better than supplies from capture sources.

Quality control and consumer apprehension concerning the supply of fish and seafood may become an important comparative advantage for U.S. aquaculture. For example, perceptions that shrimp produced under the intensive Taiwanese system may cause health problems are resulting in greater care on the part of processors and exporters in their purchasing decisions. Consumers may be willing to pay extra for fish and seafood that are certified to be of high quality and pathogen-free. Proximity to the final consumer may make this certification process easier to implement. This quality issue may result in a more distinct separation in the "bulk" market and high-quality market niches.

Demand Characteristics

An essential element of demand analysis is selection of appropriate substitute products, which is complicated by the large number of fish species and the potential competition with other meat and protein sources (5,10,25–30). Although the controlled environment in which cultured species are raised should be an advantage for cultured products relative to wild-caught species, especially during periods of heightened consumer awareness of specific or general problems with safety in wild-caught populations, a surprisingly close relationship between demand for farm-raised and wild fish has been empirically documented. Typically, the consumer does not seem to make the distinction between farmed and wild supply and tends to react to a scare associated with one particular species at one particular time as an indictment of fish and seafood generally. Thus, farm-raised species as yet have not benefited from safety concerns related to wild fish (9). Returns to promotion and advertising (31–33) may be particularly high for fish species, especially farm raised, in a market environment in which the consumer is deluged by reports of seafood safety problems (34,35).

Catfish. The Southern Regional Aquaculture Center of the U.S. Department of Agriculture commissioned a cooperative university research group to develop a comprehensive analysis of U.S. markets for catfish (10,14,36,37). The study, completed in 1988, included telephone surveys of 3,600 consumers, 1,800 restaurant managers, and 1,800 grocery managers. Some 87% of respondents reported they eat fish and seafood, and of those consumers, 60% had eaten catfish. The New England and the mid-Atlantic regions had the lowest percentage of catfish consumers and the south central states had the highest consumption. Catfish ranked third behind shrimp and lobster as the consumer's favorite fish or seafood. Catfish ranked

second to shrimp in the retail grocery survey and third to shrimp and cod in the restaurant survey. The top 10 fish and seafood products ranked by consumers, excluding canned products, were shrimp, lobster, catfish, crab, scallops, flounder, cod, salmon, haddock, and oysters. For retail grocery managers, the ranking was shrimp, catfish, cod, perch, orange roughy, flounder, haddock, red snapper, sole, and salmon. For restaurant managers, the ranking was shrimp, cod, catfish, scallops, flounder, lobster, crab, haddock, salmon, and halibut (Table 1). Figure 6a–c shows the regional preferences for fish and seafood as judged by consumers and managers of restaurants and grocery stores. Those lists provide a good indication of competing products for cultured species.

Nutrition, ease of home preparation, flavor, and consistent quality were judged to be assets of catfish, while packaging, smell, and product availability were deemed its liabilities. Most consumers did not perceive a difference between farm-raised and wild-caught catfish. Relative cost to other meats was a distinct advantage for catfish over other fish and seafood.

Lambregts, Capps, and Griffin (38) estimated seasonal demand for catfish from 1987 to 1988 in a Houston, Texas retail market. Fillets appear to have less seasonality than whole dressed catfish. Beef is a gross substitute for catfish products. Shellfish appear to be a strong complement to whole dressed catfish. Kinnucan et al. (19) determined demand elasticities for catfish to be price elastic at the processor level (−1.28) and price inelastic at the farm level (−0.37).

Potential to expand the U.S. aquaculture industry through export to Europe was investigated by Lombardi

and Anderson (39). The potential market for catfish in Germany was targeted using a conjoint analysis to provide estimates of relative value of fish attributes (e.g., size, form, and country of origin). Their analysis suggests that U.S. catfish producers may have an opportunity to export larger-sized fish to Germany.

Salmon. A survey of U.S. salmon markets for the Canadian Department of Fisheries and Oceans identified a 'salmon consumer' group of 43% and a nonsalmon consumer group of 47% (40). The majority of consumers did not perceive a difference between farmed and wild salmon. Price elasticities of −3.5 and −2.4 in the U.S. retail and restaurant sectors, respectively, were estimated. The majority of salmon consumption was concentrated in a small segment of the population. Salmon consumption would increase the most from year-round availability of fresh salmon with occasional, at-home consumers of salmon. All five areas surveyed (San Francisco, Los Angeles, Chicago, New York, and Dallas) showed good potential for increased consumption based on year-round availability of fresh salmon. In each area, gains in the retail sector are potentially higher than in the restaurant sector. Consumption patterns in Canada are similar to the United States except for a higher overall salmon consumption rate in Canada (66%). The Canadian sample indicates that at-home salmon consumption would increase if in-store recipes are made available.

Hermann et al. (41) found that demand for Norwegian Atlantic salmon was price and income elastic in both the United States and European Community and that demand was highly seasonal. Frozen chinook salmon was a

weak substitute for Norwegian-raised salmon in European markets. Price elasticity was −1.97 in the U.S. and −1.83 in Europe; income elasticity was 4.51 in the U.S. and 2.73 in Europe.

Wessells and Holland (42) addressed consumer preferences for farm-raised or wild-harvested salmon using household data from the Northeast and mid-Atlantic regions. Consumer perceptions were greatly affected by assurances of quality, with farm-raised and federally inspected products to be preferred.

CONCLUDING COMMENTS

Marketing of aquaculture products has increasingly become an important part of the U.S. food supply. Several decades ago, farm-raised catfish, trout, shrimp and pen-raised salmon were restricted geographically and temporally; however those products, along with emerging cultured species, are becoming available nationwide throughout the year. The ability to produce a standardized product, available year-round in environmentally controlled conditions, has allowed cultured fish and seafood products to establish important market niches. The concurrence of increasing population and associated environmental degradation with a rather stable supply of fish and seafood product from capture sources would suggest a rather bright future and rising importance of fish culture.

MICROALGAL CULTURE

GARY H. WIKFORS
Northeast Fisheries Science Center
Milford, Connecticut

OUTLINE

WHAT ARE MICROALGAE?

By direct translation from Latin, microalgae are "little seaweeds." However, defining microalgae further is not simple, because the microalgae represent a taxonomically diverse group of organisms, rather than a single, phylogenetic category. A functional definition of microalgae might be "photosynthetic single-celled or colonial microorganisms"; however, most of these microbes are able to grow without light if dissolved sugars are provided. Microalgal cells range in size from one micrometer—roughly the size of a bacterium—to several hundred micrometers (1 μm)—barely visible to the naked eye. Colonies and chains of some microalgal cells can attain a length of several centimeters (2.5 cm = 1 in.). This group of organisms contains remarkable morphological diversity, with shapes ranging from simple spheres to the ornate, silica shells of one group, the diatoms. Many microalgae are motile, propelling themselves with flagella, by amoeboid motion, or by gliding on extruded mucilage. Microalgae are found in an astonishing range of habitats, such as in fresh, saline and hypersaline waters, in polar ice, in soil, attached to plants and animals, and even in symbiotic relationships with fungi (e.g., lichens) and animals (e.g., corals). Historically, many of these organisms have been claimed and named by both zoologists and botanists; therefore, taxonomy has been, and remains, problematic. From the perspective of aquaculture, there are common characteristics that warrant their consideration as a functional group; the foregoing definition will suffice for this discussion.

As "microalgae" is a functional rather than phylogenetic group, a list of taxa that would reasonably fit within

Table 1. List of Currently Recognized "Microalgal" Classes and Representative Genera Used in Aquaculture

Class	Common Name	Representative Genera Used in Aquaculture
Cyanophyceae	Blue-green algae	*Spirulina*
Prochlorophyceae	Prochlorophytes	None

Pelagophyceae	None	None
Haptophyceae (Prymnesiophyceae)	None	*Isochrysis*
		Pavlova

the category is necessary (see Table 1). Higher level systematics of these groups are under revision; hence, only the class level is specified. The diversity of the group is underscored by the presence of both prokaryotic (not containing a nucleus, Cyanophyceae, or cyanobacteria) and eukaryotic (nucleated) taxa. The eukaryotic groups are thought to have arisen from the incorporation of photosynthetic prokaryotes (or, subsequently, photosynthetic eukaryotes) within protozoan-like host organisms. This hypothesized process is referred to as the endosymbiosis theory. Evidence from both electron microscope studies of microalgal cells (usually focused upon numbers and types of membranes within the cell) and more recent molecular sequencing work indicates that endosymbiotic creation of "new" organisms may have occurred a number of times in evolutionary history, leading to the diversity in morphology and physiology seen today. This diversity, especially in terms of physiology, provides opportunities for the current and potential use of these organisms in the aquaculture industry.

WHY CULTURE MICROALGAE?

There are two main reasons for which microalgae are grown: (*1*) for extractable chemicals and (*2*) as feeds for aquacultured animals. Efforts to produce foods for direct human consumption have met with limited success, and crops such as the cyanobacterium *Spirulina* remain in the

realm of "dietary supplement," rather than food crop; these cases are considered along with extractable chemicals.

Microalgae for Extractable Chemicals

Chemical analyses of microalgae have led to the discovery of many novel chemical compounds, some of which are useful as food additives, pharmaceuticals, cosmetics, or in other high-value applications. Examples of microalgae currently commercially cultured for extractable chemicals include (1) *Dunaliella* for β-carotene, a human nutritional supplement; (2) *Haematococcus* for the pigments astaxanthin and canthaxanthin, which are used as coloring agents in salmon feeds; (3) *Crypthecodinium* for docosahexaenoic acid (DHA), which is incorporated into infant formula; and (4) the aforementioned *Spirulina*, which is used as a dietary supplement or additive to cosmetic products. In most cases, the chemical compound of commercial interest is present as a small fraction of the total algal biomass; therefore, the scale of cultures for commercial production generally is in the range of many cubic meters ($1 \text{ m}^3 = 35.3 \text{ ft}^3$). When a selected portion of the algal biomass is extracted and refined, the presence of chemical and biological contaminants within production cultures is not relevant, unless overall production is constrained or an undesired chemical is coextracted with the product compound. Thus, in many cases microalgae for extractable compounds are cultured in large, open-pond facilities; *Dunaliella* ponds of several hectares (1 ha = 2.4 acres) in size are characteristic. Alternatively, industrial, "brewery-type" technology may be employed, as for *Crypthecodinium* cultured heterotrophically for DHA.

Although the list of successful commercial products that are extracted from cultured microalgae is short at present, the potential is enormous. Natural-products chemists have described numerous novel compounds from microalgae, including chemicals with antibiotic, antitumor, and neuroactive characteristics. As such products are developed for commercialization, considerable growth in microalgal culture for extractable compounds is predicted.

Microalgae as Aquaculture Feeds

The most common reason for culturing microalgae is as a feed in an aquaculture food chain (especially for marine or estuarine animals). Microalgae are consumed directly by bivalve molluscs (e.g., clams mussels, oysters, and scallops) throughout life, by young stages of crustaceans (shrimp), and even by first-feeding stages of some finfish. In addition, microalgae can be used to grow small invertebrates, such as rotifers (*Brachionus* sp.) and brine shrimp (*Artemia* sp.), that are fed to young stages of crustaceans and finfish and are used to enrich these small invertebrates with nutritional compounds, especially fatty acids and sterols, required by the larval crustaceans and finfish.

Criteria for selection of microalgae as aquaculture feeds include ease of culture, size, digestibility, and nutritional value. All but the first of these criteria are covered in another entry of this volume. Ease of culture under particular circumstances will be dependent upon the tolerance of the alga to physical, environmental conditions, such as temperature and salinity. An alga's ability to coexist with or exclude microbial contaminants, ranging from bacteria to fungi and protozoans, also is critically important in most commercial applications.

A number of specific, clonal strains of microalgae have been found, empirically, to possess desired characteristics and are in wide use; these can be obtained from aquaculture supply companies, academic institutions, and government-funded institutions that maintain microalgal culture collections. The strain level of identity is appropriate, because microalgal taxonomy remains in a state of continuing development and because different isolates of the same taxonomic species may differ widely in growth or nutritional characteristics relevant to their use as aquaculture feeds.

HOW DO MICROALGAE WORK?

Energy

Microalgae are referred to as autotrophs, a word that translates literally as self-feeding. This term is wholly appropriate because the process of photosynthesis, by which light energy is converted to chemical energy, provides sugars that are subsequently eaten, or burned, to support the heterotrophic processes of the rest of the cell. In cyanobacteria, photosynthesis occurs in cellular structures, called lamellae, that are not segregated by membranes from the rest of the cell. The photosynthetic apparatus of eukaryotic microalgae is contained within a membrane-bound structure, called a plastid or chloroplast, that is thought to have arisen, evolutionarily, from a cyanobacterial endosymbiont.

Regardless of its location within the cell, the photosynthetic process itself accomplishes nothing more than creating sugars and oxygen from carbon dioxide and water — a transforming process in the natural history of the earth, but insufficient in itself to sustain life. The reverse process, catabolism of sugars to release energy and carbon dioxide, is necessary for the cell to make use of the energy captured within the sugars. This concept is emphasized, because the energy and gas (oxygen and carbon dioxide) dynamics of microalgal cultures, particularly in natural diurnal light cycles, can vary considerably. Heterotrophic processes are active continuously to sustain life, while autotrophic processes occur only in the presence of light. In dim light, or in bright light with self-shading in dense cultures, light may be insufficient to counterbalance heterotrophic processes. The level of light energy input needed to just sustain the population without growth is called the compensation point. For the population of microalgae to increase, light energy above the compensation level must be provided.

Chlorophyll α, the chemical compound that catalyzes photosynthesis, absorbs light in the wavelength range of 400–700 nm, this range is referred to as photosynthetically active radiation, or PAR. Full, noon sunlight is in the range of 2,000 μmol photons per square meter per second of PAR; other units of PAR flux encountered may be micro-Einsteins per square meter per second, shortened by microalgal icon Ralph Lewin to Alberts. Thus, both

the quantity and quality of light is important to energy acquisition by microalgae.

An often-overlooked aspect of the energy-input requirements of microalgae is the potential to supply sugars to the heterotrophic cellular machinery from a source other than photosynthesis. Indeed, most microalgae tested are physiologically able to grow on sugars added to the culture medium as the sole energy source (i.e., in the dark). This capability has only recently been exploited commercially, and only under highly controlled, bacteria-free conditions. Bacterial sugar uptake and growth rates generally are more rapid than those of microalgae. In a competition for dissolved sugars, bacteria have an advantage over microalgae; therefore, aseptic production is necessary. In addition, while it may be more cost-effective to provide artificial sugars than artificial light to algae, the biochemical composition of microalgae grown photo-autotrophically vs. heterotrophically may affect the ultimate cost–benefit decision.

Materials, or Nutrients

Life processes require two inputs: energy and materials. The energy needs of the microalgae just discussed interact with materials—either carbon dioxide and water, or sugars and oxygen—and the material needs, predictably, interact with energy status of microalgal cells as well. At least 24 chemical elements have been identified as being essential, (i.e., nutrients) in all living cells (see Table 2). Although all of these elements could pass through membranes surrounding cells by simple diffusion, active, energy-consuming uptake processes have been demonstrated for essentially all nutrients. Beyond

Table 2. Chemical Elements Considered to be "Essential" for Living Cells, Including Microalgae

Element	Chemical Symbol	Typical Source in Microalgal Culture Media
Carbon	C	Carbon dioxide in air
Hydrogen	H	Water
Oxygen	O	Water
Nitrogen	N	Nitrate, ammonia, urea
Phosphorus	P	Phosphate salts
Calcium	Ca	Calcium carbonate
Sodium	Na	Sodium chloride
Chlorine	Cl	Sodium chloride
Magnesium	Mg	Magnesium chloride or sulfate
Potassium	K	Potassium chloride
Sulfur	S	Sulfate salts
Boron	B	Boric acid
Iron	Fe	Ferric chloride
Selenium	Se	Selenous acid
Copper	Cu	Cupric chloride or sulfate
Manganese	Mn	Manganese chloride
Zinc	Zn	Zinc chloride or sulfate
Molybdenum	Mb	Molybdenum chloride
Cobalt	Co	Cobalt chloride or vitamin B_{12}
Iodine	I	Potassium iodide
Nickel	Ni	Nickel chloride
Silicon	Si	Sodium silicate
Fluorine	Fl	Sodium fluoride
Chromium	Cr	Dichromate salts

the simple fact that diffusion would be highly rate limiting with dilute, natural nutrient concentrations, many required elements exist as chemical compounds or complexes in solution that must be modified before the element can be assimilated by the cell. Thus, nutrient uptake can be considered an active, energy-requiring process.

Microalgal nutrients can be segregated into two arbitrary categories: macronutrients and micronutrients, or trace elements. These categories are arbitrary in that deficiency in any element, macro or micro, will constrain growth. For all microalgae, nitrogen (N) and phosphorus (P) are considered macronutrients and are major structural components of proteins, nucleic acids, and the energy-management chemicals (e.g., adenosine triphosphate, or ATP) of the cells. For one class of microalgae, Bacillariophyceae or the diatoms, silica (Si) also is a macronutrient, because it is required in relatively large amounts for the formation of cell walls.

Forms of nitrogen biologically available to microalgae include ammonium (all), nitrate (some cannot use), and organic compounds (urea, amino acids, etc., available to most microalgae). Ammonium is the nitrogen "currency" within the cell, while nitrate must be reduced and urea catabolized during uptake; therefore, thermodynamics favors ammonium uptake. Most commonly used microalgal nutrient enrichments provide nitrate, though, because it is more stable in solution (not volatile) and not available to many bacteria in contaminated cultures. Microalgae that are not able to produce nitrate reductase, the enzyme that catalyzes the reduction of nitrate to ammonium, generally must be grown on ammonium. As nitrogen is a major component of proteins, deficiency arrests protein synthesis and may lead to an accumulation of energy-storage products, such as starches and lipids, in microalgal cells; this response can be exploited if increased storage-product yield is desired in cultures.

Phosphorus exists in natural waters chiefly in the oxidized form phosphate, although some organic phosphorus compounds may exist as well. Phosphate is by far the most common form of phosphorus added to microalgal culture media, and amounts added generally are in the range of one phosphorus atom for every 16–25 nitrogen atoms. Phosphorus deficiency in algal cells may lead to physiological disruption of protein synthesis, similar to nitrogen deficiency, but also may disrupt energy management within the cell; therefore, phosphorus starvation is a less dependable culture-management strategy than nitrogen starvation.

As previously mentioned, silica is required for the formation of cell walls in diatoms. As for nitrogen and phosphorus, an oxidized form, silicate, is encountered in natural waters and added to culture media. Different diatoms require different amounts of silica, and most possess the ability to make thinner "shells" under silica deficiency. Extreme silica deficiency arrests cell division and may cause cells to accumulate storage products, providing a possible culture-management strategy.

Trace elements, or micronutrients, represent a group of elements for which cellular needs are several orders of magnitude lower than the macronutrients. Micronutrients

tend to be minor but necessary components of enzymes involved in basic cell processes. Many of these elements are metals that are present in natural, oxygenated waters in highly oxidized forms, often complexed with dissolved organic molecules. In these forms, limited ability of microalgal uptake mechanisms to remove free ions from stable complexes may limit bioavailability and growth. In culture media, artificial complexing, or chelating, agents, such as EDTA, NTA, or citric acid, are added to moderate the bioavailability of trace metals, in particular. When chelating agents are used, metals must be added in excess of microalgal needs to saturate chelator-metal complex sites; thus, levels of trace metals added to media with artificial chelators may far exceed levels that would be toxic if metals were in the free-ion form. Indeed, the concentration range for many metals between deficiency and toxicity is relatively narrow; therefore, trace-element management of microalgal cultures can be quite challenging.

Some microalgae used widely in aquaculture (e.g., the prymnesiophytes) require vitamins, usually B_{12} and thiamin, and sometimes biotin. In open, bacterized cultures, bacteria generally supply these growth factors; however, pure cultures require that these vitamins be added in trace quantities for the algae that require them.

Microalgal Growth = Population Growth

If suitable and sufficient energy and materials are provided to an algal cell, it divides into two cells, which separate and become distinct individual organisms. Hence, microalgal growth is characterized in terms of increases in numbers of individual cells, rather than in terms of increases in an individual's size, which is the case for metazoan organisms. Production rate of microalgal biomass in a culture often is quantified in terms of average number of cell divisions per unit time (divisions per day), or the reciprocal, average time between cell divisions. A mathematical description of progressive cell divisions is a logarithmic function; calculation of this function from cell counts at two or more times is a straightforward procedure and a powerful tool for describing and managing a culture's performance.

There are two fundamental management strategies for microalgal cultures: batch culture and continuous culture. In a batch culture, a small population of cells (inoculum) is placed within a relatively large container supplied with sufficient energy and materials to produce a much larger number of cells. The production rate and the maximum number of cells that can be supported in the large container can be constrained by either energy or materials, but the main point is that algal growth will stop eventually, when there is no longer sufficient energy or materials to support further cell divisions. Yield and time of active growth are finite in a batch culture, and the container must be cleaned and reinoculated at the end of each growth cycle. In continuous culture, materials and energy are supplied continuously, and cells are removed at a constant rate equal to, or less than, the rate of production of new cells. Thus, a continuous culture has an indefinite lifespan, as long as the production of new cells is at least as fast as the removal of cells. There are a number of different categories of continuous cultures; the term chemostat, describing but one type of continuous culture, often is misapplied to cultures with constant fluid replacement rates (cyclostats), or constant standing biomass (turbidostats).

In theory, it would appear that continuous culture offers overwhelming advantages over batch culture, in terms of effort (labor), production-rate optimization, and management and control. In practice, however, it can be very difficult to maintain the steady-state conditions necessary for most continuous cultures. Furthermore, living contaminants, such as bacteria and protozoans, can divide more quickly than the cultivated alga, eventually replacing the intended crop. A compromise between batch and continuous culture management strategies, semicontinuous culture, offers some advantages of both. A single culture can be maintained for an extended period of time, replenishment rate (both amount and time between partial harvests) can be varied in response to culture performance, and partial harvests can be delayed to allow accumulation of lipids or carbohydrates if these are important in the application. Recent efforts to incorporate contemporary, computer process-control technology into microalgal culture have improved the effectiveness of continuous and semicontinuous microalgal culture methods.

HOW ARE MICROALGAE CULTURED?

Containers

Essentially, any vessel or structure that can contain water can be used to culture microalgae. Experimental and "seed" cultures routinely are grown in test tubes, flasks, jars, bottles, etc., made of glass and various kinds of plastic. Tanks, tubes, buckets, barrels, bags, pools, and ponds, constructed of nearly limitless materials, have been applied to production-scale microalgal cultures. For photosynthetic production, light can be provided from any direction if the container is transparent to light in the PAR range. Opaque containers with the artificial light sources immersed within the culture have been used with limited success. Alternatively, containers with an exposed surface lighted from above can have opaque sides and bottom. In addition to permitting light penetration, containers must provide for gas exchange with the atmosphere or incorporate an added gas stream. Tank and pond cultures generally are kept relatively shallow to provide for gas exchange with the atmosphere, by virtue of a high surface-to-volume ratio, and also to maintain light input above the compensation level. Gas exchange and culture mixing often are enhanced by introduction of a diffused gas stream (bubbles) through the culture. Although widely used, bubbling of open, bacterized microalgal cultures may encourage bacterial degradation of the culture; physical mixing with foils, paddles, etc., may be more successful and has been applied in many large systems. Tubular containers, consisting of many meters of narrow-diameter, transparent glass or plastic tubing have seen several periods of intense interest, as this design offers some advantages of both open containers (short light path) and closed systems

(exclusion of contaminants). Gas-transfer limitations have constrained effectiveness of tubular systems. For heterotrophic microalgal production, standard industrial bioreactors used for other microorganisms have proven to be transferrable, with few modifications, to most microalgae.

Energy

Most commercial microalgal production is based upon photosynthetic growth. Light can be provided by natural sunlight or by artificial lights. Natural sunlight is inexpensive (a function of land cost), but varies seasonally and may be unreliable daily, depending upon location and climate. Artificial lights can be controlled very precisely, in terms of both quantity and quality, but can account for up to 95% of the cost of culturing microalgae. Many small-scale fish and shellfish hatcheries culture microalgal feeds using artificial lights because feed production must coincide reliably with seasonal life-history stages of the animals that are, in turn, often nonsyncronous with seasonal light and temperature cycles. Accordingly, the cost of producing microalgal feed cultures in these facilities is among the highest of all cultivated products, ranging from $100 up to $400 per dry kg ($45 to $180 lb) of microalgal biomass. In contrast, culture of *Dunaliella* for β-carotene in desert ponds can cost over 100 times less, because of the difference in energy cost alone. For heterotrophic culture, various waste and off-specification agricultural products can be used as energy sources for microalgal culture. The economics of using reduced-carbon energy sources for heterotrophic production appear to be intermediate between artificial light and solar energy; the success of each type of energy source is dependent upon the application of the microalgal product and the specific alga that is cultured.

Materials

Fertilization of microalgal cultures ranges, in commercial practice, from animal manure added directly to earthen ponds to complex formulations prepared with pharmaceutical care. In instances where extractable chemicals are the product, industrial-grade chemicals are generally sufficient, because chemical contamination of the product is not a practical concern. When cultured microalgae are part of a food chain leading to a human food product, more refined chemical fertilizers are recommended. Culture medium formulations can be assembled from component chemicals according to recipes found in standard texts (see Bibliography), but proven microalgal fertilizer mixtures, based upon the Guillard "f/2" formulation, now are being marketed by aquaculture-supply companies.

Culture Management

Batch culture still is used in most applications. Usually, small-scale flask cultures maintained under pure (bacteria-free) conditions are increased in volume by inoculating a series of progressively larger containers until the production-scale is reached; the term for this practice is "progressive batch culture." For many aquacultured animals fed microalgal cultures, the lipid content of the algal feed is the most critical nutritionally; therefore, many farmers allow cultures to enter a nutrient-deficient (usually nitrogen) phase, during which the nondividing microalgal cells often store photosynthetic energy as lipid. Continuous and semicontinuous culture methods are employed routinely in extractable-product operations and increasingly are being developed for marine-animal feeds applications.

WHAT INNOVATIONS ARE EXPECTED?

In reviewing the history of the development of modern microalgal culture, one is struck by the existence of two, nearly independent "heritages." One line of investigation, dominated by engineers and chemists, was motivated by the potential for industrial products, ranging from human foods to synthetic fuels and oxygen factories for extended space travel. Working almost exclusively with the freshwater chlorophyte, *Chlorella*, scientists and engineers developed and built pilot plants employing state-of-the-art electronics and fluidics innovations. While most of the perceived applications for *Chlorella* biomass have not proved successful, the legacy of this research effort provided the foundation for today's extractable-product microalgal technology. The second line of investigation, dominated by biologists and ecologists, arose from laboratory-scale culture and feeding apparatus designed to maintain experimental animals for investigation of their life cycles, feeding habits, etc. These types of methods were generalized and modified to culture a wide variety of microalgal types and were used in the elucidation of nutritional requirements of animals that were to subsequently enter into aquaculture production. Little thought was given, however, to economics or problems of scaling the design for commercial use. At the time of this writing, it appears that the two "lineages" of microalgal culturists finally are communicating and collaborating on engineered systems that satisfy the biological needs of the variety of microalgae used as aquaculture feeds, as well as for extractable compounds, and do so in a cost-effective way. This cooperation holds great promise for the future of microalgae in aquaculture.

INTRODUCTION

Microbound feed is a general category of small particulate feeds ranging in size from 50 to 700 μm that are typically fed to larval stages of fish and invertebrates. The defining characteristic of these feeds is that the particles are held together by an internal binder, which may be a complex carbohydrate or a protein having adsorptive and adhesive properties (1). This differs from microencapsulated feeds, which are characterized by a distinct wall or capsule surrounding a central core of material (2,3).

There are many types of larval feeds available on the market and more are being developed in laboratories around the world. The particular feeding situation (e.g., species, water temperature, or culture system) determines which type of larval feed to use. Different feeding situations may require different types of feed. To understand the processing methods used in manufacturing microbound feeds, an evaluation of the desired characteristics of an effective feed is necessary.

Palatability, nutrient stability, nutrient availability, and particle stability are all important traits of a microbound feed. A feed of outstanding nutritional quality is of little value if it has low palatability and the animal will not consume it. Palatability is affected by factors such as smell, flavor, and texture. The smell and flavor of the feed is caused by the leaching of nutrients into the water, and thus some leaching is necessary for adequate levels of feed consumption. Excessive leaching, however, can result in a poor quality feed due to reduced nutrient content. Nutrient stability is very important to ensure adequate nutrition, but if the feed is bound too tightly, consumption and/or nutrient absorption could decrease. Feeds for finfish must be formulated, manufactured, and selected with the goals of high palatability and high nutrient stability in mind, even though those objectives seem to work in opposite directions.

Another important characteristic of a microbound feed is particle stability. This refers to the loss of material from the feed particle in water. A feed with low particle stability will disintegrate and degrade water quality, which can decrease survival of the cultured animal. Gill damage caused by high levels of particulate matter in the tank, bacterial contamination, and low oxygen levels are all problems that can be caused by a feed with low particle stability (4).

Feed characteristics are strongly affected by the type of binders and processing methods used in manufacture, so each feeding situation may best be accommodated by a particular formulation or processing method. There can also be interactions between processing method and ingredient formula, including binder source. Sometimes a particular processing method is categorized as ineffective for use in a particular situation, when the formulation itself in combination with the processing method was actually inadequate. The culture technique used when feeding formulated feeds can also determine if the program is a success or a failure. Many factors need to be considered when selecting a larval feed, but by considering formulation, processing method, palatability, nutrient stability, particle stability, and culture methods, an effective larval production program using microbound feeds can be achieved.

CLASSES OF MICROBOUND FEEDS

Microbound feeds can be separated into three major classes according to production process: crumbled, on-size, and complex particles. Crumbled feeds are produced by manufacturing a pellet, flake, or cake that is fractured into smaller pieces and sifted to obtain the desired size (5,6). On-size feeds are manufactured directly to the correct size particle (2,7), which not only saves a production step, but produces physical characteristics that differ from crumbled feeds. Complex particles

are produced by combining two or more techniques (including microencapsulation) to exploit the advantages and overcome the disadvantages of individual production methods (8,9).

CRUMBLED FEEDS

Pelleted Feeds

Pellets used in the manufacture of crumbled feeds can be produced through either steam pelleting, cooking extrusion, or cold extrusion. Steam pelleting refers to a process by which solid pellets are formed by forcing a feed mixture (mash) through holes in a rotating die after preconditioning with steam to a temperature of 70–85 °C and moisture content of 15–18% (5,6,10,11). As the pellets emerge from the die, they are cut to desired length by an adjustable knife. The steam partially gelatinizes dietary starch, which aids in binding the ingredients. Precooked corn, sorghum, potato, palm nut, wheat, and tapioca starches are sometimes added to the diet at 10–20% to increase pellet bond strength (6). Special organic hydrocolloids such as lignin sulfonate and carboxymethyl cellulose can also be added at 0.25–5.0% of the ingredient formula to aid in the pelleting process (6,12). The compressed pellets are dried, crumbled, and sifted to the desired size. The resulting particles have an irregular shape, are fairly dense, and generally have low particle and nutrient stability in water.

Cooking extrusion is a process by which a feed mash is moistened with 20–25% water, precooked at 100–150 °C, then forced through a die under high heat and pressure (5,6,13–16). As material passes through the die, pressure suddenly drops, causing water vaporization that traps air within the resulting pellets. After cooling and drying, pellet density may be such that the feed can float or sink slowly in water. The almost complete gelatinization of starch within extruded feeds produces pellets that are more tightly bound and have greater water stability than steam-pelleted feeds. The cooking of carbohydrates increases availability of dietary energy (17), but many larval fish may have limited ability to digest carbohydrates. Cooking extrusion is a very versatile processing method that can produce feeds with physical characteristics not possible with other pelleting methods.

Cold extrusion is the process of pressing a wet mash (>20% moisture) through holes in a plate without addition of heat, producing a noodle that is cut or broken to form pellets (5,15). This type of extrusion can generate pellets with diameters as small as 1.0–1.5 mm, depending upon the characteristics and particle size of the ingredients used (16). Pellet stability is accomplished through selection of ingredients with high-binding activity, such as wheat gluten or protein hydrolysates. This manufacturing method is often used to produce moist, semimoist, and soft-moist feeds, which typically do not have the long-term water stability of harder, more tightly bound feeds.

Steam-pelleted and extruded crumbles were developed for salmonid culture and have been instrumental in development of that industry. However, fish feed manufacturers are currently evaluating other processing methods for production of starter feeds. Even though steam pelleting and extrusion are different processes, the crumbled products produced with each method are fairly similar.

Flaked Feeds

For a long time, flaked feeds have been the most common type of feed fed to aquarium fish. Although a variety of methods can be used to produce flakes, the double-drum drier affords the greatest control of variables affecting flake quality (18). The equipment consists of two parallel drums rotating in opposite directions that are heated internally with steam. Feed ingredients are ground to approximately 0.1 mm and blended with water to form a slurry or dough that is coated onto the drum surface (6). The dough is flattened to a uniform thickness between the rotating drums and dried to a thin sheet. A blade scrapes the sheet from the drum at a point approximately two-thirds the drum circumference from the nip of the rolls (18). The thickness of the flake can be adjusted by changing the distance between the drums. The dried sheet is then crumbled to produce flakes or ground and screened to produce small particles. The resulting feed has a high surface area-to-volume ratio and will float for a long time before saturating with water and sinking. Long floating times are beneficial in many cases, since fish have more time to consume the feed. The high surface area-to-volume ratio, however, can also result in a rapid loss of water-soluble nutrients if they have not been stabilized. Carbohydrates are often used as binders in flake feeds, but other ingredients with good hydrocolloidal properties and tensile strength can be used (6).

Flaked feeds are often criticized because of the high temperature required for drying. Proteins can be burned, lipids oxidized, and vitamins lost by exposure to high temperatures during any manufacturing process (15,19–21). Flaked feed, however, is exposed to heat for only a short time, and studies evaluating the effect of processing methods that have not been confounded by ingredient formulation have been limited. High temperature may not be a problem if the time of heat exposure is short. The concept of flaking machines producing poor-quality products may be a result of comparisons of different feed formulations produced with different processing techniques.

Cake Feeds

Crumbled cake refers to a feed manufacturing process in which a mixture of feed ingredients and binding agents are gelled into a matrix that is dried, crushed, and sieved into appropriate size particles (1–3,22–25). Many different binders are used to produce cake feeds, including agars, alginate, carrageenan, cold-water gelling starches, egg albumin, gelatin, and zein. Each binding system is activated differently. For example, zein is an amino acid containing compound found in corn and is soluble in alcohol, but not water. Solubilizing this compound in alcohol, adding the base mix, and then evaporating the alcohol will result in a particle with high water stability. Egg albumin can also form a matrix, but it is activated

by heat. Combinations of different binders are sometimes necessary to produce particles with the desired physical characteristics. The crumbled cake method is currently being used commercially to produce some very effective larval feeds.

ON-SIZE FEEDS

Microextruded Marumerized Feeds

Microextrusion marumerization (MEM) is a two-step process adapted from the pharmaceutical industry and is now being used to manufacture small, preshaped larval feeds (7,16,26). A wet mash of finely ground feed ingredients is first formed into thin noodles by using extruders designed to reduce the operating pressure. The lower operating pressures allow for smaller diameter noodles to be produced. Radial discharge and twin-dome extruders are capable of producing noodles as small as 500 and 300 μm, respectively. Noodles are then broken and shaped in a marumerizer, which consists of a cylindrical chamber with a high-speed rotating grooved plate at the bottom. Plates are available with different depths of grooves, which affects the amount of energy transferred to the feed during marumerization. A very strong noodle requires a deeply grooved plate, while a soft noodle is processed most effectively with a shallow-grooved plate. Feed discharged from the marumerizer can be fed wet or dried. Particle size range within a given production run is very narrow, and sifting is not as important as with other processing methods. The marumerizer imparts two effects to the feed. The first is to break the noodles into lengths roughly equivalent to noodle diameter and shape the resulting particles into spheres (16). The uniformity of particle length and the amount of shaping are affected by feed formulation and moisture level, among other factors. The second effect is to increase surface density of the feed particles. As the feed spins in the marumerizer, centrifugal forces cause migration of water and small ingredient particles to the pellet surface, thus increasing surface density proportional to the pellet interior. This effect can be visualized under a microscope and has been demonstrated to increase particle stability. It is also thought to increase nutrient stability — although this has not been proved. The speed of the plate also has a profound effect on the marumerization process. The higher the speed, the more energy is transferred to the feed, causing more shaping and more centrifugal force.

Many types of binders can be used with MEM particles, provided they are moisture and pressure activated. No heat is added during this process, but some is generated at the extrusion screen due to friction. The amount of heat generated is affected by formula and moisture level, but is normally quite low. Binding systems based on gums have been used, but protein hydrolysates are also effective. Hydrolysates have the advantage of added nutrition as well as binding. Care must be taken in formulation with hydrolysates, since high levels can result in agglomeration of feed in the marumerizer into very large particles.

Feed produced by MEM can be characterized as smooth and spheroid with high density. The smooth shape may decrease nutrient leaching by decreasing the surface area-to-volume ratio, relative to a rough particle of the same size (i.e., crumbles or flakes). The high density of the feed will result in a faster sinking particle, which is a negative effect for species that feed in the water column.

Particle-Assisted Rotationally Agglomerated Feeds

Particle-assisted rotational agglomeration (PARA) is a processing method that utilizes a marumerizer without extruded noodles (U.S. Patent 5,851,574) (7,26,27). Wet mash is placed directly into the marumerizer with a charge of inert particles. The rotation of the marumerizer imparts energy to the inert particle, which in turn transfers energy to the mash, producing spheroid particles in a wide range of sizes. Feed formulation and moisture content are very important with this method. Several other process variables can be controlled to affect particle size distribution and density. An advantage of this process as compared to MEM is lower capital expenditure and lower operating costs due to elimination of the extruder from the process. The same binders used with MEM particles are effective in PARA particles, with minor modifications. The PARA particles are not as uniform in shape as particles produced by MEM. Size distribution of PARA particles is also much greater than MEM particles, thus necessitating sifting, but allowing for the production of several sizes in a single run. The PARA process is a low-pressure agglomeration method that results in low-density feed particles with a slow sink rate, useful for species that feed in the water column.

Spray Beadlets

Spray beadlets are small microbound feeds that trap high-molecular-weight, water-soluble nutrients such as starch and protein within gels of calcium alginate and gelatin (2). Particles are produced by spraying a slurry of dietary components and a selected gelling agent (e.g., alginate) into a curing bath (e.g., calcium chloride solution) (28). Many types of binders can be used with this method and produce good results. This process creates a wide range of particle sizes, so sifting is often required. (See the entry "Microparticulate feeds, micro encapsulated particles.")

COMPLEX PARTICLES

Complex particles are produced by combining two or more manufacturing techniques to exploit the advantages and overcome the disadvantages of individual production methods. This is an exciting development in larval feed manufacturing that allows for production of feeds that more closely fit specific needs. For example, microcapsules or crumbled cake particles may be embedded within larger MEM, PARA, or spray beadlet particles. Villamar and Langdon (8) embedded lipid-wall microcapsules within alginate–gelatin particles to deliver both micro- and macronutrients to suspension-feeding larval shrimp within a single complex microcapsule. Ozkizilcik and Chu (9) prepared complex protein-walled microcapsules containing lipid-walled capsules for feeding striped

bass larvae. The complex particle combines the advantages of several types of feeds and may be the larval feed type of the future.

MICROPARTICULATE FEEDS, COMPLEX MICROPARTICLES

Chris Langdon
Oregon State University
Newport, Oregon

OUTLINE

Text
Bibliography

A complex microparticle for delivery of nutrients to aquatic or marine suspension feeders consists of two or more different microparticle or microcapsule types combined into a single complex microparticle (1). The advantage of using a complex microparticle is that a single food particle can potentially deliver all required nutrients to a targeted suspension feeder. This way, the suspension feeder cannot selectively feed on one particle type versus another, which would result in a modified composition of the ingested diet.

Villamar and Langdon (1) described a complex particle for use in feeding studies with mysis shrimp larvae (*Litopenaeus vannamei*). The complex particle consisted of lipid-walled microcapsules (2) incorporated within alginate–gelatin microbeads. Lipid-walled capsules are necessary for retention and delivery of low-molecular-weight, water-soluble nutrients, while alginate–gelatin beads supply other dietary ingredients, such as protein and carbohydrate. Villamar and Langdon (1) reported that complex particles retained 85% of encapsulated glucose after 18 hours suspension in seawater. The mysis shrimp larvae were able to physically break down the tripalmitin walls of the lipid-walled microcapsules by the action of their mouth parts and assimilate released glucose.

Ozkizilcik and Chu (3) described a second kind of complex particle developed for the delivery of nutrients to striped bass (*Morone saxatilis*) larvae. This complex particle consisted of lipid-walled capsules incorporated within cross-linked, protein-walled capsules. More than 70% of encapsulated lysine was retained by these complex particles after 2 hours of suspension in seawater compared with only about 1% lysine retention by cross-linked, protein-walled capsules.

The ability of complex particles to deliver complete artificial diets to suspension feeders is an important step in the development of economic microparticulate feeds. They may provide complete replacement of living diets in hatcheries, reduce food costs, and increase the reliability of supplies of high-quality food.

MICROPARTICULATE FEEDS, MICRO ENCAPSULATED PARTICLES

CHRIS LANGDON

OUTLINE

Text
Bibliography

The structure of a microcapsule is characterized by a distinct wall surrounding core material. The chemical composition of the wall is usually different from that of the core material and is designed to meet specific functions of the microcapsule. In contrast, microbound or microgel particles lack a distinct wall and consist of a matrix of carrier material in which nutrients are bound. Microcapsules are used to deliver nutrients to suspension feeders, such as larval fish, shrimp, and bivalves [see reviews by Langdon et al. (1) and Robert and Trintignac (2)].

The objective of microencapsulating diets for freshwater and marine organisms is to reduce leakage of nutrients into the surrounding water. Leakage of nutrients results in elevated bacterial concentrations (3) and possible outbreaks of disease. The ideal microcapsule wall should be impermeable to nutrient leakage and remain intact until the microcapsule is consumed by the target organism. Once the microcapsule is eaten, then its wall should be readily broken down, liberating the capsule contents for digestion and assimilation.

The first microcapsule type to be used for the delivery of nutrients to marine suspension feeders was the nylon–protein-walled capsule described by Jones and colleagues (4). Subsequently, this capsule type has been used by many researchers and has undergone many modifications. The elimination of detergents in washing capsules free of organic solvents improved the capsule's acceptability by suspension feeders, while elimination of nylon from the wall resulted in a cross-linked, protein-walled capsule that was not potentially contaminated with toxic, nylon-forming monomers (5,6). Such modified capsules have been successfully used in feeding studies with fish larvae (7–9), crustacea (4,5,10–12), as well as bivalves (3,6,13–17). Incorporation of carbohydrate into the wall of cross-linked, protein-walled capsules (14) and coating capsules with triglycerides (16,18) allowed modification of capsule core retention efficiencies and digestibilities.

A disadvantage in the use of nylon–protein and protein-walled capsule types for diet delivery to suspension feeders is that both capsule types are typically formed by emulsifying dietary ingredients in an organic phase, such as cyclohexane. This emulsification process extracts lipids from the diet, reducing dietary lipid content. As an alternative for the delivery of dietary lipid to suspension feeders, Langdon and Waldock (19) used gelatin–acacia capsules to deliver dietary lipid supplements to oysters. Preparation of gelatin–acacia capsules does not involve organic solvents and results in capsules that are stable but digestible. Subsequently, this capsule type has been used by other researchers in feeding experiments with bivalves (20–23) and as a means of improving the fatty acid composition of *Artemia* (24,25).

A second disadvantage of nylon–protein and protein-walled capsule types is that the capsule walls are permeable to low-molecular-weight nutrients, such as amino acids and water-soluble vitamins (18). To deliver these water-soluble nutrients to suspension feeders, Langdon and colleagues (3,26) used a type of lipid-walled microcapsule to deliver water-soluble vitamins to oysters. Subsequently, Chu and colleagues successfully grew oyster larvae to metamorphosis on a diet that included lipid-walled capsules (20). A softer capsule wall that is partly made up of triglycerides with a low melting point, such as triolein or fish oil, is optimal for bivalve molluscs. (27). Lipid-walled capsules prepared with triglycerides with high melting points, such as tripalmitin, have been successfully used by Villamar and Langdon (28) to deliver glucose to shrimp larvae because the larvae are able to physically break down capsule walls with their mouth parts.

Liposomes are an alternative to lipid-walled microcapsules for delivery of low-molecular-weight, water-soluble substances to suspension feeders (29–32). Liposomes are prepared from phospholipids, while lipid-walled capsules are prepared from triglycerides. Chapman (33) described three types of liposomes: multimembrane liposomes made up of numerous layers of concentric spheres of phospholipid with the aqueous phase trapped between the layers; small, single-membrane liposomes that are 200 to 500 Å in diameter; and large, single-membrane liposomes that range from 600 Å to 10 μm in diameter. Liposomes are more fragile than lipid-walled capsules and tend to be more "leaky." Kulkarni et al. (34) described how the walls of liposomes can be strengthened and made less leaky with the addition of cholesterol and vitamin E to the phospholipid walls.

In summary, different microcapsule types have been successfully used to supply nutrients to suspension feeders. However, there are very few examples of microencapsulated diets that have been found to be complete replacements for living diets in rearing suspension feeders. Clearly, additional research is needed to improve microcapsule design and diet composition to achieve this goal.

MILKFISH CULTURE

ROBERT R. STICKNEY
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

Life History

Spawning and Larval Rearing

Growout

Bibliography

Milkfish (*Chanos chanos*) are popular foodfish in the Indo-Pacific region. In some places, they are also used as bait by the tuna fishing industry. For centuries, milkfish have been widely cultured in the tropical Indo-Pacific, and they still are. For example, milkfish culture has been practiced in Indonesia for 700 years and in the Philippines for at least 300 years (1). Until the late 1980s, the culture of milkfish was entirely dependent upon the capture of fry or fingerlings from nature.

Milkfish are popular because they can be reared in a wide range of salinities, do not require high-quality prepared feeds, and grow rapidly. Milkfish can be grown from fry to harvest size in six to eight months. The major milkfish-producing countries are Indonesia, the Philippines, and Taiwan. A recent review of milkfish culture (2) forms the basis for much of the information presented here.

LIFE HISTORY

Adult milkfish can attain sizes of up to 4.5 ft (1.4 m) and 33 lb (15 kg). The fish will live up to 15 years, are found swimming in schools in the water column (that is, they are pelagic), and are highly migratory (3). The eggs, embryos, and larvae are also pelagic. Larvae reach sizes of 0.4 in. (10 mm) within two to three weeks after hatching. The larvae move with the aid of currents and by actively swimming to shallow-water areas such as mangrove swamps and lagoons associated with coral reefs and atolls. For several months, the fish remain in the coastal region, where they become juveniles. Eventually, the young milkfish migrate offshore, to inhabit the continental shelf for the remainder of their lives.

Adult female milkfish produce eggs averaging 0.05 inch (1.2 mm) in diameter and ranging in number from about 300,000 to 700,000. Natural spawning occurs from June through October in Hawaii, at the higher end of latitudes where milkfish occur, while in the southern part of the range the fish may spawn from August through May. Multiple spawning can occur at intervals of three to four weeks.

SPAWNING AND LARVAL REARING

Milkfish fry can be collected throughout the tropical Indo-Pacific in coastal waters. Historically, the milkfish culture industry has depended solely upon fry caught in the wild for stocking ponds and net pens. In Taiwan alone, the demand for milkfish fry exceeds 100 million annually. The fish farmers are not typically involved in collecting fry. Instead, fishermen employ nets to collect the fry, and then they transport them, often in small hand-carried waterproof containers of various kinds, to the fish farmers. Significant losses can occur during transit when the fish are carried long distances by human porters.

Since the late 1980s, Taiwan and the Philippines are among the milkfish-producing nations that have achieved some independence from the need for wild fry by developing hatchery systems. In Taiwan, hatchery activity is often conducted in two separate phases involving culturists who maintain and spawn broodfish and those that rear fry to the size at which they may be stocked.

Hatcheries often implant females with a combination of cholesterol, leuteinizing hormone-releasing hormone (LHRH), and methyltestosterone to help ensure proper egg development. Implants are effective only when the fish are simultaneously exposed to long photoperiods, so the technique does not eliminate the need for at least one environmental cue.

Once proper egg development has occurred, the females can be induced to spawn with an injection of LHRH. The timing of the injection is based on an examination of the developing eggs by sampling anesthetized females. When the eggs are of the proper size, the hormone is injected, and spawning will take place within 12 to 15 hours. Each injected female is placed in a spawning tank, often in the presence of two males (2).

In the Philippines, broodfish of five years or older held in floating cages will spontaneously spawn, and their eggs can be collected for hatching and rearing subsequent of the larvae. Milkfish will also spawn naturally in (canvas-lined, concrete, or fiberglass) tanks and in ponds. Eggs need to be removed from the spawning habitats soon after they are produced, to prevent them from being consumed by the adults.

Reports have surfaced of morphological abnormalities at rates of from 3 to 26% in hatchery fry (4). Abnormalities include clefts in the branchiostegal membrane and deformities in the opercula. High mortality rates are common in deformed fry.

Hatchery-produced fry are commonly reared in ponds and fed planktonic organisms, such as rotifers, reared specifically as food for the milkfish. Rotifers should be available from hatching until the fish are 25 days old. Phytoplankton should be present at least during the first 12 days after hatching. Brine shrimp nauplii and prepared feeds may be accepted beginning on the 12th day (2). Oyster eggs are sometimes used for the first feeding stage of milkfish fry. Naturally produced copepods are also a good food source for fry in extensive culture systems. Stocking rates vary, depending on the type of culture process used (extensive or intensive).

GROWOUT

Milkfish growout is typically conducted in ponds, although an interesting exception occurs in a large lake above Manila Bay in the Philippines known as the Laguna de Bay. There, where the salinity ranges from fresh to slightly brackish, large net pens have been constructed in which milkfish are reared. Many of the pens are located near houses on stilts. The fish culturists reside in the houses, primarily to maintain the nets and forest all poaching. No food is provided for the milkfish, as the Laguna de Bay is a highly productive body of water. The proliferation of net pens in the bay in the 1970s resulted in a loss of natural productivity due to overstocking with milkfish and tilapia. (See the entry "Tilapia culture.") Regulations on the number and size of operations were imposed to increase and maintain milkfish production, which reportedly reaches 1.6 tons per acre (4 tons per hectare) in the Laguna de Bay area (1).

Pond culture also often involves providing natural food. Prior to stocking, ponds are partially filled and fertilized to encourage the growth of a mixed benthic algal, microorganism, and animal community known in the Indo-Pacific as lab-lab. The lab-lab community often includes several species of bacteria, blue-green algae, diatoms, protozoa, copepods, amphipods, ostracods, nematodes, polychaetes, molluscs, cladocerans, isopods, and other organisms. As the community develops, additional water is added until the pond is full, after which the young milkfish are introduced.

Pond production varies greatly from one nation to another, depending upon the intensity of culture, the use of prepared feeds, and overall management strategies. In Taiwan production averages some 2,000 lb/acre (approximately 2,000 kg/ha), while in the Philippines average production is about 870 lb/acre and in Indonesia is even less, 450 lb/acre (450 kg/ha) (1).

Prepared feeds have also been developed for milkfish. Research by fish nutritionists have outlined the protein and lipid requirements of milkfish, and some information is available regarding substituting dietary fiber for other feed ingredients. Detailed information on nutritional requirements, however, is generally lacking. Because milkfish are largely herbivorous during the growout phase, prepared diets can be relatively low in protein compared with carnivore feeds.

Like other aquaculture species, milkfish are susceptible to a variety of diseases. In addition to bacterial diseases, milkfish may harbor such parasites as protozoa, copepods, trematodes, nematodes, and cestodes.

MINERALS

Delbert M. Gatlin, III
Texas A&M University
College Station, Texas

OUTLINE

INTRODUCTION

Minerals comprise a distinct group of compounds characterized by their inorganic nature. Many of these elements are required by animals to support various structural and metabolic functions and thus are considered essential. It has been established that fish and crustaceans generally require the same essential minerals as terrestrial animals to support various bodily processes (1). However, a considerable amount of dissolved minerals in the aquatic environment may contribute to satisfying some of the metabolic requirements of aquatic organisms and thus influence dietary requirements. The biochemical functions of minerals in aquatic species are generally similar to those in terrestrial animals with the exception of osmoregulation, which involves maintenance of osmotic balance between body fluids and the water in which aquatic animals live (2). In terms of osmoregulation, freshwater species lose ions to the hypotonic environment and therefore suffer from hydration; thus these organisms generally do not drink water but excrete large quantities of excess water as dilute urine. In contrast, marine species drink seawater to make up for a loss of fluid from their body to the environment. Fish and crustaceans in freshwater and marine environments may obtain dissolved minerals from the water by absorption across the gills or other body surfaces or from ingestion under certain conditions. Thus, the aquatic environment has tended to complicate and limit research on mineral nutrition of fish and crustaceans. However, research efforts over the past decade have continued to advance knowledge about various aspects related to mineral nutrition of aquatic species, much of which has been applied to the production of these organisms in aquaculture.

CLASSIFICATION OF MINERALS

There are over 100 elements listed in the periodic table, and many of these elements occur in nature in an inorganic form (unbound to carbon). Of all these elements, less than 40 are present in appreciable quantities in the animal body (3). Some of these mineral elements do not have established metabolic roles and a regular dietary supply is not required; thus, they are classified as nonessential. The presence of such minerals in the animal is generally attributed to their occurrence in the environment and transmission to the animal in its food. Examples of these nonessential minerals include aluminum, antimony, bismuth, boron, germanium, gold, lead, mercury, rubidium, silver, and titanium. Other mineral elements found in the body have been demonstrated to be nutritionally essential. Their essentiality is based on the development of reproducible structural and/or physiological abnormalities with the individual deletion of each specific mineral from an otherwise nutritionally adequate diet and reversal of these abnormalities by addition of the specific mineral back to the selectively deficient diet. At least 21 different mineral elements have been established as essential for certain animals (3). It is these nutritionally important minerals that will be the focus of this article.

In addition to minerals being classified as essential or nonessential, they also are generally categorized as macrominerals or microminerals based on the amounts found in the body and generally required in the diet. Microminerals also may be referred to as trace minerals. The macrominerals and microminerals will be discussed separately in the next two sections. The individual minerals within each group will be considered with regard to their specific functions, known aspects of metabolism, and dietary requirement levels in representative fish and crustacean species. Subsequent sections will consider other aspects of mineral nutrition such as potential toxicity of certain minerals, interactions between minerals and other compounds, sources and forms of minerals for dietary supplementation, and biological availability of minerals.

MACROMINERALS

Macrominerals are generally present in the body in appreciable amounts and required in the diet in relatively large quantities. Seven macrominerals are generally considered to be essential. These include the cations calcium (Ca^{2+}), magnesium (Mg^{2+}), potassium (K^+), sodium (Na^+), and the anions chloride (Cl^-), phosphorus (PO_4^{3-}) and sulfur (SO_4^{3-}) (3).

Calcium

Calcium is a primary structural component of hard tissues such as bones, exoskeleton, scales, and teeth of aquatic animals. Additionally, calcium is essential for a variety of physiological processes such as blood clotting, muscle function, nerve impulse transmission, osmoregulation, and as a cofactor for enzymatic processes (3).

Aquatic organisms differ from terrestrial organisms in that their metabolic requirements for calcium typically can be met by absorbing this mineral from the water in which they live. Both shrimp and fish can absorb some minerals from the water via drinking (primarily marine organisms), and by direct absorption via the gills, fins, and skin (1). The gills are the most important site of calcium regulation in freshwater and marine fish (2). Dietary calcium is primarily absorbed from the intestine by active transport. In vertebrates, the vitamin D metabolite 1,25-dihydroxycholecalciferol functions in the maintenance of serum calcium levels by altering the rate of intestinal absorption (via a Ca^{2+}-binding protein), renal resorption, and bone mobilization (3). There is some evidence that vitamin D and its metabolites affect calcium homeostasis in teleosts, although the importance of vitamin D in utilization of dietary calcium via intestinal uptake appears to be less critical in fish as compared to terrestrial animals (1,4,5).

Freshwater of moderate hardness ($\sim$50 mg/L as $CaCO_3$) as well as brackish water and seawater, which contain much higher levels of calcium, generally have been shown to provide fish and crustaceans with adequate calcium to sustain metabolic functions in the absence (or presence of very low levels) of dietary calcium (1). However, in the presence of low levels of waterborne calcium, the essentiality of dietary calcium has been established for various freshwater species such as channel catfish, *Ictalurus punctatus* (6), and tilapia, *Oreochromis aureus* (7). In such low-calcium water (<1 mg Ca/L), fish fed calcium-deficient diets manifested deficiency signs similar to terrestrial animals such as reduced growth and impaired ossification of bone and scale tissues. Under such conditions, dietary calcium levels ranging from 0.45 to 0.7% of diet were required to maintain normal growth and bone mineralization (6,7).

Some of the earliest studies with marine penaeid shrimp reported dietary calcium requirements of 1 to 2% of diet (8,9). However, other studies with *L. topenaeus* and *L. vannamei* raised in seawater were not able to demonstrate a dietary calcium requirement (10,11).

Adequate calcium hardness is generally required for freshwater to be suitable for aquaculture, and brackish water and seawater contain high levels of dissolved calcium; therefore, dietary supplementation of calcium for various fish and crustacean species is generally not necessary. In fact, excessive levels of dietary calcium should be avoided because it can negatively affect the utilization of other minerals, as will be discussed in subsequent sections.

Phosphorus

In contrast to calcium, phosphorus is typically limiting in water and must be provided in the diet to meet the metabolic requirement of aquatic organisms. Approximately 80% of phosphorus in the body is associated with hard tissues (3). Phosphorus also is a component of a variety of organic phosphates such as nucleotides, phospholipids, coenzymes, deoxyribonucleic acid, and ribonucleic acid. Inorganic phosphates also serve as important buffers to maintain normal pH of intracellular and extracellular fluids (3).

Information concerning phosphorus metabolism of fish and crustacea is rather limited. Uptake of waterborne phosphorus by fish has been demonstrated (2), although significant quantities are not obtained in this manner due to the low levels in freshwater and seawater. Levels generally remain low due to the rapid uptake of phosphorus by plants and microorganisms, as well as phosphorus binding to soils. Absorption of dietary phosphorus from the intestine is most critical in satisfying metabolic requirements. Storage and mobilization of phosphorus may be influenced by numerous factors including those that control calcium metabolism. Phosphorus is primarily excreted from the body via the urine although a considerable amount of unabsorbed phosphorus from the diet is lost in the feces (2).

Due to the importance of dietary phosphorus in meeting the metabolic requirements of fish, signs of phosphorus deficiency are generally manifested quite readily and have been well established in numerous fish species (1). Some of the most prominent deficiency signs include impaired growth and reduced mineralization of scales and skeletal tissues. Many studies have been conducted to determine dietary phosphorus requirements for various fish species. These requirement values range rather widely from 0.3 to 0.9% of diet (1). Even wider ranges in dietary phosphorus requirements have been reported for some crustacean species. For example, phosphorus requirements as low as 0.34% of diet (11) and as high as 1% (9), 1 to 2% (8) and 2% (10) of diet have been recommended for penaeid shrimp. Several factors may influence the phosphorus requirements determined in these various studies. Among these are the calcium content of the diet which at elevated levels may interfere with phosphorus absorption, the form of dietary phosphorus and its availability to the organism, and other experimental factors such as size and nutritional condition of the organism and criteria used in estimating requirements.

The eutrophying effects of phosphorus in aquaculture effluents have resulted in a considerable amount of research being focused on phosphorus nutrition of fish in recent years. These efforts have focused on increasing dietary phosphorus utilization and/or limiting phosphorus excretion while meeting metabolic requirements of the organism. Further consideration will be given to these aspects of phosphorus nutrition in subsequent sections of this entry.

Magnesium

Magnesium is another macromineral with diverse metabolic functions. In vertebrates, approximately 60% of total body magnesium is located in bone (3). In soft tissues, magnesium occurs both intracellularly and extracellularly. In addition, magnesium is essential for cellular

respiration and neuromuscular transmission. It also activates many enzymatic systems involved in the metabolism of fats, carbohydrates and proteins (3). Excess magnesium is excreted in the urine of fish (2).

Freshwater and marine fish have been shown to utilize either waterborne or dietary magnesium to meet metabolic requirements (2). Dietary magnesium deficiencies have been documented for a variety of freshwater fishes (1). Deficiency signs include poor growth, loss of appetite, lethargy, muscle flaccidity, convulsions, vertebral curvature, high mortality, and depressed magnesium levels in the whole-body, blood serum, and bone (2). Fish in freshwater, which typically contains 1 to 3 mg of Mg/L, require magnesium at 0.04 to 0.06% of diet (1). Seawater typically contains high levels of magnesium (1,350 mg/L), and marine crustacea and fish generally have blood magnesium levels lower than that of the external medium. Thus, marine species may not require a dietary source of magnesium (12). Red sea bream, *Chrysops major*, reared in seawater showed no signs of deficiency when fed magnesium at 0.012% of diet (13). Supplementation of magnesium at 0.1 to 0.5% of diet was reported to be beneficial to *Marsupenaeus japonicus*; however, weight gain was very low in this experiment and dietary essentiality was not established (8). A depression in hepatopancreas magnesium levels was observed in *L. vannamei* in response to the deletion of magnesium from a semipurified diet; however, weight gain and magnesium levels of the carapace were unaffected (14). Based on the high levels of magnesium in seawater and the magnesium requirements of freshwater fish, a dietary magnesium requirement for marine species would not be expected. Because most feed ingredients, especially those of plant origin, are high in magnesium, supplementation of magnesium to practical diets is generally not necessary.

Sodium, Chloride, and Potassium

Sodium, chloride, and potassium occur principally in fluids and soft tissues of the body and are each involved in controlling osmotic pressure and acid–base equilibrium (3); thus, they are generally considered together as a group. Sodium is a primary electrolyte and the most abundant cation in extracellular fluids. Chloride is the most abundant anion in extracellular fluids while potassium is the major intracellular cation. Concentrations of these electrolytes in the body are principally controlled by the gills and kidney. Dietary deficiencies of sodium, chloride, and potassium have been difficult to demonstrate in fish due to the uptake of these elements from the water (2). The supplementation of high levels (4.5 to 11.6% of the diet) of sodium chloride (NaCl) to the diet has been reported to inhibit feed efficiency of rainbow trout raised in freshwater, presumably due to nutrient dilution (15). Additionally, there were no positive or negative effects of NaCl supplementation to the diet of channel catfish raised in freshwater (16) or Atlantic salmon, *Salmo salar*, raised in freshwater or seawater (17). In contrast, the supplementation of NaCl to the diet resulted in increased weight gain of the euryhaline red drum, *Sciaenops ocellatus*, when reared at low salinity

(<6 ppt) (18). Similar benefits were not observed when red drum were fed the same diet in seawater (32 ppt). The addition of dietary NaCl at low salinities may increase the absorption of amino acids and/or satisfy other metabolic requirements, thus resulting in a physiological advantage to the red drum. The supplementation of NaCl to practical diet formulations at 7 to 10% also has been found to increase survival of fish being transferred from freshwater to seawater (19), presumably through the stimulation of osmoregulatory function and gill sodium- and potassium-ATPase activity (19).

A dietary potassium requirement has been identified for channel catfish (20) and chinook salmon, *Oncorhynchus tshawytscha*, in freshwater (21) but not for red sea bream in seawater (22), indicating that marine fish can obtain adequate levels of potassium from the water. Deficiency signs in chinook salmon included reduced feed intake, convulsions, tetany, and death (1). Dietary essentiality of potassium for marine shrimp is less clear, although a diet containing potassium at 0.9% was reported to improve growth of *M. japonicus* as compared to diets containing potassium at 1.8% (8). The individual deletion of potassium from a semipurified diet did not result in a significant depression in tissue potassium or growth of *L. vannamei*; however, tissue levels of magnesium were affected, indicating a potential interaction (14).

Most freshwater and all seawater probably contain sufficient amounts of sodium, potassium, and chloride ions to satisfy the physiological needs of fish (1). These ions also are found in substantial amounts in most feedstuffs, making the necessity of dietary supplementation unlikely.

Sulfur

This mineral occurs almost exclusively as a constituent of numerous organic molecules in the body, including the amino acids cystine and methionine. Ingestion of inorganic sulfur is not able to satisfy the organism's requirement for sulfur-containing compounds (3).

TRACE MINERALS

Trace minerals or microminerals are present in the body and required in the diet at much lower levels than macrominerals. Minerals included in this category include chromium (Cr^{3+}), cobalt (Co), copper (Cu^{2+}), iodine (I^-), iron (Fe^{2+}), manganese (Mn^{2+}), selenium (SeO_3^{2-}), and zinc (Zn^{2+}). Dietary deficiencies of these minerals have been produced in some fish species by feeding purified diets under controlled conditions for extended periods of time. The essentiality of other trace minerals such as fluorine, molybdenum, nickel, silicon, tin, and vanadium has not been established for fish or crustaceans (1).

Chromium

Chromium in the trivalent state has been established in terrestrial animals to be a cofactor with insulin and thus influences carbohydrate metabolism (3,23). It also has been implicated in affecting protein and lipid metabolism of terrestrial animals. The role of chromium in fish nutrition has been investigated to a much more

limited extent than in terrestrial animals, although more attention has been focused on this mineral in recent years (23). One study (24) reported that chromium supplementation at 2 mg/kg diet caused significant increases in weight gain, energy deposition, and liver glycogen, as well as altered postprandial plasma glucose concentrations of hybrid tilapia (*Oreochromis niloticus* × *O. aureus*) when the diet contained glucose. In contrast, dietary chromium did not enhance the utilization of diets containing cornstarch by these fish. Also in that study, chromium in the form of Cr_2O_3 was much more effective in altering glucose utilization of hybrid tilapia as compared to $CrCl_3$ and Na_2CrO_4. In contrast, other studies such as a recent one with channel catfish reported no effect of Cr_2O_3 on dietary glucose utilization or chromium retention in the body (25). Specific mechanisms by which chromium influences dietary carbohydrate utilization of fish have not been elucidated. Chromium nutrition of crustaceans has not been investigated at this time. Supplementation of chromium in practical diets containing complex soluble carbohydrates (e.g., starch) does not appear warranted for various fish species.

Cobalt

Cobalt is a component of vitamin B_{12} and is required for microbial synthesis of that vitamin. Microbial synthesis of vitamin B_{12} in the intestine of channel catfish was reduced when cobalt was eliminated from the diet (26). In terrestrial monogastrics, a dietary supply of cobalt is generally dispensable, especially if vitamin B_{12} is provided. This would also apply to fish and crustaceans.

Copper

Copper functions in blood cell formation and in numerous copper-dependent enzymes including lysyl oxidase, cytochrome *c* oxidase (CCO), ferroxidase, tyrosinase, and superoxide dismutase (SOD) (3). Lysyl oxidase functions in the formation of cross-links during the synthesis of collagen and elastin. The failure of collagen maturation (cross-linking) in the organic matrix of bone accounts for increased fragility of bones and the associated abnormalities of copper deficiencies. Failure of collagen and elastin cross-linking and an undefined muscular defect result in enlargement of the heart and cardiac failure in copper-deficient animals (3). Copper is also involved in the absorption and metabolism of iron and functions in the formation of hemoglobin in vertebrates. In contrast to hemoglobin in vertebrates, crustaceans utilize copper-containing hemocyanin as the oxygen-carrying pigment (2). It has been estimated that, on a freshweight basis, 40% of the whole-body copper load in shrimp is found in hemocyanin (27). This suggests a considerable increase in the physiological demand for copper by crustaceans above that required by vertebrates.

Dietary deficiencies of copper have been documented for several freshwater fish (28–31), but the dietary essentiality of copper has not been evaluated in marine fish. Dietary requirements for copper range from 1.5 to 5 mg Cu/kg diet (1). In addition to growth and feed efficiency, copper-dependent enzymes such as ceruloplasmin, copper-

and zinc-dependent SOD and CCO have been shown to be excellent indicators of copper nutriture (30).

The dual deletion of iron and copper had no significant effect on growth and survival of *M. japonicus* (8). However, in this series of experiments, weight gain was low and survival was poor; hence, the nutritional stress or the quality of the diet may not have been adequate to induce a dietary deficiency. A dietary copper deficiency was demonstrated in *L. vannamei* fed semipurified diets containing <34 mg Cu/kg diet (32). Deficiency signs included poor growth, reduced copper levels in the carapace, hepatopancreas, and hemolymph, and enlargement of the heart. Similarly, based on growth, survival, CCO activity and tissue mineralization, a dietary copper requirement of 53 mg Cu/kg diet was reported for *Penaeus orientalis* (33). These results indicate that shrimp cannot meet their physiological needs for copper from seawater and that a dietary source is required for maximum growth and tissue mineralization. This also indicates that species utilizing copper as a component of their respiratory pigment have an increased copper requirement over species utilizing iron-based respiratory pigments.

Iron

Iron is a trace element that is essential for the production and normal functioning of hemoglobin, myoglobin, cytochromes, and many other enzyme systems. In vertebrates, the principal role of iron is as a component of hemoglobin. Red blood cells are regenerated periodically, and most of the iron is recycled. That which is not recycled is excreted via the bile into the intestine. Like other elements of low solubility, iron is absorbed and transported in the body in a protein-bound form (3). In vertebrates, mucosal apoferritin binds Fe^{2+} in the intestinal lumen and transports it across the mucosal brush border. Within the cell, Fe^{3+} is bound to transferrin forming transferritin. Iron-bound transferritin is then transported in the blood, where the iron is again released at target tissues (liver and hematopoietic tissue) (3).

In crustaceans, the hepatopancreas has been found to be the organ richest in iron. Storage cells containing iron have been reported in crayfish, *Procambarus clarkii* (34), and the crab, *Cancer irroratus* (35). Iron-transporting proteins also have been found in the hemolymph of two species of crabs (36,37). These observations indicate the presence of a regulatory mechanism similar to that of vertebrates. In addition to the digestive system, gills appear to play an active role in iron metabolism. In *C. irroratus*, iron accumulates by forming a coating around the branchial lamellae during the intermolt cycle, which is then rejected at ecdysis along with the integument. Absorption of iron from the water through the gills may provide an additional source of iron.

Iron deficiencies have been documented for several species of fish; however, dietary deficiencies for shrimp have not been observed (8,12,38). Iron deficiency causing anemia has been reported for freshwater fish such as the brook trout *Salvelinus fontinalis* (39) and common carp, *Cyprinus carpio* (40), and in marine fish such as the red sea bream (41) and yellowtail, *Seriola quinqueradiata* (42). However, growth depression

was not observed in these iron-deficient fish. Iron deficiency signs of channel catfish fed a semipurified basal diet (9.6 mg Fe/kg) included suppressed weight gain and feed efficiency as well as reduced hemoglobin, hematocrit, plasma iron, transferrin saturation, and erythrocyte-count values (43). In that study, a minimum of 20 mg supplemental Fe/kg diet (30 mg total Fe/kg) was required by channel catfish for best growth and hematological values. Although many practical diets may contain considerable levels of endogenous iron, little is known about its form and availability (2). Hence, a low level of supplementation (20–30 mg/kg) of an inorganic source is often recommended to ensure adequacy of the diet.

Iodine

Iodine is an essential element which is present in most cells of the body, although in vertebrates the thyroid gland is the main location of iodine reserves. Thyroid hormones, which contain iodine, are known to have roles in thermoregulation, intermediary metabolism, reproduction, growth and development, hematopoiesis and circulation, as well as neuromuscular functioning (3). The minimum dietary iodine requirement of fish has not been well defined; however, 1 to 5 mg I/kg diet have been found adequate (1). The physiological essentiality of iodine has not been evaluated in shrimp.

Manganese

Manganese functions as a cofactor in several enzyme systems, including those involved in urea synthesis from ammonia, amino acid metabolism, fatty acid metabolism, and glucose oxidation (3). Principal signs of manganese deficiency in terrestrial species include reduced growth rate, skeletal abnormalities, convulsions, reduced righting ability, abnormal reproductive function in males and females, and ataxia in the newborn (3).

Dietary manganese deficiencies in fish have included poor growth, skeletal abnormalities, high embryo mortal-ities, and poor hatch rates (1). A total dietary manganese content of 12 to 13 mg/kg has been recommended for the common carp and rainbow trout, *Oncorhynchus mykiss* (28); however, 2.4 mg Mn/kg diet was sufficient for normal growth and health of channel catfish (44). Supplementa-tion of 10 and 100 mg Mn/kg diet did not improve the growth of *M. japonicus* (8). However, it should be noted that percent weight gain during that study was low and the nutritional stress placed on the shrimp may not have been severe enough to reduce body stores and induce a deficiency. Because the manganese content of seawater is very low (0.01 mg/L), significant absorption from the water is unlikely. Thus, a dietary source of manganese may be necessary for marine shrimp and fish.

Selenium

Selenium is a trace element which functions primarily as a component of the enzyme glutathione peroxidase which converts hydrogen peroxide and lipid hydroperoxides into water and lipid alcohols, respectively. Thus, this enzyme functions in protecting the cell from deleterious effects of peroxides (45). Glutathione peroxidase acts along

with vitamin E to function as a biological antioxidant to protect polyunsaturated phospholipids in cellular and subcellular membranes from peroxidative damage (1). In addition to its enzymatic functions, selenium helps protect against mercury toxicosis by forming a mercuric–selenium complex. This protein-bound complex is diverted from the kidney (where inorganic mercury devoid of selenium is deposited) to the liver and spleen where its toxicity is considerably reduced (46).

Complementary functions of selenium and vitamin E may allow these nutrients to interact physiologically (47). Selenium and vitamin E interrelationships have been investigated in several animal species, and a variety of common and unique deficiency signs have been described (1). Differing responses, especially with respect to gross deficiency signs, were observed when Atlantic salmon (48), rainbow trout (49), and channel catfish (47) were fed diets without supplemental selenium, vitamin E, or both nutrients.

Levels of 0.15 to 0.38 mg Se/kg diet (50) and 0.25 mg Se/kg diet (51) were required to provide maximum growth and glutathione peroxidase activity in rainbow trout and channel catfish, respectively. In zooplanktonic daphnids, a selenium deficiency in the medium resulted in cuticle deformation and a depression in reproduction. In the presence of replete zinc, 1 ppb Se was adequate (52); however, in the absence of detectable zinc, 5 ppb Se in the medium was required to eliminate deficiencies characteristic of selenium deprivation (53). It was found that juvenile *L. vannamei* grew best when fed semipurified diets supplemented with 0.2 to 0.4 mg Se/kg diet (54). Although a specific level has not been quantified, it appears that shrimp have a dietary requirement for selenium.

Based on currently available dietary selenium require-ments that have been quantified for aquatic animals, it appears that supplementation of selenium to practical diets is warranted. Selenium supplementation is regu-lated by the United States Food and Drug Administration and supplemental selenium at 0.1 mg/kg is approved for minor-use animals such as aquaculture species.

Zinc

Zinc is required for normal growth, development, and function in all animal species that have been studied (3). Zinc functions as a cofactor in several enzyme systems and is a component of a large number of metalloenzymes which include carbonic anhydrase, carboxypeptidases A and B, alcohol dehydrogenase, glutamic dehydrogenase, D-glyceraldehyde-3-phosphate dehydrogenase, lactate dehy-drogenase, malic dehydrogenase, alkaline phosphatase, aldolase, superoxide dismutase, ribonuclease, and DNA polymerase (3).

A dietary requirement for zinc has been quantified for a variety of freshwater fishes fed semipurified diets: 20 mg Zn/kg diet for channel catfish (55) and blue tilapia (56); 15 to 30 mg Zn/kg diet for common carp (57); and 15 to 30 mg Zn/kg diet for rainbow trout (58). In daphnids reared under controlled trace-element exposure utilizing a controlled media system (59), the absence of detectable zinc resulted in decreased life span and increased demand on the organism's pool of available selenium (53). *L. vannamei*

was found to require 33 mg Zn/kg diet to maintain normal tissue mineralization (60). The euryhaline red drum was determined to require approximately 20 mg Zn/kg diet (61).

POTENTIAL TOXICITY OF MINERALS

A number of nonessential minerals such as arsenic, cadmium, lead, and mercury are well known as being toxic to the body. Additionally, there are certain essential minerals such as copper, iron, and selenium which may be toxic or impart other detrimental effects if consumed in large enough quantities.

Toxicity of waterborne copper to aquatic organisms is well established (62). Dietary copper in excessive quantities also can be toxic to aquatic species. However, the metal-binding capacity of inducible metallothioneins in aquatic animals is considered to be protective of cellular function (62). Typically, concentrations of dietary copper in excess of 250 mg/kg are toxic to terrestrial animals, whereas dietary concentrations of almost three times that level has no adverse effects on fish (1).

Excessive levels of dietary iron have been shown to be toxic to some aquatic organisms. For example, excessive iron supplementation appeared to have potentially adverse effects on growth of *M. japonicus* (8,12). Additionally, iron-catalyzed lipid oxidation increases with iron supplementation, which in turn adversely affects feed stability (63). Iron is one of the primary metals involved in lipid oxidation, and ferrous iron is a more potent catalyst of lipid peroxidation than ferric iron (62). Ferrous iron catalyzes the formation of hydroperoxides and free radical peroxides by providing a free radical initiator in the presence of unsaturated fatty acids and oxygen. Marine fish and crustacean diets generally contain predominantly polyunsaturated lipids; therefore, supplementation of ferrous iron to the diet could be expected to affect the stability of the diet through increased lipid oxidation (rancidity) and reduced stability of ascorbic acid (64). Consequently, limited supplements and restriction of ingredients with high levels of iron are recommended in practical diet formulations.

Selenium is potentially the most toxic of all essential minerals as relatively low dietary concentrations have been shown to have detrimental effects on various animals (46). Selenium concentrations of approximately 15 mg/kg diet caused reduced growth and feed efficiency as well as elevated mortality in rainbow trout (50) and channel catfish (51).

NUTRITIONAL INTERACTIONS INVOLVING MINERALS

There are several minerals that interact with each other and/or with other dietary constituents such that their utilization by the animal is affected. Of the macrominerals, interactions between calcium and phosphorus are most prominent. It is well established in terrestrial animals that an excess of either calcium or phosphorus relative to the other will result in impaired absorption of both. This is due to the excessive mineral being present in the intestine in a free form such that it combines with the other mineral to form insoluble tricalcium phosphate. Typically, a calcium : phosphorus ratio (Ca : P) between 1 : 1 and 2 : 1 is desired (1). In some fish species, this ratio does not appear to be as critical as in terrestrial animals (65). However, juvenile lobsters, *Homarus americanus* were affected by varying the dietary Ca : P (66). Based on growth and histological studies of the endocuticle, a Ca : P of 0.51 (0.56 : 1.10) was found to be best for lobster juveniles, while Ca : P of 1.55 and greater resulted in abnormalities of the endocuticle. In *M. japonicus*, a dietary Ca : P of 1 : 1 has been recommended (8,9). Supplementation of calcium to a semipurified diet appeared to limit phosphorus bioavailability to *L. vannamei*, but the Ca : P did not totally explain the inhibitory effects of calcium (10). Based on these studies, it appears that calcium may affect phosphorus availability and that calcium levels in excess of 2.5% of diet should be avoided. Although there does not appear to be a Ca : P that will produce optimal results, a ratio of less than 2 : 1 provides good results in commercial formulations.

High levels of dietary calcium provided by fish meal also have been shown to reduce the availability of certain trace minerals such as manganese and zinc (67). The bioavailability of zinc in various fish meals has been found to be inversely related to the tricalcium phosphate content of the meal. Thus, zinc bioavailability is generally lowest in white fish meals, which contain the highest level of tricalcium phosphate, and slightly higher in brown fish meals (67). Reduced bioavailability of zinc in response to calcium phosphate supplementation also has been observed in rainbow trout (68–70), whereas high levels of calcium from calcium carbonate did not affect dietary zinc bioavailability to blue tilapia (56) or channel catfish (71).

Zinc bioavailability to fish also can be reduced by other dietary components such as phytate, a chelating compound which is commonly associated with plant feedstuffs. The adverse effect of phytate on zinc bioavailability has been documented in a variety of animals (3), including fish (56,71–74) and shrimp (60). Calcium also promotes the complexing of zinc to phytate (56,71–74). Practical diets, especially those containing plant feedstuffs or high-ash fish meal, should be supplemented with zinc at rather high levels (100 to 150 mg Zn/kg diet) to overcome the effects of inhibitory agents.

DIETARY SUPPLEMENTATION OF MINERALS

Of the macrominerals, phosphorus is generally the most critical to supplement in prepared diets for fish. Several trace minerals such as copper, iron, manganese, selenium, and zinc should also be supplemented to the diets of fish and crustaceans due to low levels in practical feedstuffs and/or interactions with other dietary components that reduce bioavailability as previously described (54). In order to meet an animal's physiological requirements for various minerals, dietary sources must be available to the animal.

Sources and Bioavailability of Minerals

Of the feed ingredients used in practical aquatic animal diets, fish meal is the richest source of minerals. Research on the bioavailability of minerals contained in fish meals has demonstrated that there is considerable variation among fish species (perhaps due to luminal pH) and that the bioavailability of minerals is affected by meal type and ash content. Diets based on fish meal generally require supplementation of available sources of copper, phosphorus, magnesium, manganese, and zinc to prevent dietary deficiencies and maximize fish growth (67). As the aquatic animal feed industry increases its use of less expensive plant feedstuffs, which are generally poor sources of minerals and may contain factors that reduce the bioavailability of minerals, the need for mineral supplements should increase.

Phytate, which constitutes approximately 67% of the phosphorus in grains, is one of the most undesirable components in many plant feedstuffs. The phosphorus from phytate is not readily available to fish (1) and shrimp (60). In addition, phytate may inhibit the availability of other minerals such as zinc as previously described. It should be noted that phytate phosphorus can account for a considerable portion of the phosphorus in practical diet formulations. The treatment of plant feedstuffs or diets with the microbial enzyme phytase, which can hydrolyze phytate, has been shown to increase the availability of this form of phosphorus to various fish species (5,75,76). However, the cost of phytase and the need to alter feed manufacturing procedures due to the instability of phytase to heat has limited its commercial use in aquaculture at this time. Nonetheless, the present concern to minimize phosphorus in effluents from aquaculture facilities in order to limit potentially adverse eutrophication has continued to stimulate investigations of various phosphorus supplements and strategies to meet the phosphorus needs of fish while lowering phosphorus output. The relative availability or apparent absorption of phosphorus from different supplements can vary considerably for fish (1) and crustaceans (77).

In recent years, there also has been a great deal of interest in chelated trace minerals, which in terrestrial animals as well as some fish species have been shown to have higher bioavailability than inorganic forms. The chelated forms are generally more expensive than inorganic forms. If an element is chelated by a compound that will release it in ionic form at the site of absorption or will be readily absorbed as the intact chelate, this form may greatly enhance the absorption of the element by preventing its conversion to insoluble compounds in the intestine or by preventing its strong adsorption on insoluble colloids. Research on chelated minerals has been rather limited with fish. However, compared with inorganic sources, chelated forms of copper, iron, manganese, selenium, and zinc (each as proteinates) were shown to have higher bioavailability to channel catfish in purified and practical diets (78). In that study, the average improvement in net absorption of chelated minerals over inorganic minerals was approximately 39% for the purified diets and approximately 80% for the practical diets. The greater percent improvement in availability of the chelated minerals relative to inorganic minerals in practical diets is attributed to the greater number of inhibitory compounds such as phytate and fiber in practical feedstuffs to which the chelated minerals are less susceptible. Organic forms of selenium including selenomethionine and selenoyeast also have been shown to have higher bioavailability than inorganic sodium selenite for channel catfish (79). In another study (80), zinc methionine was reported to have over four times the potency of zinc sulfate in practical diets for channel catfish; whereas, no apparent differences in bioavailability of these two compounds were noted in another study with channel catfish (81).

The potentially higher bioavailability of chelated minerals may allow for lower levels of dietary supplementation and a reduction in waste production from unassimilated minerals. As the potential benefits of chelated minerals become better defined, their use with aquatic organisms is likely to increase.

SUMMARY AND CONCLUSIONS

Information on the mineral requirements of aquatic organisms has expanded considerably but is still somewhat limiting for many species. Undoubtedly, as information about mineral requirements expands along with establishment of species and environmental differences, the ability to tailor mineral delivery systems will become more precise. This increased precision will assist in enhancing the economic viability and environmental sustainability of aquaculture.

MOLLUSCAN CULTURE

K.K. Chew
T.L. King
University of Washington
Seattle, Washington

OUTLINE

Mollusc culture and harvest have been practiced for centuries, but most techniques for rearing commercially exploited groups have been refined during the twentieth century. Descriptions of basic culture methods from 1900 to 1950 may be found in the literature, which is especially true for the most desired groups such as oysters, mussels, and clams. Between 1950 and 1970 mechanization and sophisticated farming practices were developed. Culture efforts over the past two decades have provided new techniques and concepts. Such efforts have been developed to restore fisheries that have declined due to pollution, disease, and socioeconomic factors. Moreover, new fisheries utilizing introduced species or unexploited indigenous stocks have been initiated. A wide range of topics on molluscan culture could be covered. Genetic manipulation, predation control, disease, collection of seed or juveniles, nutritional requirements, site selection, harvesting, storage, depuration, environmental concerns, and equipment and its maintenance are all important to the proper culture and handling of commercial shellfish. Furthermore, appropriate changes in culture practices must be viewed as dependent on the species and in the context of traditional culture patterns.

This article discusses examples of some culture concepts and innovations, with some inclusion of historically established techniques where appropriate. Seven groups of molluscs are addressed: oysters, mussels, clams, scallops, abalone, other gastropods, and pearl oysters. The countries with the greatest production for each group are also noted from United Nations Food and Agriculture Organization (FAO) statistical records.

OYSTERS

Production

One of the predominant molluscan groups in the world is the oyster, which is an important protein source in many regions and may become even more so in the future. Total world production of oysters has been increasing steadily since 1970, and increased dramatically between 1987 and 1994, with the current production of approximately 3 million mt in 1996. The top oyster producers, along with their 1996 production estimates in metric tons, are as follows (FAO): (*1*) People's Republic of China: 2,284,663; (*2*) Japan: 222,853; (*3*) Korea: 185,339; and (*4*) France: 152,129. The People's Republic of China has shown the largest rise in recent years, with production between 1987 and 1996 rising from 400,468 to 2,284,663 mt, almost a 2-million-t increase in nine years.

Culture practices and growout methods for oysters vary. However, it must be concluded that semi-intensive culture, from hatchery and nursery phases to growout and harvest, is a well-established practice in some locations such as the Pacific Coast of North America.

Extensive culture methods requiring handling and movement of the shell stock at various times during its life history remains the most widespread technique of producing oysters, probably accounting for more than 90% of all those produced in the world. For example, the U.S. West Coast growers must prepare shell (cultch) to obtain the Pacific oyster (*Crassostrea gigas*) spat from natural field locations or hatchery sources to then plant them for growout in another location. United States oyster growers in the East and Gulf of Mexico coastal areas take advantage of natural reefs for spat production. At times they collect the natural catches of spat on the reefs and deposit them in areas more favorable for growth and survival or protection from disease. Nearly all countries with significant oyster production require some handling of the shell stock prior to harvest time.

Culture Methods

Hatcheries have become important to oyster farmers in the United States over the past 40 years. Through government and private funding commercial oyster hatcheries have been initiated in Chile, Mexico, Tasmania, and other countries during more recent years. The basic concept behind hatcheries is to promote seed availability amid unpredictable or unobtainable natural catches. Several

publications outline procedures for developing oyster hatcheries (1–4). Many oystermen on the Pacific Coast of the United States are building large tanks to catch their own spat from eyed larvae purchased from private hatcheries (5–7). One hatchery can produce several billion such larvae in any given year (8). This is resulting in significant worldwide interest in the ease of shipment and a fairly high success rate for seed settlement.

Proper food for hatchery-reared oyster larvae is essential. Many species of algae and diatoms are cultured to support the nutritional requirements of larval and adult oysters. Experiments have been conducted to provide artificial feed such as manufactured pellets (microcapsules) or simple carbohydrates. Such feed has yet to be proven practical in a commercial setting.

Innovations in oyster culture have also brought forth the four-season, all-season, or triploid Pacific oyster, which was developed and now is commercially produced in the northwest United States (9). Triploid means that instead of two sets of chromosomes, there are three sets. This altered oyster, which produces very little sex products during the summer, is sought after because of its high meat quality during the summer months. Details on how to produce the triploid Pacific oyster have been published (10).

Recent improvements in the cultivation of oysters have emphasized technique refinements, occasionally involving mechanization. Bottom culture in the United States and Europe can include the moving of seed oysters from nursery to growout areas where high growth and conditioning occur before harvest. Such gathering of oysters for transfer is still accomplished by hand picking during low tide, particularly among the smaller companies. Larger firms, mainly in the United States, are using drag dredges or specialized hydraulic or mechanical harvesters.

During the past 30 to 40 years, major emphasis has been placed on off-bottom culture as the beaches suitable for bottom culture are already under cultivation. Raft, rack, and longline methods for oyster cultivation are highly developed in Japan (11–14). Tray culture is established and used in parts of Australia, New Zealand, the United States, and Europe where new designs are continually being developed to suit the needs of growers. Tray construction has evolved from early designs using wood and wire screen to those with rubber or plastic-coated wire mesh, and, most recently, mass-produced polypropylene trays. Biofouling is still an important concern in the use of shellfish trays.

An older but extremely useful guide outlines off-bottom techniques in tropical areas, diagrams raft, rack stake, tray, and longline culture techniques, and discusses spatfall prediction systems, collectors for spat, and other subjects important to growers (15). Culture techniques from other parts of the world have been summarized (11–20).

In recent years, plastic mesh bags have become widely used in oyster culture. Growers along the Pacific Coast of the United States use these bags to hold shell (cultch) to catch seed. In Tasmania, oyster growers are using similar plastic mesh bags to hold mature animals placed on intertidal racks for three to four months prior to harvesting (21).

Lantern and pearl nets designed in Japan are used in several areas for growing cultchless seed or single oysters. The nets are constructed from durable UV-resistant polyethylene mesh and hung from rafts or longline systems. Although these nets are an accepted method, fouling of the mesh is a problem and other off-bottom hanging techniques have been investigated.

Off-bottom culture may incorporate the use of containers consisting of steel frames fitted with up to 100 trays (22,23). Each structure is supported on the sea floor with legs and covers nearly 3 m^2. Buoys delimit these containers, which are kept subtidally so as to allow the stock constant exposure to food. They are easily handled with boat-based winches and offer advantages over other off-bottom techniques that also allow for protection from predation. The system is effective against ice and turbulence and is particularly useful in muddy areas.

Some of the more sophisticated types of cultivation involve raceways and artificial ponds. Two former commercial systems in Hawaii, Aquatic Farms and Kahuku Seafood Plantation of System Culture Corporation, have grown oysters on land-based operations (24). Other experimental systems of this type have been tested with some success, but none has been adapted on a commercial scale (23,25).

Barge-based commercial mariculture has been described (26) in an attempt to reconcile conflicting environmental, legal, financial, and operating difficulties inherent in coastal facilities. This applies not only to potential oyster cultivation but also to shellfish in general. Large intensive growout systems on mobile barges, designed and operated like floating dry docks, appear well suited for attaining optimum environmental and growing conditions by selecting varied deployment sites (e.g., seasonally). Strong potential feasibility was discussed (26) along with the possibility of centralized modular mass construction with economies of scale.

Forced upwelling culture systems as part of a three-dimensional nursery and potential growout culture operation (27), a tide-powered upwelling system (28), and an offshore upwelling principle (29) were discussed in the early 1980s. An upwelling column culture technique for oysters was reported in the literature during the same time frame as the Ghent meeting (30). Since 1981, numerous performance studies on upwelling systems have been conducted for a variety of bivalve species in various countries to solve a myriad of problems (31–42).

MUSSELS

Production

The world production of marketable mussels has increased from 900,000 mt in 1987 to over 1,100,000 mt in 1996 with the People's Republic of China, Spain, Italy, and the Netherlands as the leading producers (FAO). During the same time frame France, Korean Republic, Korean Democratic People's Republic, New Zealand, and Thailand also had good production. The top mussel producers, along

with their 1996 production estimates in metric tons, are as follows (FAO): (*1*) People's Republic of China: 366,251; (*2*) Spain: 188,462; (*3*) Italy: 100,000; and (*4*) Netherlands: 94,496.

Many species of the genus *Mytilus* are cultured throughout the world (43–52). *Mytilus edulis*, which has a wide cosmopolitan distribution, is the most often discussed in the literature. It is common in Europe, North America, Chile, Asia, and New Zealand. Among the other identified species are *M. coruscus* and *M. crassitestis* in Korea and *M. planulatus* in Australia (46,53,54). There are also the fast-growing green mussels under culture, such as *Perna canaliculus* in New Zealand (49,55,56), *P. perna* in Venezuela, and *P. viridus* in Thailand (57), the Philippines, Indonesia, and Singapore. The *Mytilus* sp. of the Indian coast has been redesignated *Perna* (*Fenneropenaeus indicus* and *P. viridus*) (58).

Culture Methods

The Netherlands has historically used bottom culture. Spain, which entered the fishery business in the 1960s, is using a raft culture method. France uses the bouchot method and rack culture. Italy has traditionally used a rack or stake method for mussel production. All of these countries can provide the basic requirements for successful production, including reasonable amounts of shelter and seawater of sufficient quality and phytoplankton content.

Growth rate is an important criterion in assessing the potential of mussel culture for a given area. Depending on geographic latitudes and environmental factors (light, salinity, temperature, primary productivity, currents, and tides), growth of mussels varies. In Galicia, Spain, mussels generally reach commercial size (80–90 mm) in 1–1.5 yr. In France they reach commercial size (approximately 40–50 mm) in 2 yr, and in the Netherlands commercial size (72 mm) is reached in 3 yr (55,63). A review of mussel cultivation in Spain and France has been published (59).

Off-bottom culture methods using rafts or longlines appear to be the most popular current approach to mussel culture. Basic improvements have been along technological lines, often introducing mechanization to facilitate the handling of seed mussel strings, and crop harvesting with transport to deputation and processing plants. Countries involved with this type of mussel farming include Korea, the People's Republic of China, the United States, Canada, Chile, the Philippines, India, Thailand, Indonesia, New Zealand, and Singapore. These and other countries have begun to appreciate the value of mussels as a food product for its nutritional value as well as its availability. Efforts have advanced toward using mussels as part of a polyculture system in the waters of Puget Sound, Washington. Natural mussels are harvested from the net pens that are used to cultivate salmon for the commercial market.

Modern techniques for depuration of mussels in Europe are well known and necessary. North America has only recently entered into the production of mussels and is already aware of the potential need for depuration in certain areas. This consideration relates to oysters and clams as well. The European system of depuration presents useful precedents and experience in such techniques for other countries that share this concern.

CLAMS

Production

Historically, clams have been cultured in Spain, Portugal, Japan, the People's Republic of China, and most Southeast Asian Countries (60). The first reference to clam culture is found in Chinese literature from 746 A.D. and mentions the transplantation of clams from one bay to another (a primitive form of culture). By the mid-1600s more direct forms of clam culture had been developed (61). The culture technique practiced during that period provided the basis for clam culture found throughout the modern world (62).

Many species of clams are harvested but few are actually cultivated or handled in some fashion by humans before harvest. Most species that are cultured fall in the families Arcidae and Veneridae. *Anadara* sp. of Arcidae are regarded favorably for cultivation in countries such as the People's Republic of China, Japan, Korea, Venezuela, Thailand, and the Malaysian peninsula. Of the Veneridae, *Venerupis (Tapes)* sp. are of importance to countries such as France, Italy, Japan, Korea, the Philippines, and the United States; *Meretrix* sp. to the People's Republic of China, Taiwan, and Japan; and *Mercenaria* and *Protothaca* to the United States. The culturing of other species is being investigated but none is as well established as those within the aforementioned genera.

The total world production of clams is steadily increasing, with 1,777,543 mt being harvested in 1996 (FAO). The People's Republic of China is clearly the largest clam producer in the world with 1,093,948 mt of *Venerupis japonica* harvested in 1996 alone (FAO). The United States, Korea, Japan, Thailand, and Chile have contributed to clam production as well. However, it is generally recognized that the majority of clams harvested come from wild stocks, and only a small fraction of transplanted juveniles are actually hatchery reared. Mariculture techniques have been considered with increasing interest as natural populations continue to decline in the face of pollution, natural catastrophes, and overfishing.

Culture Methods

Japan is the world leader in the intertidal culture of clams. Extensive culture has been undertaken with the Japanese littleneck or Manila clam, *V. japonica* (also known as *Tapes semidecussata*, *Tapes japonica*, and *Ruditapes philippinarium*). Hatcheries for this species are not needed in Japan due to the abundance of natural catches. The seed clams are collected and moved successfully to intertidal growout areas. This clam was introduced to the West Coast of the United States and Canada through the importation of Japanese oyster spat (*C. gigas*) and has adapted very well. It has since been introduced from these areas as spat or adults to Europe and is now well established in the United Kingdom, France, and Italy (8). It is also cultivated in Korea (63).

In some areas, such as the Indo-Pacific region, clam culture is labor intensive and lacks mechanization. The seed is provided by fishermen who gather juvenile arcid clams from highly productive naturally occurring clam beds and then sell them to clam farmers for planting and growout to market size (62,64–66). The ground is often improved by one of the following three methods: (*1*) leveling, (*2*) harrowing to remove macroalgae and loosen the substrate, or (*3*) the addition of sand or shell fragments, depending on the particular problems of growing at an optimum growth rate while predators and pests are later removed during the growout period. As clams reach marketable size, they are harvested by hand or with hand tools for the fresh market. Any mechanization usually involves the development of new procedures to harvest or handle the clams when they are transplanted. But for the most part, all labor and harvesting throughout the Indo-Pacific region is done by hand.

The primary culture species for the West Coast of the United States and Canada is the Japanese littleneck or Manila clam (*V. japonica*). Seed is produced at hatcheries in California and Washington and planted in the intertidal beds. The Manila clam grows best in the intertidal zone at or above the +0.5-in. to +2.0-in. tidal level. Several techniques have been tried to enhance its survival and growth. The use of gravel, screens, or other protective devices on the beds reduces predation and makes it possible to plant small seed for growout to commercial size (67–70). The use of plastic netting accords several advantages to the grower, including the exclusion of predators, stabilization of beach substrate, and the possible enhancement of natural settlement, thus allowing the use of both hatchery and wild seed (68–71).

The hard clam, *Mercenaria mercenaria*, is spawned in commercial hatcheries on the East Coast of the United States (72). Juveniles from the hatchery are transplanted to nursery growout systems until they are ca. 25 mm before being planted out into the natural shellfish beds for further growout and eventual harvest (73,74).

Venerupis decussata has been overexploited in Italy, and the gonadal cycle of this species has been studied as a preliminary step toward its culture (75). Although *V. decussata* is being investigated, Manila clam (*V. japonica*) production is growing rapidly because of ease in obtaining hatchery seed for planting and natural spawning populations being established in parts of France and Italy (8). The United Kingdom has also experimented with *M. mercenaria*, and researchers have successfully reared the clam to 10 mm in hatcheries (76). Clams planted in the field must then be protected from predators with some form of mesh covering, as already mentioned.

The use of upwelling systems for juvenile oysters as part of the nursery program has been mentioned in the section on oysters. This system is equally applicable to clams (8,27–30,42).

Investigations into the culturing of the giant clam, *Tridacna* sp., have occurred in the South Pacific since the late 1970s. There are currently four hatcheries that supply juveniles which are transplanted throughout the Indo-Pacific area. One attraction as a cultured animal is the fact that they do not need to be fed algae because they obtain energy through a symbiotic algae. After the hatchery phase, they are transferred to a land-based nursery system. After nine months, they are then put into an ocean nursery system where they must be protected from predators by being placed in enclosures. They are slow-growing animals and reach a harvestable size in four or five years.

SCALLOPS

Production

World production of scallops in 1996 reached approximately 1,275,958 mt. The FAO fisheries statistics records also indicate that the People's Republic of China, Japan, and Chile were the leading producers in 1996 with 999,573, 265,553, and 9,779 mt, respectively.

Japanese scallop harvests are dominated by *Patinopecten yessoensis*, and the recent rise in production can be attributed to well-developed methods for catching wild seed for culture. The Japanese have led world technology in scallop culture by a wide margin. However, researchers in other countries have been testing Japanese culture techniques for catching wild spat and have shown potential for local varieties. The People's Republic of China has introduced the bay scallop (*Argopecten irradians*) from the United States with great success. Scallop culture on the East Coast of the United States has centered on the bay scallop (78–82).

Culture Methods

As early as 1934, scallop larvae were collected on scallop shells hung from rafts in Japan for the purpose of later releasing the juveniles into favorable rearing grounds (83). By 1941, spat was being collected commercially. Bottom conditions during summer in Japan can be unfavorable, inducing mortality rates that can be above 99% (84). This problem soon stimulated a trend toward extending the culture operations for longer periods of time. By the late 1950s, collected larvae were routinely reared in hanging cages or holding ponds until the scallops exceeded 3 cm shell length (after about seven months) and were then released. Subsequently, increasing quantities of scallops were raised to market size in aquaculture systems. Although successful hatchery spawning techniques have been developed, the dependable and abundant set in certain bays has so far precluded the necessity for hatchery seed in Japan. Other species account for only a small fraction of effort relative to that devoted to *P. yessoensis*.

An excellent outline of commercial scallop culture in Japan describing larval development, different types of collector, float designs, and other useful information has been published (84,85). In the early 1980s, the scallop industry in Japan returned to the previous cultural practice of sowing juvenile seed scallops to growout on subtidal beds. One of the advantages of sowing scallop juveniles rather than culturing them in a lantern net is the reduction of deformed shells (only 10% as compared to 30% in lantern culture) (86).

Notwithstanding the general success of scallop culture in Japan, it should be noted that outbreaks of paralytic shellfish poison (PSP) in past years have reduced the

scallop harvest for human consumption. The whole scallop is eaten when the shellfish does not contain PSP. However, when scallops do have PSP, some harvest still takes place for the adductor muscle only. The fishery is depressed with the persistence of this natural phenomenon. PSP, which recurred each year from 1977 to recent years, affected mostly hanging culture (86). This greatly impacted areas such as Mutsu Bay in Aomori Prefecture.

In regard to the subject of capturing larvae from natural spawnings, a study from the Isle of Man in the Irish Sea found two species of scallops, *Chlamys opercularis* and *Pecten maximus*, in collectors, which were essentially identical to those developed by the Japanese (87). Various factors affecting settlement and early survival of the larvae were investigated. In Newfoundland in the early 1970s, the natural setting of the deep-sea scallop *Placopecten magellanicus* was the subject of a pilot study by the Department of Fisheries aimed at developing a commercial-scale operation (92). It was observed that polyethylene film bags were more suitable than nylon netting, burlap, or fiberglass bags. The results of this study indicated the biological feasibility of collecting the deep sea scallop spat in sufficient numbers for cultivation.

The purple hinge or rock scallop *Hinnites multirugosus* is a prime candidate for mariculture along the Pacific Coast of the United States. Culturing this species from egg to harvest size (10−15 cm) within a period of 2−2.5 yr has been achieved by applying methods similar to those of oyster culture (89). A unique characteristic enables it to attach permanently to the substrate (like an oyster) after it has reached a size of approximately 3 cm. Although various experimental techniques have been used to grow this scallop to commercial size, the authors concluded that large-scale production by aquaculture must await the solution of two principal problems: (*1*) production of substantial numbers of seed stock for prospective scallop farmers, and (*2*) development of economical and effective procedures for containment and maintenance of stocks in natural waters until ready for harvest.

ABALONE

Production

The two major abalone-producing countries are the People's Republic of China and the United States. Mexico, South Africa, Korea, Chile, Australia, and the Channel Islands also show catches through the years, but considerably less than the two main countries (FAO). Total world production of abalone decreased from 14,300 t in 1987 to 2,185 mt in 1996.

Culture Methods

The Republic of China (Taiwan), Japan, and the United States are the principal countries culturing abalone. Japan has several government laboratories in which abalone research is being conducted. The culture of juveniles in the hatchery will continue to boost abalone production in the future.

Abalone culture in the United States is still generally in the experimental stage, even though some companies in California are producing small quantities for the commercial market. There are several companies in California producing abalone (90). In the past, firms sold juveniles to local volunteer groups and government agencies to plant in depleted abalone beds for enhancement purposes. Although land-based companies are producing small abalones (2−3 in. in diameter) for the specialty market with some success, a polycheate worm was inadvertently introduced impacting the California culture fisheries. This worm infests the shell, affecting growth and rendering the shell useless for sale as a value-added product.

Advances in the culture of abalone expanded greatly when successful spawning induction techniques were unlocked (91). Temperature was found to be important in conditioning abalone for spawning (92). Irradiated seawater (93) and hydrogen peroxide were found to induce spawning in adults (94,95). The later has also been tried on other species to determine the nature of its effect. It appears that both stimuli act to create oxides in the seawater. A combination of desiccation, elevation of temperature, hydrogen peroxide, and sperm from the male abalone has also proved successful in generating spawning (96).

A special chemical additive known as GABA (γ-aminobutyric acid), which acts as a potent neurotransmitter and has been commercially successful in the stimulation of larval setting, was derived from crustose coralline red algae (97). It was also reported that the development of an advanced biological engineering system for abalone seed production in Japan resulted in a technique to synchronize the spawning period (98). Suitable conditions for larvae to settle on the collector plates were produced by using the mucus of juvenile and adult animals together with certain types of diatoms.

There have also been studies demonstrating the importance of food type at all stages of development (99,100). Japan has made improvement in the use of artificial diets (pellets) in recent years (101). Furthermore, raising abalone at high temperatures was found to increase growth rates (102). Portable habitats have been designed to protect abalone seed when being planted at sea (103). Constructed of either concrete blocks or shelves, they serve as attachment sites during land transport and provide temporary refuge on the sea bed.

Areas of low production in Japan have been improved through a combination of longline kelp culture and predator removal. Sea urchins are grown first and then harvested, removing competition for the abalone seed while nearing the size required to eat the kelp. The urchins often pose strong competition in prime abalone sites, but fortunately their roe is a valuable commodity in Japan.

In the United States it is difficult to obtain private control of prime abalone growout areas. For this reason one company has grown abalone in large concrete conduits placed vertically in subtidal waters (104). Another has reared its stock in cages suspended from oil rigs (105). There is a trend toward growing abalone in the open ocean off California because of the high cost of land and seawater systems, but boat transportation for cleaning the cages and feeding the stocks is expensive and there is less control over the total operation.

OTHER GASTROPODS

Production

Gastropods other than abalone are consumed in various parts of the world, and in some areas provide an important protein source. These include *Helix pomatia* and *Helix aspersa*, the escargot of France; *Strombus gigas*, the queen conch of the Caribbean; *Littorina littorea* and *Bucciunum undatum* of France; *Turbo cornutus* of Japan and Korea; *Trochus niloticus* of the Caroline Islands; *Concholepas concholepas*, commonly called loco of Chile; and *Neptunea* sp., the marine snails from the Bering Sea.

Gastropods (excluding *Haliotis*, the abalones) make up a small percentage of the world total molluscan landings, amounting to only 1,164 mt annually (FAO). With the exception of *H. pomatia* and *H. aspersa*, production occurs almost entirely from the capture fisheries. Only recently has the culture of other gastropod species been attempted and then usually on an experimental basis.

Culture Methods

H. pomatia and *H. aspersa* have been cultured in France for nearly 2,000 yr and are still typically raised in fenced gardens called cochleria (106). They are also raised in caves and fed a variety of fungi (107). Although it appears that little innovation in culture methods has occurred in recent years, the area under cultivation has expanded. *H. aspersa*, considered a pest in the United States, has been raised and marketed in California. Snails were purchased from botanical gardens and farms that do not use pesticides. The snails were starved for 24 hours to purge them of pollutants and were then fed a combination of cabbage, wheat meal, and bran for two to three weeks before being processed.

Methods are also being developed to culture the queen conch *S. gigas*, but are thus far underway only on an experimental basis (108–110). A problem presently being solved involves the rearing of larvae through metamorphosis in sufficiently high densities to be economically feasible (111). This problem has been addressed by studying the feasibility of raising the queen conch in shallow-water fenced enclosures (112).

Although commercial culture of the topshell *T. cornutus* does occur along the Seowipo coast of Korea and the Japan coast (113,114), further research is needed. Similarly, another topshell, *T. niloticus*, has been cultured on an experimental basis in the Caroline Islands by the Micronesian Mariculture Demonstration Center (MMDC) and the Palau Marine Resources Division (115). Culture of this species using methods developed by the MMDC is also being considered in the Philippines.

The culture of gastropods has generally been limited to but a few species, essentially a condition of economics. With the exception of *H. pomatia*, *H. aspersa*, and *Haliotis*, the market price of gastropods is quite low compared to that of other shellfish. In addition, their mobility (ability to forage), together with a vulnerability to a variety of predators, does not make them a particularly attractive group to culture.

PEARL OYSTERS

Production

There has been little change in pearl culture techniques since the 1940s. The main change has been a decrease in the stocks of wild oysters for natural pearls. This is especially true in countries that have historically exploited this resource. If the industry is to survive, cultured pearls are the only hope. However, it has been pointed out that one cause of the hiatus in Japan's pearl farming was an unstable price situation induced by an increase in poor-quality pearls (116). A mere increase in pearl production in the future is not foreseen because the aim of the industry is to improve the quality, rather than quantity, of cultured pearls.

Four different genera are used in the cultivation of pearls: *Pinctada*, *Pteria*, *Cristaria*, and *Hyriopsis*. The latter two are freshwater genera. According to FAO statistics, the pearl and pearl shell production industry has depended on three major areas: Japan, Australia, and the Philippines to Fiji. Before 1969 both Ethiopia and Madagascar produced pearls, but no statistics were found for African countries since then. Japan has been a steady producer with about 100 t (live weight) through the 1960s, then dropped to 30 t by 1974, rose again to approximately 48 t in 1980, and dropped to 34 t in 1987. In 1980, Australia produced 310 t, then dropped to 42.5 t in 1987.

General pearl culture techniques have been discussed and generally presented (116–119). The majority of cultured pearls in Japan is produced by the pearl oyster *Pinctada fucata*. This is the species of choice for the cultivation of tiny round pearls, their size being generally less than 10 mm in diameter (118). A large pearl (to 15 mm) can be cultured in *Pinctada maxima*, which inhabits tropical and subtropical Pacific waters, such as off northern Australia and the Philippines. Major efforts are being made to culture the "black steel" pearl from the South Pacific species *P. margaritifera* (119).

Beyond the increased production of cultured pearls in the industry, there have been efforts to mechanize operations toward facilitating the handling of culture animals. There is also a need for more experimentation leading to higher quality and colored pearls. Steps must be taken to obtain good culture grounds and to exercise vigilance to preserve them from environmental deterioration (116).

CONCLUSIONS

This article has highlighted some of the techniques and concepts in the culture of molluscs. All of the techniques could not be covered here because the subject of molluscan culture is broad in scope. Any emphasis on a given group of animals depends on geographical location and the most desired local commercial species. Historic techniques developed in one country may be considered new innovations and concepts in another. In recent years the search for improved culture methods has predominated as the need for increased protein production and high-valued products are recognized in most countries.

From reviewing various groups of molluscs, it is clear that countries long involved in the culture of desired species continually seek to improve their technology and introduce mechanization to facilitate growing and harvesting. This includes an emphasis on improved hatchery, nursery, and growout techniques; off-bottom culture; diet and nutritional concerns; disease and predator control; genetic manipulation; and other phases of the total molluscan culture scenario. Depending on the country, modernization and changing techniques relate to sociopolitical concerns and, more specifically, to traditional cultural patterns.

Global molluscan production could be increased greatly by applying methods that are currently used in certain parts of the world. This is particularly true for oysters, mussels, clams, and select species of gastropods such as abalone and land snails (escargot). It is also evident that developing countries have begun to engage in molluscan culture because they have recently discovered unexploited indigenous stocks or commercial prospects for introduced species. This especially applies to the oyster species because of its worldwide distribution and acceptability in the commercial market. Other molluscan species available for potential culture are now being considered favorably. Given the growth potential for local and world markets, it is expected that the culture of molluscs will increase markedly in the years ahead.

MUD CRAB CULTURE

DAN D. BALIAO
Southeast Asian Fisheries Development Center
Tigbauan, Philippines

OUTLINE

Mud crabs are one of the most widely sought crustacean species that inhabit the estuarine areas and tidal rivers and creeks of the Asian and Indo-Pacific regions. Hailed as "food for the gods," the mud crab is recognized as a candidate species for culture in brackishwater ponds and/or other suitable impounded brackishwater environments.

In the past, mud crabs were a secondary species to cultured finfishes or crustaceans. Larvae entered ponds with incoming water and became trapped. Although conceived as a fishpond crop, the mud crab has also been considered a nuisance in ponds it because it burrows into dikes and causes damage and leaks.

Farming of mud crab has been progressing rapidly due to a promising market and profitability.

With the availability of mud crab juveniles from the wild throughout the year and the recent development in hatchery technology, there is a strong indication that production of mud crabs on a commercial scale could be a lucrative industry.

The information presented here is based on the recently published extension manuals and literature on mud crab culture both in brackishwater ponds and pen enclosures in mangroves (1−3).

TAXONOMY, FOOD HABITS, AND DISTRIBUTION

Mud crabs are of the genus *Scylla* and reported to consist of three species: *Scylla serrata*, *S. oceanica*, and *S. tranquebarica*, and a variety of *S. serrata*, var *paramamosain*. It is generally called mud or mangrove crab in Australia, "Samoan" crab in Hawaii, *alimango* in the Philippines, *tsai jim* in Taiwan, *nokogiri gazami* in Japan, *kepiting* in Indonesia, *kalapu kakuluwa* in Sri Lanka, *haubba kankera* in Bangladesh, and *ketam nipah* or *ketam bakau* in Malaysia.

In its natural habitat mud crabs mainly feed on crustaceans, while adults and subadults consume molluscs (4,5). Fish remains are rarely found and it was concluded that *S. serrata* does not normally catch mobile forms such as fish and penaeid shrimp. Mud crabs usually remain buried during the day, emerging at sunset to spend the night feeding, which occurs intermittently even when unlimited food is available (2).

Mud crabs inhabit both marine and brackishwater environments and prefer muddy and sandy bottoms. They are found in many countries of the West Indo-Pacific region, from South Africa to Hawaii and from North Australia to Southern Japan.

SOURCE OF JUVENILES

In the Philippines, mud crab juveniles [10 to 40 g and 5 to 20 cm (0.3 to 1.3 oz or 2 to 8 in.) in carapace breadth] are available throughout the year, with a peak occurring from May to September. Most crab juveniles from the wild are sourced from coastal provinces of the country. Common collecting gear includes crab lift nets (*bintol*), bamboo cage traps (*panggal* or *bobo*), tube traps (*patibong*) and crab hooks (*panukot*). Mud crabs are also caught using fish corrals (*baklad*), baited lines with scoop nets, and even with bare hands. Depending on size, quantity, sex, and species, crab juveniles are ordered in advance from collectors. This gives ample time for collection, handling, storage, and transport. Technology in the hatchery of mud crabs has been developed in the Southeast Asian Fisheries Development Center, Aquaculture Department (SEAFDEC/AQD) based in Tigbauan, Iloilo, Philippines.

Young crabs (Fig. 1) obtained from the wild are normally transported inside bamboo wicker baskets, cardboard boxes, or palm (*pandan*) bags to the rearing ponds and pens. A pandan bag can carry 150 to 200 juvenile crabs, each weighing 20 to 50 g (0.7 to 1.7 oz) during a transport of up to 10 to 12 hr. No immobilization of chelipeds is required for crabs weighing less than 30 g (1 oz), but the chelipeds of larger crabs should be tied shut. Fronds of mangrove trees *Rhizophora* spp., (*pagatpat*) or *Avicennia* spp., (*bungalon*) are provided inside the basket to keep the temperature cool and to minimize fighting among crabs. It is recommended that active and healthy juveniles with complete body parts be procured. Juveniles falling short of these requirements should be discarded.

GROWOUT OF MUD CRAB IN BRACKISHWATER PONDS

Earthen or concrete-lined ponds, preferably rectangular in shape (Fig. 2) and of areas 250 m^2 to 1.0 ha (0.06 to 2.5 ac), could be utilized for culture of mud crabs. Enclosed areas of newly or partially developed fish ponds provided with water control structures could also serve the purpose. The soil type should be sandy clay or clay loam with a rich organic matter base and, preferably, alkaline. A good quality water coming directly from the sea or a tidal river should be available year-round. The most desirable

Figure 1. Mud crab juveniles ready for stocking.

Figure 2. Growout pond with a nylon fence.

ranges of water quality are as follows: salinity 10–34 ppt, temperature 23–30 °C (73–86 °F), and dissolved oxygen above 3 ppm and pH 8.0–8.5 (6). To prevent an increase in salinity, especially during the summer months, it is advantageous to have a freshwater source. This will enable the farmer to adjust the salinity to a level favorable to the growth of the crabs.

Other socioeconomic factors such as cheap and skilled labor, market accessibility, proximity to construction materials, and production inputs, as well as the peace and order situation in the locality should be considered.

The pond should be capable of holding water of depth 1 to 2 m (3 to 6 ft) and have a double gate system (one each for entrance and exit) made either of concrete or wood. The pond bottom must be level and clean to allow easy harvesting.

Each pond compartment is provided with about 12 earthen mounds [5 m³ (6.7 yd³)] installed in strategic areas (Fig. 3). These mounds serve as breathing spots where mud crabs can climb out during periods of low dissolved oxygen. The mounds should be installed in the middle of the pond and be high enough so that the peaks remain above water even when maximum water depth of 60 to 80 cm (24 to 31 in.) is reached. Used tires stacked and tied vertically in layers and separated horizontally by

Figure 3. Growout pond with bamboo fence and mud mounds.

wooden or bamboo poles are also utilized as substitutes for earthen mounds. Shelters made of sawed bamboo or used PVC pipes [50 cm (20 in.) long with a 15 cm (6 in.) diameter opening at both ends] should be added to avoid mortality due to fighting and cannibalism.

To prevent the crabs from escaping, the area should be fenced with either bamboo slats or nylon net [1–2 cm (0.4–0.8 in.) mesh size] fence extending about 30 cm (1 ft) above the waterline. The fence is kept in place by supporting it vertically with bamboo or wooden posts driven 50 to 70 cm (20 to 27 in.) deep into the pond bottom sediment and supported horizontally with some bamboo splits. A plastic strip or sheet about 30 cm (1 ft) wide should be installed along the top edge to prevent crabs from climbing over the top of the net fence. For concrete-lined ponds with relatively steeper slopes, nylon net fence is no longer necessary. Catwalks and feeding trays may be provided for feed monitoring and sampling. Life-support systems, such as a water pump (axial or centrifugal), and paddlewheel aerators may be necessary for emergency water exchange and aeration, especially during neap tides and calm days at night, or when water conditions so require.

Stocking and Rearing

Preparation of ponds for the culture of mud crabs does not require such meticulous procedures as growing natural food. However, prior to stocking, proper installation of the net fence, earthen mounds, and other physical requirements should be considered. Ponds should be drained completely and the bottoms allowed to dry for a week or two. Eradication of pests and predators is done during the pond preparation stage by applying teaseed powder at the recommended rate of 15 to 30 ppm (depending on salinity) or a combination of hydrated lime, Ca(OH)₂, and ammonium sulfate fertilizer (21–0–0) at the ratio of 1:5. Other environmentally friendly organic pesticides such as tobacco dust and derris root extracts are also recommended.

Stocking may be done early in the morning or late in the afternoon, but most preferably at night when the temperature is cool. During stocking, pincers are united and crabs are released directly into the ponds at densities of 5,000 to 10,000 juveniles 1 ha (2,000–4,000/ac).

It is advisable to stock uniform-sized mud crabs in order to obtain a relatively uniform size at the end of the rearing period mud crabs of may 50 g (1.7 oz) be grown in polyculture with milkfish, *Chanos chanos*, at the rate of 2,500 fingerlings 1 ha (1,000/ac).

It is essential to maintain good water quality during the culture period. When considerable numbers of crabs start to crawl on top of the earthen mounds or cling to the walls of bamboo or the net fence, this indicates that water conditions are not favorable. It is advisable, therefore, to change at least one-third of the pond water, especially during spring tides. An irrigation pump may be necessary in case water change is needed during neap tides. Dikes, gates, and net fences should be regularly inspected for possible leaks and dilapidation.

Trash fish, animal hides or entrails, snails, and other locally available and cheap protein sources may be

provided as feed for mud crabs. Feeds are broadcast evenly throughout the pond each day. The recommended feeding rate is 10% of crab biomass initially. That rate is reduced by 1% each month until 5% is reached. One-half of the daily feed requirement is given in the morning and the other half in the afternoon.

Filamentous green algae, locally known as *lumut* or *gulaman* (*Gracillaria* spp.), when readily available in quantity may also be used as feed.

Partial harvesting of crabs should be done when some reach 200 to 250 g (6.7 to 8.3 oz) by using baited traps or hand lines with scoop nets. In the Philippines, this is commonly known as the *pasulang* method. The ponds are partially drained (50%) during low tide, and at high tide new seawater is admitted, thereby causing the crabs to swim against the current toward the water gate. The majority of the catch using this technique will be females with maturing eggs (*aligue*), because the marine phase of life or spawning stage of the animal is about to begin. While swimming against the current and concentrating along the gate, the crabs are caught by using scoop nets and the pincers are then securely tied by using strips of soaked coconut sheath (*suwak*) or plastic straws. Care coupled with skill in tying the pincers safeguards workers from being severely pinched. Baited traps (*bintol*) or baited hand lines can also be used if selective harvesting falls on an ebb or neap tide. This method minimizes competition for food and space by the remaining stock and reduces the incidence of cannibalism.

Harvesting by totally draining the pond is done during low tide, when the remaining crabs are collected by hand. Earthen mounds are examined to ensure complete retrieval of crabs. Normally, this requires a day or two using five workers.

Newly harvested mud crabs (Fig. 4), mixed or sorted by size, are always tied in bunches either by the kilogram (2.2 lb) or dozen. Sometimes, females with maturing eggs are sorted from the males with large pincers for delivery to discriminating customers. For long-distance travel, they are kept inside wooden or Styrofoam boxes or bamboo (*tiklis*) or palm (*buri* or *pandan*) baskets. Mud crabs are a hardy species that can stay alive for up to one

week when sprinkled occasionally with water. Prolonged holding periods, however, will lessen the weight (*hagas*) or eventually cause death. Price varies from region to region in the Philippines. Crabs of average weight [150 to 200 g (5 to 6.7 oz)] bring from 120 to 180 pesos per kilogram (2.2 lb); larger crabs [200 g (6.7 oz)] bring 160 to 250 pesos per kilogram (2.2 lb). Generally, female crabs with developing gonads are more expensive than males. In the Philippines and abroad, the demand for mud crabs exceeds the supply.

PEN CULTURE OF MUD CRAB IN MANGROVES

Using net enclosures to grow mud crabs in mangroves or tidal zones offers the latest bright prospect for aquaculture. The technique is environmentally friendly, sustainable, and can provide additional income for coastal communities.

Net Enclosure Construction

The mangrove area selected for culturing mud crabs should be unpolluted and have a water depth of 0.8 to 1.0 m (2–4 to 3 ft) at high tide. Areas that are susceptible to large waves should be avoided. Salinity should range from 10 to 30 ppt, and temperature from 25° to 30 °C (77° to 85 °F).

Net enclosures (Fig. 5) can be constructed by driving 3 to 4 m (9 to 12 ft) long wooden or bamboo poles into the sediment. The tops of the poles should extend above the high water level by at least 30 cm (1 ft). Horizontal bamboo crossbars are secured between the vertical wooden poles, both at the high water level and 30 cm (1 ft) above the high water level, to provide structural support and attachment sites. Polyethylene netting with mesh size of 1 to 2 cm (0.4 to 0.8 in.) is hung from the top bamboo crossbars with the bottom of the netting buried in the sediment to a depth of 70 cm. Plastic sheeting is hung between the two bamboo crossbars to keep the crabs from climbing over the top of the enclosure. Ditches or depressions should be dug to a depth of at least 20 to 40 cm (7.9 to 15.8 in.) and placed in from 20 to 30% of the enclosed area to provide

Figure 4. Harvested mud crabs with drained pond in background.

Figure 5. A net-enclosed mangrove area. Repairs are being made on the plastic above the mesh.

refuge areas for crabs during extreme low tides. Caution should be taken to avoid cutting mangrove roots during the digging process. Catwalks should be constructed around the enclosure's perimeter or across the middle of the pen for feeding and observation of the crabs.

Enclosure size and shapes can vary. The Southeast Asian Fisheries Development Center, Aquaculture Department (SEAFDEC, AQD) test enclosures were of an area of 4,000 m² [(3,640 yd²)]. Manageable sizes appear to range from about 0.2 to 1 ha (0.5 to 2.5 ac).

Stocking and Rearing

Prior to stocking, the net enclosure is cleared of debris and unwanted organisms, such as predators. The perimeter of the pen should be carefully checked prior to stocking to ensure that integrity of the structure is intact.

The recommended stocking rate for juvenile mud crabs weighing from 20 to 50 g (0.7 to 1.7 oz) is 5,000 to 10,000/ha (2,000 to 4,000/ac). Stocking should occur when the pen is filled with tidal water and during early morning, or late afternoon, to avoid the hottest part of the day. The crabs should be tempered (acclimated) to the temperature and salinity of the pen before release. Tempering can be achieved by placing the crabs in plastic basins and gradually exchanging the hauling water with water from the pen. The process should be completed in about one hour. Ties on chelipeds should be removed before the animals are released.

Crabs can be fed chopped trash fish, animal hides or entrails, mussels, snails, or prepared feed (commercially available in the Philippines and formulated for mud crabs). Feed should be broadcast as evenly as possible throughout the pen each day. If possible, this should be done on an incoming tide. The recommended initial feeding rate is 10% of crab biomass daily. The rate should be reduced by 1% each month until 5% is reached, which will be at the end of a culture cycle.

Baited lift nets should be used to collect samples each month. To provide an estimate of growth and biomass (for adjustment of feeding rate), 30 to 50 crabs should be collected, weighed, and measured.

SEAFDEC, AQD recommends that a determination of dissolved oxygen, temperature, salinity, and turbidity be made at least three times each week. If stressful conditions occur, good management strategy would involve cessation of feeding until the water quality improves. Enclosures should be inspected frequently. Debris should be removed and any tears in the netting should be repaired. Nightly inspections are recommended to deter poachers.

Harvest should begin after the crabs have been in the enclosure for three months (Fig. 6). Baited lift nets are used and only marketable animals are taken (submarketable crabs are returned to the enclosure). The average size of marketable mud crabs in the Philippines is 275 g (0.6 lb). Partial harvest should be conducted until the sixth month of culture, at which time, the remaining crabs are removed and marketed. The enclosure can then be restocked, giving two crops annually. Each crop should yield about 485 kg (1,067 lb) when an aquaculturist used a 0.4 = hectare (1 ac) enclosure.

INTRODUCTION

Striped mullet (*Mugil cephalus*) is one of the most popular cultured species with both euryhaline and eurythermal

characteristics. It is also known as grey, flathead, and jumping mullet. As a cosmopolitan species, mullet are found in all coastal waters between latitudes 42 °N and 42 °S. They are found as far north as Hokkaido, Japan and as far south as South Africa, Cuba, and India (1). From mitochondrial DNA genotype analysis, striped mullet from ocean basins around the world revealed pronounced population genetic structure (2). Taxonomically, striped mullet belong to the family Mugilidae (order Perciformes). A total of 14 genera and 64 species have been identified throughout the world (3). Presently, about 20 species are farmed in different regions of the world (4). Striped mullet is the most desired species among them.

Mullet are consumers of low trophic layers. They have a complex pharyngobranchia filter which, associated with the gill raker system, enables them to feed on a variety of microorganisms and decaying organic matter, as well as larger food such as algae, insect larvae, and small molluscs (4). Because of high tolerance to both temperature and salinity variations, mullet can be found in a wide range of waters, from freshwater to seawater. Thus, mullet farming has been practiced throughout history and has become a tradition in many parts of the world such as the Mediterranean, southeast Asia, east Asia, and some Pacific islands.

SOURCE OF FRY

Liao (1), in 1981, estimated that about 99% of fingerlings stocked in nursery ponds around the world are from the wild. Although no survey was conducted to identify the sources of fry for striped mullet farming, the majority of farms are still using wild-caught fry. The easy access to wild-caught fry and high cost of hatchery-produced fry may be the explanation. The labor cost for fry production, representing 51% of operational costs, must be reduced to make hatchery fry more affordable to farmers (5). At this time, hatchery-produced mullet fry are still uncommon among farmers.

Wild Supply

Collection Methods. Mullet fry appear seasonally in coastal areas at the age of approximately two months. They tend to concentrate in shallow estuarine environments, converge in the mouths of lagoons and rivers, and migrate in schools against currents with different water quality. Fry can be collected in gear with passive (fixed) or active methods. Active gears such as scoop nets, skimming nets, and beach seines are commonly used to collect wild fry. Lights with 600 lux, 400 W bulbs are used in addition to scoop nets to attract fry in Taiwan (1). Motor boats equipped with fry collection gear (Fig. 1) have also been used in recent years. Passive gear, such as fish traps with a short wing pointing toward shore and a longer wing protruding into deeper water to guide the fish into the trap, are placed in areas where fry naturally gather or migrate, usually along the banks of streams.

Different collection techniques are used due to the distinct behaviors among various sizes of fry (1). Fry smaller than 30 mm (1.2 in.) generally swim weakly in

Figure 1. Boat equipped with fry collection gear.

schools and can be collected by nets and seine. However, these smaller fry are fragile and survival after stocking is less than 30%. Fry larger than 50 mm (2 in.) do not swim in schools and are hardier and active; therefore, they are more difficult to collect. Because larger fry tend to swim against the freshwater current, they are commonly collected through sluice gates directly into fish farms.

Handling, Transportation, and Stocking. Striped mullet fry are sensitive to handling. Improper handling can cause massive losses. Fry die from infections and shock due to careless handling, drying in air, abrasions from nets, and brain hemorrhages from knocking into hard walls of containers (6). Other factors such as extremely low or high dissolved oxygen, sudden temperature and/or salinity changes, disease, and starvation can also lead to mortalities. In Egypt, it was reported that only 1.6% of wild fry survived to market size. Most mortalities occurred during transportation and stocking.

Acclimation is a necessary step to reduce mortality caused by osmotic and thermal shock. Sarojini (7) reported that acclimation reduced mortality to less than 1% in *M. cephalus* and *M. seheli*. Tolerance of fry to salinity change varies according to fish size, water temperature, and initial salinity. Sudden transfer of fry from 100% seawater to 11 ppt resulted in negligible mortality; however, when fry were transferred from 4 ppt to freshwater, 100% mortality ensued (8). Normally, large fingerlings [35–42 mm SL (1.38–1.65 in.)] were more resistant to lower salinities than smaller fry [23–31 mm SL (0.91–1.22 in.)] (1). In spite of greater salinity changes at 17 °C (62.6 °F), *M. cephalus* fry had a better survival than at 10 °C (50 °F) (8). Sylvester (9) also found that juveniles [80–120 mm SL (3.15–4.72 in.)] require longer acclimation times at lower temperatures.

During the process of collection, large numbers of fry are forced into a small area where fry expend much energy. They jump, scrape against the net and each other, swirl in circles, and are exposed to air. The shock from capture can eventually lead to mortality. To increase the survival, some collectors use anesthetics to slow down fish activities or reduce the energy expenditure of the fry during collection (6). Anesthetics such as MS-222, chloral hydrate, tertiary amyl alcohol, chlorobutanol, quinaldine,

paraldehyde, and tertiary butyl alcohol have been used during the transport of mullet seed (10). Using anesthetics is expensive and must be monitored closely to prevent death from overdosing. The drug must be used at sublethal dosages and for a specified amount of time, dependent on fish species and size.

Hatchery Supply

The interest in culturing this species as a source of food has resulted in numerous investigations regarding control of their reproductive cycle (11,12). Likewise, considerable attention has been given to developing techniques for mass rearing of early larvae to juvenile stage (13–16). Broodstock source has to be identified before the production of fry in the hatchery can be realized. Mature spawners can be obtained from the open water or culture facilities (17). Collection of broodstock during spawning migration by barrier net such as the one shown in Egypt (Fig. 2) results in less damage to fish than those collected from gillnet fishing in the open sea. However, the most reliable source is from culture facilities. Broodstock can be grown in either seawater or freshwater environments prior to the spawning season (18,19). Indoor facilities fail to provide mature fish that produce good-quality eggs. The shortage of arachidonic acid may be the cause (20). Induction of spawning should be carried out in full-strength seawater for the best fertilization and embryonic development (19). The life cycle of striped mullet has been closed under captive conditions (21). Natural spawning of this species in any holding facilities has yet to be documented.

The first step in propagating mullet begins with the successful induction of spawning using a variety of hormonal treatments (Table 1) (12,22). Control over the maturation process of males and females by the use of either environmental or hormonal methods has

Figure 2. Barrier net used to collect broodstock during spawning migration.

demonstrated that sexually mature broodstock can be produced throughout the year (23–25). In Hawaii, fish were held in outdoor tanks under photoperiod and water temperature control to reach final maturation at the desired time. Each outdoor tank was covered

with a light-proof black fabric sheet to obtain a shorter photoperiod than under natural conditions. The black sheet was manually removed during the daytime cycle. To extend the photoperiod, fluorescent lamps were added. The water temperature was lowered by adding cold freshwater instead of using a chiller. This approach has avoided the requirement of high-cost environment-controlled facilities. Frequency of spawning has also been altered from once per year up to three times per year. When undergoing chronic hormonal treatment or placed under controlled environmental conditions, broodstock can be induced to spawn more than once without any appreciable loss in egg quality (26–28). It is obvious that major advances have occurred with regard to delivering fertilized eggs on demand (29).

Development of techniques that can produce a large number of fertilized eggs and larvae has been ongoing for over 20 years (13–16,30,31). It is now possible to consistently mass-produce mullet fry in hatcheries. However, production costs for mullet fry need to be reduced.

Fertilized Eggs. The fertilized eggs required in larval rearing can be easily obtained from induced spawning, utilizing the method described by Lee et al. (22). Females that possess oocytes with average diameters of 600 μm and above are selected and held in 170-L (180-qt) aquaria for hormonal induction of spawning. They are given a priming injection of carp pituitary homogenate [20 mg/kg (ppm) body weight] followed 24 hours later with a resolving injection of 200 μg/kg (ppb) body weight of LHRH-a. Two running ripe males are placed with the female when she receives the second hormonal injection and spawning usually takes place 12 hours after the second injection. Spawning and fertilization of the eggs occur naturally. After fertilization, eggs are removed from spawning tanks to incubation tanks or larval rearing tanks for hatching.

Live Feed Production. The green alga *Nannochloropsis oculata* has been identified as the most suitable phytoplankton to be used for feeding rotifers in mullet larval rearing. Stock cultures are initially grown on slightly modified Miquel culture media. Amplification of the phytoplankton volume is achieved with an outdoor batch system strategy using three 500-L (132-gal) intermediate tanks, four 5,000-L (1,321-gal) fiberglass raceways, and three 30,000-L (7,926-gal) fiberglass tanks, as described by Eda et al. (16).

Brachionus rountiform (S-type, 110–230 μm lorica length) is the zooplankton commonly used for first feeding of mullet. The culture method for rotifers varies among hatcheries and is selected based on a hatchery's specific needs. In Hawaii, rotifers are cultured indoors using a batch system strategy. Rotifers are initially stocked into 600-L (158.5 gal) of *N. oculata* (a minimum of 10 million cells/mL) at a density of 100 rotifers/mL. Twenty-four hours later, the volume is raised to 1,200 L (317 gal), and the culture is allowed to grow for another 24 hours. After 40 hours, the entire tank is harvested by draining the culture through a 60-μm nitex bag. The main food source for the rotifers is *N. oculata*, but is frequently supplemented by yeast. The nutritional quality of the rotifers should be manipulated to increase the highly unsaturated fatty acid (HUFA) content. When low content of HUFA in rotifers is detected, enrichment of rotifers prior to providing them to mullet larvae is necessary to obtain better larval survival.

Larval Rearing. Temperature was found to be the determinant in the rate of development of mullet embryos, as in other finfish species studied (32). Salinities between 15 and 45 ppt did not affect the time of hatching, nor was any consistent variability observed between the median time of hatching between females. Hatching times ranged between 65 and 73 hours when incubated at 20 °C (68 °F) to 25 to 27 hours when incubated at 32 °C (90 °F). Mortality of mullet embryos was observed to be affected by both temperature and salinity. The upper and lower thermal tolerances for normal development is above 30 °C (86 °F) and below 18–20 °C (64.4–68 °F), respectively. Salinities of 15 to 45 ppt examined did not appear to limit survival (33). The calculated optimum hatching (96.6%) was found to be at 25.5 °C (78 °F) and 37.4 ppt. When larval rearing was conducted in 5,000-L (1,321-gal) tanks from hatching to 50 days posthatching, no significant differences in survival and growth were found between the 22–23 ppt salinity group and the 32–35 ppt salinity group (34).

At 70 hours posthatching, rotifers were found in the gut of the fish larvae (16). Over the next 10 hours, the number of fish fed gradually increased, and by 104 hours posthatching 75% of the larvae were feeding (16). The number of rotifers eaten per larva ranged between 0 and 11. The incidence of feeding observed was influenced significantly by the number of rotifers introduced into the rearing tanks. By the second day posthatching, 40–50% of the larvae presented with 10 rotifers/mL began feeding. In contrast, less than 1% of the larvae presented with 1 rotifer/mL were found to be feeding. Food preference changes as fish larvae grow. Initially the gut contents mirrored the composition of food organisms found in the water column. However, the larger food organisms began to predominate as early as the fourth day posthatching and remained throughout the duration of the experiment (35). The forage ratio ranged from highest to lowest for *Artemia* nauplii, L-type and S-type rotifers, respectively.

Growth of larvae from the same spawning can vary when they are reared in a separate 5,000-L (1,321-gal) tank with a different feeding regime. Larvae fed according to their feed preference were found to be significantly ($p < 0.05$) larger by the 20th day posthatching than individuals from the tank where S-type rotifers were the only live food organism. The growth of mullet larva from hatching to 50th day posthatching is shown in Figure 3.

The quality of food organisms also affects larval survival. Larvae fed on rotifers grown on the combination of *N. oculata* and yeast or *N. oculata* alone exhibited significantly higher survival than those fed exclusively on yeast-fed rotifers (31). Survival was significantly higher at 42 days posthatching for larvae fed rotifers grown on *N. oculata* alone as compared to that of yeast. In contrast, at the end of the 42-day rearing trial no significant differences could be detected in total length among the
Figure 3. Growth rate of mullet larvae during intensive rearing trials.

treatment groups. There were significant differences in sizes of the larvae between days 15 and 30 posthatch. Enriching *Artemia* is not necessary for mullet larval rearing (16). While enrichment did not increase larval survival, it significantly ($p < 0.05$) enhanced larvae size (16). Similarly, larvae fed nonenriched *Artemia* were significantly ($p < 0.01$) larger than those fed exclusively on S-type rotifers.

Tamaru et al. (36) indicated the importance of using low levels of phytoplankton as background during the rearing trials. There is a significant ($p < 0.01$) improvement in the overall survival of mullet larvae (15 days posthatch) when the rearing process is conducted in the water with background algae. This is consistently observed even when the rotifers are of a high nutritional quality (i.e., have been reared on algae or yeast). There is also significant improvement in growth by using background algae.

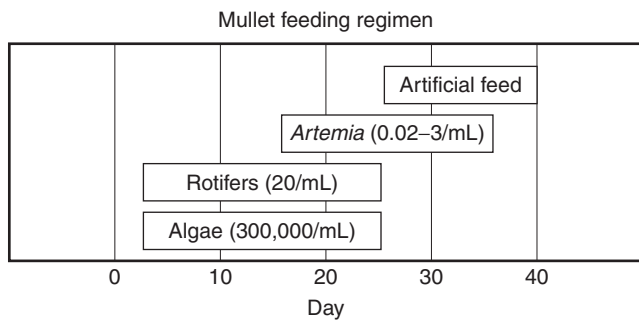
Currently, the best feeding regimen (Fig. 4) developed for mullet larval rearing provides rotifers at a density of 20/mL for the first 25 days posthatch and green algae at 300,000 cell/mL in the larval rearing tank. From day 17 until day 35, brine shrimp are given at a density of 0.02 to 3 individuals/mL, while larvae are trained to feed on artificial feed from day 25 until fry are harvested on day 40. This feeding regime can provide consistent production of 5 mullet fry/L (19 mullet fry/2 gal).


Figure 4. Recommended feeding regimen for mullet larvae.

GROWOUT

M. cephalus is successfully cultured in many countries such as China, India, Japan, and Israel, as mentioned by Hepher and Pruginin (37), on a smaller scale in Greece (a lagoon), India (experimental level) and Yugoslavia (the Vrana lagoon), reported by Uwate and Kunatuba (38); and in Vietnam (39), Japan (40), France, India, Indonesia, Hawaii, and Pakistan as reported by Hickling (41) and Ling (42). At different locations, different culture methods were employed.

The effect of water quality on survival and adaptability of mullet was studied by Azariah et al. (43). Fry survival was high in the first 24-hour period after release at high tide; however, survival was low at low tide. Low survival was due to lack of dissolved oxygen and the presence of sewage in the inland river water at low tide. Dissolved oxygen should be maintained above 50% of saturation (44). Liao and Chao (45) also reported the high sensitivity of striped mullet to oxygen depletion. The iron crush effluent (0.07 ± 0.25 mg Fe/L; pH 7.8 ± 0.60) from an iron crush factory in Egypt did not affect growth of *M. cephalus* (46). Growth rate of 0.70 g (0.02 oz)/day was similar to that in Egyptian fish farms. The appearance of a blue-green algal bloom (*Lyngbya limnetica*) at 775,000 organisms/L led to high mortality in one pond [death of 100 kg (220 lb) of fish].

Mullet can be cultured under conditions ranging from freshwater to seawater. They were successfully reared in salinities of 60–70 ppt (47). Bardach et al. (48) reported that mullet [50 g (1.61 oz)] and tilapia [50 g (1.61 oz)] were stocked at 214/ha (87/ac) and 139/ha (56/ac), respectively, into a pond close to the Dead Sea in Israel, which has a salinity of 36 to 145 ppt. After 109 days, harvest revealed a yield of 512 kg/ha (455 lb/ac) of mullet. Tungkang Marine Laboratory in Taiwan compared growth of mullet in seawater (16.4 to 32.7 ppt), brackishwater (11.8 to 20.6 ppt), and freshwater. Mullet with initial weight of 113.8 g (3.66 oz) attained the average weight of 278.6, 287.0, and 227.0 g (8.96, 9.22, and 7.30 oz), with daily

weight gains of 0.53, 0.64, and 0.49 g (0.02, 0.02, 0.02 oz), respectively, after 190 days in seawater, brackishwater, and freshwater. There were no significant differences ($p > 0.05$) in seawater and brackishwater growth rates. The mullet cultured in freshwater were more prone to injuries during handling and were not tame and docile.

Cultivation Methods. Extensive culture, polyculture, and intensive culture are the three most common methods used throughout the world to culture mullet fry to marketable size. As a feeder of low trophic layers, mullet have been cultured extensively for centuries, mostly in polyculture with other species. Polyculture is the practice of stocking more than one species in the same pond to increase the total production.

Growth of mullet depends on many factors such as stocking density, and genetic strains. Generally, the growth of *M. cephalus* in the wild is much slower than in culture. In nature, 4-year-old mullet range from 229 g (7.4 oz) in the Black Sea to 1,217 g (39.1 oz) in the Mediterranean (49). *M. cephalus* on the Mediterranean coast of Egypt are 300 g (9.7 oz) at 2 years and 900 g (28.9 oz) the next year (50). In several lakes of India, Rangaswamy (50) found mullet that were 300 g (9.7 oz) at 2 years, and 600 g (19.3 oz) at 3 to 4 years. However, mullet fry of 20 to 35 mm (0.8 to 1.4 in.) stocked at the density of 25,000/ha grew to 100 to 140 mm (3.94 to 5.51 in.) in length in four months. An average size of 375.6 mm/505.9 g (14.8 in./16.3 oz) at the end of the first biological year was also reported in India (51). The monthly growth rate was 75.3 mm/70.6 g (3.0 in./2.3 oz). In Taiwan, striped mullet of 0.36 g (0.01 oz) grew to 471 g (15.1 oz) in a year (45). In Taiwan, mullet are harvested at two to three years of age (45). Mullet are also harvested at greater than three years to harvest the roe of females. Dried mullet roe (Fig. 5) are in high demand and can command a high market price. In Israel, market-size fish at one year is 400 g (12.9 oz), and at two years is 600 g (19.3 oz) (37). In general, cultured mullet attain marketable size [400–1,000 g (12.86–32.15 oz)] in a little over a year to four years.

Extensive Culture. Extensive culture, a common method for growout of mullet in the world, is usually practiced in ponds on shores, near estuaries, or in freshwater ponds
Figure 5. Dried mullet roe is processed in Taiwan.

located inland (45). Fenced lagoons, creeks, and swamps are also used (38). In Hawaii, mullet is traditionally cultured in fish ponds formed by lava rock near the shore. Fish are entirely dependent on food available in the pond. Yield is usually low and does not justify the investment (52). Most of the production is for subsistence purposes.

Growth depends on stocking density and pond condition (1). In Taiwan, low stocking density and good weather conditions produce mullet with a weight range of 300–600 g (9.7–19.3 oz) after one year (45). A well-known method of extensive culture is "kawa culture" practiced in Aichi Prefecture, Japan. In kawa culture, fry are stocked in waterways at very high densities [15,800–19,750/ha (6,394–7,992/ac)]. Mullet is the main species and is sometimes polycultured with common carp (*Cyprinus carpio*), crucian carp, sea bass (*Dicentrarchus labrax*), perch, and eel (*Anguilidue*). Extensive culture ponds often include other species in addition to mullet. In Japan, various studies reported average mullet production of 480 kg/ha (428 lb/ac) (53), 392 kg/ha (349 lb/ac) (54), and 663 kg/ha (590 lb/ac). Water temperature was as high as 29–31 °C (84.2–87.8 °F) in summer and as low as 4–6 °C (39.2–42.8 °F) in winter. In Hawaii, mullet production varies from 100 to approximately 2,000 kg/ha (89 to 1,780 lb/ac), depending on the management style.

Polyculture. Polyculture is the predominant system used for growout of mullet. Striped mullet is most suitable for polyculture due to its feeding habits (herbivore and detritophore), peaceful nature (does not compete for food or attack other fish), and easy adaptation to various salinities. While mullet obtain food both from the benthos and plankton, they efficiently exploit fine detritus and small zooplankton not used by other cultural species (55). On the other hand, mullet have a detrimental effect on large zooplankton and chironomid midges, which are diets of common carp and tilapia (*Oreochromis* sp.). Thus, selection of the appropriate species for polyculture with mullet is an important factor for overall production. Aquatic species most commonly cultured with striped mullet are shown in Table 2 (45,56–60).

The species that have been polycultured with striped mullet in freshwater environment include grass carp (*Ctenopharyngodon idella*), silver carp (*Hypopthalmichthys molitrix*), bighead (*Aristichthys nobilis*), common carp (*C. carpio*), milkfish (*Chanos chanos*), and mullet (*Mugil capito, M. auratus*). Grass prawn (*Penaeus monodon*), milkfish (*C. chanos*), mullets (*Liza ramada, L. auratus, L. saliens* and *Chelon labrosus*), gilt-head seabream (*Sparus aurata*), sea bass (*D. labrax*) and eel (*Anguilla anguilla*) were cultured with striped mullet in brackishwater. The role of striped mullet in polyculture is equally important as other species in total production or as a secondary crop to others. Striped mullet were produced in brackishwater ponds as a secondary crop to milkfish in Indonesia (4), and to milkfish and grass prawn in Taiwan. The following is an overview of the practice of polyculture in several countries.

In Egypt, production of *M. cephalus* in fertilized ponds gave yields of 192–350 kg/ha (170.9–311.5 lb/ac) or 36–77% higher as opposed to 131 kg/ha (116.6 lb/ac)

Table 2. Most Common Species Polycultured with *Mugil cephalus*

Species	Water Type	Country	Reference
Grass prawn, *Penaeus monodon* Milkfish, *Chanos chanos*	Brackishwater	Taiwan	Liao and Chao (45)
Grass carp, *Ctenopharyngodon idella* Silver carp, *Hypopthalmichthys molitrix*	Freshwater		
Bighead Grass carp Common carp Milkfish, *C. chanos*	Freshwater	Hong Kong and Taiwan	Sinha (56)
Mullets (*Liza ramada*, *L. auratus*, *L. saliens* and *Chelon labrosus*) Gilthead seabream (*Sparus aurata*) Sea bass (*Dicentrarchus labrax*) Eel (*Anguilla anguilla*)	"Valli" (modified lagoons), brackishwater	Italy	Jhingran and Natarajan (57); Brown (58)
Common carp *M. capito* *M. auratus*	Freshwater	Israel	Pruginin and Kitai (59); Sinha (56); Yashouv (60)

without fertilization. Additionally, 162−219 kg/ha (144.2−194.9 lb/ac) of other species were harvested. Similar results were achieved in Hong Kong and Taiwan (61). Yields of mullet were increased by 96% due to the simple application of fertilization.

In India, milkfish (*C. chanos*), grey mullet (*M. cephalus*), and prawn (*Fenneropenaeus indicus*) were cultured together in a salt pan reservoir (62). Mullet had the best survival and production among the three species. Marketable size was achieved in nine months.

In Israel, six species of mullet are abundant along the Mediterranean coast. Of the six, *M. cephalus* and *L. ramada* adapt easily to freshwater, have good growth rates, and thus are selected for polyculture (52). Immediately after collection, fry are held over the winter for 140 days and cultured with carp. From an initial weight of 0.2 g (0.01 oz), mullet fry attain a weight of 15−50 g (0.48−1.61 oz) at which time they are ready to be stocked at low densities into nursery ponds. Ponds are fertilized weekly for eight months and fish are fed daily, initially with sorghum, and followed later by pellets with 25% protein at 3,000 kcal. Feed is mainly aimed toward the carp and tilapia, with the mullet subsisting on food available in the pond. Water qualities are 18−32 °C (64.4−89.6 °F); pH 8.0−9.0; and dissolved oxygen level is variable due to phytoplankton blooms, 5−10% saturation in morning and 150% in afternoon. Aeration is supplied to offset variable oxygen levels. Mullet is the secondary crop to carp in freshwater ponds. However, if mullet are stocked at 800−1,200/ha (324−486/ac), carp growth is slightly lower when compared to those grown in monoculture (60).

In Italy, "valle" and "lagoon" culture had a total annual yield from 90 to 200 kg/ha (80−178 lb/ac) of fish (48). The "Vallicoltura" is an ancient practice of extensive culture of euryhaline species in confined areas of the Italian North Adriatic lagoons, which spread out to the Mediterranean. Mullet were stocked as juveniles at densities of 1,000−4,000/ha (405−1,619/ac) and reached

marketable size in three to five years, with minimum survival of about 10%.

In Japan, polyculture of mullet with carp and eel or with carp and crucian carp did not show any relation between total production of other species and mullet production (54). It was concluded that mullet can be stocked at the maximum optimal density without considering stocking ratio of mullet to other fishes. Mullet had quite different feeding habits from other species in the system. Nakamura (63), however, showed that mullet cultured with eel and carp had better survival and generally higher weight gains when stocked at lower densities (0.6−1.8/m²) rather than at high densities (1.8−2.5/m²). Average survival and weight gain for low and high densities was 66.1% ± 17.4 and 104.9 g ± 93.9; and 42.9% ± 10.8 and 85.7 g ± 42.2, respectively. The only supplemental feed given was 57−227 g/m² of rice bran. These results indicate the stocking density for mullet was too high.

The marketable size of mullet is 400−1,000 g (12.9−32.2 oz), and the average time to grow mullet to marketable size from initial capture size [0.2 g (0.01 oz)] is approximately 450 days, when no supplemental feed is given. In one study, 30−70 g (0.1−2.3 oz) two-year-old mullet were stocked in carp ponds at 500−800/ha (202−324/ac) and harvested 120−150 days later at a final weight of 400−700 g (12.86−22.51 oz) (60). Stocking of mullet for two years to achieve 1 kg (2.2 lb) size fish is also practiced.

The typical practice of polyculture in freshwater ponds is as follows. After collection, fry may be directly stocked at 30,000 fry/ha (12,141/ac) into nursery ponds (37). If necessary, fry may be placed into adaptation tanks prior to stocking the nursery ponds. Here, farmers disinfect fry with formalin and clean them of parasites and protozoans (52). Grass carp [200−300/ha (81−121/ac)] are added to control filamentous algae. Fry should be transferred to larger ponds at 1−3 g (0.03−0.10 oz) after 60−100 days. As mullet fry are delicate in muddy waters and at temperatures higher than 30 °C (86 °F), handling of fry should occur in the early morning. Yashouv (60)

recommends no more than 800 mullet/ha (324/ac) in a carp–mullet culture while Pruginin et al. (64) indicates density can be increased to 1,200/ha (486/ac) in a tilapia, carp, and silver carp culture due to advanced technology.

Intensive Culture. Intensive culture is the least common method used for growout. This technique requires advanced technical equipment to sustain high stocking density, but results in higher production. Several studies were conducted in the past to evaluate the performance of mullet under high stocking density and/or intensive feeding.

In Taiwan, Liao and Chao (45) reported the highest mean daily weight gain of 2.32 g (0.07 oz) was achieved when 50 juveniles were stocked in a round concrete pond [8.25 m (27.07 ft) diameter] and were provided aeration and artificial feed. That growth rate was achieved at salinity ranging from 11.8 to 20.6 ppt. Survival rates during the experiment ranged from 88 to 94%. Mean daily weight gain in other experiment groups ranged from 0.49 to 2.28 g (0.02 to 0.08 oz).

In Japan, fry [18.1–30.0 mm (7.13–11.81 in.)] stocked at a density of 2/m^2 were fed silkworm pupae at 0.3–2.0 kg/m^2. In eight months, final body weight reached 75–360 g (2.65–12.70 oz) with total production of 1,290 kg/ha (1,148 lb/ac) (54). Survival rate was about 48%.

In another study, Linder et al. (65) cultured mullet using heated effluent from a power plant. Mullet were fed commercially prepared feed. The feed cost to yield 1 kg (2.2 lb) of mullet was US$0.61–0.87. The average daily weight and standard length gains ranged from 0.36 g (0.01 oz) to 0.67 g (0.02 oz) and from 0.17 mm (0.01 in.) to 1.03 mm (0.04 in.), respectively. Survival was 50–85% with a final production of 293–804 kg/ha (261–716 lb/ac). Feed conversion ratio was 2.24–3.31.

Intensive farming requires formulated feed to support the rapid growth. Nour et al. (66) concluded that a diet containing 30% crude protein supported normal growth of striped mullet in freshwater ponds. Commercial diet supplemented with vitamin E to 190 and 290 mg/kg (ppm) significantly increased body and ovary weights for mullet (67).

Production. World production of mullet in 1996 according to FAO (68) was about 41,047 tons (Table 3). The production data might not necessarily represent the actual annual yield due to the difficulty of species identification.

DISEASES/PARASITES AND TREATMENTS

Because of the small number of striped mullet cultured intensively, disease problems have been infrequent. Occurrences of disease usually result from polluted waters, a poor culture environment, and management (high stocking density, excessive handling). Lin et al. (69) investigated the diseases of cultured brackish and freshwater *M. cephalus*. From 39 diseased fish, 41.4% of the fish had a bacterial infection, 33% were infected by protozoa (*Trichodina* sp. and *Apiosoma* on the gills), 20.5% were infected by a combination of bacteria and protozoa, and 5.1% were initiated by oxygen deficiency and bad water quality. Disease outbreaks were more common during warmer temperatures (August to September) than cold temperatures (November to February).

For the successful prevention and treatment of the unicellular parasites *Chilondonella* sp., *Costia* sp., and *Trichodina* sp., *M. cephalus* fingerlings [5–30 g (0.16–0.96 oz)] may be treated with 30–40 ppm technical formalin for six hours (70). Aeration should be provided during treatment as oxygen levels drop at night due to phytoplankton mortality. As temperatures increase, formalin toxicity increases as well. Lahav and Sarig (71) reported that Bromex (0.2 ppm) can effectively treat mullet infested with the parasite *Ergasilus sieboldi*. Sparolegnia infection can be treated by maintaining fingerlings in brackishwater (seawater : freshwater ratio of 1 : 9 or 1 : 4) to reduce mortalities. Baticados and Quinitio (72) also reported the mortalities of cultured mullet caused by dinoflagellate-like parasites. *Amyloodinium* attached to the gill filaments led to the disruption of the lamellae and lamellar tissue degeneration. Infection by the copepod ectoparasite, *Caligus bombavensis*, was recorded in laboratory-reared striped mullet and was treated effectively by 0.02% formaldehyde solution (73).

Frequent inspection of broodstock for any skin and gill parasites is an important step in preventing the outbreak of disease. During the holding of broodstock, it is very common to encounter fish lice such as *Argulus* or gill parasites such as *Oodinium*. For treatment, a change of salinity is currently the only legal treatment accepted by the U.S. Food and Drug Administration (FDA). Other possible parasite treatments which are considered to be of low regulatory priority by the FDA but not tested for mullet are: 10 minute dip in 1,000–2,000 ppm acetic acid, 5 second dip in 2,000 ppm calcium oxide, 250–500 ppm hydrogen peroxide, 5–10 minute dip in 30,000 ppm magnesium sulfate followed by a similar dip in 7,000 ppm NaCl. Treatments approved for other species

but not for mullet are oxytetracycline, sulfamethoxine, formalin, and sulfamerazine. The effective chemical treatments for mullet, but not approved by the FDA, include 0.5 ppm of Furacin (Nitrofurazone) for 1 hour and repeated for several days for bacterial infections, and 0.5 ppm of Trichlorfon (Masoten) once a week for four weeks for treatment of *Argulus*.

FUTURE PROSPECTS

Historically, striped mullet has been a traditional cultured species and an important subsistence species in many parts of the world (Fig. 6). Mullet will continue to be cultured and will play an important role in fish farming. However, the expansion of mullet culture requires efforts in the advancement of both culture technology and marketing. Mullet farming has depended primarily on wild-caught fry, which are inconsistent and not reliable. With the establishment of mullet fry production technology, farmers should be encouraged to use and upgrade the available technology. Further development of mullet hatchery technology can make the hatchery-produced fry more cost-effective.

Depending on the strain of striped mullet, the growing period from juvenile to market size will take one to three years. In order to be profitable, cultivated species should reach marketable size in one year, particularly in areas with cold winter seasons. Traditional genetic selection or advanced genetic engineering technology should be used to improve growth performance of mullet.

Figure 6. The harvesting of mullet is an important social and cultural event in countries such as Egypt.

Although mullet can be a desirable table species for more consumers, little effort has been made to market the species beyond its traditional consumers. The current market demand for mullet is very limited. Consequently, the price of mullet stays low and farmers are moving away from culturing subsistence species to high-valued species in response to profit-driven operations. A marketing effort for mullet is an essential step to encourage more farming. Developing the technology for producing special products such as dried ovaries could also expand the currently limited market.

MULTICELLULAR PARASITE (MACROPARASITE) PROBLEMS IN AQUACULTURE

ERNEST H. WILLIAMS, JR.

OUTLINE

We call the multicellular parasites in the animal kingdom macroparasites because they are, for the most part, large enough to be seen without the use of a microscope. Many species of macroparasites are important in aquaculture for causing destruction, disfigurement, and a reduction in the growth and vitality of cultured organisms.

Modern aquaculture encompasses an overwhelming multitude of cultured species. Even animals as exotic and diverse as marine mammals and reef-building corals are now raised, traded, and sold. The assortment of macroparasites that attack this huge variety of organisms is both numerous and complex. In this contribution, we discuss the macroparasites most important in aquaculture and provide a list of all the macroparasite groups known to bother aquaculture animals (see Table 1). We cite popular references for information on most of those groups we do not discuss for lack of room.

In wild animals, macroparasites are always present, and they constantly tax a portion of the hosts' growth and productivity. [For example, isopod parasites may, amazingly, infect 10% of a fish population, reduce its growth by 15%, and cause the loss of billions of kilograms (1 kg = 2.2 lb) of fish flesh annually in a single fishery (1). And that is just the loss caused by one species of the many that may infect each host!] When we take wild aquatic animals out of their natural environment and place them into aquaculture, most macroparasites are unable to make the transition and die or waste away. Unfortunately, though, this happy scenario does not always occur: Some natural parasites are able to survive and even flourish in the new, biologically peculiar set of circumstances.

Table 1. A Listing of All Known Macroparasites of Aquaculture Organisms[a]

Classification[b] — Common Names	Page
Kingdom Animalia — animals	
Phylum Mesozoa — urine microworms (33,35)	
Class Rhombozoa — cephalopod mesozoans	
Class Orthonectida — invertebrate mesozoans	
Phylum Porifera — sponges (35)	
Phylum Cnidaria — jellyfish etc.	
Class Myxozoa (?) — myxosporidians[c] (1)	
Class Hydrozoa — sturgeon hydroid, etc.	
Class Anthozoa — sea anemone, ctenophore parasites, etc.	
Phylum Ctenophora — tunicate parasite, etc. (35)	
Phylum Platyhelminthes — flatworms	564
Superclass Acoelomorpha — acoels	
Superclass Rhabditophora	
Order Rhabdocoela — mollusc/crustacea turbellarians, etc. (33)	
Order Alloeocoela — fish turbellarian, etc. (33)	
Order Tricladida — elasmobranch turbellarian, etc. (33)	
Order Polycladida — oyster turbellarian, etc. (33)	
Superclass Cercomeria	
Class Temnocephalida — *Macrobrachium* turbellarian, etc. (19)	
Class Udonellea — copepod worm (1)	
Class Cercomeridea	
Subclass Trematoda — flukes and soleworms (33)	
Infraclass Aspidobothrea — soleworms (33)	
Infraclass Digenea — flukes	564
Superfamily Didymozoidea — tissue flukes	565
Subclass Cercomeromorphae	
Infraclass Monogenea — gillworms	565
Order Gyrodactylidea — live-bearing gillworms	566
Order Dactylogyridea — simple gillworms	567
Order Montchadskyellidea (33)	
Order Capsalidea — capsalids	567
Order Monocotylidae (33)	
Order Polystomatidea (33)	
Order Mazocraeidea — complex gillworms	568
Order Diclybothriidea (33)	
Order Chimaericolidea (33)	
Infraclass Cestoidea — tapeworms	568
Cohort Gyrocotylidea (33)	
Cohort Cestoda — tapeworms	
Subcohort Amphilinidea — simple tapeworms (33)	
Subcohort Eucestoda — true tapeworms	
Phylum Nemertea — ribbonworms (35)	
Phylum Rotifera — rotifers (35)	
Phylum Nematoda — roundworms	569
Class Enoplea	
Class Rhabditea	
Phylum Nematomorpha — horsehair worms (35)	
Phylum Acanthocephala — spiny-headed worms	571
Class Archiacanthocephala — of higher vertebrates	
Class Palaeacanthocephala — of vertebrates	
Class Eoacanthocephala — of lower vertebrates	
Class Polyacanthocephala — of fish	
Phylum Annelida — segmented worms	
Class Polychaeta — polychaetes[d] (35)	

Table 1. *Continued*

Classification[b] — Common Names	Page
Class Myzostomida — symbiotic annelids (35)	
Class Hirudinida — leeches	571
Subclass Acanthobdellida — primative leeches	
Subclass Branchiobdellida — crayfish leeches (19)	
Subclass Hirudinea — true leeches	
Phylum Arthropoda — armored animals	
Subphylum Cheliceriformes — spiders, etc.	
Class Arachnida	
Subclass Acari — mites (2), bird and seal ticks (33), etc.	
Class Pycnogonida — sea spiders (35)	
Subphylum Uniramia	
Class Insecta — insects	
Order Anoplura — sucking lice (33,35)	
Order Mallophaga — bird lice (33,35)	
Order Diptera — goby mosquito, etc. (35)	
Order Trichoptera — seastar caddisfly, etc. (35)	
Subphylum Crustacea — aquatic armored animals	572
Class Maxillopoda	
Subclass Ostracoda — seed shrimp (1,19)	
Subclass Copepoda — copepods	572
Subclass Branchiura (?)	
Order Branchiura — fish lice	574
Order[c] Pentastomata — tongueworms	574
Subclass Cirripedia — barnacles	575
Order Thoracica — acorn and goose barnacles (1,19)	
Order Acrothoracica — burrowing barnacles	
Order Ascothoracica — coral, urchin, barnacles, etc.	
Order Rhizocephala — crustacean barnacles (33)	
Subclass Tantulocarida — crustacean ectoparasites (33)	
Class Malacostraca	
Order Decapoda — crabs, shrimp, etc. (33)	
Order Isopoda — isopods	576
Order Amphipoda — amphipods (20,33)	
Phylum Tardigrada — sea cucumber, water bear, etc. (35)	
Phylum Mollusca — seashells, etc.	577
Class Aplacophora — wormlike molluscs	
Class Bivalvia — clams, oysters, etc.	
Order Mytiloida — marine mussels[e] (17)	
Order Unionoida — freshwater mussels, glochida (2), etc.	
Order Veneroida — fingernail- and peaclams (2,14)	
Class Gastropoda — snails and slugs	
Order Mesogastropoda — echinoderm snails, etc. (35)	
Order Neogastropoda — elasmobranch nutmeg, etc.	
Order Pyramidelloida — giant-clam snail, etc.	
Order Nudibranchia — seaslugs	
Phylum Echinodermata — seastars, etc.	
Class Ophiuroidea — coral and crinoid brittlestars, etc. (35)	
Class Holothuroidea — fish, sea cucumber, etc. (35)	
Phylum Vertebrata — backboned animals	

Table 1. *Continued*

Classification[b] — Common Names	Page
Subphylum Pisces — fishes	
Class Agnatha — jawless fishes	
Order Petromyzontiformes — lampreys (1)	
Class Chondrichthyes — cartilaginous fish	
Order Squaliformes — cookiecutter sharks (1), etc.	
Class Osteichthyes — bony fishes	
Order Ophidiiformes — pearlfish (35), etc.	
Order Siluriformes — pencil catfishes, candiru, etc.	
Order Perciformes — remoras (1), pilotfish (1), etc.	

[a]Items with page numbers are discussed in this contribution, and most of the other items have citation numbers that refer to references where you can look up additional information.

[b]Classification systems are difficult, but they are necessary to understand the relationships among the parasites discussed in this chapter and those that were only listed, and to gauge some of the complexities from which this contribution was simplified. This classification system is particularly important, since so much of it has, rather recently, changed drastically and most available reference books are not up to date. [See discussion in (49).]

[c]This classification is disputed and is often placed in its own phylum.

[d]Very few parasitic forms exist, but one has caused mass mortalities of oysters in southern Australia, and another feeds on the blood of eels and other fish in the Mediterranean.

[e]Larval forms cause disease in pen-reared salmonids.

Often, our first reaction is to blindly throw powerful, generalized chemical treatments at the invaders. However, an overdependence on chemical treatments may, ironically, create stronger and more resistant parasites and may eventually render our chemical weapons obsolete and useless.

Then how can we avoid damage to our aquaculture stocks by macroparasites? First, if we keep our culture animals as "happy and healthy" as possible, we will probably see few macroparasite problems. Second, many macroparasites have vulnerable life cycle stages that can be easily eliminated by removing intermediate hosts in the system and by maintaining a flow of water that is sufficient to wash away the intermediate stages of the parasites. Chemical treatments are necessary in emergencies, but by knowing a particular parasite and its life cycle, you can control that parasite with rational and effective management.

Thus, the identification and biology of macroparasites are not mere curiosities and irrelevances to aquaculture. We need to know the identity of each macroparasite that is causing problems in order to chose the proper control measure, and we need to know the biology of the macroparasite in order to devise the simplest and most effective long-term management practices so as to avoid the problem in the future.

METHODS

The terms for the sizes of parasites and the levels and frequency of infection employed in this entry are defined and explained in (1). Treatments are mentioned only briefly in the sections that follow, because the topic is

considered in detail elsewhere (see the entry "Disease treatments"). We cite only popular or semipopular books, papers, or electronic references with additional information, as scarce as these may be in the aquaculture-parasite literature. More technical information may be found in Refs. 1–47 or in the references cited in the bibliographies of these works. If all else fails, hire a parasitologist.

FLATWORMS (PLATYHELMINTHES)

Flatworms form a phylum of soft-bodied, bilaterally symmetrical, flattened wormlike animals. Usually, each worm has a set of both female and male reproductive organs (i.e., the worms are hermaphroditic). Flatworms either have a primitive blind gut and a mouth or absorb nutrients through their bodies. They respire through their "skin" (tegument) and possess specialized cells that maintain a water balance and secrete nitrogenous waste products. There are about 20,000 species of flatworms, including fish turbellarians, copepod worms, soleworms, flukes, tissue flukes, gill worms, and tapeworms.

FLUKES (DIGENEA)

Flukes or digeneans (formerly called digenetic trematodes) form an infraclass of flatworms. Flukes reproduce as adults and again as larvae — hence the name "digenetic" or "of two births." They cause serious and fatal diseases in many animals, including humans. Bilharzia diseases infect humans in fresh waters in many tropical regions and are a threat to aquaculturists. Flukes are important fish parasites, serving as an intermediate host for grubs and as a final stage. The adult host for fluke almost never causes problems in aquaculture animals, but grubs can encyst in vital organs and can often become abundant enough to be important. Figure 1 shows the yellow grub, *Clinostomum complanatum*, which causes problems in aquacultured fishes. More than 9000 species of digeneans have been described. Adults range in size from less than 0.2 mm to greater than 10 cm (0.008 to 3.9 in.). One of the largest, *Hirudinella ventricosa*, occurs in the stomachs of wahoos, *Acanthocybium solandri*, and other offshore big-game fishes.

Flukes usually look like typical flatworms, with a mouth in the anterior region and a blind gut and reproductive and other organs in the trunk region. Unlike generalized flatworms, many flukes have two suckerlike holdfast organs. One (the oral sucker) is located near the mouth, and the other (the ventral sucker, or acetabulum) is usually in the middle of the worm on the ventral side. Great differences in shape, size, and orientation of structures occur in different species. The internal organs illustrated in Figure 2 can be seen if worms are placed in saline wet mounts and viewed with a compound microscope. For study, flukes either must be relaxed and preserved in hot 5% formalin or must be arranged flat in a wet mount on a microscope slide with slight coverslip pressure; then 5% formalin can be slowly drawn into one edge of the coverslip by absorbing the water out of the opposite edge
Figure 1. The yellow grub, *C. complanatum*.
Figure 2. Adult fluke, with distinctive structures labeled.

with a paper towel. To identify species of flukes, the specimens must be stained so that the internal organs are distinguished. The animals are usually placed on microscope slides in permanent mounting media under coverslips.

Flukes have a complex life cycle, usually with two or three intermediate hosts, possible transfer hosts, and a final host. Typically, eggs from the body of the fluke pass out of the intestine of the final (definitive) host. The eggs either are eaten by the first intermediate host or hatch into a swimming ciliated larva (miracidium) that infects the first intermediate host, almost always a snail. Once inside the snail, the miracidium transforms into a sporocyst. Each sporocyst asexually produces many larval parasites (rediae), which in turn produce many swimming infective larvae (cercariae) that leave the snail. The cercariae infect the second intermediate host, encyst,

and become metacercariae. If the appropriate final host eats this infected host, the cyst is digested and the metacercariae emerge and become adult flukes. There are many variations in the life cycle of the fluke, especially in the asexual phases. Since each fluke has both female and male reproductive organs, self-fertilization is possible, but cross-fertilization is more common.

Flukes are permanent parasites in most marine fishes and in many freshwater fishes, amphibians, reptiles, mammals, and birds. Larval stages occur in a variety of invertebrates and vertebrates. Flukes usually inhabit the intestine, stomach, mouth, or, occasionally, the lungs and other organs. Larval forms occur in almost any tissue. Sometimes predators (false hosts) temporarily support flukes digested from prey, but these soon pass out of the predator.

Didymozoids, or tissue flukes, belong to the subclass Digenea, but their exact taxonomic positions and relationships are not clear. The classification issue will not be resolved until the life cycle *in toto* and especially its early stages are studied. We consider both of these topics next.

Popular references on this subject are (50–53).

TISSUE FLUKES (DIDYMOZOIDEA)

These vivid and often spectacular worms are found encapsulated in the tissues of marine fishes, including greater amberjack and yellowtail, big-game fishes (1), groupers (family Serranidae), and snappers (family Lutjanidae), but a few (probably of marine origin) infect freshwater fishes. The capsules (and the damage they cause) are frequently seen in fishery products, but have been of no consequence in aquaculture. Tissue flukes may cause considerable problems in the culture of dolphin, greater amberjack, and other big-game fishes. The scientific name is from "didymos," which means "double" or "twin," and "zoë," which signifies "life." The name refers to the characteristic two worms that usually occur in each capsule. The bright, usually yellow, color that makes the capsules so conspicuous is due to masses of eggs that occupy much of the hosts' bodies. Figure 3 illustrates *Koellikeria bipartita*, which occurs in greater amberjack and tunas.

Tissue flukes in fish muscle may cause it to deteriorate more rapidly, making the meat less desirable for
Figure 3. A tissue fluke, *K. bipartita*, a parasite of the greater amberjack and tunas.

consumers. Flesh from a heavily infected Atlantic mackerel, *Scomber scombrus*, has to be discarded in processing, and wahoo in eastern Australia is undervalued due to its reputation for having large tissue flukes (a third of the animals are infected). Heavy to very heavy infections are routinely found in big-game fishes. In the Indian Ocean, 100 or more capsules are found in every wahoo and in half the tuna. Superinfections of up to 1167 capsules have been reported on occasion in tuna from the southern Gulf of Mexico.

Approximately 200 species are known. Encapsulated pairs of various species range from a few millimeters (1 mm = 0.04 in.) to the size of an adult human fist. They are usually colored yellow or orange, but blue capsules occur in wahoos (*A. solandri*) from Australia. Worms vary in length from a few mm to over 12 m (0.08 in. to 13.2 yd). The body of the worm may be elongated, filamentous or ribbonlike, and intricately tangled, or it may be divided into a narrow anterior and a broadly swollen posterior.

The complete life cycle is not known. Eggs are released annually from encapsulated worms in the gills, ovaries, or other exposed locations. More deeply embedded or inaccessible worms may release eggs only after the death of the host and survive passage through the gut of the predator. In some cases, the capsule and surrounding tissue break down or ulcerate when the tissue flukes mature, releasing both eggs and adults. A nonciliated miracidium with two or more circles of spines around the oral sucker hatches from the egg. Tissue fluke cercariae occur in plankton, and metacercariae parasitize arrowworms, barnacles, copepods, krills, squids, small bony fishes, and sharks.

All species are hermaphroditic (have both sexes in each worm), but often associate in pairs, one individual of which has more developed female organs and a smaller partner that has more developed male organs. Other pairs are fused to each other in the genital region.

Popular references on this subject are (1,12).

GILLWORMS (MONOGENEA)

Simply stated, gillworms are the most important macroparasites in aquaculture. No other macroparasites come close in the amount of damage they do to fishes, the terror they pose to aquaculturalists, the diversity of their species, and the difficulty they present in controlling them. The name "Monogenea" means "born once" and refers to a simple life cycle. In very heavy infections, gillworms can kill captive fishes and, occasionally, wild ones. Heavy infections cause irritation to the fish, excess mucus production, cell proliferation, and smothering of the gills, resulting in death. Complex gillworms routinely cause tissue damage even in light infections. A treatment of 250 parts per million (ppm) of formalin for one hour will remove most gillworms (15). More than 1500 gillworm species have been described, but they are probably only a small percentage of those existing. Gillworms include more host-specific species than any other group of parasites. This property often makes them more easy to control in aquaculture, but we have found some breakdown in specificity after long culture with similar hosts (2).

Adults range from 30 μm to 20 mm (0.0012 to 0.79 in.) in length and are translucent, cream, or pink. In general, live-bearing gillworms are microscopic, with simple gillworms microscopic to tiny and capsalids and complex gillworms small to large (1). Both simple, live-bearing gillworms and capsalids have a distinct attachment organ on their posterior end called a haptor (or opisthaptor) with hardened anchors or specialized clamps to pierce the epithelium of the host and grab hold of it. Sclerotized marginal hooks often surround the haptor, and bars, disks, scales, or spines may occur on or near the haptor. The head may have eyespots or specialized holdfast organs (Fig. 4). Complex gillworms have large suckers or numerous clamps adapted for attachment. Most reproduce by laying eggs that hatch free-swimming, ciliated larvae (oncomiracidia) which quickly mature and then find and attach to a host. Live-bearing gillworms rapidly produce new worms from embryos that are born able to immediately attach to the parental host with no intervening free-swimming stage. Since none require intermediate hosts, they all multiply rapidly. When intensive culture crowds fish together, most gillworm offspring survive and can quickly kill fishes. Gillworms are permanent (33) parasites in the gills, in the mouths, or on the bodies of fishes. In general, the relatively smaller live-bearing and simple gillworms occur naturally on a host in greater numbers than the relatively larger capsalids and complex gillworms. This difference may have something to do with the carrying capacity of

the host. Typically, live-bearing gillworms prefer the skin and fins of hosts; simple gillworms the gills; capsalids the skin and the gill, mouth, and nasal cavities; and complex gillworms the gills. Some occur in the nares, pockets in the lateral line, or, rarely, the gut of fishes. Some species occur in the urinary bladder of fishes, frogs, or turtles; the intestine of tilapias; or even the eye of hippopotamuses. Most gillworms feed on mucus or sloughed-off epithelial cells, though some complex gillworms feed on blood. Gillworms are common on fishes in all aquatic environments. Live-bearing gillworms are largely limited to freshwater fishes, but occur on some euryhaline and brackish-water hosts. Simple gillworms appear to have more species on freshwater fishes, but more genera on marine fishes, which could indicate a marine origin and a more recent spread to fresh waters. Simple gillworms are found in almost all aquatic habitats, with the exception of the offshore pelagic realm (1). Their absence from that region may be due to the inability of their free-swimming larval stages to find hosts in the open ocean. Capsalids and complex gillworms are marine animals, except for a few species that parasitize freshwater fishes of obvious marine origin that seem to have taken some of their parasites with them to fresh waters.

A popular reference on this subject is (52).

LIVE-BEARING GILLWORMS (GYRODACTYLIDEA)

Gyrodactylids, largely in the genus *Gyrodactylus*, have simple attachment organs: a haptor with one pair of anchors, a connected shield, and, often, interconnecting bars and accessory bars or plates. These worms differ from other gillworms by having embryos in their bodies. They are generally smaller than simple gillworms and much smaller than capsalids and complex gillworms. Figure 5 illustrates *Gyrodactylus cichlidarum*, which causes problems in tilapia culture.

Live-bearing gillworms can normally be found in wet mounts of skin scrapings or clippings of gills observed with a compound microscope. Their absence in samples does not assure that the associated populations of fishes are free from these worms: Live-bearing gillworms are small, and when they occur in low numbers, they can often be difficult to detect. To identify species, the parasites can be relaxed in 1 part of formalin to 4000 parts of water until they are dead, after which they may be fixed in 5% formalin and mounted in glycerine jelly. Relaxed specimens can be stored in 5% formalin.

In heavy infections, the attachment of the hooks causes skin or gill irritation and a heavy production of mucus. The skin may be flecked with white patches, especially behind the fins, and the gill filaments may thicken. Fishes may also exhibit flashing behavior and scrape their bodies on the sides of containers. Swimming may alternate between wild activity and lethargy. Secondary bacterial infections can enter damaged areas, further weakening the fish. In confined tanks and raceways, live-bearing and simple gillworms sometimes rapidly increase their populations on fishes. Often, the simple management technique of increasing the flow of water will flush early life-cycle stages of these gillworms out of the tanks and slow their

accumulation on the bodies and gills of fishes. No simple treatment or U.S. aquaculture-legal series of treatments will eliminate all gillworms; treatments merely reduce the levels to tolerable loads for fishes. Gillworm-free stocks can be established in fishes with host-specific gillworms, albeit with difficulty, but this is pointless if everyone else is using "dirty" stocks. Once a gillworm becomes established in a widely cultured fish species, it is almost impossible to eliminate. This fact should be kept in mind when one is contemplating importing fishes to new geographic areas.

SIMPLE GILLWORMS (DACTYLOGYRIDEA)

Dactylogyrids occur in a great variety of shapes, sizes, and forms and in a myriad of different host genera and species. No single genus is representative, although *Dactylogyrus* may be most ubiquitous and important in fresh waters and *Ancyrocephalus* or *Haliotrema* in salty waters. The dactylogyrids have simple attachment organs, usually a haptor with one or two pairs of anchors with interconnecting bars. They are distinguished from live-bearing gillworms by the fact that they lack an embryo in their bodies and are generally much smaller than capsalids and complex gillworms. Figure 6 illustrates *Haplocleidus furcatus*, which causes problems in the culture of basses and bream (sunfishes, family Centrarchidae). Simple gillworms can be collected, examined, and treated in the same manner as the live-bearing gillworms.

CAPSALIDS (CAPSALIDEA)

These relatively large, broad, and flat gillworms attach to the host with a large cup-shaped haptor on the posterior of the worm and two smaller suckers on the anterior. A microscopic pair of anchors are found on the haptor. Figure 7 illustrates the notorious "killer capsalid," *Neobenedenia melleni*, which causes problems in the cage culture of fishes in Atlantic tropical and subtropical waters. We have seen thousands of these worms covering tilapias reared in seawater, upon which they look like the scales of the fish. This capsalid caused the failure of otherwise promising efforts to raise tilapias in seawater cages and ponds in the Bahamas, Jamaica, and Puerto Rico (2). It was unnecessarily introduced to Hawaii, Hong Kong, Okinawa, and the main islands of Japan along with greater amberjack fry in mariculture (1).

Larger adult worms are plainly visible on the host, and small or developing worms can be found in wet mounts of skin scrapings observed with a compound microscope. Capsalids will quickly leave a captured fish and can often be found in the sediment of plastic bags containing fish samples. Their absence in samples does not assure that the associated populations of fishes are free from capsalids: These worms can hide effectively in the nares, mouth, and gill chambers of fishes.

Capsalids and complex gillworms often do not relax well in 1/4000 formalin. Most can be relaxed by freezing. They can also be flattened in a wet mount on a microscope slide, as described previously for flukes. They may be mounted in glycerine jelly to distinguish their hard parts, but
Figure 7. The killer capsalid, *N. melleni*.

Figure 8. A complex gillworm, *A. mcintoshi*, of the greater amberjack.

additional specimens must be stained, again in a manner similar to the way flukes are stained, to discern internal structures. Like the live-bearing gillworms, hosts infected with capsalids can be treated with formalin. Freshwater dips also are effective.

Many capsalids are less host specific than other gillworms. Often, these worms infect fishes in a genus, a family, or many families. Those capsalids that lack host specificity are the most dangerous to aquaculture fishes.

COMPLEX GILLWORMS (MAZOCRAEIDEA)

These worms have more complex haptors than other gillworms. Most complex gillworms can easily be seen with the naked eye. They have intricate attachment organs composed of a series of complicated clamps or suckers, often on extensions of a complex haptor. Figure 8 illustrates *Allencotyla mcintoshi* from cultured greater amberjack. The complex gillworms produce few, relatively large eggs and thus increase in numbers more slowly than other gillworms. However, they feed on blood and cause considerable damage to the gills of their hosts. Only slight increases in abundance can injure or kill fishes. These worms can be prepared, studied, and controlled in the same manner as noted for capsalids.

TAPEWORMS (CESTOIDEA)

Tapeworms or cestodes form a large infraclass of the flatworms, or platyhelminths. The common name comes from the long series of body segments, which resemble a tape measure. Most adult tapeworms look like long, flat cooked noodles. Most larval forms look like the tiny pieces of noodle that stick in the colander. A giant, broad tapeworm that lives in the body cavity of freshwater fishes in Europe is apparently routinely eaten by humans, who mistake it for parts of the fish! Tapeworms can reduce the growth and affect the reproductive success of fishes. Most do not survive under culture conditions, but some destructive exceptions are the bass tapeworm, *Proteocephalus ambloplitis*, whose larvae infect a variety of freshwater fishes, and the Asian tapeworm, *Bothriocephalus acheilognathi* (Fig. 9), which parasitizes fishes cultured for bait in the United States and tilapias in Cuba.

Some tapeworms that infect humans occur as immature or larval forms in freshwater fishes. A small boat fishery for tunas on the northwest coast of Puerto Rico was closed by the government because of reports of "wormy" flesh in these food fishes. When we were contacted to examine these parasites, we found that they were larval tapeworms, and we recommended that the fishery be immediately reopened. We knew that previous experimental attempts to infect mammals with similar larvae failed because the parasites mature only in sharks and rays. The fishery was quickly reopened, averting major losses to local fishermen. Occasionally, we receive similar samples of wormy fillets from individuals. People do not like seeing larval tapeworms moving around in the flesh of their fish, but most of those that occur in marine fishes are relatively harmless (particularly when cooked). For example, *Pseudogrillotia zerbiae* larvae, which are found in the flesh of the greater amberjack (Fig. 10), offend humans, but these would not develop in cultured amberjack.

More than 5000 species of tapeworm are known. Adults range from less than a mm to more than 30 m (0.04 in. to 33.3 yd) in length. Tapeworms usually consist of a chain of segments (proglottids), each of which has a set of female and male reproductive organs. The segments

Figure 9. The Asian tapeworm, *B. acheilognathi*.
Figure 10. Tapeworm larvae of *P. zerbiae* in the flesh of the greater amberjack, *Seriola dumerili*.

are continuously budded in the anterior portion of the body or neck and enlarge and mature as they slowly move posteriorly. The scolex or "head" on the anterior end is usually armed with various combinations of suckers, hooks, bothridia (outgrowths), or bothria (sucking grooves) for attachment in the host intestine. Eggs escape through pores, or a whole, mature egg-filled segment may break off and pass out of the intestine. A successful tapeworm may produce millions of eggs over its lifetime.

In aquatic life cycles, larvae (ciliated coracidia) that hatch from the egg are eaten by the first intermediate host (insect, crustacean, or annelid) and become elongate procercoids. This host is subsequently eaten by a vertebrate (the second intermediate host), and the larvae develop into partially differentiated plerocercoids or plerocerci, which can be passed from one host to another when an infected fish is eaten by another fish. Feeding infected viscera to fish therefore can greatly concentrate or increase the intensity of infection by these worms. Indeed, we have seen this practice cause a superinfection in caged red hind, *Epinephelus guttatus*, in Puerto Rico and in caged fishes raised in the northern Gulf of Mexico. If viscera must be used as fish food, they should be cooked or frozen for several days to kill parasites. When the correct final or definitive vertebrate host eats the second intermediate host, the adult tapeworms develop in the intestine.

As mentioned, most tapeworms have both female and male sex organs in each proglottid. A few have separate sexes. Tapeworms occur in all kinds of vertebrates and in all habitats around the world. All are permanent (33) parasites. Because the intestine of these worms has been lost through evolution, food from the gut of the host is absorbed directly through the body wall. Few species of adult tapeworms are found in marine bony fishes, but many species of larval tapeworms are found in the intestinal tract, often in large numbers, and a few are encapsulated in the tissues. Most of these larval forms are found as adults in sharks or rays. A necropsy is necessary to find adults or larvae in the gut and encapsulated larvae in internal organs. Adult tapeworms can be relaxed in tap water until they no longer react to touch, after which they may be preserved in 5% formalin. Specimens must be stained as has been described for flukes in order to distinguish the internal organs for identification purposes.

Popular references on this subject are (38,54).

ROUNDWORMS (NEMATODA)

Roundworms, also called threadworms or nematodes, constitute a phylum. Along with flatworms and spiny-headed worms, they are sometimes called helminths. Few roundworms cause problems in aquaculture, because their complex life cycles cannot be completed in culture facilities, but some damaging exceptions occur. *Camallanus cotti* (Fig. 11) causes disease in cultured aquarium fishes and has been spread around the world. The Asian roundworm devastated the culture of European eels (46), *Anguilla anguilla*, and has spread to the American eel, *Anguilla rostrata* (48). Eel culture is increasing, and the potential for the introduction of this destructive parasite into new regions is great.

Roundworms cause serious diseases and even death in humans. The recent increase in popularity of Japanese raw-fish dishes has caused a concomitant increase in the number of fish-roundworm-related illnesses around the world. Modern refrigeration of fish catches has also allowed dangerous roundworms that would have been discarded by quick cleaning to migrate from the gut and mesenteries into the edible flesh. The unwise practice of swallowing live fish has produced severe gastric distress in humans when roundworms from fish burrowed through the intestinal wall into the person's body cavity. In one case, a roundworm from the flesh of a Hawaiian jack penetrated a wound in the hand of a man cleaning the fish.
Figure 11. A roundworm, *C. cotti*, of cultured aquarium fish.

Figure 12. A generalized nematode, with the distinctive structures labeled.

The entry was painful, and the worm could be removed only with surgery.

More than 12,000 species have been described of the 500,000 to 2 million roundworms that probably exist. They are one of the most abundant multicellular organisms on earth, both in number of individuals and in number of species. Roundworms occur in such high numbers in almost all vertebrates and invertebrates, that it has been suggested that the shapes of all living animals could be seen from space merely by seeing the mass of worms in each animal!

Most adult free-living forms are small to microscopic, but parasitic forms are large, up to 8 m (8.6 yd) long. As the name implies, roundworms are circular in cross section. The body is nonsegmented, elongate and slender, often tapered near the ends, and covered with cuticle. Three to six lips of various shapes surround the mouth. The digestive tract is complete, the musculature has only longitudinal fibers, and a pseudocoel (false body cavity) is present. A nerve ring is usually visible in the anterior end of the body. The sexes are separate. The male has a cloaca, a pair of chitinized copulatory structures (usually spicules), often with a variety of papillae, alae (long, thin flaps of cuticle), and suckers in or on the posterior end. All of these male structures are important in identifying species (Fig. 12). Eggs are released into the intestine of fishes or, through holes in the host skin in tissue-dwelling roundworms, into the water. The eggs of some species contain developed roundworms, while those of others are expelled in a less developed stage. Some larvae are eaten by fishes and develop directly into an adult. Usually,

larvae must go through two to five molts in one or more crustacean or fish intermediate hosts. Roundworms are found in all marine, freshwater, and terrestrial habitats. Flying insects, birds, and bats take them into the skies.

A necropsy is needed to find the larvae in the organs and mesenteries and the adults in the stomach and intestine. Roundworms can be relaxed in acetic acid and stored in a mixture of 70% ethanol with 5% glycerine. Adult roundworms from tissues of fishes are exceedingly delicate and tend to explode if placed in freshwater or preservatives. These small worms can be put into a steaming 0.8% saline, 5% formalin solution. Once fixed (15 minutes for small worms and up to 24 hours for large ones), worms can be rinsed in freshwater and slowly transferred into gradually increasing concentrations of ethanol, until they are stored in a mixture of 70% ethanol and 5% glycerine. Roundworms are usually examined in wet mounts. Semipermanent mounts may be prepared using glycerine jelly. Most larval species are difficult to identify, but most genera can be readily determined. Knowledge of the entire life cycle of a roundworm may be necessary to identify a given species of larvae.

No treatment is possible for roundworms in the body cavity or tissues of fishes, and treatment is seldom necessary for intestinal roundworms. Worms that perforate the intestine of humans must be surgically removed.

A popular reference on this subject is (41).

SPINY-HEADED WORMS (ACANTHOCEPHALA)

These worms form a small phylum in the animal kingdom. The name "acanthocephala" means "spiny headed." Despite their formidable and highly destructive armaments (Fig. 13), they seldom, if ever, cause problems in aquaculture animals, because their complex life cycles cannot be completed under culture conditions. Figure 13 illustrates *Rhadinorhynchus pristis*, which occurs in the dolphin (*Coryphaena hippurus*) and other big-game fishes. All spiny-headed worms are permanent (33) parasites in the intestine of most vertebrates, including humans. Over 1000 species are known.

Adult females vary from 1 mm (0.04 in.) to longer than 1 m (1 yd, 3.4 in.), but are usually about 2 cm (0.8 in.) long. Males of the same species are typically smaller than females. Spiny-headed worms may be white, yellow, orange, or red in color. (*Pomphorhynchus lucyae* seems to absorb orange pigments from crayfish in the intestines of fishes inhabiting southeastern U.S. coastal waters.) They are bilaterally symmetrical and unsegmented, and they attach to the gut of their host with a globular or cylindrical, protrusible spiny proboscis. The proboscis pops out like an everting plastic glove, and the spines fold out and lock like a compact umbrella. Muscles invert the proboscis, and a hydraulic system (lemnisci) pops it back out (Fig. 14). Some species have spines on the body as well (Fig. 13). The sexes are separate, fertilization is internal, and embryos develop in the body of the female. Shelled larvae (acanthors) are shed into the intestine of the host, pass out with the fecal material, are eaten by a crustacean,

Figure 13. A spiny-headed worm, *R. pristis*, of the dolphinfish, *C. hippurus*.
Figure 14. A spiny-headed worm, *Acanthocephalus alabamensis*, with distinctive structures labeled.

insect, mollusk, or fish intermediate host, and develop first into an acanthella and then into an encysted cystacanth larva in the second intermediate host. When the final host consumes an infected intermediate host, the cystacanth develops into an adult in the intestine. Adults absorb nutrients from the contents of their hosts' guts. Proboscis spines (or hooks) cause some mechanical damage, which is serious only in a heavy infection. Treatments seldom are necessary. Natural infections in most fishes usually consist of only a few worms per host. Some inshore New England fishes are routinely infected with hundreds to thousands of spiny-headed worms. The worms rarely harm humans, since they are usually discarded with the intestine and other internal organs when fish are cleaned, but contamination is possible. Thorough cooking kills these parasites. Tuna, salmon, and other fishes known to harbor dangerous worms are prized ingredients of Japanese raw-fish dishes, but most of these products are frozen long enough to kill the parasites before the dishes are served "fresh" in Japan.

A necropsy is necessary to find spiny-headed worms in the intestine. For routine examinations, the worms can be identified in wet mounts. For more detailed study, the proboscis must be fully everted before preserving the animals. Worms must be refrigerated in distilled water or freshwater for 12–24 hr before preserving them in 5% formalin. The thick cuticle of these worms does not allow alcohol solutions or stains to penetrate them readily. The cuticle must be pierced before dehydrating the worms in alcohol solutions and then staining them.

LEECHES (HIRUDINIDA)

Leeches form one of the classes of segmented worms, or annelids. The most familiar member of this phylum is the earthworm. Leeches are often called bloodsuckers for

their feeding habits. They are sometimes used as hook-and-line bait for fishes. Predacious leeches have also been used to control snails which have parasites that cause swimmers itch (the cercariae of a bird fluke that attack and irritate the skin of humans). Leeches occasionally invade aquaculture systems, and their direct development allows them to build up their numbers and cause problems. Inexplicably, they rarely damage aquaculture organisms, but a few spectacular cases have occurred. Figure 15 illustrates *Myzobdella lugubris*, which has killed fishes and crabs in the continental United States and Puerto Rico (2).

More than 300 species of leeches have been described. Adults vary from 0.5 to 45 cm (0.2 in. to 18 in.) in length, although they can greatly change their size and shape through powerful muscle contractions and enlargement during feeding. A leech's body is pigmented (sometimes brightly), depressed (dorsoventrally flattened), and made up of 34 segments that may be further subdivided by shallow creases or lines into annuli. One sucker occurs on the posterior end of the body, and another usually is found on the anterior end surrounding the mouth. A poorly formed saddle-shaped midportion (clitellum) functions in copulation and cocoon formation. The body cavity (coelom) is reduced to a few channels. Eggs are usually deposited in cocoons formed of epithelial tissue and mucus. Development is direct (i.e., there are no larval stages). The complex reproductive system of the animal contains both female and male sexual organs (i.e., leeches are hermaphroditic). Leeches occur in fresh, brackish, and marine waters and also in moist conditions on land around the world, except in Antarctica. They can crawl and attach with their suckers, and many are able to swim. Leeches come in three varieties: permanent (33) to temporary parasites, predators, and scavengers. Parasitic forms feed on whole blood of crustaceans, fishes, amphibians, reptiles, birds, and mammals. They are often vectors of
Figure 15. A leech, *M. lugubris*, that causes kills of fishes and crabs (2).

pathogenic protozoa, roundworms, and tapeworms. They have also been accused of spreading lymphocystis disease and bacterial diseases between hosts.

CRUSTACEANS (CRUSTACEA)

Crustaceans are one of the subphyla of animals with hard, segmented shells (exoskeletons), something like medieval knights in armor (arthropods). They are largely aquatic, whereas insects, spiders, and their allies (arachnids) are mostly terrestrial. Crustaceans generally have two pairs of antennae, respire through gills or the body surface, have paired, segmented, usually biramous appendages anteriorly or throughout their length. More than 40,000 living species and many fossil species have been described, including seed shrimp, copepods, fish lice, tongueworms, barnacles, isopods, and amphipods.

COPEPODS (COPEPODA)

Copepods form a subclass of the crustaceans. The common name "copepod" means "oar foot." Copepods occasionally cause significant losses of aquaculture fishes. They parasitize or otherwise associate with many kinds of invertebrates, but are not an important problem in the aquaculture of invertebrates. Two of the most destructive types of copepods in freshwater fish aquaculture are *Ergasilus* spp. (Fig. 16) and the anchorworm, *Lernaea cyprinacea* (Fig. 17). The anchorworm is an international superparasite that causes problems in fishes around the world, from culture ponds near the equator in Brazil to culture facilities near the Arctic Circle in Japan. *Ergasilus labracis* also damages pen-reared salmonids in brackish water and saltwater. Relatively large salmon copepods (caligids [sometimes erroneously called salmon lice or sea lice, common names reserved for branchiurans]) cause losses to salmonids (family Salmonidae) cultured in cages and pens, and these parasites transmit microbial diseases.

Copepods are found in marine water and freshwater; most are free living and are very important sources of food for a variety of aquatic life. Approximately 10,000 species have been described, and about 2,000 of these parasitize fishes. Many of the species that parasitize fishes remain to be named. Copepods range in length from 0.5 to 25 cm (0.2 in. to 10 in.), but most are less than 1 cm (0.4 in.) long. Egg strings of some species may exceed 60 cm (2 ft). Body shapes vary greatly, from a generally cylindrical shape to a flattened or saucer shape. Theoretically, the body is divided into 16 segments, or somites (five head or cephalic somites, seven thoracic somites, and four abdominal somites), but most of these are fused together, combined, or overlapped, so they cannot be seen. The first six to nine somites are fused into an expanded "head," cephalothorax, or cephalosome, and the remainder are variously fused or separated into thoracic and abdominal units. Appendages are modified into mouthparts and other structures in the cephalosome and legs and other appendages in the thorax. The abdomen has no appendages and usually terminates in a bifurcate tail with projections (caudal rami). We illustrate females,
Figure 16. The copepod, *Ergasilus caeruleus*, of striped mullet, *Mugil cephalus*.
Figure 17. The anchorworm, *L. cyprinacea*, an international superparasite.

use their morphological characters, and seldom mention males, because females are usually larger, are more available, and have more diagnostic characteristics.

In most parasitic forms, the life cycle is direct, but typically involves a series of free-swimming planktonic stages. Some copepods have intermediary hosts, such as *Pennella* spp. on squids and shark copepods embedded in coral-reef fishes. The hatching nauplii can often be observed merely by holding egg strings in bowls of seawater until the eggs hatch. Nauplii of many species have never been described or drawn. Raising the other planktonic stages of parasitic copepods is more complicated, but can be accomplished. A newly hatched nauplius of *Caligus elongatus*; an early nauplius, later nauplius, and metanauplius of *C. bonito*; and a chalimus of *C. elongatus* attached to a host scale are illustrated

in Figure 18. The sexes are separate, with males often much smaller than females. The life-cycle stage that first attaches to fishes (the copepodid—sometimes chalimus) can be very damaging to young fishes. Copepods frequently occur on the gills or skin of fishes, but highly specialized species burrow into the flesh or head sinuses or crawl into the nose (nares, nasal fossae, or lamellae) or eyes (orbits). They also associate with or parasitize a variety of invertebrates. Large copepods that are parasitic on fishes are capable of biting humans, but such injury has seldom been reported. Indeed, most aquaculturalists would not admit being attacked by a mere copepod! These parasites can be of value to humans: Eskimos eat the *Gadus morhua*, a giant parasitic copepod that attacks the gills of Atlantic cod. Those on fishes are usually permanent (33) parasites, feeding on mucus, sloughed epithelial cells, and
Figure 18. A newly hatched nauplius of *Caligus elongatus*; an early nauplius, later nauplius, and metanauplius of *C. bonito*; and chalimus of *C. elongatus* attached to a host scale.

tissue fluids. Copepods can directly transmit microbial diseases.

Copepod specimens can be preserved and stored in 70% ethanol. They can be examined in alcohol or in a mixture of alcohol and glycerine to clear some structures. Smaller specimens or parts can be mounted in glycerine jelly for convenience in handling.

Popular references on this subject are (20,55).

FISH LICE (BRANCHIURA)

Fish lice, argulids, or branchiurans form a small subclass of crustaceans. They can be very harmful to fishes, especially those in hatcheries or other rearing facilities. Fish lice can infect the eyes of humans who carelessly handle live fishes. Approximately 150 species have been described in four genera, more than 120 in the genus *Argulus*. *Argulus japonicus* (Fig. 19) is an international superparasite transported on goldfish and carp. Fish lice are relatively large parasites, varying from a few to 20 mm (0.1 to 0.8 in.) long.

The body is flattened (strongly depressed) and has a large, expanded head (carapace), a thorax, and an abdomen. The thorax has four ill-defined segments and the abdomen is completely fused. The two pairs of antennae are modified into attachment hooks. Some appendages of the carapace also are modified (maxillule into suckers and maxilla into leglike structures), and those of the thorax are four pairs of unmodified legs (Fig. 19). Most fish lice have large suckers on the underside (ventral surface) of the front of the carapace. Many have a long and vicious stinger (stylet) in front of the mouth and between the antennae. The abdomen terminates in a bifurcate tail with tiny rami.

Fish lice mate while free swimming, off the host. Eggs are held in the body of the female, which leaves the host to deposit eggs in clusters attached to the substrate. *Argulus* spp. hatch as nauplius larvae, but members of the other genera hatch as juveniles from eggs in 15–55 days and develop directly into adults. Swimming juveniles must find a host in 2–3 days and, once attached, develop into adults in 30–35 days. The sexes are separate.
These parasites attach to the body, fins, gills, and mouth of fishes and sometimes to frogs and tadpoles. Fish lice are more important in fresh, brackish, and inshore marine waters. They are obligate parasites, feeding on blood, but adults are capable of changing hosts and spending prolonged periods off any host. Fish lice may prefer some fishes, but are usually not host specific. Heavy infections can kill fishes. Combinations of moderate infections of *Argulus lepidostei*, *Anilocra acuta* (an isopod), a bacterial infection, and polluted conditions have caused mortalities in wild inshore fishes in the Gulf of Mexico. Fish lice directly transmit viral and bacterial diseases. They have introduced microbial diseases into culture facilities and caused epizootics.

Fish lice are the only crustacean fish parasites known to infect humans. Other parasites may bite or attack humans, but only *Argulus* spp. penetrate, survive in, and cause diseases in humans. The first reported case of human argulosis was in a child infected by *Argulus laticauda* while swimming in saltwater off the Atlantic coast of the United States (1). We recently interviewed an aquaculture specialist from South America who became infected with an *Argulus* sp. during her attempt to control losses of cultured tilapias caused by very heavy infections of this parasite in freshwater. One of the argulids she was working with was splashed into her face and lodged between her eye and the orbit, causing severe irritation and minor tissue damage for 24 hours before it was discovered and removed. She was able to sleep with the organism in her eye. All fish lice should be treated with caution.

Popular References on this subject are (20,33).

TONGUEWORMS (PENTASTOMATA)

Tongueworms, or pentastomes, form a small order of strange animals. They were dinosaur parasites, and most of them perished with these spectacular hosts. "Tongueworm" refers to their shape. "Pentastome" means "five mouths" and refers to the fingerlike projections supporting the four legs and a mouth in some species. Larval tongueworms (Fig. 20) could damage or kill fishes in aquaculture, but they are more likely to cause problems as adults in the culture of alligators and crocodiles. They can also infect humans as larvae or adults. About 95 species are known. Adults are a few mm to 15 cm (0.08 in. to 5.9 in.) long. They are flat and elongate, and their soft body is reduced and wormlike. Two pairs of legs occur under the anterior end and may be reduced to only single or double hooks or claws. The body covering is chitinous, highly porous, and marked with striations, rings (annuli), or segments. Molts occur between growth stages. The sexes are separate and males are smaller than females. The latter hold up to several million small thick-shelled eggs that pass up the trachea or down the nasal passages of the host, are swallowed, and emerge from the intestine. Eggs on vegetation or bottom mud are inadvertently eaten by a vertebrate, whereupon three

Figure 19. A fish louse, *A. japonicus*, an international superparasite [upside-down (dorsal) view].

Figure 21. The striped goose barnacle, *C. virgatum.*

larval (nymphal) stages develop, and infective stages either break out or are digested out when an appropriate predator eats the intermediate host. Fishes may suffer massive infections. Adult parasites occur in the lungs, nostrils, and nasal sinuses of reptiles primarily, but may occur in some birds and mammals. Larval forms infect fishes, amphibians, reptiles, and a few mammals. In humans, the larvae become encysted in calcareous capsules, soon die, and usually do little damage. Many people who ingest them do not even realize that they have been parasitized. However, some species can develop in the nasal passages or the throat of humans, can damage the eyes and other vital organs, and can cause severe irritation or even death. Tongueworms are permanent (33) parasites that feed on mucus, tissue fluids, and blood of their host.

BARNACLES (CIRRIPEDIA)

Barnacles form a subclass of the crustaceans. The common name "barnacle" is from the Middle English "bernak" (a goose) or the French "bernicle," apparently for the shape of goose barnacles. In Europe, the barnacle goose (a bird) was reputed by the ancient Greeks to spawn spontaneously from goose barnacles. Barnacles occur on or in fishes, sea turtles, and marine mammals. For example, the striped goose barnacle, *Conchoderma virgatum* (Fig. 21), occurs on all of these animals and on parasitic copepods and isopods. Barnacles do not cause problems in the culture of any vertebrates. They cause serious diseases in crustaceans that are important fishery products, but none of these crustaceans are involved in aquaculture. Barnacles may cause problems when crustaceans are more frequently cultured. They also associate with or parasitize a variety of other commercially important marine organisms. Famous for encrusting the bottoms of boats and other marine structures, barnacles are more important as pests to

marine aquaculture facilities than as parasites. Cleaning barnacles from structures, antifouling methods, and the transport of exotic organisms involve serious economic and environmental problems.

A great variety of organisms eat these animals, including "barnacle eaters" (filefishes, *Alutera* spp.). Barnacles were eaten by native Americans and are a delicacy in Europe. The world's largest barnacle supports an important fishery in Chile.

More than 1000 living species have been described, and most are free living. Barnacles vary in size from the minute acrothoracicans, which burrow into the calcareous skeletons of corals and seashells, to parasitic rhizocephalans anastomosing throughout the body of large crabs. The crustacean body form is greatly modified in all barnacles, but is drastically altered in some parasitic species. Most barnacles have a heavy calcareous shell that is unique among crustaceans in that it is composed of several to many parts embedded in a soft mantle surrounding the animal. Free-living forms are attached either by long stalks (goose barnacle) or directly to the base (dorsum) of their shells (acorn or volcano barnacle). Free-living barnacles filter feed by sweeping slender, jointed appendages (cirri) through the water. Parasitic forms live on or in various marine crabs and other crustaceans, echinoderms (sea stars, etc.), and soft corals; most have lost the shell, appendages, and body segmentation of free-living barnacles. Some barnacles are specialized associates of particular crabs, seashells, other invertebrates, turtles, and whales; others attach to a variety of substrates or organisms.

The larvae are planktonic. Most barnacles have both female and male sexual organs (i.e., they are hermaphroditic), but some groups, particularly parasitic ones, have separate sexes. Parasitic barnacles attach externally and burrow inside the skeleton or endoparasitically in a variety of hosts. Barnacles vary from free living through various levels of association to permanent (33) parasites. Parasitic barnacles feed on the tissues of their host. The shells of barnacles fossilize well and have left a good fossil record. Fertilization occurs in the mantle cavity

or at the base of the oviduct; eggs (ova) generally develop to the first-stage nauplius within the mantle cavity and are expelled by pumping movements of the body. The triangularly shaped nauplius larva has corners tipped with prominent spines. It molts through six stages in plankton and then seeks a host or substrate. The thin, transparent, bivalve, ostracodlike cyprid larva rapidly swims and crawls around a substrate, selects a site for attachment, cements itself in place, and metamorphoses into a subadult.

Popular references on this subject are (20,33).

ISOPODS (ISOPODA)

Isopods are an order of the crustaceans. The name means "all legs (pods) approximately similar in size and shape (iso)." Isopods kill, stunt, and damage commercially important fishes. Approximately 9.4% of chub mackerel (*Scomber japonicus*) along the Peruvian coast are parasitized by *Ceratothoa gaudichaudii*, causing a 15% loss in body weight and costing Peruvian fishermen approximately 1.3 billion kilograms (2.9 billion pounds) of fish annually. Other species of isopods also cause significant losses to commercial fishermen, including severe damage and losses in salmonid culture in southern South America. *Cymothoa oestrum* can cause superinfections in caged fishes in the Caribbean. Figure 22 shows a female in the mouth of a jack. Sea gnats (larval gnathid isopods) also kill caged cultured eels and salmonids. A larval *Gnathia* sp. is illustrated in Figure 23. Epicaridean isopods damage crustaceans that are important fishery products, including shrimp, freshwater prawns, crabs, and other hosts that are also involved in aquaculture or that may be cultured in the future.

A few isopods that are parasites of fish actively swim after and bite humans, sometimes alarmingly in mass attacks, but bites are more likely to occur in the handling infected fishes. Free-living isopods are reported to clean *Saprolegnia* spp. (water mold) from fishes. In Puerto Rico, *Anilocra* spp. are dried and used to make a tea to treat colds. New England fishermen use "salve bugs" (*Aega* spp.)
Figure 23. Sea gnats, larval gnathid isopods, kill cage-cultured fishes. A larval *Gnathia* sp. is illustrated.

for medicinal purposes. Isopods are eaten by a variety of animals. Giant isopods (*Bathynomus* spp.) are fished commercially for human food in Japan and Mexico, and Hawaiians eat a smaller species. The presence of parasitic isopods on marine tropical fishes supposedly indicates that these fishes do not contain high amounts of ciguatera, a poisonous toxin. This relationship is not proven, but is highly interesting, particularly because large barracuda and jacks are commonly implicated in ciguatera poisoning and often have attached isopods.

Approximately 4000 species of isopods have been described, of which more than 450 species are known to associate with fishes. They vary from 0.5 mm to 44 cm (0.02 in. to 17 in.) in length. The world's largest species, *Bathynomus giganteus*, is found in the Western Atlantic and the Caribbean Sea. The head of an isopod is fused with first thoracic segment (cephalothorax), and the animals have a seven-segmented thorax and six-segmented abdomen (often fused into two to five segments). One pair of thoracic appendages is modified into mouthparts, and seven pairs are unmodified. The abdomen has six pairs of appendages and ends in a terminal, often shield-shaped segment called the pleotelson (Fig. 24). Eggs, larval forms, and juveniles develop either in a brood pouch beneath the abdomen of the female or in pouches inside the abdomen. Most isopods have a stage of free-swimming juveniles that develop into adults, but gnathiid juveniles parasitize the gills and skin of fishes, and the adults are free living. The sexes are separate in most species, while others begin life as males and later become females (i.e., they are protandrous hermaphrodites). Isopods are common in most environments, including dry land. They parasitize fishes, crabs, shrimp, and other isopods. Isopods associated with fishes vary from accidental (cirolanids) and temporary or casual (corallanids and aegids) parasites to permanent (33) (cymothoids) parasites (57). They attach at a variety of locations, including the skin, the gills, inside the mouth, and on the fins, and some even burrow under the skin to form a cyst in the flanks of fish. They exhibit a broad range of food habits. The forms

associated with fishes feed on blood or ooze from wounds. The wounds isopods cause may provide entry points for microbial diseases. Isopods can be preserved and stored in 70% ethanol (151-proof rum will do) or 40% isopropanol (rubbing alcohol).

SEASHELLS AND ALLIES (MOLLUSCA)

Seashells, or molluscs, form a phylum in the animal kingdom. "Shell" refers to their hard calcium-carbonate coverings. "Mollusc" means soft and refers to their soft bodies. Seashells include the familiar black abalone, *Haliotis cracherodii*; eastern oyster, *Crassostrea virginica*; Japanese pearl oysters, *Pinctada martensii*; northern quahog, *Mercenaria mercenaria*; and queen conch, *Strombus gigas*, all aquaculture animals. Glochidia, the larvae of freshwater mussels (Fig. 25), infect the gills or skin of freshwater fishes and may cause problems in aquaculture. Similar larvae of marine mussels have severely damaged pen-reared salmonids (17). *Turbonilla* spp., ectoparasitic gastropods of giant clams, have caused mass mortalities under culture conditions. Some aquaculturists of giant clams in the West Indies have attempted to eliminate this pest and other dangerous parasites. Molluscs serve as intermediate hosts for many dangerous and harmful parasites of humans and aquaculture animals. Extraneous molluscs should be excluded from aquaculture facilities whenever possible.

More than 50,000 living species of molluscs have been described. They range from the size of sand grains to the 1.3-m (51-in.) giant clam, *Tridacna gigas* (also an aquaculture animal), and 20-m (65-ft) giant squid, *Architeuthis sanctipauli*. The shells of molluscs can be external or internal, or they may be absent; shells are produced by a fold in the body wall (mantle). Usually, the sexes are separate and fertilization occurs in the water, but some species have internal fertilization. Eggs are normally encased in various kinds of coverings. Typically, free-swimming larvae (trochophores) hatch and develop into veligers in plankton, but there are many other methods of development. The larvae (glochidia) of most freshwater clams and mussels develop as parasites in fishes. Many molluscs are predators, grazers, or filter feeders. Only a few adult molluscs associate with or parasitize other organisms. We described the only sea slug (nudibranch) known to associate with a fish. Molluscs inhabit marine waters, freshwaters, and moist areas on land.
GENERAL DISCUSSION

The vast majority of macroparasites have complex life cycles on multiple hosts. Placing the final host in aquaculture situations eliminates almost all of these parasites: The intermediate hosts and natural conditions that support multiple life stages are simply not available under culture conditions. Thus, most of the "gut worms," or helminths, are absent from aquaculture, and many diagnostic services that specialize in aquaculture diseases do not even look for intestinal helminths, because they assume that none will occur.

Those macroparasites with simple or direct life cycles (gillworms, fish lice, copepods, leeches, etc.) are the ones that are most damaging in aquaculture conditions. All parasites produce many times more offspring—often astronomically so—than are necessary to maintain their numbers in nature. This fecundity exists because being a parasite is a hazardous occupation. Most young parasites are washed away, lost, and never find a host, or else they get eaten. In aquaculture conditions, the hosts are crowded together in a small, safe environment, ensuring that most parasite offspring (that would ordinarily be lost in nature) thrive. Thus, the hosts quickly become overcrowded with, and damaged by, parasites. Cage culture in natural waters also allows parasites distributed in plankton (copepods and isopods) and migrating parasites (copepods, leeches, and isopods) to accumulate and cause problems.

Intermediate stages of quite damaging macroparasites can also be introduced to aquaculture animals through poor management practices, such as allowing the animals to come into contact with birds or other predators and allowing extraneous snails or other invertebrates into the system. Direct introductions can occur when macroparasites are fed to aquaculture animals along with raw and unfrozen living materials. For example, marine plankton often contains parasitic isopods, so feeding live plankton can result in direct infections of aquarium and pen-reared fishes.

Biological parasite control is far superior to chemical control, but has been little considered in aquaculture. A good example of such control is the simple removal of an intermediate snail host from the culture system; this measure can totally eliminate an otherwise difficult-to-control parasite. Recently, some attempts have been made to control "salmon copepods" and "killer capsalids" (Fig. 7) with cleaner wrasse (family Labridae). This tactic is something like adding the striped mullet, *M. cephalus*, to pompano (*Trachinotus carolinus*) culture cages to eat the encrusting materials off the mesh so that the cages do not have to be cleaned. Cleaners do not completely eliminate parasites, but can keep them at tolerable levels. If we can identify a parasite, we can accumulate biological information on the species that may be used to develop an effective, intelligent biological control.

Most parasites could, in fact, be eliminated from commercial aquaculture stocks; however, through economic considerations, time restraints, or carelessness, this is often not accomplished. Once a parasite is spread around in the world of aquaculture, it is almost impossible to eliminate. By placing animals into unnatural aquaculture conditions, we select for those parasites best able to thrive under those conditions, and chemical regimens may subsequently select for treatment-resistant parasites. Overcrowding and poor nutrition may weaken the resistance of cultured animals to parasites, and epizootics may ensue, further favoring the more destructive parasites. Aquaculture conditions in themselves sometimes select for and develop, albeit inadvertently, the "international superparasite."

Most cultured animals and almost all of the problematic macroparasites are exotic introductions. Conducting aquaculture with an exotic animal is the same thing as introducing it. Animals always escape. At this point, three things may occur, all of which are negative: Exotic hosts themselves can damage or endanger the environment, exotic parasites may infect native susceptible hosts, and native parasites may infect the exotic hosts. Native hosts infected with exotic parasites may have no evolutionary experience with, and thus no defenses against, an exotic parasite, resulting in drastic reductions in their numbers. Native parasites on exotic hosts may have the same effect, but escaped exotic hosts then serve as a reservoir for potential movement into the culture environment, again with drastic results. These scenarios should be avoided at almost all costs. Careful testing in "neutral" or controlled conditions should be carried out before introducing any exotic species.

Some macroparasites (roundworms, tapeworms, tongueworms) that are found in aquaculture animals can be injurious or fatal to humans, but such injuries or fatalities are much more likely to result from eating wild fishes. The danger can be avoided by *(1)* never eating a raw or improperly cooked crustacean (some shrimps, crabs, and crayfishes are particularly dangerous), *(2)* freezing fishes for several days before using them in "raw" fish dishes (even the Japanese freeze most of their sushi and sashimi fishes), and *(3)* avoiding native raw dishes and do-it-yourself raw dishes (professional preparations cost more, but are safer) (1). Isopods are the only macroparasites known to directly attack humans, but fish lice and tongueworms can infect aquaculturalists.

MYCOTOXINS

R.T. Lovell
Auburn University
Auburn, Alabama

OUTLINE

Aflatoxins

Cyclopiazonic Acid

Ochratoxin

Fusarium Toxins

Conclusions

Bibliography

The mycotoxins of concern in the United States are produced by three genera of molds: *Aspergillus*, *Penicillium*, and *Fusarium*. These molds are ubiquitous (found widely in nature) and grow and produce toxins under the proper conditions, which include adequate substrate (carbohydrate), moisture greater than 14%, relative humidity greater than 70%, temperature, 15–35 °C (59–95 °F) and oxygen. The most familiar mycotoxins are the aflatoxins, ochratoxins, and some fusarium toxins. There are others, such as cyclopiazonic acid, which have received less notoriety, and some newly discovered toxins, such as moniliformin. Effects of mycotoxins on livestock and poultry are fairly well documented. However, much less is known about the effects of mycotoxins in fish. Mycotoxins are usually produced in feedstuffs prior to harvest, but can develop in finished feeds that are not properly dried or stored.

AFLATOXINS

In the late 1960s (1), Dr. John Halver at a U.S. Fish and Wildlife Laboratory in Washington state tested aflatoxin B_1 (AFB$_1$) in rainbow trout (*Oncorhynchus mykiss*) and found that young rainbow trout are one of the most sensitive animals tested. The oral LD$_{50}$ for 50-g (1.7-oz) rainbow trout was 500 ppm (parts per million), and prolonged feeding (20 months) of a dose as low as 0.5 ppb (parts per billion) would cause liver cancer. Bailey et al. (2) demonstrated that rainbow trout were more sensitive than other salmonids to diets containing 20 ppb of AFB$_1$, and 62% of the fish developed liver tumors; however, they fed coho salmon 40 ppm of AFB$_1$ and found no tumors. The salmon tended to produce benign liver adenomas when exposed to AFB$_1$ in contrast to the trout, which produced malignant liver carcinomas. DNA binding by aflatoxin in the liver was 20 times faster in trout than salmon.

Channel catfish (*Ictalurus punctatus*), however, are much less sensitive to aflatoxin BI than are rainbow trout. Studies were conducted at Auburn University to demonstrate the effects of acute and subacute doses of purified AFB$_1$ on channel catfish. In these studies, both oral and intraperitoneal (IP) administration of 12 mg of AFB$_1$ per kg of body weight caused the stomachs of channel to catfish to regurgitate their contents (3). Ammonia detoxification of AFB$_1$ significantly reduced its effect on regurgitation. When AFB$_1$ was injected intraperitoneally, the median lethal dose (LD$_{50}$) for 35-g (1.2-oz) channel catfish was 11.5 mg/kg (2×10^5 oz/lb) of body weight. Fish examined before death showed extremely pale gills, liver, and other internal organs, and hemoglobin concentration was about 10% of that of the control fish. Histological lesions in these fish included sloughing of intestinal mucosa and necrosis of hematopoietic tissues, hepatocytes, pancreatic acinar cells, and gastric glands.

To determine the effects of prolonged feeding of subacute does of AFB$_1$ to channel catfish, Jantrarotai and Lovell (3) fed semipurified diets containing 0, 100, 500, 2,000, or 10,000 ppb to 7-g (0.2-oz) fish in flowing-water aquaria for 10 weeks. Only the highest concentration of AFB$_1$ had adverse effects on the fish. The growth rate, hematocrit, hemoglobin concentration, and red-blood-cell count were lower, and the white-blood-cell count was higher in fish fed 10,000 ppb of AFB$_1$ than in fish fed lower concentrations. At the highest concentration, AFB$_1$ caused necrosis and basophilia of hepatocytes, enlargement of blood sinusoids in the head kidney, accumulation of iron pigments in the intestinal mucosa epithelium, and necrosis of gastric glands.

The maximum concentration of aflatoxin allowed by FDA in feedstuffs (feed ingredients or finished feed) in interstate commerce is 20 ppb. However, concentrations of 400 ppb have been found in locally produced (noninspected) grain sold for use in catfish feed. This concentration is well below the oral toxicity level for channel catfish, which appears to be between 2,000 and 10,000 ppb.

CYCLOPIAZONIC ACID

Cyclopiazonic acid (CPA) is produced by several species of *Aspergillus* and *Penicillium* fungi. It is indigenous to warmer latitudes and appears to be fairly widespread. It is often found in combination with aflatoxins. Gallagher et al. (4) reported that CPA occurred more frequently (found in 52% of samples tested) than aflatoxins (found in 33% of samples tested) in peanuts contaminated with *Aspergillis flavis*. Leistner (5) identified 20 different mycotoxins from 1,481 *Penicillium* molds isolated from livestock feeds and found that CPA occurred with the highest frequency.

Because of the potential for CPA to occur in fish feeds made in the southern United States, laboratory studies were conducted at Auburn University with channel catfish to compare relative toxicity of CPA with AFB$_1$ at both acute and subacute doses (6). To determine acute toxicity (LD$_{50}$), channel catfish fingerlings weighting 19 g (0,602) were injected intraperitoneally with 0, 2.4, 2.8, 3.2, 3.6, 4.0 or 7.0 mg (1 mg = 0.4×10^{-5} oz) CPA per kg of body weight and observed for 96 hr. The intraperitoneal LD$_{50}$ for CPA was 2.82 mg/kg (5.1×10^{-5} oz/lb). The effects of CPA were characteristic of a neurotoxin. Affected fish showed severe convulsions and were dead within 30 minutes after injection. There were no changes in organs of intoxicated fish examined. To determine subacute effects of prolonged feeding of CPA, channel catfish fingerlings were fed purified diets containing subacute concentrations (0, 100, 500, 2,000, or 10,000 ppb) of CPA for 10 weeks. The fish were evaluated for weight gain and signs of pathology. The lowest concentration of CPA, 100 ppb, significantly reduced the growth rate, but produced no other toxicity signs. The highest concentration, 10,000 ppb, caused necrosis of the gastric glands.

According to available data, CPA is more toxic to channel catfish than aflatoxin. The intraperitoneal LD$_{50}$ for AFB$_1$ is 11.5 mg/kg body weight and for CPA is 2.82 mg/kg body weight. The subacute toxicity dietary doses are between 2,000 and 10,000 ppb for AFB$_1$ and approximately 100 ppb for CPA. The facts that CPA is more toxic than AFB$_1$ and is often found in combination with, and perhaps more frequently than, aflatoxins indicates that CPA may be a more serious contaminant than aflatoxins in fish feeds made in the southern United States and other regions of the world with a similar climate.

OCHRATOXIN

Ochratoxins are produced by *Aspergillus* and *Penicillium* mold species that are widely found in nature. Although not recognized as causing widespread problems in animal feeding in the United States, it is suspected that these toxins cause poor growth and feed conversion in livestock in undetected cases because of widespread occurrence. Ochratoxins are recognized as kidney toxins, causing pale, swollen kidneys and renal tubular failure in swine, rats, and mice. The intraperitoneal LD$_{50}$ for ochratoxin A in six-month-old rainbow trout is 4.7 mg/kg (8.5×10^{-5} oz/lb) of bodyweight (7). Pathological signs in trout fed ochratoxin A are severe necrosis of liver and kidney tissues, pale kidneys, pale, swollen livers, and death.

FUSARIUM TOXINS

The *Fusarium* toxins that are most often associated with animal health are vomitoxin, T$_2$ toxins, and zearalenones. More recently, the effects of fumonsins and moniliformin have been reported. The zearalenones are a group of estrogenic metabolites, some of which cause reproductive problems in farm animals consuming 0.6 mg/kg to 5 mg/kg (1.1 to 9×10^{-5} oz/lb) in diets. The tricothecenes usually develop in corn in storage in the Midwest, with alternating cooling and warming trends in the fall. Toxicity signs in fish have not been described, but in livestock and poultry they are reduced growth, reduced red-blood-cell formation, widespread hemorrhage, slow blood clotting, and impaired immune responses. Rainbow trout are highly sensitive to the *Fusarium* toxin, vomitoxin (8). Trout fed diets with as low as 20 ppm of the toxin refused feed, and their growth rate decreased when they were fed diets containing 1 to 13 ppm. Poston (9) found that dietary doses of T$_2$ above 2.5 ppm reduced the weight gain of rainbow trout.

Very recently, fumonsins, produced by the mold *Fusarium moniliforme*, have received a great deal of attention. Apparently, fumonsins have been found to be fairly widespread, and they are highly toxic or carcinogenic to certain animals. In 1989, numerous episodes of equine leukoencephalomalacia in horses (ELEM) and porcine pulmonary edema in pigs (PPE) were reported in various areas of the United States, including the Midwest and the South. Case studies showed that horse feeds containing 8 ppm were associated with cases of ELEM and that swine feeds containing 20 ppm were linked to PPE (10,11). Both conditions are highly fatal to the affected animals. A fumonsin concentration of 8 ppm seems to be the minimum toxicity dose for horses and 20 ppm is the minimum toxicity dose for swine (10). These concentrations have been frequently found in commercial feedstuffs. In a recent report from the University of Illinois (11) in which swine feeds were sampled from 21 farms in an area where PPE was found, 12 of the farms had cases of PPE. Only one sample from the 21 farms was free of fumonsin. The lowest concentration of fumonsin was 6 ppm, and the highest concentration was 73 ppm.

Corn and corn screenings seem to be the most serious sources of fumonsins. These products are used in catfish feeds, so a study was conducted by Auburn University (12) to examine the sensitivity of channel catfish to fumonsins in feeds. A wide range of dietary levels of fumonsin B1 were used, 0, 20, 80, 320, and 740 ppm, because of uncertainty of the sensitivity of catfish to fumonsins. Some animals, such as rats and chickens, seem to be relatively insensitive, while others, such as horses, are highly sensitive.

Strain 826 of *F. moniliforme*, a high producer of fumonsins, was used to inoculate sterilized corn to produce cultures of toxic corn. Different combinations of clean and toxic corn were used to formulate diets containing the various concentrations of fumonsins. Year 1 [2-g (0.07 oz)] and year 2 [30-g (1.0 oz)] catfish fingerlings were fed. At six weeks, the small fish had shown significant repression in growth rate at the lowest dose of fumonsin, 20 ppm. The larger fish were not sensitive to 20 ppm, but did show reduced weight gain and lower resistance to bacterial infection when fed 80 ppm. Fish fed the two highest dose levels essentially stopped eating after the third week. Subclinical evaluations showed that the liver was the only organ damaged by fumonsin. Sphingolipid synthesis was suppressed, which seems to be a mechanism for the toxicity of fumonsins.

Moniliformin is produced by *F. moniliforme* and also by *Fusarium proliferatum*. This toxin has not been associated with practical problems in commercial animal production, but is found in corn and corn products from the Midwest. Moniliformin apparently interferes with enzymes in the tricarboxylic acid (TCA) cycle, such as pyruvate dehydroglucose. Laboratory studies have revealed lesions in the cardiac muscle of chickens fed the toxin. Studies with channel catfish indicate that the oral dose causing chronic toxicity is 20 to 80 ppm, similar to fumonsin B$_1$.

CONCLUSIONS

Comparative sensitivity of channel catfish and rainbow trout to various mycotoxins is presented in Table 1. Note that some values are related to fish body weight and other to dietary content.

Aflatoxin B$_1$ seems to be much more toxic to some fish, such as rainbow trout, than to others, such as channel catfish. This indicates that fish species vary in their sensitivity to aflatoxin. There are opinions that generally, warmwater fish are less sensitive than coldwater species; however, rainbow trout are markedly more sensitive than coho salmon, which also dwells in cold water. The study described in this report indicates that aflatoxin B$_1$ is not a major problem in channel catfish because (a) the fish apparently regurgitate acutely toxic concentrations of the toxin, and (b) subacute toxic concentrations (with prolonged feeding) would be between 2,000 and 10,000 ppb, which would be highly unusual in commercial feedstuffs and would only occur with severely molded batches of feed. It is recognized that crude aflatoxin (composed of a mixture of aflatoxins, synergists, and possibly other toxins) would likely be more toxic than the pure aflatoxin B$_1$. Also, the presence of aflatoxins may indicate the presence of other toxins in the feedstuff.

Table 1. Sensitivity of Fish to Acute and Subchronic Mycotoxins: MG of Toxin per kg of Diet or Body Weight[a]

	Acute		Subchronic	
Mycotoxin	Channel Catfish	Rainbow Trout	Channel Catfish	Rainbow Trout
Aflatoxin B$_1$	11.5(BW)	500	2–10	0.005–0.020
Cyclopiazonic acid (CPA)	2.8(BW)	—	0.10	—
Fumonsin				
Crude	>720	—	20–40	—
Pure FB$_1$	—	—	>250	—
Vomitoxin	—	—	—	13
Tricothecene (T$_2$)	—	—	—	2.5
Ochratoxin A	—	4.7 (BW)	—	—

Sources: Channel catfish: aflatoxin and cyclopiazonic acid (3,6); fumonsin (12); Rainbow trout: aflatoxin (1); vomitoxin (8); T$_2$ toxin (9); ochratoxin (7).
[a] 1 mg/kg = 1.8×10^{-5} oz/lb; BW, body weight.

Cyclopiazonic acid appears to be a more serious problem than aflatoxins for fish feeds and may be more prevalent in feedstuffs than aflatoxins. It is more toxic to catfish than aflatoxins; the subacute toxicity dose concentration is 1/20 to 1/100 of that of aflatoxin and is within a range that would be more likely to occur in commercial feeds.

Fumonsins could be the mycotoxin of greatest concern to catfish feed manufactures who use corn products. The subacute toxicity dose for catfish is 20 to 80 ppm, and based upon the limited surveys with animal feeds and feedstuffs, this concentration might occur often enough to cause concern. Episodes of fumonsin toxicity in livestock have been found in northern and southern areas of the United States, indicating that the toxins are ubiquitous.

Effective field screening tests are available for detecting aflatoxins, and fish-feed mills routinely use them. However, feed ingredients are not routinely screened for CPA, ochratoxin, or *Fusarium* toxins. ELISA screening tests are available for aflatoxin, vomitoxin, ochratoxin, fumonsin T_2 toxin, and zearalenone. Aflatoxin screening is used routinely by most segments of the feed industry, and other toxins are tested where problems are suspected.

Mycotoxins are generally heat tolerant, so even extrusion processing will not inactivate them. Because of this and the ubiquity of mycotoxins, fish feeds and ingredients should be carefully surveyed for the presence of mycotoxins. If certain mycotoxins are suspected of being associated with certain feedstuffs, geographic regions, or climatic conditions, screening tests for the suspected mycotoxin(s) should be implemented.

NET PEN CULTURE

WILLIAM T. FAIRGRIEVE
Northwest Fisheries Science Center
Seattle, Washington

OUTLINE

Traditionally, aquaculture of fish in seawater has been restricted to enclosed natural bays or small, fixed cages. However, few natural bays or protected near-shore locations have abundant, high-quality water with appropriate chemical and physical characteristics, while the demand for aquacultured species continues to grow. This constraint to the expansion of intensive marine aquaculture has been addressed by the development of movable buoyant enclosures, which are called net pens, specifically designed for use in large, open bodies of water. Because of design limitations, net pen farms have historically been located in areas protected from waves, wind, and high currents. However, recent technological advances in net pen design have permitted the expansion of net pen farming to open ocean, high-energy locations. This entry provides a basic overview of pen designs currently in use or under development and discusses their advantages and limitations. Netting selection, net bag construction, and pen-mooring systems are also discussed.

NET PEN SYSTEM DESIGNS

Modern net pen aquaculture probably originated in Japan in the early 1950s, where the first commercial culture of yellowtail (*Seriola quinqueradiata*) commenced in 1957 (1). During the 1960s, pen rearing of Atlantic salmon (*Salmo salar*) in Norway began (2), and experiments were initiated with coho salmon (*Oncorhynchus kisutch*) in net pens in seawater in southern Puget Sound, Washington, United States (3). At the same time, pen culture methods for plaice (*Pleuronectes platessa*), turbot (*Scophthalmus maximus*), and Dover sole (*Microstomus* sp.) were being developed by researchers in the United Kingdom (Colin E. Nash, personal communication). By 1970, the White Fish Authority, Scotland, had developed several successful designs for floating-net enclosures for marine fish culture (1). Today, net pens are the mainstay

of industrial scale farming of Pacific and Atlantic salmon and rainbow trout (*O. mykiss*), as well as many other marine and freshwater species.

During the past 40 years, net pen aquaculture systems have evolved rapidly from their origins as simple net-enclosed cages surrounded by floating, wooden catwalks to a myriad of carefully engineered floating, submersible, and submerged structures, many of which are specifically designed to withstand extreme wind, wave, and water-current conditions encountered at open-water farming sites. Despite their intrinsic differences in design and construction, commonalities in the means used to maintain net volume and shape permit their convenient classification (4): Class I — Gravity (buoyancy and weight); Class II — Anchor–Tensioned (buoyancy and external rigging); Class III — Semirigid (flexible internal structure and special rigging); and Class IV — Rigid (rigid internal structure). The defining characteristics and attributes of pens in each classification are discussed next.

Class I: Gravity Pens

Gravity pens consist of a flexible net bag supported by a floating collar. Net bag shape and volume are maintained by weights attached at intervals along the lower perimeter of the net. Weight and buoyancy offset the effects of water currents, waves, and accumulation of fouling organisms on the net, and must be adjusted to accommodate local conditions. Gravity pens are the type most commonly used in commercial aquaculture today.

Floating collars used with gravity pens take two basic forms: circular or rectangular. Circular pens are most often constructed of two or three concentric rings of high-density polyethylene (HDPE) pipe interconnected at intervals by molded HDPE or galvanized steel collars. Rectangular pens generally are fabricated from articulated galvanized steel catwalks supported by polystyrene-filled steel or plastic floats. The net bag is attached by ropes or hooks to the collar, while stanchions and handrails located on the inner edge support light weight netting, which prevents fish loss due to jumping or predatory birds (2).

Circular pens commonly used today range from 15–30 m (49–98 ft) in diameter [ca. 175–700 m^2 (1,900–7,500 ft^2)] and are moored individually. Rectangular pens may be as large as 30 m (98 ft) on each side [900 m^2 (9,700 ft^2)] and are often interconnected to form large rafts. Net bag depth ranges from 5 to 20 m (16–66 ft), depending on the requirements of the species in culture and the depth of water under the pen complex.

Gravity pens are relatively low cost, can often be constructed from locally available materials and, in the case of rectangular pens, may be linked to form stable platforms. However, pens in this classification suffer from a number of disadvantages which limits their use to protected, low-current locations.

The principal forces acting on any net pen are those arising from the effects of wind, waves, and currents. In the case of Class I pens, the floating collar is exposed to

wind and wave action that can be extremely destructive to the integrity of the structure. High-density polyethylene pipe used in modern circular-pen construction is flexible and resists breakage, but improperly moored pens are easily deformed and may collapse. Wave action is most destructive to rigid steel collars, because cyclic vertical and horizontal motion imposes severe bending and shear forces that must be absorbed by relatively few articulated linkages. In recent years, linkage designs incorporating rubber bushings, chain, or other flexible materials have been introduced, but fundamental problems with wave energy absorption continue to restrict the use of steel pen collars to protected locations.

The greatest problem with Class I pens lies in the difficulty of maintaining net-enclosed volume and shape. Because this class of pen relies on gravitational accelerations to offset horizontal forces, increasing current velocity requires that increasingly heavy weights and more buoyant collars be employed. In practice, even low or moderate currents cause net bag deformation that reduces rearing volume and imposes severe stresses on individual net twines. Consequently, net bags are usually reinforced by a grid of vertical and horizontal cables attached to both the collar and suspended weights. Detailed engineering studies have shown that gravity cages able to withstand stresses imposed by open ocean currents [>50 cm/sec (1.64 ft)] and adequately resist net collapse are not practical (4).

Class II: Anchor-Tensioned Pens

Anchor-tensioned pens are specifically designed for use in open ocean, high-energy locations. They differ from typical gravity cages in that they do not use a flotation collar, relying instead on fixed anchors, buoys, and special rigging to maintain shape and position in the water column. In general, four vertical semisubmerged spar buoys interconnected at the top and bottom form a boxlike grid which is tensioned by a system of anchors and buoys that compensate for tidal fluctuations and wave action (4). The net bag is closed with a sewn-on cover to prevent loss of fish should the pen become submerged by wind or wave action. The net is attached to the grid at the corners.

Anchor-tensioned pens have several major advantages over conventional gravity configurations. First, anchor line tension, grid stability, and thus resistance to net bag deformation increase proportionately with water current velocity. Second, hydrodynamic forces imposed by moving water on the net enclosure are distributed uniformly to the perimeter of the net, making tearing less likely. Third, because rigid or articulated floating structures are absent and tensioned pens tend to submerge as current increases, the risk of storm damage is greatly reduced.

Although anchor-tensioned systems are technologically superior to gravity pens, in many ways, they suffer from operational disadvantages that complicate some routine farming activities. For example, individual gravity pens may be detached from their moorings and moved to another location in the farm system to facilitate grading or harvesting, or to reduce exposure to waterborne disease organisms. In contrast, Class II pens are immobile,

because they require constant tension to maintain their shape and volume. This factor also makes anchor positioning and holding characteristics more critical in tensioned systems, compared with self-supporting or gravity pens. Most reported failures of tensioned systems have been attributed to anchor movement during storms (7).

Class III: Semirigid Pens

In contrast with gravity and tensioned pens, which rely on external support systems to counteract static and dynamic loads, semirigid pens are self-supporting. In general, they are structurally similar to a typical bicycle wheel: a rigid steel ring (rim) is connected by equally tensioned ropes (spokes) to a central, buoyant column (axle). The entire structure is fully enclosed by taut netting, allowing the pen to be fully submerged without loss of fish. Buoyancy is controlled by changing the volume of air within the central column (6,7). Pen volume ranges from ca. 1000 m^3 to over 20,000 m^3 (35,000–706,000 ft^3) (5).

Design characteristics of Class III cages specifically address structural and operational problems with gravity and anchor-tensioned pens, making them ideally suited for use in high current, exposed locations. These include absence of joints or articulations that may fail under high static or dynamic loads, excellent resistance to lateral net deformation by currents, and control of operating depth to avoid storms or meet the environmental requirements of the species under cultivation. Finally, semirigid pens may use simplified single-point mooring systems that permit them to change position or submerge automatically when currents exceed a predetermined threshold, making them highly resistant to storm damage (6). Despite their many advantages, self-supporting cages of this type have not gained wide acceptance within the aquaculture industry, mainly due to their high initial cost and lack of a proven track record under commercial conditions.

Class IV: Rigid Pens

Rigid pens rely on a system of jointed columns and beams forming a boxlike or cylindrical structure that directly supports the net enclosure. Because the frame is not flexible, welded wire netting is often used in place of the synthetic materials used with other pen designs. Class IV pens are supported by buoys or floats or may be organized into large, floating "barges" (2). Some designs incorporate a collar that can be inflated to move the structure up and down within the water column (8).

Rigid pens have some advantages over conventional gravity pens, insofar as they are highly resistant to current-induced net deformation. However, light weight, resilient materials such as high density polyethylene pipe are not sufficiently rigid to resist compression, bending, and torsional forces encountered in high-energy environments. Metal cage frames are costly to build and maintain, and are prone to breakage during stormy conditions. Nevertheless, rigid metal cages, which utilize welded metal mesh in place of synthetic netting have proven useful in protected locations, where predation by marine mammals is problematic.

NET BAG MATERIALS

Net pens of all designs rely on mesh enclosures to contain the cultured species and exclude predatory fish, birds, and mammals.

Materials used in modern pen bag construction fall into two general categories: flexible netting, manufactured from various natural or synthetic fibers and semirigid or rigid mesh, from extruded plastic or welded-metal materials. Most pen bags in use today are manufactured from flexible, synthetic coal or oil-based materials, such as polyamide, polyester, polyethylene, and polypropylene. Of these, polyamide (nylon) net is perhaps the most commonly used, because of its wide availability, low cost, light weight, and high-breaking strength. Natural fibers are rare because they cannot be used to manufacture knotless netting, have a relatively high diameter to strength ratio, and are prone to sun damage and rotting.

Choosing appropriate netting materials for pen bag construction requires considerable knowledge of the characteristics of the various materials and experience in matching them to the pen type and environmental conditions that will be encountered. Factors to consider include weight of the net relative to the buoyancy or structural characteristics of the collar or frame; strength, extensibility, and resistance to abrasion; resistance to fouling; and the ability to accept antifouling paints or treatments. Knotless meshes are preferred over knotted types to minimize abrasion damage to eyes, fins, and scales of the fish. Additional information on net material characteristics, net weaving techniques, and net bag design and fabrication may be found in references 1 and 2.

Modern rigid frame pens may be covered with panels of flexible netting, but rigid or semirigid mesh fabricated from extruded plastic or welded metal are widely used. Extruded-plastic netting is available in a wide variety of mesh sizes, is light weight, and somewhat more resistant to fouling than flexible netting. Compared with flexible netting of the same mesh size, plastic meshes have a lower percentage of open area and thus permit less water exchange. They also have a higher drag coefficient.

Metal meshes have been used for many years in the construction of rigid-frame pens. They are strong and easily attached to the pen frame when new, but are subject to galvanic corrosion when placed in water. Metal meshes and their supporting structures are often galvanized, and sacrificial anodes are used to extend their service life. Chain-link wire netting used in the past has been largely replaced by wire meshes that are galvanized after welding. The service life of wire mesh varies according to the quality of galvanizing, composition of the wire, and the chemical characteristics of the water. In general, the service life of wire mesh in seawater is less than two years (2).

PEN MOORING

Mooring systems include dead weights or anchors; lines, cables, and chains connecting them to the pens; and buoys or floats that compensate for tidal fluctuations. The mooring system absorbs shock loads, and its design affects the behavior and stability of the pens in inclement weather and their ability to withstand the static and dynamic loading imposed by wind, waves, and currents. This factor is especially important in high energy, open ocean locations where extreme vertical and horizontal displacement must be accommodated. Consequently, modern pens and their moorings are engineered to function as systems and must be installed together to meet design specifications.

There are two main types of mooring systems: single and multipoint. Single-point mooring systems have been suggested for semirigid pens (Class III) used in open ocean environments (6,7). Single-point mooring has the advantage of allowing the pens to move to a position of least resistance to wind, waves, and currents. However, most gravity pen systems utilize multipoint moorings, especially those which are joined by articulated linkages into large rafts, or circular pens that rely on opposing forces to maintain the shape of the collar.

A variety of anchor types can be used, depending on bottom type and wind, wave, and water-current conditions. In protected sites, concrete dead weights, that can be fabricated on shore are often used. The holding power of concrete blocks is low, and in some situations may be attached to an embedded anchor to increase security. Where substrate permits, embedded anchors may be used alone. Many types of anchors exist and should be chosen based on a thorough evaluation of the substrate characteristics at the mooring site (2,9).

Mooring lines may be attached directly to the anchor, or to a ground chain, which increases holding power, absorbs shock loads, and compensates for the rise and fall of the tide. Steel mooring lines are sometimes used, but are heavy, prone to corrosion, lack elasticity, and will abrade plastic pen collars or floats. Nylon lines are often preferred because they effectively absorb cyclic and shock loads, which would otherwise be transmitted to the anchor and cage system. Other synthetic materials, such as polypropylene or polyester, are also commonly used (2,9). Mooring lines may be connected directly to the pen frame or attached first to one or more buoys sized to compensate for the weight of the line and increase mooring flexibility (10). Nylon lines or chains connect the pen to the mooring. The total length of the mooring line depends on the depth of the water at the site, substrate composition, and type of anchor used.

OUTLINE

Toxicity

Bibliography

Nitrogen is required by all living organisms, because it is an important component of protein and of other essential chemical substances. Nitrogen is taken up by plants primarily in the form of nitrate (NO_3^-) ions. Animals satisfy their nitrogen requirements through the intake of food. Nitrogenous wastes are excreted by animals in several forms: ammonia, creatine, creatinine, free amino acids, urea, and uric acid. Nitrogenous compounds are also released during the bacteriological decomposition of plant and animal matter. The primary source of nitrogen from aquaculture animals is in the form of ammonia (NH_3). Bacteria in the genus *Nitrosomonas* are responsible for nitrifying ammonia to nitrite (NO_2^-); bacteria in the genus *Nitrobacter* are responsible for the step from nitrite to nitrate. The nitrification reactions are critical to efficient biofilter operation, but they also occur in ponds and in other types of culture systems.

Other bacteria are able to denitrify nitrate and convert it to elemental nitrogen (N_2) gas. Such denitrifying bacteria can be found in the genera *Pseudomonas*, *Achromobacter*, *Bacillus*, *Micrococcus*, and *Corynebacterium* (1). Energy for the reduction reactions involved may come from certain carbohydrates and alcohols. Recirculating water systems have been designed that employ special chambers to promote these reactions by supplying the proper substrate.

In pond environments, there is little concern over the accumulation of nitrate, because primary producers in the system generally remove it from the water nearly as rapidly as it is produced. In closed systems, including some hatchery systems where susceptible species such as shrimp are produced (2,3), nitrate levels may sometimes become sufficiently high to produce stress or even mortality. Various types of water systems that receive high levels of organic or inorganic fertilization can also exhibit high nitrate concentrations.

Although nitrogen is available to plants in the form of nitrate, it apparently must be reduced to ammonia once again before it can be absorbed into plant tissues (5). The reaction appears to be light-catalyzed and to proceed as follows:

$$NO_2^- + H_3O^+ \xrightarrow{\text{light}} NH_3 + 2O_2$$
This entry is adapted from an earlier publication (4). It is used with permission.

TOXICITY

Nitrite and ammonia are both toxic to aquatic animals at much lower concentrations than is nitrate. Nitrite is rare in natural waters, because it is an intermediate that is quickly transformed by bacteria to nitrate, but it sometimes occurs in high concentrations in aquaculture systems.

Historically, the problem has been found largely in flowing water systems and has been resolved through the incorporation of efficient biofiltration or through suitable exchange rates with new water. Nitrite toxicity has occurred in ponds when very high densities of animals are being maintained. Channel catfish (*Ictalurus punctatus*) farmers in Mississippi, for example, have experienced nitrite toxicity during the late summer or early fall, when fish biomass is at the highest level of the year, the water is warm, and the feeding rate is extremely high.

Because the growth of *Nitrobacter* is inhibited by the presence of ammonia, nitrite may become concentrated in biofilters until the ammonia concentration is greatly reduced (6). Once the biofilter begins to operate efficiently, nitrite usually ceases to be a problem unless some change occurs that results in destruction of the *Nitrobacter*. This problem can happen when chemicals are used to treat for diseases or if the system becomes anaerobic.

Nitrite toxicity in fish was reviewed by Lewis and Morris (7). Their review included species of aquaculture interest and other species. The authors indicated that salmonids were among the most sensitive fishes tested. Results from some of the studies that have been conducted with species of aquaculture importance are presented in Table 1.

Experiments to determine the LC_{50} of a chemical on an aquatic species over a discrete time period (usually not more than 96 hours) are called *acute* studies. Long-term or chronic exposure to much lower levels of a toxicant like nitrite might be lethal or could cause pathological changes. Thus, safe levels are often considered to be some fraction

[a]Several values were obtained over a salinity range of from 0 to 36 parts per thousand. Tolerance to nitrite increased with increasing salinity. The values shown are for salinities of 0 and 36 parts per thousand.
[b]The low value was obtained in fresh water, the higher one in water of 16 parts per thousand salinity.
[c]Two sizes of fish were tested.
[d]Trials were run at temperatures ranging from 17 to 27 °C (From 63 to 81 °F). Toxicity decreased with increasing temperature.
[e]The value represents what the authors considered to be a safe level for postlarvae [1.36 mg/L (ppm)] and nauplii [0.11 mg/L (ppm)].
[f]Experiments were run on animals of 91–8 mm (3.5–0.3 in.).

(e.g., 1/10 or even 1/100) of the acute toxicity level. Most studies report the LC$_{50}$ value, though some have developed from the LC$_{50}$ data what they consider to be a safe level of exposure (8).

Effects of nitrite on the eggs, alevins, and fry of Atlantic salmon (*Salmo salar*) by Williams and Eddy (1989) have shown that the early development stages can tolerate very high levels: 24-hour LC$_{50}$ values were 3,276 mg/L (ppm) for eggs and 2,940 mg/L for early alevins, decreasing to 121.8 mg/L as the alevins developed (9). However, exposure of eggs to as little as 14 mg/L (ppm) of nitrite in either fresh or brackish water delayed hatching and had measureable effects on the cardiovascular system.

The results of studies on the same species can vary considerably, as is shown in Table 1 for such species as *A. anguilla*, *I. punctatus*, and *P. monodon*. The duration of the studies is one factor, the size of the animals tested another. As indicated by Russo (10), pH, chloride concentration, and calcium concentration also affect nitrite toxicity. A study with eels and milkfish (*C. chanos*) demonstrated that salinity can have a significant influence on the tolerance of fish to nitrite (11). Different strains of channel catfish have been found to respond differently to nitrite, with some strains being susceptible to nitrite and others being resistant to nitrite (12).

Greater toxicity has been found in exposure of *P. monodon* to mixtures of ammonia and nitrate than in exposure to either chemical alone. The synergistic effects of the two forms of nitrogen became apparent after 96 hours of exposure (13).

In fish, nitrite combines with hemoglobin in the blood to produce methemoglobin and a condition known as methemoglobinemia. Hemoglobin that has been converted to methemoglobin is unable to carry oxygen, so affected animals are asphyxiated. Suspected incidents of nitrite toxicity can be confirmed quickly if the culturist sacrifices a fish and examines the blood. Nitrite is believed to enter the blood in conjunction with chloride/bicarbonate exchange. Eddy and Williams (14) concluded that fish such as salmonids that have high chloride uptake rates are much more susceptible to nitrite toxicity than fish such as carp that have low chloride uptake rates. In the common carp (*Cyprinus carpio*), there is a high correlation between chloride level and nitrite toxicity (15). On the other hand, while chloride ion increased the tolerance of channel catfish for nitrite, there was no such response in largemouth bass (*M. salmoides*) (16).

In fish with methemoglobinemia, the blood will be chocolate brown in color. In the case of channel catfish, affected fish will rest on the bottom of the culture chamber and will swim erratically for up to one minute immediately before dying. They die with their mouths open and their opercles closed (17).

Exposures to sublethal concentrations of nitrite can cause pathology in fish. Hemolytic anemia was reported in the sea bass (*D. labrax*) (18). Arillo et al. (19) concluded that liver hypoxia was the cause of mortalities in rainbow trout (*Oncorhynchus mykiss*) exposed to nitrite. Gill hypertophy has been reported in rainbow trout (20) and in tilapia of various species and their hybrids exposed to sublethal levels of nitrite (21).

Steelhead trout (*O. mykiss*) demonstrated increased tolerance to nitrite when the dietary level of vitamin C (ascorbic acid) was increased (22). It was speculated that ascorbic acid acted to reduce methemoglobin to hemoglobin, but the report also indicated that the vitamin has a protective effect against stress in fish; that effect may have played a role.

Ammonia is one of the variables in water that is of primary concern to aquaculturists. Other forms of nitrogenous waste are relatively unimportant in most cases, so it is the ammonia level in water that has generally been monitored. As we have seen, nitrite can also be a critical factor, so it is also sometimes closely

watched. Colorimetric tests that can be conducted virtually anywhere have been developed and are in wide use.

Fishes excrete most of their nitrogenous waste through the gills, in the form of ammonium ion, NH_4^+ (23). Ammonium ion, or ionized ammonia, accounts for as much as 60 to 90% of the total nitrogen excreted (24–26). In addition to the ionized form, un-ionized ammonia (NH_3) occurs in water. The toxicity of ammonia to aquatic organisms is associated primarily with the level of un-ionized ammonia (27–32); the ionized form appears to be relatively harmless (33).

Both ionized and un-ionized ammonia can occur together, but the ratio between them is dependent on temperature, pH, DO, carbon dioxide concentration, bicarbonate alkalinity, and salinity (24,32,34–37). Un-ionized ammonia increases relative to ionized ammonia with increasing temperature and pH (Table 2), but it decreases as carbon dioxide increases and in hard and saline waters (36,37). Long-term exposure of aquatic animals to elevated ammonia levels can result in reduced growth, impaired stamina (38), gill abnormalities, and, ultimately, death.

Ammonia electrodes used in conjunction with a pH meter and colorimetric tests for ammonia can provide the aquaculturist with a total-ammonia value, which is satisfactory under most circumstances. Seawater interferes with the colorimetric technique for ammonia determination, so such samples should be distilled prior to testing. Ammonia concentration in the distillate is not changed, but the chemicals causing the interference are not passed in the condensed steam. Tables such as those produced by Emerson et al. (35) will provide the culturist with a means of determining that actual level of un-ionized ammonia.

Studies of ammonia toxicity have been conducted on a number of species of aquaculture interest and under a variety of conditions. Table 3 provides an indication of how such factors as pH, life-cycle stage, salinity, and the form in which ammonia is added for purposes of the bioassay influence the results. In general, coldwater fishes are less tolerant of ammonia than are warmwater species. Calamari et al. (39) proposed a water-quality standard of 0.02 mg/L (ppm) NH_3 for rainbow trout. Haywood (40), who reviewed the effects of ammonia on teleost fishes, recommended maximum total-ammonia exposure levels of

[a]Reported as mg/L (ppm) total ammonia.
[b]Reported as mg/L (ppm) un-ionized ammonia.
[c]ppt is parts per thousand.
[d]Ammonium chloride.
[e]Ammonium sulfate.

1.0 mg/L (ppm) for salmonids and 2.5 mg/L (ppm) for other freshwater and marine fishes.

Thurston et al. (41) found that rainbow trout and cutthroat trout (*Salmo clarki*) were more tolerant of constantly elevated ammonia levels than of fluctuating concentrations. Thurston and Russo (42) indicated that the median tolerance limit for un-ionized ammonia ranged from 0.16 to 1.1 mg/L (ppm) in rainbow trout, with susceptibility to ammonia decreasing as the fish developed from sac fry to the juvenile stage. They also found that toxicity decreased as temperature increased, over the range of 12 to 19 °C (54 to 66 °F). Redner and Stickney (43) found that *O. aureus* could develop an increased tolerance to ammonia when exposed to sublethal levels in advance of bioassays.

Both fish (44,45) and shrimp (46) become more tolerant of elevated ammonia with increasing pH. Shrimp appear to be more sensitive to ammonia in the periods just before, during, and after ecdysis (47,48). Further, the toxicity of ammonia is enhanced as DO concentration is reduced (49). The relationship between ammonia toxicity and DO has also been shown in gilthead seabream (50).

Sublethal concentrations of ammonia can cause histological changes in fish (39,43,51–53) and will also affect growth (54,55). Gill hyperplasia is a common sign of chronic ammonia toxicity (52,56).

NORTHERN PIKE AND MUSKELLUNGE CULTURE

ROBERT R. STICKNEY
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

Spawning and Hatching
Larval Rearing and Fingerling Production
Conclusions
Bibliography

Northern pike (*Esox lucius*) and muskellunge (*E. masquinongy*) are members of the family Esocidae, which are popular freshwater sport fish that are reared in some state hatcheries for stocking. Northern pike can be found in temperate and arctic regions of the northern hemisphere, while the muskellunge has a limited distribution in the eastern United States and Canada. A hybrid between the two species, known as the tiger muskellunge, has been produced in hatcheries and distributed into selected water bodies.

Northern pike of 10 to 15 kg (22 to 33 lb) are common, and fish as large as 20 kg (44 lb) have been caught. Muskellunge that are caught are commonly in the same size range as northern pike, but can also reach 30 kg (66 lb). Large northern pike and muskellunge are sought after as trophy fish. Neither species is considered to be a foodfish.

In addition to the United States, esocids are produced in Canada, Germany, Austria, Switzerland, the Netherlands, France, Belgium, and Sweden. Their culture has been reviewed by Westers and Stickney (1). Low hatchability, cannibalism, and highly variable production rates in hatcheries have been cited as major barriers to large-scale propagation.

SPAWNING AND HATCHING

It is rare for captively reared broodstock to be used in the production of northern pike and muskellunge. More

commonly, broodfish are collected from nature and taken to hatcheries for spawning. Adults, as well as fingerlings, can be readily sexed, through external examination of the urogenital region.

In nature, spawning of northern pike occurs in the spring at temperatures ranging from 5 to 10 °C (41 to 50 °F), while muskellunge spawn later, when the water temperature is between 10 and 14 °C (50 and 57 °F). Large females of both species produce about 100,000 eggs each year. Some hybridization has been observed in nature, though the two species do not commonly live in the same water bodies, because fingerling northern pike may already be present when muskellunge fry become available as food.

Low hatchability has been a problem for northern pike and muskellunge culturists. Broken eggs were once a significant problem, but the practice of anesthetizing broodfish to immobilize them during egg taking has alleviated the problem to a considerable extent. Anesthetizing both male and female broodfish also reduces the risk of injury to hatchery personnel by the thrashing about of the fish.

Carp pituitary hormone has been used to accelerate ovulation in females. Male northern pike and muskellunge tend to produce milt in small amounts, but milt production can be increased two-to threefold by injecting males with appropriate dosages of the hormone progesterone. Very small amounts of milt can successfully fertilize all of the eggs from a female, and the sperm can be stored for several days at temperatures from 3 to 5 °C (37 to 41 °F). Both eggs and milt can be obtained by stripping the adults, though milt can be more effectively obtained with the use of a catheter. Catheterization avoids contact between water and the milt; once exposed to water, sperm are viable only for a minute or two.

Incubation is usually conducted in some type of hatching jar. The eggs are very susceptible to mechanical stress during the first several days of incubation, so they are kept in static or nearly static conditions during that period. Water flow through the jars is then increased to remove metabolites and maintain a high level of dissolved oxygen. Under proper conditions, the percentage of eggs that reach the eyed stage can be increased dramatically. The optimum temperature range for incubating both species is from 9 to 13 °C (48 to 55 °F), though viable fry can be produced at somewhat lower and higher temperatures. Temperatures below about 3 °C (37 °F) and above 24 °C (75 °F) are lethal to embryos and sac fry.

Approximately 12 days at 10 °C (50 °F) are required to hatch northern pike eggs. Muskellunge eggs will hatch in 18 days at the same temperature. Under ambient conditions, it can take as long as six hours for a batch of eggs to hatch. This period can be greatly reduced by rapidly elevating the temperature several degrees [e.g., from an initial temperature of 10 °C to a final temperature of 16 °C (50 °F to 60 °F)] when the eggs first begin to hatch.

LARVAL REARING AND FINGERLING PRODUCTION

Once the fry hatch, they can be placed in incubators through the period of yolk sac absorption. The technique, which was developed by Michigan fish culturists, employs Heath trays, which are commonly used to incubate salmon eggs. The standard screens in the bottom of the trays need to be replaced with screens of a finer mesh size, to retain the fry. A typical Heath tray can hold from 30,000 to 35,000 fry. The fry are kept in the trays for 6 to 10 days and are provided with water at 16 to 17 °C (61 to 63 °F).

There is some production of fingerlings in raceways and cages, but the most common approach is to stock fry into ponds for rearing. Pond stocking rates have varied from 25,000 to 250,000 fry per ha (10,000 to 100,000 fry per acre), but it is recommended that stocking be within the range of 80,000 to 125,000 per ha (32,000 to 50,000 per acre).

Prior to stocking, ponds should be fertilized to induce zooplankton blooms. Fertilization rates vary, depending on the response of a given pond, but a typical scheme might involve the application of from 300 to 400 kg/ha (300 to 400 lb/acre) of alfalfa meal or pellets. Using 15 kg/ha (15 lb/acre) of dry-matter swine manure daily until the proper bloom is obtained has also worked well for some culturists.

Northern pike and muskellunge can become cannibalistic within a few days after first feeding. Cannibalism can be reduced by maintaining a good zooplankton bloom. In most cases, the fish are captured and stocked by the time they reach about 8 cm (3 in.) in length. At that size, they have a fairly good chance of survival after stocking, and losses in the ponds due to cannibalism may not have reached catastrophic levels.

Intensive culture of esocid fingerlings in raceways has been developed in recent years. The fish are initially fed live food, but can be trained to accept pelleted rations. The typical prepared feed for northern pike and muskellunge contains 50% or more protein, primarily from fish meal and other animal protein sources. Tiger muskellunge are often used in raceway culture, because they are much easier to convert from live to prepared feeds than are either northern pike or muskellunge.

Fry need to be fed to excess every 3 to 5 minutes for 15 hours daily to keep the rate of cannibalism low. Once the fish reach about 10 cm (4 in.), they can be fed every 15 minutes, though in most cases the fish will be stocked into lakes before reaching that size. Automatic feeders are usually used to supply the feed, since the time between feedings is so short. It is necessary to siphon waste feed and feces from the raceways at least daily to avoid deterioration of water quality.

CONCLUSIONS

A considerable amount of progress in the culture of northern pike and muskellunge has been made since these fishes were first spawned in captivity in the late 19th century. There is still much to be accomplished, however. The nutritional requirements of both species need to be better elucidated, so that nutritionally complete diets can be developed. Using the proper attractants and making pellets of the proper texture may help reduce the time required to train the fish during conversion from live to prepared feeds. It may even be possible, eventually,

to produce prepared feeds that will be accepted at first feeding.

Selective breeding may be used in the future to improve the growth rates of esocids during the hatchery phase and sometime later could possibly lead to some reduction in the cannibalistic tendency of these fish. Before successful breeding programs can be developed, however, it is necessary to produce captive broodstock that contain sufficient genetic diversity, so that fish geneticists can select for desirable traits.

NUTRIENT REQUIREMENTS

IAN FORSTER
The Oceanic Institute
Waimanalo, Hawaii

OUTLINE

The dietary requirement for a nutrient can be defined as the minimum level of that nutrient in a complete diet that will meet the physiological needs of a healthy animal. In the past century, advances in chemistry and nutrition have led to the identification and quantification of the requirement for numerous nutrients. Some of the advances in our understanding of aquatic animal nutrition have come about through the application of methodology developed on mammals and birds. In recent years, a great deal of work has been done to quantify the requirement of those nutrients. Knowledge of the nutrient requirements for a particular species allows greater flexibility in feed design and permits prediction of the performance on a formulated feed. This is of particular importance to researchers investigating alternative nutrient sources for use in commercial feeds and to those responsible for ensuring that a commercial feed will meet the needs of the customers.

Although the nutrient requirements of aquatic animals have been investigated, there is considerable uncertainty in some of the values obtained. Indeed, in many instances there are several different values reported for the requirement of a particular nutrient by the same species. This variability is, in large part, caused by differences in the methodology used in the various studies. This entry describes some of the methodology used to determine nutrient requirements of aquatic animals and some of the techniques used to minimize variability in those estimates. Other reviews of this subject include those of Baker (1), Cowey (2) and D'Abramo and Castell (3).

EXPERIMENTAL PROCEDURES/METHODOLOGY

Most of the methods employed to measure dietary requirements for nutrients involve dose–response experiments. This type of trial involves three steps: (*1*) feeding a series of diets containing a range of concentrations of the nutrient for a period of time; (*2*) analyzing one or more measured responses with respect to a model or statistical method; and, (*3*) estimating a dietary requirement from the model. This entry is almost exclusively concerned with this dose–response-type methodology.

There is a great variety in the type of responses that are monitored. Some common ones include growth rate, feed efficiency, protein retention, absence of disease signs, survival, enzyme saturation, maximum tissue storage, blood-plasma levels, oxygen consumption, and excretion rate of the nutrient. Which of these are suitable in a given case depends on the nutrient under investigation and the species used. Generally, more than one response is measured to increase the confidence in the requirement value arrived at.

Aquatic animal nutrition work has developed more recently than that for other cultured animals, and the variability of reported values for requirement estimates is often considerable. The goal of research undertaken to investigate requirement values is to provide a true representation of the actual requirement. To accomplish this, nutritionists have attempted to standardize the conditions under which their research is performed. To make use of requirement values in practical situations,

however, it is necessary to extend our knowledge of the relationship between dietary nutrient level and response to include conditions other than those obtained in research settings.

MODELS

Multiple Comparison of Means

One of the simplest ways of estimating a requirement based on dose response is to compare the mean response of animals fed diets containing various levels of the nutrient under investigation using analysis of variance procedures and a multiple-means comparison test, or a range test. Using this methodology, the requirement is estimated to be the minimum level of the nutrient producing a response that is not significantly different from the response obtained from the maximum level (4,5). This approach can be useful in preliminary investigations, but is unsuitable for quantitative requirement determination for several reasons. The most important of these reasons is that the estimate of the requirement is overly dependent on the variability of the responses within each treatment, as measured by the pooled standard error. Conducting a feeding trial under conditions of poor recording of feed intake or an inappropriate feeding regimen will result in high within-treatment variability in growth and feed efficiency data, leading to an underestimation of the dietary requirement. (The mean response of animals fed diets containing less than the requirement will not be statistically different than the maximum response.) A related difficulty with using range tests for requirement studies is that the value of the estimation is influenced by the value of the error probability used to access the statistical significance of differences between values of treatment means (i.e., alpha). For instance, an alpha of 95% will give a lower estimate of the requirement than a value of 99% will. Finally, using ANOVA and range tests to analyze data from a feeding trial consisting of a series of dietary treatments containing a graded level of a nutrient is statistically indefensible. Data from this type of study should be analyzed using some sort of regression analysis.

Quadratic Model

The quadratic model has been used to estimate the requirement of protein and amino acids in fish (6,7). In this method, a quadratic equation is used to fit the response data obtained from feeding a dietary series:

$$R = a + bI + cI^2 \qquad (1)$$

where R is the measured response; I is the dietary nutrient concentration; and a, b, and c are constants that are calculated to provide the best fit of the data.

The value of I that produces the maximum response (I_{max}) is calculated as follows:

$$I_{max} = -0.5\,(b/c) \qquad (2)$$

The requirement is then determined to be either the concentration of the nutrient that produces the maximum response (Imax) or the concentration of the nutrient that produces a response that is some arbitrary level below the maximum (e.g., 95% of maximum or 95% confidence limit of the maximum). This model assumes that feeding diets containing a nutrient at concentrations either above or below the requirement will produce responses that are less than the maximum and that the degree of the reduction will be symmetrical. Although this model has been successful in investigating optimum dietary levels for protein when a suitable response is measured, the assumptions of the model are unlikely to be met in many cases. Most nutrients do not become toxic at any level likely to be encountered by an animal, and even in cases where this may happen, there is no reason to suppose that the dose-response curve will similarly reflect this.

Enzyme Kinetic Models

A model based on enzyme kinetics has been developed to determine nutrient requirements (8,9). This model uses four parameters to fit a response equation for dietary nutrient concentrations.

$$R = [b(K.5^n) + R_{max}(I^n)]/[(K.5^n) + (I^n)] \qquad (3)$$

where

R = measured response
I = dietary nutrient concentration
b = intercept on y-axis (y-intercept)
R_{max} = maximum theoretical response
n = apparent kinetic order
K.5 = nutrient concentration for $R = 1/2\,(R_{max} + b)$.

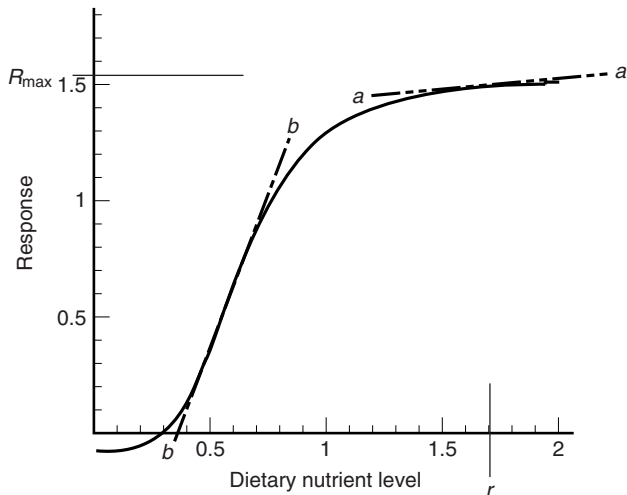
The observed responses for the dietary concentrations in the experimental diets are then fitted to this equation, using standard nonlinear curve-fitting techniques, to obtain values for the four parameters (b, R_{max}, n, and K.5). This model generates a sigmoid curve to characterize the dose–response of a dietary series (Fig. 1), where increasing levels of a nutrient produce a smooth, but diminishing, increase in response up to an asymptotic maximum (R_{max}; Fig. 1). The requirement is then determined to be the nutrient concentration that produces a response within some arbitrary range of the asymptote (10), for example, the level (r; Fig. 1) that will reduce the maximum slope (line b; Fig. 1) of the relationship by 95% (line a; Fig. 1). For a variety of nutrient-specific reasons any nutrient is harmful at sufficiently high levels. For example, some amino acids are known to interfere with other amino acids for intestinal absorption, and if they are present at high levels, there can be an induced amino acid imbalance. Other examples include the toxicity of many minerals (and some vitamins) and the inhibitory effect of high levels of energy on feed intake. Each of these conditions will result in reduced growth, feed efficiency, and perhaps even health. To account for this, the enzyme kinetic model has been extended by the addition of a fifth parameter to include nutrient levels high enough to result in suboptimum response (11). One feature of this model claimed by its authors is that the level that produces the maximum


Figure 1. The relationship of physiological response to the concentration of a required nutrient, using the enzyme-kinetics model. The slope of line *b* has the maximum slope of the curve. The requirement (*r*) is arbitrarily defined as the dietary nutrient level corresponding to the point on the curve where the slope is 5% of maximum (i.e., the slope of line *a*).

response (i.e., the requirement) can be calculated directly, instead of some arbitrary reduction in response or slope reduction, as previously mentioned. To this date, the five-parameter equation has been used in limited cases, and not at all in aquatic animals. Potentially, the information that can be obtained from this approach is more than merely determining nutrient requirements. If this extended model can be shown to be predictive of dose−responses over the full range of dietary nutrient concentration in aquatic animals, then this information can be used to ensure that acceptable diets are formulated. For example, this model can be used to determine if a 5% reduction in growth rate or feed efficiency is acceptable in order to utilize a cheaper, alternative nutrient source that contains suboptimum levels of some nutrients. The relative toxicity of the nutrients can also be calculated from this model (12,13).

Broken-Line Model

The broken-line model is the most common method used in estimating nutrient requirements of fish and other animals. It has the desirable features of fitting the data well in most cases, while providing a definite value for the requirement. This model assumes that the observed response is linearly related to levels of the nutrient below the requirement and that the response to dietary levels above the requirement is constant (i.e., a plateau with a slope of zero; Fig. 2). The physiological response (dependent variable) of animals fed diets containing the nutrient at concentrations below the putative requirement are fitted to a straight line against the dietary nutrient level (independent variable), while those above the putative level are averaged. The requirement is then determined to be the value of the independent variable that elicits the average value of the plateau region (i.e., the breakpoint). Researchers have sometimes used their
Figure 2. The relationship of physiological response to the concentration of a required nutrient, using the broken line model. The requirement (*r*) is determined to be the nutrient concentration corresponding to the intersection of the two parts of the line.

own judgment to decide which data points are below the requirement and which are at or above this level. The use of continuous nonlinear regression analysis, available on many computer software packages, eliminates the subjective assignment of nutrient levels to the deficient or plateau region of the response (14). The model used is described by the next equation.

$$R = R_{max} - a(r - I); \text{ for } r > I; \qquad (4)$$
$$R = R_{max}; \text{ for } r \leq I,$$

where

$r =$ requirement
$R =$ physiological response
$I =$ dietary nutrient concentration
$a =$ slope of the line below the requirement
$R_{max} =$ the theoretical maximum response.

Despite its prevalence in requirement work, the use of the broken-line model has been criticized because of its discontinuity at the requirement level, where the slope abruptly becomes zero, instead of gradually leveling off. In some studies, a progressive change in the slope of the relationship of the response to the dietary nutrient level, especially at nutrient levels only slightly less than the requirement, seems to better describe of the physiological response pattern than does a broken line. Baker (1,3) proposed an explanation for this curvilinear response pattern based on the individual requirements of each member of the test population. At dietary nutrient levels slightly below the calculated requirement, the requirement will be met for some of the test animals, resulting in a change in the overall slope in response to higher levels. As the nutrient is increased to levels near the overall requirement, the slope of the response curve tends toward zero as the requirement is met for an increasing proportion of the test population. According to

this explanation, reducing the variability within the test animals should reduce the deviation of the relationship from linearity. Reducing the variability in test animals is further discussed later. Where the deviation from linearity of the deficient region of the response curve is apparent, alternative models (e.g., the saturation kinetics model discussed here) may fit the data better and should be considered.

A/E Ratio

It has been observed that, in many species of aquatic animals, whole body essential amino acid (EAA) patterns are highly correlated to the reported requirement values. On the basis of this correlation, Arai (15) proposed the concept of A/E ratio to formulate diets for fish. The A/E ratio for a specific EAA relates the level of this amino acid in the whole body of fish to the total amount of all EAA, including cystine and tyrosine.

$$\text{A/E ratio} = 1000\,(AA_x/EAA_{total}) \qquad (5)$$

where

$$AA_x = \text{whole body content of a specific EAA}$$
$$EAA_{total} = \text{total whole body content of all EAA, including cystine and tyrosine.}$$

Animals fed diets containing amino acids in proportion to their A/E ratios have shown good growth and feed efficiency (16).

A/E ratios provide an index of relative balance among essential amino acids, but are not themselves requirements. Once the requirement for one EAA has been determined, the A/E ratios can be used to estimate the requirements for the others (17–19).

OTHER EXPERIMENTAL CONSIDERATIONS

Range of Nutrient Levels

To estimate a requirement value for a nutrient by the methods just described, it is necessary to measure responses over a range of dietary levels, including both those below and those above the requirement. Establishing the slope of the line in the deficient region (below the requirement) of the broken-line model requires at least two points, and an equal number of points in the plateau region (above the requirement) are required to ensure that the slope of the plateau is zero. Thus, a minimum of four dietary nutrient levels are required to use the broken line method, although to ensure that a sufficient numbers of points are above and below the requirement it is prudent to include five or more levels. A similar number of dietary levels are needed to use the enzyme kinetic model, as well. For ease of calculation, the levels should be equally spaced and cover a wide range. Nutrient levels that are considerably in excess of the requirement can be deleterious to the animal and result in depressed response. In this event, it is appropriate to select a model that can account for this (e.g., the five-parameter enzyme saturation kinetics model discussed earlier).

The nutrient content of each of the diets should be determined directly prior to commencement of the feeding trial. It is not sufficient to rely on calculated levels in most cases.

If even the approximate requirement is not known, a preliminary trial using a few widely spaced levels may be conducted to provide this information, prior to conducting a more detailed trial. In nutrition work, at least two replicate groups of animals are assigned to each treatment in most cases. This is not only insurance against the loss of a group during the course of the study, but it reduces the overall experimental error and improves the quality of the values obtained.

Duration of Trial

The duration of a trial is critically important to the reliability of the results. If a trial is carried out for an insufficient period, the differences in response to the dietary treatment may be too small to draw meaningful conclusions. The duration of the trial necessary for requirement studies depends on a variety of factors, including the response measured, the susceptibility of the animals to nutrient deficiency, and the nature of the nutrient under consideration.

Some physiological responses can be detected very rapidly and with sufficient accuracy to allow one to estimate the requirement. Enzyme activity and blood levels are examples of this type of response. Examples of responses that cannot be detected quickly include growth, feed efficiency, and survival.

The susceptibility of animals to a dietary nutrient deficiency is dependent on the initial level of the nutrient in the animal, the ability of the animal to sequester the nutrient, and the absolute need of the nutrient for growth and maintenance (i.e., the rate of nutrient turnover) by the animal. Sequestered fat-soluble vitamins and some minerals, for example, can be mobilized under conditions of dietary deficiency, with the effect that deficiency signs may be delayed. Water-soluble vitamins, essential amino acids, and some minerals, on the other hand, are essentially not stored, and deficiency signs may show more quickly.

Rearing the test animals under conditions conducive to good growth is the most effective way to reduce the time needed to detect response differences among treatments. Wherever possible, requirement studies should include a treatment where a feed that has proved to promote good growth is fed; often a high quality commercial feed. The growth rate of the animals fed that feed should be similar to what is known to be typical for the feed and the best growth rate of the animals fed the experimental diets should be comparable to that rate. In general, requirement studies should not be terminated until the average weight of the fastest growing treatment is at least three times the initial weight (i.e, a 200% increase in weight). Some researchers suggest even higher weight gains.

The time required to elicit differences in response can be minimized by maintaining the animals on the experimental diet containing the lowest level of the nutrient before the actual start of the trial, thereby partially depleting the nutrient. The duration of this

preconditioning period will be longer for relatively slow-growing, adult organisms than for young, fast-growing ones. Obviously, knowledge of the dietary history of the animals used in a trial can be useful in deciding on the duration of preconditioning. Establishing the whole-body levels of the nutrient under investigation prior to the commencement and at the termination of feeding is important for some nutrients, for example, minerals and essential fatty acids, to determine if there has been accretion of the nutrient.

Variability of Test Animals

Reducing the initial variability among test animals improves the sensitivity of requirement trials (20). The simplest and most effective way of reducing the variability of the test animals is to obtain closely related individuals of the same age (ideally, siblings), that have been reared together and that are selected to be of the same size. As pointed out by D'Abramo and Castell (3), organisms of similar size may not be the same age, due to different histories of nutrition, disease or intraspecific interactions. Preconditioning the animals to be used in a requirement study is often effective in reducing the variability in response to dietary nutrient levels.

Interaction with Other Nutrients and Dietary Components

When designing a requirement study for a particular nutrient, interactions that the nutrient may have with other elements of the diet must be considered. Several such interactions are known to occur, although the effects can be species specific. A requirement for a particular nutrient obtained from a feeding trial can be over- or underestimated by the presence of other constituents. There are several ways that this can occur: The nutrient can be synthesized endogenously from precursors in the diet; the bioavailability of the nutrient can be affected by the presence of certain substances in the diet; or, the nutrient can work synergistically with other dietary components.

Some essential amino acids can interfere with the utilization of others. High dietary concentrations of lysine, for example, are known to interfere with arginine, while excess levels of the branched-chain amino acids (leucine, isoleucine, and valine) are known to interfere with each other in chickens, but not in channel catfish (*Ictalurus punctatus*) (21,22). Another example of an interaction between dietary constituents that can result in an over-estimation of requirement values is the reduction of the bioavailability of bivalent cations (e.g., zinc and calcium) in the presence of phytate (23), which is found in appreciable amounts in several plant meals (e.g., canola or rapeseed meal and soybean meal).

It is sometimes possible to account for the influence of a dietary constituent by expressing the requirement for a nutrient in terms of the level of the other constituent. For example, the minimum level of an essential amino acid that is necessary to maximize protein synthesis and growth is proportional to the level of the protein in the diet, up to the level of protein required for maximum growth. The requirement for essential amino acids is,

therefore, most commonly expressed in terms of the percent of dietary protein. If the arginine requirement in a trial is found to be met by diets containing at least 2% of this amino acid, and if the test diets contained 40% protein, then the arginine requirement is reported as 5% of dietary protein. Similarly, some vitamins are expressed as amount (weight) per unit of available dietary energy. Diets containing high concentrations of crystalline amino acids, such as those commonly used in amino acid requirement trials, can have low pH. Some species of fish, especially those without an acidic stomach, cannot utilize those diets effectively, resulting in impaired growth and protein utilization. Amino acid test diets must, therefore, be neutralized before they can be used in requirement studies for these species (24,25).

Exogenous Nutrient Sources

To obtain meaningful results from requirement studies, it is important to ensure that the test animals cannot meet some or all of their requirement for the nutrient under investigation from exogenous sources, such as the water supply or from plant growth in the culture container. Many aquatic organisms can meet some or all of their requirements for some minerals directly from the surrounding water. This is particularly true of those animals that live in saltwater, of course, but it is also the case in fish reared in fresh water. Requirement estimates obtained from animals reared in conditions under which the requirements for some minerals are partially met from the water may result in deficient conditions when applied to the manufacture of feed for animals cultured in water containing only low mineral levels. It is therefore important to account for this possible source of error. One way to do this is to culture the animals in deionized water, although this is difficult to do in many cases. Generally, the level of the mineral under investigation in the culture water is reported in requirement studies. Shearer reviewed some of the methodology used to estimate mineral requirements (26).

Similarly, other required nutrients can be partially or totally met from organisms or particulate matter suspended in the water or from the consumption of algae or bacteria growing on the culture vessel. The degree to which this is a concern in requirement studies is related to the nature of the nutrient under investigation and the conditions of the trial. In many cases, passing the incoming water through a simple sand filter is sufficient to remove organisms that might interfere in this type of work. When studying animals that are capable of ingesting algae or bacteria growing on the culture vessel, it is essential to scrupulously clean the inside surfaces of the containers regularly. Algae growth can be reduced with suitable lighting, but the buildup of bacterial organisms can interfere with the trial.

Frequency of Feeding

Utilization of essential amino acids in the free form (i.e., not as part of protein) for protein synthesis is improved when the animals are fed frequently (27,28). The explanation for this is that amino acids are absorbed

from the intestine much more rapidly when present in the free form than are those that are present as part of the dietary protein. As amino acids are absorbed, they become available for protein synthesis, but they are also susceptible to being used for other purposes, such as the production of high-energy compounds. If diets containing high levels of free amino acids are fed in large, infrequently spaced meals, the postprandial endogenous level of amino acids will exceed the ability of the animal to utilize them for protein synthesis, and these "excess" amino acids will be metabolized into other compounds. Feeding smaller levels of those same diets more frequently, evens out the endogenous levels of the amino acids, thereby permitting more efficient protein production. This is particularly important in amino acid requirement trials, where the majority of the dietary amino acids are often present as part of protein, except for the amino acid of interest, which is present, in large part, in the free form. If the diets are fed infrequently, then the free amino acid will arrive at the sites of endogenous protein synthesis ahead of the others and become susceptible to destruction, resulting in reduced utilization for protein synthesis and possibly inflating the estimate of the requirement. If, on the other hand, the diets are fed more frequently, then the rapidly absorbed amino acids from the diet will be met at the sites of protein synthesis by those amino acids derived from the dietary protein, which are absorbed more slowly and over a longer period of time, of previous meals. As a result, the endogenous free-amino-acid levels will be better balanced for efficient protein synthesis.

Another strategy to improve the utilization of dietary free amino acids is to blend them with a substance that will retard their absorption. Cho et al. (10) used agar in this manner to examine the dietary arginine requirement of rainbow trout.

Water Stability/Leaching

In trials conducted to ascertain the requirement for a nutrient, the form of the nutrient that is supplemented to the diet is often highly water soluble. This is the case with many amino acids, vitamins, and some minerals. Loss of appreciable amounts of the nutrient from the diet prior to ingestion will result in an overestimation of the requirement. This problem is of particular significance when studying species that ingest meals over a prolonged period of time, such as shrimp. The stability of feed pellets is of concern as well, since rapid disintegration of pellets in water increases the exposure of the nutrient to the aquatic environment, with a concomitant increase in the likelihood that the nutrient will be unavailable to the animal.

The loss of the nutrient due to leaching can be reduced to acceptable levels by ensuring that the diets are prepared using suitable binders. Embedding the nutrients directly in a binder, as previously mentioned, can further assist in decreasing the loss to leaching. Care must be taken in selecting the type and level of the binder for use in these diets, however, as some have been shown to diminish nutrient availability (29,30).

Substitution of Ingredients

In preparing a series of diets for requirement studies, nutrients or nutrient-containing ingredients are supplemented in replacement of some other ingredient. It is often important to consider this replaced ingredient. For example, when studying the requirement for an essential amino acid, the amino acid under investigation is usually added in substitution for a nonessential free amino acid, typically glutamic acid or a mixture of nonessential amino acids. In this way, the total level of free amino acids in the dietary feeds is equalized.

Form and Digestibility of Nutrient

The effective level of the nutrient in a diet may, in fact, be considerably lower than the amount provided by the ingredients used to make it. This can happen if the bioavailability of the nutrient is low or if the nutrient is partially destroyed during manufacture or storage of the diet.

The bioavailability of nutrients from different sources can vary considerably, and this can have major consequences on the results obtained from requirement trials. For example, if the nutrient from a source used in a trial is only 50% available, then the dietary level of the nutrient needed to satisfy the requirement will be twice the actual requirement. Conversely, to use data from requirement studies in the formulation of practical feeds, it is necessary to know the availability of the nutrients in the sources being contemplated for inclusion.

Essential amino acids are a somewhat controversial special case of this. As mentioned earlier, the minimum dietary amount of an essential amino acid that will maximize endogenous protein synthesis is dependent on the dietary protein content. In most amino acid requirement studies, graded amounts of an essential amino acid are added in crystalline form to a basal diet containing a mixture of protein and other amino acids to form a series of diets. The bioavailability of crystalline amino acids is generally higher than those derived from protein (approximately 100%), and the requirement, expressed as a proportion of dietary protein, based on this type of trial may underestimate the actual requirement. Instead, the requirement level should be based on the amount of available dietary protein. This value can be obtained by dividing the amount of supplemental free amino acid required to maximize growth and protein synthesis by the digestibility of the dietary protein.

Examples of nutrients that are susceptible to degradation during processing and storage are vitamin C (ascorbic acid) and essential fatty acids (highly unsaturated fatty acids). Ascorbic acid is particularly prone to destruction from the heat applied in the pelleting of diets. Using low temperature during the preparation of a diet or supplementing a diet with a chemical (L-ascorbyl-2-polyphosphate) that is not very heat labile, but which is readily transformed into active ascorbic acid once ingested, are examples of techniques that are used to counter this problem. Essential fatty acids, on the other hand, are commonly protected using a variety of commercial antioxidants (e.g., ethoxyquin, BHT, and BHA).

Precursors of Nutrients

When formulating dietary series for use in requirement studies, it is important to eliminate, or at least to account for, precursors of the nutrient. For example, beta-carotene is a precursor of vitamin A. If the feeds in a trial conducted to determine vitamin A requirement contain unaccounted levels of beta-carotene, the requirement level determined for this vitamin will be erroneously low. Two nonessential amino acids are capable of being transformed into essential ones; cysteine (into methionine) and tyrosine (into phenylalanine). Requirement studies with these amino acids usually report the levels of the sum of both amino acids.

PARAMETERS

When examining nutrient requirements using a series of diets, the responses that are appropriate depend on the experimental design and the species and size of the animals under consideration. In general, more than one response is measured. The following list describes some common ones:

Growth

Weight gain is considered by many nutritionists to be the most meaningful response in requirement studies. Weight gain is so important partly because of the unambiguity of measurement and partly because of it's comprehensiveness (all aspects of an animal's physiology must be optimized for maximum growth). There are, however, some limitations in the use of growth data. Crustaceans, for example, go through periods of molting (ecdysis), and their growth, as measured by weight gain, is discontinuous, adding to the complexity of using this criterion (3).

Growth is a function of, among other things, both the nutritional quality and the rate of consumption of the diet. If a nutrient contributes positively to the consumption of the diet at levels of inclusion in excess of its requirement, then the requirement level, as determined from growth data alone, will be overestimated. Taking this argument to it's logical conclusion, any substance that stimulates consumption rates and that is not toxic can be said to be required using growth as the sole criterion, even if there is no physiological necessity for this substance. As animals grow during the course of a requirement trial, their growth may become impaired by limitations of the culture environment. Within a species, larger animals consume higher amounts of oxygen than do smaller ones in similar conditions, and their need for living space is greater. The ability of a trial to distinguish differences in growth rates between dietary treatments can be seriously impaired if care is not taken to ensure that the culture conditions are conducive to good growth of all the groups of animals throughout the duration of a trial.

There are a number of descriptive measurements for growth used in requirement studies. The simplest is usually weight gain (WG).

$$WG = (W_f - W_i) \qquad (6)$$

where

W_f = the weight of the animals at the end of the trial
W_i = the initial weight of the animals.

The relative weight gain (RGW) is more commonly used:

$$RWG = [(W_f - W_i)/W_i]100 \qquad (7)$$

Another common descriptor of growth in fish is the specific growth rate (SGR). The weight gain of animals is different at different sizes. For example, the time required for a 1-g (0.03-oz) rainbow trout (*Oncorhynchus mykiss*) to double in size is less than for this same fish to grow from 100 to 200 g (4 to 8 oz), given the same conditions for optimum growth. The SGR index attempts to minimize the effect of differing growth rates of animals of the same species that are of different size.

$$SGR = [(\ln W_f - \ln W_i)/\Delta t]100 \qquad (8)$$

where

$\ln W_f$ = the natural logarithm of the final weight
$\ln W_i$ = the natural logarithm of the initial weight
Δt = time period of the feeding in days.

Jobling points out that there is a reduction in the "growth potential" of fish with increasing body size, resulting in a gradual decrease in SGR as the fish increases in size (31). He therefore suggests the use of a linear equation that relates the logarithm of SGR with the logarithm of fish size as a more suitable approach to relating results of experiments with a specific nutrient conducted on animals of differing sizes or under different exeperimental conditions.

Another measurement of growth, the daily growth coefficient (DGC), was used by Cho et al. to estimate the arginine requirement of rainbow trout (10). The DGC is based on the cube root of the initial and final body weights, so it is little affected by differences in initial body weight:

$$DGC = [(\sqrt[3]{wt} - \sqrt[3]{wi})/\Delta t]100 \qquad (9)$$

Feed Efficiency

Feed efficiency (FE) is defined as gain in body weight divided by the dry weight of diet consumed. Using FE as a response eliminates the aforementioned difficulty for weight-gain data associated with different feed intakes occurring among animals in different treatments for reasons unrelated to the nutritional value of the diets. Calculating FE poses it's own difficulties, however. Because it is the ratio of weight gain and feed consumption, the experimental error of FE is higher than both of these. Feed consumption is difficult to measure accurately in many situations, principally because of problems in determining the amount of the diet that is presented to the animals, but not consumed. Such uncertainty seriously erodes the value of FE information. Under laboratory conditions, it is often possible to reduce the wasting of feed to acceptable levels by careful feeding. Indeed, it

is possible to determine the actual consumption of the diets by accounting for feed wastage, by counting uneaten pellets, for example. When feed intake can be accurately measured, FE is generally preferable to weight gain in ascertaining the nutritional quality of diets (32).

A related technique is to equalize the feeding for all dietary treatments over the course of the trial. Under this type of feeding regime, the animals in the dietary treatments are fed each of the test diets amounts equal to the feed rate of the lowest consuming treatment. This technique provides information about the relative nutritional quality of diets, without the complication of differing feeding rates. Equalized feeding works best on animals that are housed singly (for example, some crustaceans), but is limited in its suitability in trials for which the animals are reared communally, which is the most common type of trial. Restricting the feed intake of groups of animals that are reared together may promote the establishment of dominance hierarchies within each culture vessel, resulting in some animals consuming the majority of the meal at the expense of others in the group and an increase the likelihood of cannibalism. Such situations reduce the accuracy of the results and should be avoided.

Feed conversion ratio (FCR), the inverse of FE, is sometimes reported in nutritional work. Baker discussed why the use of this parameter is inappropriate for this type of work and should be avoided (1).

Protein Retention

Protein retention is defined as the gain in animal protein divided by the protein consumed. This parameter is commonly used in amino-acid requirement trials, as it measures the efficiency of utilization of dietary protein for endogenous protein synthesis (ignoring differences in protein catabolism). For protein synthesis to occur, all amino acids need to be available at the appropriate locations and in suitable balance. A dietary deficiency of any one of the essential amino acids will be manifested by a reduced rate of protein synthesis. The other amino acids, which are not used for protein synthesis, will instead be directed into one of a myriad of biochemical pathways, where they will be catabolized. Thus, protein retention is a more direct measure the amino acid utilization than is growth or feed efficiency.

Survival

In some situations, survival of animals fed experimental diets is a suitable parameter to assist in determining nutrient requirements. In the case of the larval stage of some organisms, there is no practical way of measuring feed intake, and survival is a good backup indicator of the nutritional quality of the diets.

Animals may be more susceptible to environmental stressors when maintained on diets that are deficient in an essential nutrient. Forster provided an example of this (33). Juvenile rainbow trout were fed a series of diets containing graded levels of arginine. The water supply of the culture system was recirculated through a biofilter that was coupled with a chiller to maintain the water

Figure 3. Cumulative mortality of rainbow trout fed diets containing various concentrations of arginine. The fish were held for four weeks in a partial recirculating fresh water system. The nitrite levels in the culture water during the fourth week frequently exceeded those known to cause stress in these fish. Each point represents the mean of 6 groups ± standard error bars.

at an acceptable temperature for this species. The water ammonia and nitrite levels were monitored and the nitrite levels were frequently close to or above the reported toxic level [0.5 mg/L (ppm) of water] for these fish in fresh water. After 28 days of feeding, the mortality was higher for the fish fed the arginine deficient diets and was linearly related to the degree of deficiency (see Fig. 3). The fish fed the diets containing arginine at or above requirement level (as determined by other studies), exhibited a much lower mortality rate.

Enzyme Activity

The activity of specific enzymes in response to dietary vitamin levels can sometimes be used to assess dietary nutrient requirements. This is especially true of some water-soluble vitamins, which, in modified form, function as coenzymes (2). For example, the hepatic enzyme FAD-dependent D-amino acid oxidase has been used to estimate the riboflavin requirement of channel catfish (*I. punctatus*) (34).

Liver and Blood Levels

The level of several water-soluble vitamins in the liver is positively related to dietary levels in excess of the amount required for maximum growth and absence of deficiency signs. The minimum dietary concentration that maximizes liver levels is used as an estimate of the requirement for these nutrients (35), even if this exceeds the requirement for maximum growth. Free essential amino acid concentration of the blood, especially of the serum or plasma, is sometimes used to estimate the requirement. At dietary levels below the requirement, the postprandial blood concentration of an essential amino acid is uniformly low, as the majority of this nutrient is utilized for synthesis of protein and other compounds (provided that all other nutrients are present in sufficient amounts). If the dietary level exceeds the requirement,

then its concentration in the blood will be positively related to its dietary content. Several studies have used this model to provide information about the requirement for essential amino acids, but with variable success (10,36). Because of this uncertainty, such information can only be used in support of the values obtained using growth, FE, and PR data.

O

OFF-FLAVOR

ROBERT R. STICKNEY
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

Incidents and Causes
Amelioration

Undesirable flavors and odors sometimes occur in various species of fish and shellfish and can negatively affect the acceptability of affected seafoods to consumers. Many off-flavor problems, such as off-flavors associated with oxidative rancidity and bacterial spoilage, occur after the animals are processed. Since those problems occur, in the majority of cases, after the aquaculture species leave the control of the producer, they are not considered here. Rather, the emphasis here is on off-flavors that occur when the animals are under culture.

Off-flavors can occur in response to ingredients in prepared feeds. For example, if high levels of fish oil are added to a prepared feed, the animals that consume that feed may develop a "fishy" flavor, which is often considered to be undesirable by consumers who are looking for a more bland taste. That problem can easily be overcome by adjusting the feed formulation to reduce or remove the offending ingredient(s).

Another source of off-flavors is pollutants. Hydrocarbons, for example, can produce off-flavors in aquatic animals. If there is contamination of an aquaculture facility, for example, by an oil spill, it is unlikely that the affected animals would ever appear in the market. Aquaculturists may experience such problems, but in all cases take every precaution to avoid them.

The off-flavors discussed here are those associated with blooms of certain organisms, usually blue-green algae, which can occur naturally in aquaculture systems. Chemicals in the algae can give fish what has been referred to as an earthy or musty flavor. The presence of off-flavor from this source can have devastating economic ramifications to both producers and processors. Faced with off-flavored fish, consumers have tried to mask or neutralize the problem with mustard, lemon juice, and other substances before the meat is cooked, though usually to no avail. The best approach is to ensure that no off-flavor fish ever reach the marketplace.

INCIDENTS AND CAUSES

Off-flavors have been reported in a number of cultured fish and shellfish species. In the United States, the reports have been most common with respect to channel catfish (*Ictalurus punctatus*) reared in ponds. As high-density culture in recirculating water systems has developed in recent years, reports of off-flavors in fish reared in such systems have also appeared. Tilapia, which have rarely demonstrated off-flavors in ponds in the United States, have been known to develop the problem in recirculating systems. Catfish and other species also have developed off-flavors in recirculating systems when held at high density.

Flavor problems in fish can emanate from a number of sources, including, as previously mentioned, postharvest problems and pollution. While contamination of cultured fish with pollutant chemicals is a possibility, virtually all off-flavor problems of aquacultured fishes are natural in origin. While affected fish may have an objectionable taste, they do not appear to pose a health threat to consumers.

The dominant sources of the earthy or musty flavor that has been reported from cultured animals are 2-methylisoborneol and geosmin. Produced by many species of blue-green algae, possibly by actinomycetes, and perhaps by other types of organisms, 2-methylisoborneol and geosmin are absorbed into fish flesh primarily through diffusion across the gills. Secondarily, absorption may occur as a result of normal feeding activity and the incidental ingestion of organisms containing the chemicals.

The same chemicals that produce off-flavors in aquatic animals are, in fact, a common problem in drinking water. While there has been a significant economic price associated with off-flavors in aquaculture products, it is undoubtedly trivial compared with that associated with off-flavors in domestic water supplies.

With respect to the early years of the commercial catfish industry, off-flavor incidence often increased late in the growing season, when the weather was hot, pond biomass was high, and other conditions promoted the growth of blue-green algae. With the adoption of intermittent harvest, fish densities and biomasses continued to be high throughout much of the year, so the period during which the problem was expected to occur was extended.

Similarly, fish reared in recirculating systems are held at high density and biomass. In addition, if an off-flavor chemical is produced within a closed system, it will be retained within the system and can become concentrated, because of the low water-turnover rates within such systems. Frequent replacement of the water might reduce or eliminate the problem, but that approach runs counter to the very basis upon which closed-system aquaculture is established.

AMELIORATION

Geosmin, 2-methylisoborneol, and perhaps other chemicals responsible for off-flavors in fish and shellfish will be metabolized, excreted, or diffused back into the water within several hours or a few days if the source of the chemical is removed. Moving affected fish from a pond into flowing well water is an excellent way to deal with

the problem. However, that approach may be impractical if appropriate facilities and supplies of water are not available, and it will add to the expense of rearing the fish.

A second approach is to wait. In most instances, algae blooms in ponds will eventually decline, and the source of the off-flavor chemicals will be removed. Once that happens, the chemicals in the fish will ultimately be eliminated. In closed systems, the dynamics of microorganisms may be quite different than those in ponds. The off-flavor chemicals may persist for long periods (a problem that can also occur in ponds that are harvested intermittently), so purging the fish by maintaining them in water free of the off-flavor chemicals prior to processing may be necessary. Alternatively, as previously mentioned, the system might be flushed with new water, to allow the fish to eliminate the off-flavor chemicals prior to harvest.

The channel catfish industry was the first to face the problem of off-flavors. Recognizing that the consumer who purchases or is served an off-flavor catfish may be reluctant to purchase or order the product in the future, a quality-control process was implemented by the fish processors. Farmers were instructed to collect a fish from each pond that was scheduled to be harvested and take it to the processor a week or two in advance of the harvest date. A portion of each fish is then cooked in a microwave oven and evaluated for odor and taste. If there is doubt on the part of the inspector as to whether a particular fish has an off-flavor, a second opinion is sought.

If the pond passes the first evaluation, the farmer brings another fish to the processor to undergo the evaluation process a few days (usually three) before harvest. If the pond passes the second test, the producer is given permission to harvest. On the day that the fish are delivered to the processor, but before they are unloaded, a third evaluation is made from a random sample of the fish on the truck. Only after the pond passes the third test is the load of fish accepted by the processor.

If an off-flavor is detected during any of the evaluations, the fish will not be accepted at the processing plant. If an off-flavor is detected during one of the first two evaluations, the farmer will merely have to wait until the problem is resolved through natural processes. Returning a truckload of fish to a partially harvested pond poses a more significant problem, however, since the stress of harvesting and hauling can lead to disease outbreaks and, subsequently high mortality rates.

The problem of off-flavors can be very severe. I visited a catfish processing plant in Alabama and was told that the percentage of fish that had to be rejected that day was quite low. It was about 50%, while on some days, 80% or more of the ponds scheduled for harvest demonstrated off-flavors.

ORNAMENTAL FISH CULTURE, FRESHWATER

Frank A. Chapman
University of Florida
Gainesville, Florida

The culture of ornamental fish is primarily for the home aquarium. Considered a luxury item, ornamental, or tropical, aquarium fish are kept for hobby and are gaining popularity as pets and companion animals.

The retail value of the aquarium hobby worldwide is estimated between US$4,000 and US$7,200 million. The aquarium industry is worth some US$1,500 million, of which the United States has the largest share. The aquarium hobby is also a major segment of the Japanese, British, German, French, Italian, Belgian, South African, and Chinese pet industries.

Traditionally not recognized as a form of aquaculture, ornamental freshwater fish culture is one of the most economically profitable areas of fish farming activities. A list of the most valuable fishery commodities worldwide is summarized in Table 1. In Florida in 1997, ornamental freshwater fish sales totaled US$57.2 million and were cultured by 203 growers in approximately 622 ha (1,536 acres) of water surface area. Another US$57 million worth of ornamental fish were exported from Singapore. (See Table 2.)

Several thousand species and hundreds of varieties of ornamental fish are sold through the pet trade, from both freshwater and marine origin. Although the largest

Table 1. The Most Valuable Fishery Commodities Worldwide[a]

Selected Fishery Commodities	US$/ton
Fish for ornamental purposes	45,564
Abalone	28,553
Caviar and caviar substitutes	15,891
Lobster, frozen	14,531

World total	193,000	World total	328,095

[a] The data are compiled from the average value of exports and imports for 1994–1996, from *FAO Yearbook 1996*, Fishery Statistics, Commodities Volume 83, 1998. Value = US$1,000.
[b] Primarily fish of marine origin.

volume of fish (approximately 95%) in the aquarium trade is from farm-raised, freshwater species, the greatest diversity of species is collected from the wild. Major sources for wild-caught freshwater aquarium fishes are the basins of the Amazon and Congo Rivers and streams in the watersheds of major rivers in India and Southeast Asia. Ornamental fish are farm raised principally in Southeast Asia and the United States. (See Table 2.) In the United States, the major center for ornamental freshwater fish production is in Florida, near both Tampa and Miami. (See Fig. 1.) Many retail fish are also raised by advanced aquarists in home garage or "backyard" facilities.

Written information on the requirements and practices for ornamental fish production is limited. Although many techniques used for ornamental fish culture are similar to those used in the production of foodfish, the husbandry methods for specific ornamental fish species are closely

Figure 1. A beautiful farm in Florida for the aquaculture of fish for ornamental purposes. Courtesy of 5-D Tropical, Inc., Plant City, Florida.

guarded secrets. Farmers have operated almost entirely on their own, developing their own methods and relying on many years of experimentation.

This contribution was written to provide an overview of ornamental freshwater fish culture. Because of the great diversity of species in production, only basic information is presented on husbandry technology and marketing. Emphasis is placed on providing a summary of essential biological characteristics and requirements that typify the wide variety of species. The intent is to provide a set of guidelines that blends theory with practical applications, to assist in the development or formulation of appropriate management practices for ornamental freshwater fish culture. Also, this contribution is designed to highlight industry and research needs.

The information in this contribution is based primarily on my own experiences with the ornamental fish industry in Florida, popular ornamental fish literature, and laboratory investigations dealing with the experimental culture of several dozen species representing the major fish groups in the trade. I have avoided the direct use of references in the text, because written information on the biology and husbandry of ornamental fish is primarily found in the popular or hobbyist's literature. Instead, the bibliography contains introductory sources for more detailed information on the culture of ornamental freshwater fish and their trade. Although koi and goldfish are important ornamental fish, their culture is not emphasized.

Historical Account

Little information exists that dates the origins of ornamental fish culture, but it can be assumed that it was developed in China, where the goldfish is the traditional ornamental fish and the culture of foodfish had its beginnings (believed to have been somewhere in the year 2000 BC). Accounts of several goldfish hatcheries

in China date to the Sung Dynasty between 960 and 1279 AD. By the mid-nineteenth century, the aquaculture of goldfish and koi was well established in Japan.

Contemporary aquaculture of ornamental aquarium fish can be identified with the beginnings of the hobby in England, during the years 1841 to 1852. The Germans were also aquarists and without delay became prominent fish breeders. The Americans soon followed, with records for goldfish farms in Ohio and Maryland dating to 1878 and 1889, respectively. By the early 1900s, a significant number of fish were being bred and imported into the United States. It was not until the mid-1920s and 1930s that ornamental fish keeping became popular and spread throughout the world. To supply the growing market for ornamental fish, the first commercial farms and numerous hobbyists began to raise aquarium fish in indoor tanks and outdoor pools. In the United States, the largest commercial farm at the time (in the 1920s) was Schaumberg's Crescent Fish Farm, in New Orleans, Louisiana. In Florida, the first fish farms date to the late 1920s. In Singapore, the center for world trade in ornamental fish, commercial production of ornamental fish began in the late 1940s and early 1950s.

POPULAR ORNAMENTAL FRESHWATER FISH

Over 1,000 freshwater species in about 100 families are represented in the ornamental fish trade at any one time. Despite this diversity, only about 150 species in 30–35 families are in great demand and account for the largest volume in the trade. Those species in commercial production represent close to 15 taxonomic families (e.g., Cyprinidae, Characidae, Callichthyidae, Mochokidae, Pangasiidae, Loricariidae, Melanotaeniidae, Pseudomugilidae, Telmatherinidae, Poeciliidae, Cyprinodontidae, Cichlidae, Belontiidae, and Helostomatidae). New species are constantly entering production, and there is continuous development of new varieties from species such as goldfish (*Carassius* sp.), koi (*Cyprinus* sp.), danios (*Brachydanio* spp.), angelfish (*Pterophyllum scalare*), bettas (*Betta splendens*), guppies and mollies (*Poecilia* spp.), and swordtails and platies (*Xiphophorus* spp.). Several hundred strains or varieties of these species have already been developed. A list of the most popular species in the ornamental fish trade is presented in Table 3.

GENERAL CHARACTERISTICS OF AQUARIUM FISH

Ornamental or tropical aquarium fish are numerous, geographically widely distributed and reflect great taxonomic and ecological diversity. This diversity is displayed in an astonishing variety of colors, body shapes, locomotion, behavioral patterns, reproductive tactics, feeding strategies, and other unique environmental adaptations.

Except for a few popular species, like goldfish and koi, the majority of ornamental fish are native to tropical regions of the world and cannot tolerate water temperatures below 18 °C (64 °F); hence they are given the generic name "tropical fish."

A useful distinction between freshwater and marine fish is an ability of the species to tolerate or acclimate to salinities above or below 10 parts per thousand (ppt). Popular freshwater species do not do well above 2 ppt salinity. For example, characins, certain cyprinids, and catfish are especially intolerant of saline water. Freshwater species are more prevalent in the trade than saltwater species, because of ease in care and shipping. Saltwater, or marine, ornamental species will become more popular as their husbandry and the necessary technology for their care are simplified and further developed.

Aquarium fish are relatively small and usually attain their adult body proportions and coloration in the first two to eight months of their life. Most species appearing in the market weigh between 0.3 and 40 g (0.1 and 1.4 oz) and range from 2 to 15 cm (0.8 to 6 in.) in total length. Aquarium fish regularly live 6–10 years. Some koi have been recorded as living for 70 to 80 years.

Ornamental freshwater fish are conveniently divided into egg layers and livebearers. These two modes of reproduction reflect the way in which most fish are bred and raised commercially. Livebearing fish have internal fertilization and give birth to their young as larvae, commonly referred to as fry. Egg-laying fish deposit their eggs or broadcast them for external fertilization. Among egg layers, there are mouth brooders; bubble, cavity or material nesters; open-water spawners; and substrate spawners.

PRODUCTION TECHNOLOGY

Typically, an ornamental fish farm is small and is owned and operated by a family. An average-size farm ranges from 0.5 to 6.0 hectares (1.2 to 15 acres). Customarily, farms combine the use of indoor and outdoor facilities for fish production. (See Fig. 1.) More and more farmers are beginning to produce ornamental fish strictly in indoor facilities. The use of outdoor ponds and tanks is restricted to conditioning broodstock. Some of the most advanced, specialized, and innovative techniques in aquaculture and wastewater treatment are used in the production of these fish. Because of their small size and high individual value, ornamental fish can be raised intensively and profitably indoors.

Buildings for indoor production customarily consist of modified greenhouses and wooden or steel sheds that are insulated and protected from the elements. Fish are reared in tanks or aquaria no larger than 2 m^2 (21.5 ft^2). The air and water temperatures inside each facility are closely regulated, and the photoperiod is controlled. Operation, monitoring, and maintenance of each production unit is facilitated through alarm and computer systems.

The indoor area is used primarily for breeding, hatching eggs, and raising larvae. The remaining areas of the building are devoted to holding, sorting, packaging, and shipping fish. Office space, wash areas, and an occasional laboratory bench are available. Quarantined and sick fish are sometimes treated indoors. Specialized foods are prepared and stored indoors as well. Indoors, fish are maintained primarily in concrete vats (e.g., burial vaults) and glass aquaria of various sizes. Tanks made of plastic and fiberglass are also becoming common.

Table 3. Major Taxonomic Groups of Fish for Ornamental Purposes [a]

CYPRINODONTIFORMES

Poeciliidae: *Poecilia reticulata*[1] A, *P. velifera*[13] A, *P. sphenops*[14] A, *P. latipinna*[22] A, *Xiphophorus maculatus*[5] A, and *X. helleri*[11] A

Cyprinodontidae: *Aphyosemion australe*, *A. gardneri*, and *Nothobranchius* spp.

CHARACIFORMES

Characidae: *Paracheirodon innesi*[2] A,W, *P. axelrodi*[31] W, *Hyphessobrycon bentosi*, *Hyphessobrycon erythrostigma*, other *Hyphessobrycon* spp., *Metynnis* spp., *Nematobrycon palmeri*, *Pristella maxillaris*, *Thayeria boehlkei*, *Phenacogrammus interruptus*, and *Hemigrammus* spp.

Lebiasinidae: *Nannostomus* spp.

Anostomidae: *Anostomus anostomus* and *Chilodus punctatus*

Gasteropelecidae: *Thoracocharax* sp., *Gasteropelecus* sp., and *Carnegiella* sp.

CYPRINIFORMES

Cyprinidae:

    Cyprinins: *Carassius auratus*[3] A and *Cyprinus carpio*

    Other cyprinins or Barbins: *Barbus tetrazona*[15] A, *Barbus conchonius*, *Barbus titteya*, and other *Barbus* spp.

    Systomins: *Balantiocheilus melanopterus*[16] A

    Labeonins: *Labeo bicolor*[21] A and *L. erythrurus*[27] A

    Banganas: *Epalzeorhynchos siamensis*

    Rasborins: *Rasbora heteromorpha*[28] A, *Rasbora* spp., *Brachydanio rerio*, and *Tanichthys albonubes*

Gyrinocheilidae: *Gyrinocheilus aymonieri*[30] W

Cobitidae: *Botia macracantha*[6] W and *Acanthopthalmus kuhlii*[25] W

PERCIFORMES

Cichlidae: *Astronotus ocellatus*[7] A,W, *Pterophyllum scalare*[8] A,W, *Symphysodon discus*[9] A,W, *Apistogramma ramirezi*[10] A,W, *Pelmatochromis kribensis*[24] A, *Pseudotropheus* spp., *Labidochromis* spp., and *Melanochromis* spp.

Belontiidae: *Betta splendens*[4] A, *Colisa lalia*[12] A, and *Trichogaster* spp.

Helostomatidae: *Helostoma temmincki*

Chandidae: *Chanda lala*[23] W

Gobiidae: *Brachygobius* sp.[32] W,A

SILURIFORMES

Pimelodidae: *Pimelodus pictus*[19] W

Pangasiidae: *Pangasius sutchi*[26] A

Siluridae: *Kryptopterus bicirrhis*[18] W

Mochokidae: *Synodontis multipunctatus*, *S. angelicus*

Callichthyidae: *Corydoras paleatus*, *C. aeneus*, *C. panda*, and *C. trilineatus*

Loricariidae: *Hypostomus plecostomus*[17] A,W, *Ancistrus* sp., and *Peckoltia* sp.

ATHERINIFORMES

Melanotaeniidae: *Melanotaenia splendida*, *M. boesemani*, and *M. praecox*

Pseudomugilidae: *Pseudomugil furcatus*

Telmatherinidae: *Telmatherina ladigesi*[29] W,A

OSTEOGLOSSIFORMES

Osteoglossidae: *Osteoglossum bicirrhosum*[20] W, *O. ferreirai* and *Scleropages formosus*

Notopteridae: *Notopterus ornata* or *chitala*

Mormyridae: *Mormyrus petersii*

[a] Includes the most popular fish (top 32) in terms of value [data adapted from (5)], and the status of the fish [i.e., primarily from a fishery (wild caught, W, $n = 8$), primarily cultured (aquaculture, A, $n = 16$), or both from a fishery and cultured ($n = 8$)].

Outdoor production facilities typically consist of earthen ponds and concrete tanks. Some ponds have concrete sides, and net cages are placed inside each pond, for better management and handling of the fish. Pond sizes vary greatly; a Florida outdoor pond is 20−25 m (65−82 ft) in length, 6−9 m (20−30 ft) wide, and 1.5−1.8 m (5−6 ft) deep. Ponds are simply excavated, with no built levees, have steep slopes, and there are no drain lines. In south Florida, pools slightly larger than a bathtub are carved into the limestone bed for raising the fish. In Asia, a typical large cement pond may be 10−18 × 2−9 × 1.5 m (33−59 × 3.3−30 × 4.9 ft), a large tank 4−7 × 2−2.5 × 0.5 m (13−23 × 6.6−8.2 × 1.6 ft), and a square tank 1.5 × 1.5 × 0.5 m (4.9 × 4.9 × 1.6 ft). Net cages to place inside ponds measure 3 × 1 × 1 m (9.8 × 3.3 × 3.3 ft). Many farmers cover ponds and tanks with nets to protect the fish from predators. Depending on the location or time of year, farmers provide shade and enclose ponds with plastic to prevent the water temperatures from being too low during the winter.

Water Quality

Ornamental freshwater fish are highly adaptable to culture conditions and are capable of living under a wide range of environmental conditions. Despite the great number of species, the overall quality standards for culture water are similar to those for foodfish. Some of the most important factors are salinity, temperature, dissolved oxygen, hardness, conductivity, pH, carbon dioxide, and nitrogenous products (e.g., ammonia and nitrite). Another factor that may need to be considered are fish pheromones, such as crowding factors (e.g., in white cloud or zebra danios), which can inhibit growth or reproduction of other fish in the culture system.

Although freshwater fish cannot tolerate high salinities, the use of salt for transport and disease treatment is highly beneficial. The occurrence of disease also has been lowered when fish are raised in slightly saline waters (0.1−2 ppt). The preferred temperature for raising most ornamental freshwater fish is between 24 and 30 °C (75 and 86 °F). The incidence of diseases and water quality deterioration is increased drastically when the temperature is above 30 °C (86 °F). Although many species can tolerate low levels of dissolved oxygen (e.g., gouramies, several catfish), concentrations in production systems should be maintained above 5 mg/L or 5 parts per million [ppm] to support optimum growth and reproduction. High levels of free carbon dioxide (e.g., 100 mg/L or 100 ppm) are often encountered when water is pumped from shallow wells and when fish are raised or transported at high densities. Because of the influence of carbon dioxide on respiration, prolonged exposure to high levels of carbon dioxide may result in poor growth. Normal tolerance levels for carbon dioxide in foodfish have been established at 10−20 mg/L (10−20 ppm).

The hardness and pH of the waters from which many of the species originate can vary from a pH of 5 to 9 or 10 and a hardness of 5−20 mg/L (5−20 ppm) to over 300 mg/L (300 ppm) of calcium carbonate. However, most of these species can be acclimated to local conditions and raised successfully. Although not well understood, the stringent water requirements for temperature, pH, and hardness appear to be for breeding, hatching, and rearing the larvae. Black water directly from stream beds or small lakes is used for breeding and rearing larvae of certain species. This type of water is characteristically transparent, but dark brown in color (above 40 color units), because of dissolved organic matter, primarily from humic acids. The origin of these waters has been the same for many decades, and their specific locations have been kept secret.

Water Management

Well water is used to fill ponds and furnish the water to recycle systems. Water is supplied to each tank, often in spray form and flow-through fashion. Ground water, rainfall, and surface runoff typically maintain the water level in ponds. For species that require soft water, well water is usually treated with cation exchange resins and passed through reverse-osmosis units.

Intensive systems recycle 60−100% of their water. Each tank is supplied with water that often is injected below the surface and saturated with pure oxygen. Exchange of other gases is achieved with degassing chambers, air blowers, and oxygen. The water is treated with mechanical and biological filters. Removal of suspended and settleable solids (e.g., waste, feed, and feces) is accomplished with settling basins, baffles, screens, and upflow solids contact clarifiers. Microbes in trickle filters, modified upflow clarifiers, and fluidized media are used for nitrification and decomposition of organic wastes. Ozone is also used for further oxidation of the organic compounds. Fine suspended solids (scum) and other dissolved organics are stripped with dissolved air flotation or foam fractionation technology. For disinfection of treated water, ozone and ultraviolet light are often used. If necessary, the treated water is reconstituted with specific chemicals before it is used again. The effluent sludge is usually diverted and collected in small ponds to undergo further aerobic and anaerobic digestion.

Breeding and Propagation

Perhaps the greatest difficulties in the cultivation of ornamental fishes lie in obtaining and conditioning the broodstock for breeding. Also challenging are artificial incubation of embryos, initial feeding of larvae, and weaning from the larval stage. Reproductive conditioning and performance of ornamental freshwater species are greatly dependent on the species strain, age of the fish, body size, fish density, population structure, water quality characteristics (e.g., temperature, conductivity, and hardness), and other environmental conditions, such as availability, quantity, and quality of foods.

Most egg layers are artificially bred in indoor hatcheries. Broodfish are paired in tanks or spawned together in large groups. Fish are stimulated into breeding by using spawning mats and by manipulating environmental factors such as water flow, temperature, hardness, and pH. Hormone preparations from pituitaries or artificial sources, such as Ovaprim™, are also used to induce spawning. After spawning, the eggs are allowed to hatch where they are laid or are placed in various types of artificial incubators. The larvae that hatch are pooled and

transferred to rearing tanks or outdoor ponds. This period is a critical time in the management of a hatchery. At this time and up to two weeks after stocking, incurred larval losses may reach or exceed 75%.

Standard temperatures for spawning and incubation fall between 23 and 29 °C (73 and 84 °F). Optimum spawning and incubation temperatures for individual species should not vary more than 2 to 3 °C (3 to 5 °F). Natural spawning takes between 30 to 90 minutes. The number of deposited eggs varies from hundreds to a few thousand or more. Eggs that are laid are mostly demersal or adhesive and are between 0.7 and 1.1 mm in diameter (slightly less than 1/16 in.). Some mouthbrooders (e.g., cichlids) and catfish may lay fewer than one hundred eggs, but these eggs are large (several millimeters in diameter), and the larvae are precocial. Depending on the species and water temperature, embryos may hatch in as little time as 12 hours (e.g., danios) or as much time as up to several months (e.g., killifishes). In general, embryos hatch within 1 to 4 days at 25–28 °C (77–82 °F). Curiously, this period is prolonged to seven days in rainbow fishes (Melanotaeniidae) and 14–24 days in blue-eyes (Pseudomugilidae). Upon hatching, larvae of egg-laying fish are generally 2–3 mm in length and 3–4 mm (approximately 1/8 in.) at the beginning of external feeding.

Larvae of many species are phototactic at hatch, but after a few hours avoid bright light. Swim-up, or swim bladder inflation, normally occurs close to the initiation of external feeding. Duration of the larval period is variable, but, in general, juvenile fish become apparent at three to five weeks.

Most species typically attain sexual maturity between five and seven months of age. Species that mature at older ages (e.g., labeos) enter puberty during their first and second year of life. Loaches and certain catfish may not mature until age three and four. Although the stage of sexual maturity is difficult to assess in many species, the sex of each fish is relatively easy to determine, particularly close to spawning: Males usually show brighter colors than females and display a variety of secondary sexual characteristics, such as longer fins, modified fin rays, and proportionally larger heads, sometimes with tubercles or bristles. Most characteristic is the alteration in sex behavior in males, who become more aggressive. The female's abdomen is distended when full of eggs, and the ovipore becomes distinct.

Broodfish are capable of spawning many times during their life. Completion of one reproductive cycle may take from two weeks in tetras and barbs and up to one year in labeos, goldfish, and koi; these annual species may spawn several times during a reproductive season. However, the frequency of spawning (i.e., in commercial production) greatly affects the reproductive output of the fish. For example, the reproductive performance (i.e., the number of eggs laid and the larval survival) of most species increases after the second or third spawning. Also, if the fish are spawned continuously (e.g., tetras that are spawned every two weeks), reproductive activity ceases after approximately one year.

The fertilization and spawning of livebearing fish is allowed to occur naturally in breeding ponds or tanks. Broodfish are typically stocked at 100–150 fish/m^3 (3–5 fish/ft^3), at a 1-to-4:7 ratio of males to females. Broodfish of four to six months in age are preferred. The number of young produced by a female ranges from 1 to less than 300. The average brood size is between 20 and 50 larvae every 26 to 63 days. In production, this fecundity estimate may be extrapolated to 0.7–1.1 larvae per female per day. The gestation period, or period of embryonic development, averages 30–35 days. At parturition, the larvae measure between 5 and 12 mm (about 3/16 to 1/2 in.) and consume a variety of foods, including brine shrimp (Artemia). In production, it is good practice to separate the parents from their offspring, as the parents will tend to eat the newly born.

Some species of livebearing fish (e.g., Poecilia sp.) can reach sexual maturity as early as four to five weeks from birth and 16–28 mm (about 5/8–1 in.) in body length. Swordtails (Xiphophorus sp.) may reach sexual maturity in 9–12 weeks of age or at 25–30 mm (about 1 in.). The age and body size at sexual maturity in livebearers have been demonstrated to be highly heritable traits.

Among the greatest potential factors for increasing the productivity of commercial farms are a better understanding of the nutritional and water quality requirements for conditioning egg-laying broodstocks and the development of breeding programs for livebearing fish. Because most species in the trade are imported or collected from the wild, the development of domestic broodstocks is perhaps the most important consideration for assuring the continual expansion of the industry.

Growout to Market Size

Most aquarium fish are grown for retail in outdoor ponds and tanks. Some fish are grown in indoor tanks, vats, and aquaria. In general, it takes three to six months to attain market-ready fish. Depending on the species, fish are sorted by age, sex, size, and color, beginning as early as three weeks from birth.

Stocking densities and survivorship estimates are difficult to assess and vary greatly between species and production systems. A typical-size pond [e.g., 200 m^2 (approximately 2,152 ft^2) of water surface] may be stocked with 10,000 to 80,000 fish from egg-laying parents or with a couple hundred livebearing broodfish. After two months, the livebearing population in the pond can reach approximately 30,000 fish, and harvest is initiated. A typical survival estimate for fish in a production pond is 40 to 70%. The survival rate of livebearing fish is slightly higher. The primary losses on an outdoor system are due to predation, deterioration of water quality, and diseases. High stocking densities in intensive culture systems may approach 4,000 fish/m^3 (15 fish/gal) without oxygen injection and 15,000 fish/m^3 (58 fish/gal) with oxygen injection. Losses under these conditions are minimized, and fish survival may increase to 85% and above.

Husbandry practices for the growout phase in ponds are designed primarily for obtaining fast growth, reducing predation, and maintaining proper health. Success is determined to a large extent by the amount and quality of natural food in the pond, the time of stocking, and proper handling at harvest time.

Ponds used for growout of juvenile fish are prepared for stocking by draining, washing, or removing the sludge; disinfecting; and fertilizing. Although species dependent, some ponds have remained in production unwashed for a year or two. When disinfected, ponds are treated with hydrated lime after cleaning. A variety of fertilizers is used in ponds. After a few days, the ponds are filled with water, and an algae bloom is allowed to develop. The ponds are then stocked with fish.

Management practices in intensive systems are aimed at maintaining a high exchange of good-quality water and at providing the proper nutrition, including pigments, to the fish. Only under these conditions can fish be raised at high densities, be in good health, and attain uniform size and coloration.

Many species exhibit schooling behavior, while others are solitary. Aggression toward members of the same species is common among solitary species and can be deterred by increasing the water flow in the culture tank or providing significant amounts of individual cover.

Fish are harvested with fine seine nets, dip nets, and traps. The process of harvesting ornamental fish differs from that for foodfish, because the fish are individually selected and must be kept alive and in good condition. The selection process includes sorting by color and size, which is labor intensive, as the sorting is done by hand and is subjective. The industry is in great need of a machine designed to count small fish and selectively grade and sort fish by color and size.

Feeding Fish

Very little information exists on the nutrition and feeding of ornamental fish. Knowledge of their dietary requirements has evolved primarily from trial-and-error tests by individual farmers and a few studies in research laboratories in universities and feed manufacturing companies. However, from analysis of these experiences and practices in the aquarium hobby, it is fair to conclude that the nutrient requirements of ornamental fish are, in general, similar to those of foodfish species.

Feeding habits among aquarium fish are highly diversified, but under culture conditions, most species become opportunistic feeders and take a variety of foods. Yolk-sac larvae in many species normally commence external feeding three to six days after hatching. Since many larvae have small mouths or esophagi, they require live foods between 50 and 150 μm in size (e.g., rotifers, trocophores, *Paramecium*). Larvae prefer to feed under dim light, and the initiation of external feeding occurs close to swim-up, or swim-bladder inflation. After one or two weeks, larvae will readily accept 250–400-μm particle feeds [e.g., brine shrimp (*Artemia* sp.) and formulated feeds]. Thereafter, the pellet size for feeding most fish varies between 1 and 3 mm (approx. 1/8 in.). The success in culturing many of the catfish, cichlid, and livebearing fishes is attributed to the ability of the larvae to eat large-particle foods, such as brine shrimp, at the initiation of external feeding.

The natural diet of fish raised in ponds is supplemented with formulated diets. However, many of the essential nutrients and pigments are obtained from the available natural foods. To stimulate the production of natural food in ponds, a combination of organic and inorganic fertilizers is used. A favored organic fertilizer is cottonseed meal.

Used for feeding fish cultured indoors, popular feed mixtures from commercial sources contain from 33 to 35% protein. Farm-made feeds usually are made up of 45% to 60% protein. Proteins from animal sources (e.g., fish meal, beef heart, and liver) are preferred ingredients in the formulation of diets. Ingredients from plant proteins (e.g., *Spirulina*, soybean, and alfalfa meals) and fiber are incorporated into diets for goldfish, koi, and herbivorous fishes (e.g., certain catfishes and cichlid species). To enhance coloration in fish, a combination of synthetic and natural carotenoid pigments is added, at a level of 0.04–2% of the diet.

Feed is delivered primarily by hand or automatic feeders. Because of the small particle size and the low volume of feed involved in growout, feed is allotted at a constant rate (3–10% of fish biomass per day). It is good practice to feed primarily floating or neutrally buoyant feeds, as sinking pellets are easily mixed with sediments or bottom debris and are not efficiently utilized. Fish are fed at least twice a day and sometimes almost continuously, depending on the species and culture system.

Fish Health Management

Poor health of the stock and loss of fish are due primarily to predation, diseases caused by substandard water quality, excessive handling, and inadequate nutrition. These losses can be minimized with the establishment of an integrated health management program that includes proper husbandry, the management of water quality, appropriate nutrition, proper sanitation, quarantine, diagnosis of illness, proper use of medications, and identification of the source of disease. A daily system for maintenance and monitoring is essential for early detection of diseased or malnourished fish. Symptoms of sick fish include physical changes, odd behavior, and a lack of feeding activity.

The industry has used a variety of chemicals, sedatives, and water additives to reduce the stress and possible injury of fish during handling, sorting, crowding, harvesting, and shipping. To prevent skin abrasions and scale loss, water additives containing polymer formulations (e.g., Polyaqua™) and salt have been very successful.

Ornamental freshwater fish are afflicted by diseases similar to those found in the foodfish industry, ranging from viruses to opportunistic aquatic bacteria, parasites, and fungal infections. However, an understanding of epidemiology, etiology, and pathology of infectious agents of ornamental fish is in its infancy. Also, knowledge of the immune system in these fish is limited.

Parasites and bacteria are two of the most common causes of infectious diseases in ornamental fish. The most prevalent of the external parasites are ciliated protozoans, primarily *Ichthyophthirius multifiliis*, or "ich," and *Trichodina*. Also, monogean trematodes, or flukes (e.g., *Dactylogyrus* and Gyrodactylus); nematodes; and the flagellated protozoans *Hexamita* and *Spironucleus* are frequently encountered internal parasites that debilitate and compromise the health of fish. Salt, formalin, copper

sulfate, and potassium permanganate are used to treat external parasites. Fenbendazole and Metronidazole are recommended for internal nematodes and flagellates, respectively.

Among the most prevalent of the infectious bacteria are those in the aeromonad (*Aeromonas*) and columnaris groups (e.g., *Flavobacterium columnaris*). Common drugs used to treat bacterial infections are tetracycline, erythromycin, nitrofurazones, nalidixic acid, potassium permanganate, and copper sulfate. Correct use of antibiotics, based on bacterial isolation and sensitivity testing, is strongly recommended.

Fungal diseases (e.g., saprolegniasis) are widespread when fish are stressed, primarily during temperature shifts or following handling. Salt and potassium permanganate are two compounds commonly used in dip and bath treatments to minimize fungal invasions and other problems of an external nature. Once fungal infections become systemic, treatments using other compounds are necessary.

Only a few viral diseases have been identified in ornamental fish (e.g., iridovirus in gouramies). Although no specific medications are available for treating viruses, temperature manipulation and reduction of crowding may be methods to prevent the spread of the disease.

MARKETING

From the farm, fish are sold to large distributors or regional wholesalers, which, in turn, resell the fish to local retail stores. Fish collected from the wild, by fishers, are sold to a collector, who, in turn, resells the fish to the distributor or wholesaler. Although prices vary greatly, the wholesale price for many common egg-laying fish can average US$0.45 and the right livebearer US$0.20–0.30.

The centers for ornamental freshwater fish production and distribution are Singapore and Florida. From those two locations, fish are dispatched to all corners of the world. The fish are transported by air freight, and their survival and health are totally dependent on proper handling, packing, and timely arrival to their destinations. A shipment will arrive at its destination typically within 15 hours; however, the fish are packed for an extended trip duration of 48 to 72 hours. Fish are shipped inside insulated boxes, wherein they are placed in plastic bags, usually filled with one part water and three parts pure oxygen, on a volume-to-volume basis. The number of fish per box varies with species, the size or weight of the fish, and duration of the trip. A box may contain between 50 and 500 fish, or about 25 g/L (3 oz/gal). Cold or heat packs are placed inside containers to limit temperature fluctuations during shipment. Buffers, sedatives, and bacteriostatic chemicals may also be added to reduce water quality deterioration, the possibility of injury, and disease outbreaks. Fish are starved for at least 48 hours prior to shipping.

Competition in the ornamental fish market is keen, since many species are collected from the wild, and the bulk of the fish production is for a selected or preferred number of species. Another major source of competition, particularly in the United States, is from imported fish from southeast Asia, primarily in Singapore and Hong

Kong. Markets for common fish are difficult to enter, since the structure and procedures for buying and selling fish are very complex and embedded in tradition. Perhaps the most important attribute of the market is the availability of a large number of the species in the trade. Access to an assortment of imported and cultured fish has allowed Singapore and Florida to become worldwide hubs for the purchase and distribution of ornamental fish.

Production of ornamental freshwater fish provides one of the best business opportunities in aquaculture, because most species in the trade are still collected from the wild, and the largest markets are in regions that must import fish. The fish are imported and exported either through interstate boundaries (e.g., from Florida to New York) or from international locations (e.g., from Singapore to the United States). Ornamental fish culture can be practiced on a small scale, with the business being both family owned and family operated. Although outdoor production can be practiced only in warm climates, many fish can be raised intensively indoors and close to the markets. On a per-weight basis, ornamental fish command among the highest prices of aquacultural products, often several hundred dollars per kilogram. The recognition of opportunities provided by ornamental fish aquaculture is best represented by the rapidly expanding industry in the Czech Republic and Israel. In only a few years, both countries have become major participants in the world market. (See Table 2.) Development of ornamental fish aquaculture has allowed for rapid diversification of traditional aquaculture practices and enhanced economic opportunities.

Essential for the establishment and development of an ornamental fish industry is a consistent supply of a wide variety of species. The expansion of and future opportunities in the ornamental fish industry are dependent on the continued development of new varieties and the establishment of domestic broodstocks for species that are imported or collected from the wild.

ORNAMENTAL FISH CULTURE, MARINE

G. JOAN HOLT
University of Texas
Port Aransas, Texas

OUTLINE

Keeping an aquarium is a hobby that engages an estimated 10–20 million enthusiasts, who own more than 90 million tropical fish (1). The retail value of the ornamental fish trade is approximately $1 billion (2). Although many of the freshwater ornamental fish sold to the public are farm raised, essentially all of the marine reef products (fish, invertebrates, live rock) are collected from the wild.

The Asian/Pacific region is the global center of marine diversity; it supports more species of coral and fish than does any other region on earth. This region is home to over 4,000 species of reef fish and more than one-third of the world's coral reefs. In this region, and throughout the tropics, natural populations of coral reef fish are increasingly threatened by development, dredging, coral collecting, and the live food-fish and aquarium-fish trade. Unfortunately, many of the common collection methods (dynamite, sodium cyanide) are destructive (3), and cause irreparable damage to coral reefs in addition to greatly reducing the area of natural habitat available for the settlement of new fish recruits.

Japan and the United States lead the market for aquarium fish; these two countries account for over half of the world's ornamental fish trade. The Philippines is a major exporter of marine aquarium products for the global aquarium trade, supplying an estimated 75–80% of the market (3). It is estimated that up to 90% of all aquarium fish imported by the United States from the Philippines have been collected by using cyanide (4). There are several cyanide fishing techniques, all of which damage corals. Cyanide is a broad-spectrum poison that acts on enzyme systems involved in respiratory metabolism (3). Exposing a fish to cyanide causes internal damage to its liver, intestine, and reproductive organs. Fish that survive exposure to cyanide, but are not taken by divers, can be expected to suffer impaired chances of survival, growth, and reproduction, and lowered disease resistance.

Less is known about the specific impacts of cyanide on reef invertebrates, but it seems likely that similar debilitating effects occur to them. In general, invertebrates seem to be more susceptible to cyanide than are fish. Loss of zooxanthellae (coral bleaching), inhibition of photosynthesis, and impaired respiration of coral in response to cyanide concentrations used in fishing have been documented in invertebrates (4).

BREEDING MARINE ORNAMENTAL FISH

The ability to meet demands for marine ornamentals by utilizing wild-caught fish is decreasing due to more stringent regulations on collections that deplete wild stocks and cause damage to fragile coral reef ecosystems. In the Philippines, one of the important suppliers of marine ornamental species to the United Kingdom, Europe, and the United States of America, destructive collecting techniques damage reef habitats. Furthermore, the marine environments in which these species exist under natural conditions are increasingly being threatened by various forms of human interference and natural disasters that result in extensive damage to coral reefs. Recently, some countries have taken steps to protect several species of marine fish and invertebrates.

Sri Lanka and other countries in the region are showing an increasing interest in the breeding of marine ornamental fish and invertebrates, both to reduce dependence on wild stocks and as a means of generating income for coastal communities. Increasing pressures on natural populations of coral reef organisms, and their expanding popularity in the aquarium trade, have spurred interest in the development of culture techniques for marine ornamentals. There is a strong call for tank-reared fish by both marine aquarium hobbyists and professional aquarists. Currently, few species of marine fishes are regularly reproduced in captivity and sold in the aquarium trade. The most commonly available are clownfish (*Amphiprion* spp. and *Premnas biaculeatus*), the neon goby (*Gobiosoma oceanops*) and relatives, and more recently the dottybacks (*Pseudochromis* spp. and *Ogilbyina novaehollandiae*) (5). Some other species have been bred and raised in captivity during the last 30 years (6), but not reliably or efficiently enough to sustain an industry. There are generally fewer problems in the spawning of tropical marine fish and invertebrates than in culturing the young. In fact, larval culture is the most difficult biological aspect of the culture of most marine species.

Why are some species raised successfully while most others are not? The easiest to raise, clownfish, have the advantage of being sequential hermaphrodites (they can change sex), which eliminates the problem of obtaining a spawning pair, and they produce demersal eggs for which the adults provide parental care (7). Although parental care ceases with the hatching of the eggs, the larvae are large enough at hatching to consume cultured rotifers (*Brachionus plicatilis*) (6).

Many of the more popular and costly marine aquarium fish, such as butterflyfish, angelfish, and wrasses, are more difficult to raise in captivity. They produce small free-floating eggs that are only about one-third the size of clownfish eggs, and the adults do not provide parental care. The newly hatched larvae are less than 2.5 mm (0.1 in.) long, and they have no eye or mouth development and very limited swimming ability. Traditional prey for the rearing of marine fish larvae (rotifers and *Artemia* spp. or brine shrimp) are not accepted, and may not be nutritionally adequate, for these marine ornamentals.

Early Life History

Survival through the early life stages has proved to be the major obstacle to large-scale production of a wide variety of marine ornamentals in captivity. Production of sufficient numbers of healthy juvenile fish for the market depends primarily on the refinement of larval rearing methods. Appropriate environmental conditions and proper prey for different stages during development are unknown and must be determined. Development of rearing systems for the tiny, delicate larvae is a challenge. Since they have rudimentary sensory and motor development, the larvae cannot swim and search large volumes of water to find food. This necessitates the feeding of dense blooms of live prey, and it often results in deteriorated water quality. Simple systems, such as the one described by Henny and coworkers (8), provide a confined volume for larvae and their prey, which facilitates high feeding density, and also allows for constant exchange of water. Water in the completely closed system is filtered, aerated, and heated, if necessary, in order to maintain adequate water quality (Fig. 1).

The next problem is that of finding appropriate prey. The first food for marine larvae is live plankton, generally zooplankton. Cultured rotifers are the most commonly-fed food in aquaculture, but many marine ornamentals do not grow and thrive on them. It may be because rotifers are too large, do not give appropriate behavioral signals, or are not nutritionally adequate. Natural plankton (including algae) would be the best choice, but they are not always accessible-and often when they are the species composition and nutrient quality vary over time. For reliable production, cultured prey must be available. Phytoplankton is relatively easy to culture but is not an adequate food by itself. Copepods are generally considered the best food overall for larval marine fish, however, culture success has been marginal at best. Gut analysis (9) showed tintinnids, dinoflagellates, protozoans, diatoms and copepods, in that order, as the most important prey for small (less than 3 mm or 0.12 in.) coral reef fish larvae. These findings suggest that the best first foods for rearing ornamentals are microzooplankton and large phytoplankton.

SPECIES COMMONLY REARED IN CAPTIVITY

Clownfish or Anemonefish (Pomacentridae)

Types of fish commonly raised in ornamental fish culture (10) are species that have three characteristics: they can change sex (sequential hermaphrodites), they have eggs that take several days to hatch, and they produce relatively large larvae (>2.5 mm or 1/10 in.) that have fast development. The clownfish is a good example. These fish can change sex from male to female (protandry). Generally two to four fish might occupy an anemone, including a large dominant female, a smaller male and one or two adolescents. If something happens to the female, the male, now dominant, will change into a female and one of the smaller individuals will become a male. Most commercial operations typically have only pair housed in the breeding tank. Clownfish spawn about twice a month by laying adhesive eggs onto a hard substrate. Eggs are tended
Figure 1. Rearing system for development of larvae of marine ornamentals. (From Hinney et al. 1995.)

by the male and hatch after a week. Newly hatched larvae feed on rotifers for several days, followed by brine shrimp. Within one to three weeks they metamorphose into juveniles. High survival of the young is possible with many of the 12-plus species that are regularly produced in captivity, and several commercial establishments produce and sell captive-bred clownfish. Joyce Wilkerson's new book *Clownfish: A Guide* (11) is an excellent source of information on the captive care and breeding of these fish.

Gobies (Gobiidae)

Gobies are typically small benthic fish that often act as cleaners, removing parasites from other fish. They are protogynous hermaphrodites, which means they can change sex from female to male but not the other direction. In captivity, gobies spawn regularly (every 2–3 weeks) and produce demersal adhesive eggs that are usually attached to the underside of a rock or to the roof of a small cavity. In most cases, spawning requires only the presence of a mated pair plus a suitable spawning site. The male guards and tends to the eggs for the 4–10 days between fertilization and hatching. Neon goby eggs are quite large; the larvae are 3–4 mm (0.1–0.2 in.) and are relatively advanced at hatch (12). Young can be raised on rotifers and wild zooplankton, and, later, brine shrimp nauplii. Metamorphosis to the juvenile stage takes about a month. Several species are regularly spawned in captivity.

Commercially available gobies include the neon goby, the yellow-striped goby, the West Indian cleaner goby, the genie goby, and the masked goby (13).

Dottybacks (Pseudochromidae)

Dottybacks or fairy basslets are also protogynous hermaphrodites. They lay a gelatinous ball of eggs (about 2.5 cm or 1 in. in diameter), which is guarded by the male for a few days before the eggs hatch into 2–4 mm (0.1–0.2 in.) larvae. While the male is caring for the eggs, he chases away the female. When he wants to spawn, he aggressively invites the female to join him to spawn. The rotifer is readily accepted as first food by the larvae, and is replaced by brine shrimp nauplii after about two weeks. Metamorphosis occurs at about 30 days, followed closely by the development of full adult coloration. During the last three years, several species have been successfully reared (14) and are now offered for sale (13). M.A. Moe (15) has written a book that details the care and breeding of the orchid dottyback (*Pseudochromis fridmani*).

Seahorses (Syngnathidae)

Seahorses typically live in shallow areas and cling on to vegetation, rocks and other suitable substrates with their tails. Several species are monogamously pair-bonded and will not change spawning partners unless one of them

Table 1. Life History Characteristics of Popular Marine Aquarium Fishes that have been Spawned in Captivity

Mode of Reproduction	Egg Type	Number of Eggs	Egg Size mm (in.)	Incub Time in Days	Hatch Size mm (in.)	Larval Stage in Days	Reared in Captivity	Commercial	Species Reared
GONOCHORISIM (separate sexes)									
Syngnathidae — seahorses	Pouch brooder	50–1500	?	20–28	6–13 (.2–.5)	?	Yes	No	Six species (17)
Apogonidae — cardinalfish (nocturnal)	Oral brooder	20+	1–2.5 (.04–.1)	21–24	3–6 (.12–.24)	21	Yes	No	Banggai Cardinalfish (20)
Sciaenidae — drums	Pelagic	2000–5000	.8–1.2 (.03–.05)	1	2.5 (.1)	20–30	Yes	No	Jackknife fish, cubbyu (18)
Ephippidae — spadefish, batfish	Pelagic	1000–5000	1 (.04)	1	2.5 (.1)	15	Yes	No	Spadefish (21)
Chaetodontidae — butterfly fish (coral polyp feeders)	Pelagic	3000–4000	.7–.9 (.03–.035)	1	1.4–2 (.06–.08)	40–60	No	No	
Opistognathidae — jawfish (live in burrows)	Oral brooder	1000	.85 (.03)	7–9	4 (.16)	21–28	Yes	Yes	Yellowhead jawfish (22)
Blenniidae — blennies (benthic)	Demersal (attached)	1000	.8 × 1 (.03 × .04)	4–10	4 (.16)	18–20	Yes	No	Black-lined blenny (23) marbled blenny (24), + others (25,26)
Callionymidae — dragonets	Pelagic	?	.6–1 (.02–.04)	1	1–2 (.04–.08)	20–30	Yes	No	Mandarinfish (13)
SEQUENTIAL HEMAPHRODITISM (can change sex) PROTANDOUS (change from male to female)									
Pomacentridae (in part) — anemonefish or clownfish	Demersal (attached)	400–1500	1.5 (.06)	4–10	2.5–3 (.1–.12)	7–21	Yes	Yes	About 12 species of Amphiprion or clownfish (11 and references therein)
PROTOGYNOUS (change from female to male)									
Cirrhitidae — hawkfish	Pelagic	500	0.7 (.03)	1	1.5 (.06)	35–50	No		
Serranidae (in part) — swissguard basslet and reef basses	Pelagic	300	.6–.9 (.02–.035)	1	1.5–3 (.06–.12)	20	No		
Pseudochromidae — dottybacks or basslets	Demersal (egg mass)	500–2000	1–1.4 (.04–.055)	4–7	2–4 (.08–.15)	21–35	Yes	Yes	Dottybacks (13,14), royal gramma (27), blackcap basslet (28,29)
Plesiopsidae — comet or marine beta (secretive in caves/crevices)	Demersal (egg mass)	300–400	.95 (.04)	5–6	3–4 (.12–.16)	60	Yes	No	Marine beta (30–32)
Labridae — wrasses	Pelagic	500–7000	.5–1.2 (.02–.05)	1	1.5–2 (.06–.08)	30	Yes	No	Hogfish (33) spotfin hogfish to day 18 (32)
Pomacanthidae — angelfish	Pelagic	150–75,000	.6–.9 (.02–.035)	1	1.5–2.5 (.06–.1)	30	Yes	No	French, grey angelfish (34,35)
Pomacentridae (in part) — damselfish (intraspecific aggression)	Demersal (attached)	500–1000	.6–.9 (.02–.035)	3–5	2–4 (.08–.16)	30	Yes	No	Beaugregory (36), yellow-tailed damsel (37,38) threespot and white-tailed damsel (39)
Gobiidae (in part) — reef gobies	Demersal (adhesive)	100–1000	1–2 (.04–.08)	4–10	2–7 (.08–.28)	25–35	Yes	Yes	Green-banded, citron, neon goby + (40,41)
SIMULTANEOUS HEMAPHRODITISM									
Serranidae (in part) — hamlets, sea basses	Pelagic	1500	.7–1 (.03–.04)	1	2.2 (.09)	20–30	No		

dies or is lost (16). Seahorses exhibit an unusual type of parental care in which the male becomes 'pregnant.' After a courtship that extends over several days, the female deposits her eggs in the pouch of the male, where they are fertilized. The male carries the eggs in his pouch for several weeks. By the time young seahorses are released from the pouch, they are approximately 10 mm (0.4 in.) in length, are well developed, and are able to feed on small plankton like rotifers and crustacean nauplii. Young seahorses can triple in size in 3 to 4 weeks, and they reproduce within a year. Seahorses have been successfully bred and reared in captivity by researchers and hobbyists alike. Information on captive spawning and rearing of seahorses may be found in an article by Amanda Vincent (17).

Drums (Sciaenidae)

An exception to the general characteristics for easy-to-rear ornamentals are the sciaenids or drums. The drums are gonochorists, i.e. an individual is either male or female for its entire life. These fish produce floating or pelagic eggs that hatch in less than 1 day into 2.5 mm (0.1 in.) long larvae. The larvae are able to feed on small rotifers at first feeding, but may do better with added wild zooplankton. Growth is fairly rapid; metamorphosis to the juvenile stage occurs at about three weeks. Several species, including the jackknife fish and highhat, have been spawned and reared in captivity (6,18,19) but none are yet produced in sufficient quantity for the tropical fish industry.

SPECIES WITH POTENTIAL FOR CAPTIVE BREEDING

Many of the marine ornamentals that have been spawned in captivity are listed in Table 1. Some are already commercially available, and others have the potential to be reared successfully in captivity. Based on previous successes, the most obvious species for future work might include fish that change sex, care for their embryos, produce large larvae (>2 mm or 0.1 in.) that can feed on rotifers or brine shrimp nauplii, and quickly develop into juveniles.

OSMOREGULATION IN BONY FISHES

JOSEPH J. CECH, JR.
University of California, Davis
Davis, California

OUTLINE

Osmoregulation and Ionic Regulation of Marine Fish

Osmoregulation and Ionic Regulation of Freshwater Fish

The blood and body tissues of bony fishes (teleosts and chondrosteans) must have suitable proportions of water and the correct dissolved solutes to meet the requirements of their living cells (1–3). Solutes such as ionized substances (e.g., Na^+, Cl^-, Ca^{2+}, PO_4^{2+}, H^+, OH^-, NH_4^+) and dissolved organic compounds (e.g., amino acids, fatty acids, and sugars) must be regulated because of the vast solute concentration differences that typically exist between fish bodies and their environments. The regulation of body water and its total dissolved solutes is termed osmoregulation, for which two life-dependent strategies evolved among bony fishes that allow them to exist in marine and freshwater environments. Osmoregulation is inexorably linked to ionic concentration regulation (ionic regulation), the excretion of nitrogenous waste (principally ammonia), and acid-base balance. Although fish culture environments rarely undergo dramatic changes in salinity, routine fish-handling and transport procedures associated with culture operations usually stress fish. The consequences of these stresses often include increased internal acidity and increased movements of ions (via diffusion) and water (via osmosis) between fish tissues and the environment, due to increased gill permeability. Also, fish in high-density culture

environments may be stressed by hypoxic (low dissolved O_2), hypercapnic (high dissolved CO_2), or hyperoxic (higher than atmospheric levels of dissolved O_2) conditions. Hypercapnia, especially, increases environmental acidity, affecting the movements (particularly across gill tissues) of several ions between the fish and its environment. Overall, adequate regulation of the body's water and dissolved solutes is critical for the well-being of fish. To maximize production efficiency, culturists seek to optimize fish well-being, components of which include the understanding of fish osmoregulatory structures and mechanisms, and the understanding of osmoregulatory consequences of culture-related activities.

OSMOREGULATION AND IONIC REGULATION OF MARINE FISH

Marine environments (like the oceans) have dissolved salt concentrations that are more concentrated (termed "hypertonic") that those in the bodies of marine bony fish, and the bodies of marine bony fish have salt concentrations approximating one-third that of their environment (Table 1). Consequently, they tend to continually lose water to the environment and gain monovalent ions from it by diffusion, especially over the thin membranes of the gills. Teleosts (2) and chondrosteans, such as sea water-acclimated sturgeon (4–6), continually replace lost water by drinking (ingesting) sea water, but this results in an even larger dissolved salt intake (Fig. 1). Excess salts must be excreted via special (chloride) cells in the gill and opercular skin tissues and via the kidney. When sea water is ingested to replace water that has diffused into the environment, many ions, as well as water, are absorbed into the bloodstream across the intestinal wall. Teleostean kidneys primarily excrete the excess divalent ions (e.g., Mg^{2+}, SO_4^{2-}) that are ingested with the sea water, but they are of little help in excreting the much larger quantity of ingested monovalent ions. In fact, many marine

Figure 1. Diffusive (dashed lines) and carrier-mediated (solid lines) movements of major ions between bony fish and their hypertonic (seawater) and hypotonic (freshwater) environments. Arrows emanating from the posteriors of the fish models mostly reflect urinary excretions, although intestinal excretions may also play minor roles.

teleosts [e.g., oyster toadfish (*Opsanus tau*) and plainfin midshipman (*Porichthys notatus*)] have an aglomerular kidney to minimize water losses. Instead, the chloride cells, which are activated by cortisol and growth hormone secretions (see later), actively transport the excess monovalent anions against their overall concentration gradients back into the environment. The chloride cells are larger than the flat epithelial cells of the gills specialized for respiratory gas exchange (7). They are often termed alpha chloride cells to distinguish them from beta chloride cells, which are found in freshwater teleosts (8), and they are typically located on the gill filaments at the base of lamellae. Besides gill locations, chloride cells have also been found on the skin of several species, including the opercular epithelium of sea water-acclimated Mozambique tilapia (*Oreochromis mossambicus*) (9) and on larval turbot (*Scophthalmus maximus*) (10). Compared with most cells, chloride cells are packed with mitochondria, display extraordinary development of cytoplasmic microtubules, and contain an abundance of Na^+-K^+-ATPase (the enzyme

system that facilitates salt pump function). The Na^+-K^+-ATPase is located along the basolateral areas and in the extensive microtubular system of the chloride cell; it actively transports Na^+ out of the cell in exchange for K^+ (11). In this way, this enzyme maintains a high trans-cell-membrane Na^+ gradient, with high $[Na^+]$ in the tubules and the adjacent plasma and low $[Na^+]$ in the chloride cell cytoplasm (12). This high transmembrane Na^+ gradient drives a linked Na^+-Cl^- carrier system, increasing the cytoplasmic $[Cl^-]$. The buildup of Cl^- inside the chloride cell also increases the cell's electronegativity, and Cl^- follows its electrochemical gradient (including a negative-to-positive transmembrane potential) by passively moving out of the apical pit area into sea water (Fig. 2). Na^+ probably exits passively to sea water via shallow tight junctions between chloride cells or between chloride cells and accessory cells, driven by the positive-to-negative transepithelial potential (11). Researchers Utida and Hirano (13) have shown that both gill Na^+-K^+-ATPase concentrations and numbers of gill alpha chloride cells increase with exposure to increasing environmental salinity in the Japanese eel (*Anguilla japonica*).

OSMOREGULATION AND IONIC REGULATION OF FRESHWATER FISH

Freshwater environments (including lakes and streams) have much lower (hypotonic) salt concentrations than those in the bodies of freshwater fish, which contain about one-fourth to one-third the salt concentration of seawater (Table 1). Freshwater fish continually gain water from their environment and lose monovalent ions to the environment through diffusion (Fig. 1). The excess water is continually excreted through the kidneys as a large volume of dilute urine (up to one-third of the body weight per day). Control of diuretic (urine-producing) processes is influenced by many factors, including blood pressure, glomerular filtration, and kidney tubular reabsorption changes, which are mediated by hormones such as the renin-angiotensin system (14−16), atrial natriuretic peptide (17−20), and arginine vasotocin (21). Diffusional losses of monovalent ions (e.g., across the gill membranes) are reduced in environments that have higher calcium concentrations (i.e., hard water) (22) and from secretions of the pituitary hormone, prolactin (23−25; See the section

Figure 2. Current ideas on the mechanisms for Na^+ and Cl^- excretion across the gills of a seawater-acclimated fish via alpha chloride cells (CC) and adjacent pavement (PC) and accessory cells (AC). The many lines between the CC and the PC represent a deep tight junction, whereas the single line between the CC and the AC represents a shallow tight junction [based on (11)].
"Hormonal controls"). Lost internal salts are replaced with those taken in with food or those taken up at the gills, through the use of active transport mechanisms (Fig. 1). Therefore, an energy-requiring salt pump operates in special cells (including beta chloride cells) of the gills in freshwater fish as well, except that ions are pumped inward, rather than the reverse, as exhibited by the marine teleosts.

From the pioneering work of Krogh (26) and of Maetz and Romeu (27), a model has been formulated that describes ion-exchange mechanisms across the gills in freshwater teleosts. These ion-exchange mechanisms apparently reside in epithelial cells (including chloride cells). These beta chloride cells (8) occur on gill filaments between lamellae; and in fishes in very soft (low dissolved-ion concentrations) water, on gill lamellae (28). They resemble chloride cells in marine fish in that they contain mitochondria, the tubular system, and Na^+-K^+-ATPase; but they are different in that they are less numerous, usually occur singly, lack the apical crypt, and generally assist movement of Na^+ and Cl^- into the fish, rather than out (29). Figure 3 diagrammatically shows current ideas concerning these Na^+ and Cl^- movements. It is not known whether all of these movements take place in beta chloride cells or in other (e.g., flat epithelial) types. These ion-exchange mechanisms serve several functions besides maintenance of $[Na^+]$ and $[Cl^-]$ in the fish. The Na^+ exchange for NH_4^+ conveniently rids the fish of part

of its ammonia production, the principal waste product of protein digestive breakdown. Experimental injections of NH_4^+ into freshwater goldfish (*Carassius auratus*) thereby stimulated Na^+ influx (28). Both the Na^+ exchange for H^+ and the Cl^- exchange for HCO_3^- tend to maintain internal acid-base homeostasis. Interestingly, these same exchanges also occur, presumably for NH_4^+ elimination and acid-base balance, in marine fish (30). These exchanges exacerbate the osmotic and ionic regulation problems of marine teleosts in hypertonic sea water by bringing in extra Na^+ and Cl^- for elimination. There is also evidence for Na^+ uptake via a Na^+ specific channel, which is driven by the electrical gradient created by the active (H^+-ATPase system) extrusion of H^+ (Fig. 3). Although the presence and relative magnitudes of these different routes of Na^+ uptake in various fish remain uncertain, they are functionally equivalent in terms of their effects on acid-base balance.

The general "exchanges" of H^+ (or NH_4^+) for Na^+ and of HCO_3^- for Cl^- generally balance the acid-base and ionic requirements in good fashion (Fig. 3). However, this link can force unwanted adjustments in one system, while compensating for a disturbance in another. The osmotic problems fish face in maintaining their acid-base balance are among the main reasons they have a hard time surviving in high-acid waters, such as streams that drain many mines, or lakes contaminated by acid rain or acid snow. Because high environmental $[H^+]$ can both
Figure 3. Current ideas on the mechanisms for Na^+ and Cl^- movements across the gills of a freshwater-acclimated fish via beta chloride (or other) cells, with allied movements of CO_2 and NH_3 in various forms, via diffusive (dashed and dotted lines) and carrier-mediated (solid lines) processes [based on (99)].

inhibit H^+ excretion associated with Na^+ uptake across gill epithelia and increase passive ionic losses via paracellular pathways, acid-exposed teleosts often die from insufficient plasma NaCl. For example, Leivestad and Muniz (31) attributed the death of brown trout that were exposed to low-pH conditions in the Tovdal River (southern Norway) to extreme reductions in plasma NaCl.

OSMOREGULATION AND IONIC REGULATION IN EURYHALINE AND DIADROMOUS FISH

Whereas most bony fish are stenohaline (meaning that they have narrow salt-tolerance range) and have evolved the exact osmotic structures (e.g., the appropriate sorts of chloride cells and intercellular junctions between cells) and mechanisms (e.g., hormonal controls) necessary to cope with the relatively constant salt concentration of either marine or freshwater habitats, euryhaline fish have broader salt tolerance ranges. Examples of euryhaline fish include the sheepshead minnow (*Cyprinodon variegatus*), Mozambique tilapia, and striped bass (*Morone saxatilis*). Diadromous (meaning "to run across") fish move between freshwater and marine environments at discreet life stages. Examples of diadromous species include the Pacific lamprey (*Lampetra tridentata*), Pacific salmon (*Oncorhynchus* spp.), and the American eel (*Anguilla rostrata*). Regardless of the range of salt tolerance and how it may change during the life cycle of a fish, osmoregulation requires energy. Indeed, growth rates and swimming performance of fish may be affected by how much energy they allocate toward osmoregulation or other energy costs, such as activity. For example, euryhaline sciaenid fish (drums) are able to maximize metabolic efficiency [e.g., for optimal growth (32) or swimming performance capacity (33), when held near the midpoints of their salinity tolerance ranges, compared with those near their tolerance extremes]. In contrast, cultured milkfish (*Chanos chanos*) in southeast Asia grow best at very high salinities (55 ppt), compared with lower salinities (15 and 35 ppt) for other fish, because the fish reduces its voluntary activity rates at high salinities (34). The cost of osmoregulation is generally considered to be a small fraction of the overall energy costs of fish (35), although it probably increases with increases in activity (36).

Hormonal Controls

Cortisol (a steroid hormone from the interrenal tissue associated with the kidney) is critical in ionic regulatory control in hypertonic environments. Anguillid eels are catadromous (meaning "to run down") fish that migrate down rivers as adults to spawn in the ocean. Forrest et al. (37) noted that plasma cortisol concentration showed a five- to seven-day increase in freshwater-adapted American eels (*A. rostrata*) when they were transferred to seawater. Cortisol injection experiments support the notion that this transient peak morphologically prepares diadromous or euryhaline fish for survival in hypertonic environments (38). For example, cortisol injections stimulated an increase in chloride cell density in freshwater-acclimated Mozambique tilapia (39). Conclusively, direct exposure of freshwater-acclimated tilapia opercular membranes to cortisol increased chloride cell density, size, and Na^+-K^+-ATPase activity (40). Adaptive mechanisms, such as increased Na^+ excretion and Na^+-K^+-ATPase activity at the gills, increased water permeability of the urinary bladder (to retain water), and the increased uptake of ions and water in the gut (related to seawater drinking) have been associated with such cortisol-stimulated changes (41).

Changes in the ion-regulatory abilities of diadromous fish are typically associated with ontogenetic changes, mediated by hormones. Adult salmon and some trout are anadromous (meaning "to run up") fish that migrate up rivers from the ocean (or a lake) to spawn. Juvenile salmon and trout migrate down the rivers, usually to saltwater, after changing from a freshwater (parr) form to a seawater-capable (smolt) form. Seawater readiness among young salmon and trout species ranges from a modest springtime rise in resistance shown by underyearling steelhead trout (*Oncorhynchus mykiss*), and other trouts and charrs, to complete tolerance and survival in recently hatched chum (*O. keta*) and pink (*O. gorbuscha*) salmon alevins. For most salmonids, tolerance of marine conditions develops in the spring, prior to the seaward migration of the silvery smolts. Hoar (42) pointed out the importance of lengthening springtime photoperiods for timing these changes. On a finer scale, Grau et al. (43) showed that plasma thyroxine surges, which occur in coho salmon (*O. kisutch*) during their smoltification period, correspond to new moon phases during spring. High and low tidal heights and resulting tidal currents are accentuated when the gravitational pulls of the moon and the sun are additive (i.e., during new moons or full moons). New-moon-related strong outflowing currents, and dark nights, may decrease the young coho's predation vulnerability (through faster transit and poorer visibility) during their movements down tidally influenced rivers to the estuary. A few weeks after the thyroxine peaks, increased plasma cortisol concentrations (44) and the cortisol-related changes in chloride cells, urinary bladder, and intestine are observed (45), and the coho smolts migrate to the sea. Besides cortisol, the pituitary hormone, growth hormone (GH), also plays an important role in the parr−smolt transformation among anadromous *Salmo* and *Oncorhynchus* species (46). For example, freshwater-acclimated sea-run brown trout (*S. trutta*) yearlings regulate plasma ions better and survive in greater numbers after seawater exposure with injections of both GH and cortisol, compared with noninjected controls (47). Further, GH's effectiveness regarding young salmonid's ionic regulation in hypertonic environments may be linked with insulinlike growth factor-I (48).

Prolactin and Ca^{2+} play important roles in regulating Na^+ gill permeability in freshwater-acclimated teleosts. Prolactin prevents Na^+ diffusive loss in freshwater-adapted bony fish and minimizes increases in passive Na^+ loss as euryhaline forms pass from seawater to freshwater. For example, hypophysectomy (removal of the anterior lobe of the pituitary, where prolactin is synthesized) of freshwater-acclimated mummichogs (*Fundulus heteroclitus*) promotes a marked drop in plasma ion concentrations compared with sham-operated controls (49). The many ion-regulatory roles of fish prolactin are essentially opposite

those of cortisol regarding various physiological and morphological changes in the gills, gut, kidney, and urinary bladder of various species (50). Gill permeabilities in many species are also affected by the concentration of calcium (Ca^{2+}) in the water. It is known that addition of 10 mM Ca^{2+} to freshwater will reduce prolactin synthesis rates by 50% in tilapia (51). The sodium efflux from the plains killifish (*Fundulus kansae*) in freshwater is reduced by 50% when 1 mM Ca^{2+} is added to the water (52). Calcium can also reduce Na^+ permeability across the branchial epithelia of fish in seawater, such as *Anguilla* (53). Water permeability of rainbow trout gills is decreased as the number of calcium-binding sites in the gills increases (54). Gundersen and Curtis (54) showed that acclimation of rainbow trout to high-hardness (1.0 mM Ca^{2+}, as $CaCO_3$) water produced significantly fewer high affinity Ca binding sites in their gills, compared with those acclimated to water of low hardness (0.1 mM Ca^{2+}, as $CaCO_3$).

STRESS RESPONSES AND EFFECTS

Stressors such as extremely vigorous exercise, netting and handling, pronounced hypoxia (including air exposure), hypercapnia, hyperoxia, and dietary deficiencies may all have effects on the osmoregulation or ionoregulation of bony fish. Some of these factors may stimulate adaptive physiological changes (including enhanced aerobic performance capabilities). Mild and short-term stressors stimulate secretions of catecholamines, from chromaffin tissues, and cortisol, from the interrenal. The catecholamine (especially, epinephrine) and cortisol secretions lead to glucose mobilization for metabolic needs and cardiovascular adjustments to optimize aerobic efficiency (55,56). Epinephrine promotes shifting more of the gills' blood flow from filamental pathways to thin-walled lamellar pathways (a process termed lamellar recruitment) for enhanced gas exchange (57) at higher pressures due to increased cardiac output and systemic (body) vasoconstriction (58,59). In concert, cortisol mobilizes more epinephrine receptors on RBC membranes for maintenance of blood O_2 transport (60). However, prolonged or especially severe stressors overtax the stress response system and lead to ionic imbalances, decreased growth, increased metabolic exhaustion and disease incidence, and possible mortality (55). The increased lamellar blood flow increases gill permeability to water and small ions (61), as well as to oxygen, leading to the possible hydromineral imbalances in fish (62). Thus, stress will invoke water losses (and some monovalent ion gains) in marine fish and water gains (and some monovalent ion losses) in freshwater fish. Exercised *Oreochromis niloticus* that are acclimated to seawater tend to increase plasma osmotic pressure (from water loss) and tend to decrease osmotic pressure (from water uptake) after acclimation to freshwater (63). This trade-off between enhanced O_2 uptake and gill permeability is probably more costly for less-active species (e.g., sunfish) from lakes than for more-active ones (e.g., trout and shiner minnows) from streams (64). Gonzales and McDonald (64) showed that the former group has a much higher "Na^+ loss" to "O_2 gained" ratio after vigorous exercise (chasing in a tank) than the latter group.

Handling/Forced Swimming

If bony fish are stressed because of netting, tank transfer, or forced swimming, hormones are secreted and gill permeability to water and monovalent ions increases (62). When a stressed striped bass (*M. saxatilis*) is in freshwater, water rapidly diffuses into the fish (as revealed by a rapid gain in water weight) and overwhelms osmotic and ionic regulatory controls. The consequent mortality is high, compared with a group kept in brackish (near-isosmotic) salt concentrations (10 ppt salinity; 65,66). When intensively exercised and stressed from netting and handling, subadult striped bass incur an acidotic state. During stress recovery from exercise or handling in a hypertonic environment, both plasma Cl^- concentration and mortality rate increase, compared with a group recovered in 10 ppt salinity (near isosmotic) conditions (66). The addition of salt (NaCl, i.e., "rock salt") to the tanks or transport vessels holding stressed fish minimizes the osmotic gradient (and, consequently, water and ionic diffusion rates) between the environment and the fish's plasma, thus increasing survival. For striped bass, environmental salt (NaCl) concentration effects are more significant than those of water hardness ($CaCl_2$), regarding survival. Mazik et al. (65) found that juvenile striped bass that were transported and subsequently held in 1% NaCl solutions showed significantly more stable plasma Na^+ and Cl^- concentrations, and increased survival, compared with those in either soft freshwater or moderately hard (0.1% $CaCl_2$) freshwater. These authors attributed the observed striped bass mortalities to osmoregulatory dysfunction. Further, both cultured and wild young-of-the-year striped bass that had been exercise-conditioned (trained in flowing water) for 60 days at 1.2–2.4 body lengths/sec regulated plasma ions significantly better than unexercised striped bass, after capture and net-confinement stress (67). Truck-transport stress of largemouth bass (*Micropterus salmoides*) was reduced and related mortality was eliminated when fish were treated for diseases, starved for 72 hours before loading, lightly anesthetized, hauled at a cool temperature in physiological concentrations of salts, and allowed to recover in the same medium, minus the anesthetic (68). Transportation-related mortality of delicate delta smelt (*Hypomesus transpacificus*) was minimized after addition of salt and a commercial water conditioner that contained polymers (69).

Hypoxia

If significant decreases in environmental dissolved-oxygen levels (hypoxia) affect osmoregulatory function, the effects appear to be minor ones. Thomas and Hughes (70) found no change in plasma Cl^- concentration after 12-, 20-, and 120-minute exposures to mild hypoxia [60 mm Hg partial pressure of oxygen (PO_2); ca. 40% air-saturation] in freshwater rainbow trout. Claireaux and Dutil (71) show a slight, but significant, increase in Atlantic cod (*Gadus morhua*) plasma Cl^- (ca. 6 meq/L) after 6 hours exposure to mild hypoxia (ca. 60 mm Hg PO_2) in dilute seawater (21–28 ppt salinity), while Na^+ shows no significant change. In contrast, both plasma Cl^- and

Na^+ concentrations significantly increased (ca. 10 meq/L) when exposed to more-severe hypoxia (ca. 30 mm Hg PO_2) under the same salinity conditions. These authors explain their results in terms of fluid shifts (i.e., plasma water diffusing into white muscle, which contains increased lactate concentrations) and other exchanges at the gills.

Hypercapnia

Hypercapnic (high-dissolved CO_2) stress is becoming more common in cultured fish, as culturists increase the densities of fish in rearing tanks. The use of O_2 injection systems to hyperoxygenate water flowing into the rearing tanks allows dissolved O_2 levels to remain high at higher fish densities. However, the larger respiring biomass of more densely cultured fish produces more excreted CO_2, resulting in the hypercapnic conditions. The CO_2 is hydrated in the water and makes carbonic acid, which partially dissociates to H^+ (and HCO_3^-) ions, lowering water pH. The H^+ ions diffuse into the fish, lowering their internal pH. Fish respond by conserving their metabolically produced HCO_3^- ions (to buffer the H^+) and increasing their excretion of H^+ ions to restore pH towards the levels that exist under normocapnic (low, normal CO_2 levels) conditions. The H^+ efflux occurs mostly at the gills, but some of the acid excretion [e.g., 16% in rainbow trout (72)] can be accounted for in the urine. Interestingly, conserving HCO_3^- ions decreases HCO_3^- efflux, decreasing Cl^- influx, according to the ionic exchanges outlined earlier (Fig. 3). Thus, plasma Cl^- decreases in freshwater fish such as Arctic grayling [*Thymallus arcticus* (73)], rainbow trout (74), and carp [*Cyprinus carpio* (75)]. The magnitude of this response varies among species. Channel catfish (*Ictalurus punctatus*) show progressive plasma Cl^- decreases as environmental hypercapnia intensifies (76), whereas freshwater American eels show very slight Cl^- decreases with hypercapnic exposure (77). Simultaneous with the decreases in plasma Cl^-, increases in H^+ efflux also increase Na^+ influx, according to the previously discussed ionic exchanges (Fig. 3), and result in an increase of plasma Na^+. These increases vary with species, but they return to normal levels faster in a seawater, at least in rainbow trout (78). The result of these plasma Cl^- decreases and Na^+ increases is a widening difference between these two important plasma ions' concentrations, under hypercapnia. The longer-term physiological implications of these compromises between the regulation of ionic concentrations vs. acid-base status associated with hypercapnia in cultured fish have yet to be resolved (79). However, long-term (weeks to months) exposure to hypercapnia is known to decrease the growth rate of juvenile white sturgeon [*Acipenser transmontanus* (80)] and produce nephrocalcinosis in rainbow trout (81).

Hyperoxia

Dissolved oxygen levels greater than air saturation (hyperoxia) may be observed in some fish culture systems. For example, lightly loaded ponds with a significant plant biomass may show higher-than-atmospheric levels of dissolved oxygen during daylight hours, due to photosynthetic production by the plants (algae or macrophytes). Interestingly, these systems may show significant hypoxia during nighttime periods (especially, predawn) when all of the animal and plant biomass is using oxygen for respiration, and the lack of light prevents photosynthetic oxygen production. Another example is hyperoxia that results from improperly controlled oxygen injection systems (over-injection) in high-density culture systems. Because fish (at least, rainbow trout) gill ventilation is controlled by oxygen receptors in the gills (82,83), the high environmental PO_2s limit adequate excretion of CO_2 from the gills. Consequently, hyperoxia produces an internal hypercapnia (84), and the hyperoxic responses parallel those to hypercapnic conditions. For example, Wilkes et al. (85) showed that white sucker (*Catostomus commersoni*) exposed to 2.2–3.5 times atmospheric oxygen levels showed a significant (ca. 15 meq/L) decrease in plasma Cl^- with no significant change in plasma Na^+, apparently due to a reduction in branchial Cl^-–HCO_3^- exchange. Goss and Wood (86) also showed significant branchial efflux of Cl^- in rainbow trout during hyperoxic exposure (3.6–4.3 times atmospheric oxygen levels).

Dietary Deficiencies

Deficiencies in dietary nutrients, either in a total sense, via food deprivation, or in a partial sense, via inadequate nutrient concentrations, may affect the concentration of plasma ions. Food-deprived tilapia (*O. mossambicus*), when acclimated to seawater, show increases in plasma Cl^- concentration (87). Rainbow trout that are fed five diets with various fatty acid compositions showed similar plasma Na^+ and Cl^- concentration responses to exposure to 33 ppt. seawater at both 2° and 17 °C (36 and 63 °F) (88). Finally, juvenile carp [ca. 100 g (3.3 oz)] showed low plasma Mg^{2+} concentrations when fed a low-magnesium diet for 17 weeks (89).

OUTLINE

Ozone has been widely used in the disinfection of culture and rearing water. Ozone can achieve a higher level of disinfection than can ultraviolet radiation or the addition of chlorine and hypochlorite. Under ambient conditions, ozone gas or ozone gas dissolved in water is unstable and will rapidly decay back to oxygen. In freshwater, the half-life of ozone is typically measured in minutes, and the lack of a long-term residual is an important design advantage of ozone in aquatic systems. The ozonation of seawater can result in oxidation of the bromide ion into hypobromous acid, hypobromite ion, and bromate. These compounds (residual oxidants) are stable, and their toxicity must be considered in the design and operation of seawater ozone systems. The literature on aquatic uses of ozone is large, and general information on the uses of ozone in water treatment can be found in (1); the comprehensive bibliography prepared by Rosenthal and Wilson (2) is also very useful.

A general schematic of an ozone disinfection system is presented in Figure 1. Key components are (a) an air-preparation or liquid-oxygen supply, (b) two or more ozone generators, (c) an ozone contact system, (d) an ozone destruct system for off-gas, and (e) an ozone destruct system for removing ozone from the process water. Not all of these components may be present in a given system.

PHYSICAL AND CHEMICAL PROPERTIES OF OZONE

Physical Properties of Ozone

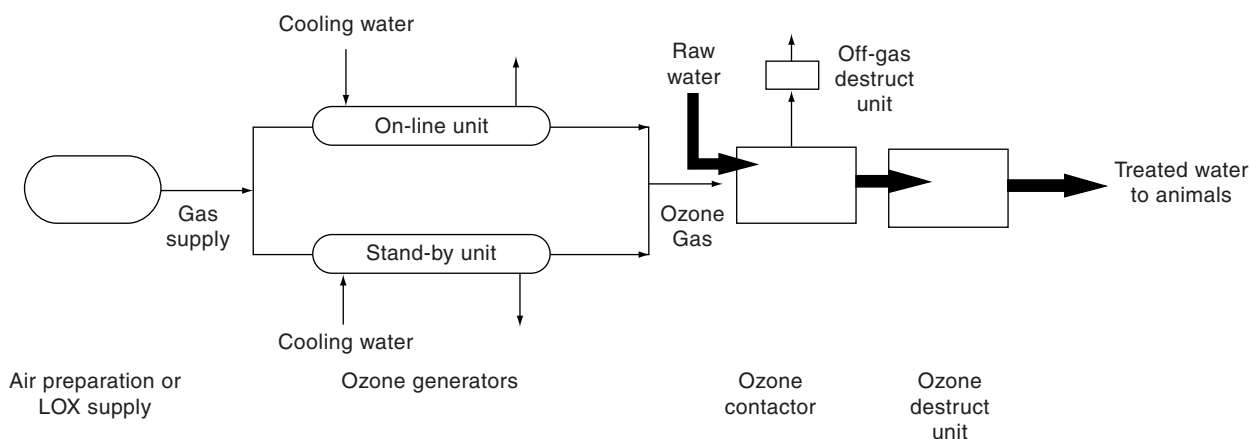
The ozone molecule contains three atoms of oxygen (O_3) with a molecular weight of 48 g/mole, and has a density


Figure 1. Typical process schematic diagram for an ozone system.

of 2.144 g/L [0 °C, (32 °F), 1 atm]. It is colorless and has a distinctive, pungent odor. Ozone gas is unstable and must be generated on-site. Ozone will react with a number of organic and inorganic molecules and will decay to the dioxygen molecule (O_2). The solubility of ozone at 0 °C (32 °F) is approximately 1,400 mg/L for pure gas or 70 mg/L for a 5% gas concentration (3).

Reactions of Ozone in Pure Water

The stability of ozone in water is affected by pH, temperature, exposure to ultraviolet radiation, and ozone concentration (3). The oxidization potential of ozone in an acidic solution is −2.07 v, compared to the −2.8 v for the hydroxyl radical. The hydroxyl radical is one of the most reactive unstable molecules known. Because of the reactivity of the hydroxyl radical, the effectiveness of ozone in a specific application may be related to the hydroxyl radical concentration rather that the concentration of dissolved ozone.

Reactions of Ozone with Inorganic and Organic Compounds

The reactions of ozone with inorganic compounds generally follow a first-order kinetic law with respect to both ozone and the oxidizable compound (1). The rate constant may depend on the pH and concentration of other chemical constituents.

Oxidation of Ammonia. Ammonia can be oxidized by the following reaction (3):

$$4O_3 + NH_3 \longrightarrow NO_3^- + 4O_2 + H_3O^+ \tag{1}$$
The ammonia oxidation rate is pH-dependent and is slow for pH less than 9 (4). In typical freshwater applications, only 5−15% of the ammonia will be oxidized to nitrate by ozone. In seawater, the oxidation of ammonia by ozone is increased by the presence of the bromide ion (5). Unlike the direct ozonation of ammonia (Eq. 1), this reaction is affected very little by changes in pH.

Oxidation of Nitrite. Nitrite is quickly oxidized by ozone to nitrate (4):

$$NO_2^- + O_3+ \longrightarrow NO_3^- + O_2 \tag{2}$$

Oxidation of Iron and Manganese. Reduced iron and manganese (Fe^{2+} and Mn^{2+}) are common in groundwaters and at the bottom of surface-water reservoirs. Oxidization of these compounds to their insoluble forms (Fe^{3+} and Mn^{4+}) allows their removal by sedimentation or filtration. Manganese is often more difficult to remove than iron, especially when organics and humic acids are present (3).

Oxidation of Aquatic Humic Substances. Humic substances are an extremely complex and diverse group of organic materials that are produced by decomposition of natural plant and animal matter. The build-up of humic acid substances is responsible for the yellow-brown to black color of natural waters. Ozone is the treatment of choice for decreasing the color of natural water and increasing the biodegradability of humic acids. The use of ozone in large marine aquariums is often for color control as well as for disinfection and removal of organic compounds.

Oxidation of Bromide. In seawater, ozone can react with the bromide ion and ammonia (6,7) to form the hypobromite ion, bromate ion, hypobromous acid, and bromamine. Hypobromite ion and hypobromous acid are unstable oxidants with half-lives ranging from 1 to 12 hours (8). Bromate ions and bromamines are stable compounds. In seawater systems that use marine water sources, residual bromide compounds may become critical concerns when attempts are made to culture sensitive species.

Reaction of Ozone with Microorganisms. The reactions of ozone with cell constituents of microorganisms are not well understood, even *in vitro*. It is thought that the disinfection reaction of ozone occurs between proteins that are contained in the cytoplasmic membrane. Effective inactivation of protozoa, bacteria, and virus has been demonstrated in a variety of culture applications.

Ozone Demand and Decay Rates. When ozone is added to water, there is commonly an immediate ozone demand. This demand is related to the chemical composition of the water, its solids content, and its temperature. This chemical demand must be satisfied before the disinfecting chemical oxidation reactions can proceed. Measurement of the ozone demand involves dosing a water sample with a known amount of ozone gas and measuring the ozone concentration in solution (residual). The decay rate of ozone is also quite specific to water. The test for decay rate involves adding ozone until a given residual is achieved, and measuring the ozone residual as it decays.

Kinetics of Disinfection. In general, it has been observed that for a given concentration of disinfectant, the longer the contact time, the greater the kill (9):

$$\log \frac{N_t}{N_0} = -k't \qquad (3)$$

Here

$$N_t = \text{Number of organisms at time } t$$
$$N_0 = \text{Number of organisms at } t = 0$$
$$t = \text{time (minute)}$$
$$k' = \text{constant (1/minute).}$$

Because microorganism concentrations are sometime quite large, it is common to express these concentrations in terms of log units. Therefore, a concentration of 1,000,000 bacteria/mL would be equal to 6 log units. It takes the same contact time to reduce the concentration from 6 to 3 log units (1,000,000 to 1,000/mL) as it takes to reduce the concentration from 2 to −1 log units (100 to 0.1/mL). An infinite contact time is required to reduce the number of microorganisms to zero (sterilization).

Impact of Contact Time and Concentration. Within limits, it has been observed that concentration and contact time are related by the following relationship (9):

$$Ct = \text{Constant} \qquad (4)$$

Here

$$C = \text{concentration of disinfectant}$$
$$t = \text{time required to achieve a given kill.}$$

To achieve a given level of disinfection, the product of Ct must equal the given constant. Therefore, the size of the contact basin can be made smaller if the concentration is increased, and vice versa.

GENERATION OF OZONE

The corona discharge method (3) is the most widely used technique for aquatic systems. Ozone is formed in a corona discharge caused by the interaction between an electrical discharge and oxygen molecules. An alternating current is applied across the two electrodes. One of the electrodes is coated with glass or ceramic dielectric material to evenly distribute the electrical discharge over the surface. An ozone generator can contain two to hundreds of separate tube assemblies, depending on the required output capacity.

Ozone generators are typically defined by their operating frequency. Generally, the higher the frequency, the more concentrated the output gas. Typically, the energy requirements of an ozone generator are approximately 3 kWh/kg (6−7 kWh/lb) of ozone.

MEASUREMENT OF OZONE

Ozone is difficult to measure accurately, especially in the liquid phase. In most facilities, it is necessary to measure ozone concentrations in both the gas and the liquid phases.

Gas Phase

The most commonly used, and most reliable, method for determination of continuous gas-phase ozone levels is the UV absorption technique. This method relies on the absorption of ozone by UV light at 260 nm, according to the Beer−Lambert law.

Liquid Phase

Numerous analytical methods have been developed for the determination of liquid-phase ozone concentrations. Because of the rapid decay of ozone in water, no holding time is allowed; samples must analyzed immediately. Two methods of liquid-phase analysis are recommended for aquaculture applications where low-concentration determination is needed. One is the indigo trisulfonate wet chemistry method for standardization; the other is the potentiometric method for on-line continuous monitoring.

Indigo Trisulfonate. This method is based on the rapid stoichiometric decolorization of indigo trisulfonate in acidic solution. The change in absorbance, measured at 600 nm, is proportional to the concentration of ozone. This method is not subject to interferences from ozone oxidation and decomposition products.

The Potentiometric Method. The dissolved ozone probe's (DOP) sensor consists of a working electrode, a reference electrode, and a buffered salt electrolyte solution. As ozone diffuses through the membrane, it is reduced at the cathode. The resulting flow of electrons is proportional to the ozone concentration.

Monitoring and Control of Ozone Systems

A monitoring and control program is necessary to safely and accurately control ozone dosage and to ensure that the residual ozone concentration in the water supply for the rearing units is safe for the culture species. Manual monitoring and control systems may be adequate for some applications.

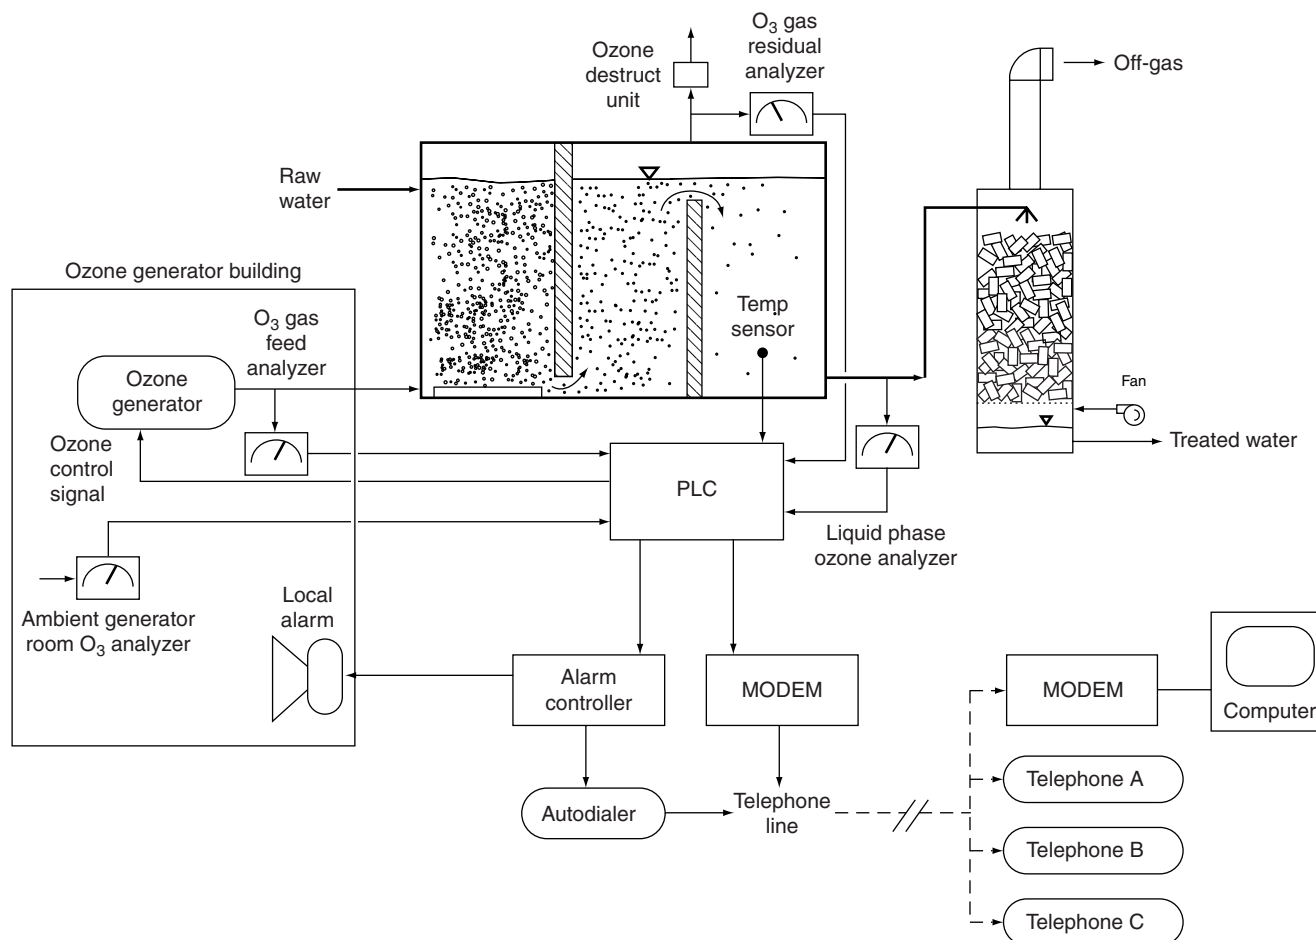
For critical applications or where influent water quality changes significantly over the day, an on-line system


Figure 2. Typical schematic of an on-line ozone monitoring and control system (the PLC, or programmable logic controller, is a fault-tolerance industrial computer that is commonly used for process control).

may be necessary. An on-line monitoring and control system will consist of on-line gas-phase monitoring equipment, on-line liquid-phase monitoring equipment, and a programmable logic controller. Figure 2 provides a representative schematic of a typical on-line ozone monitoring and control system.

TOXICITY OF OZONE

Personnel

Ozone gas is toxic to humans, and in the United States (10), exposures are limited as follows:

- 0.1 ppm by volume (0.2 mg/m^3 NTP) determined as a time-weighted average over a full working day (8-hour maximum),
- 0.2 ppm by volume (0.4 mg/m^3 NTP) as maximum 10-minute exposure.

At low concentrations, ozone has a very distinctive smell, and it can be detected well below the daily safety criteria limit.

Pathogenic Organisms

Information on the impact of ozone on pathogenic organisms can be obtained through inoculation of a water sample with the test organism, followed by ozonation of the sample and measurement of the number of surviving organisms with time. A curve is then fitted through the experimental data. The required concentration, detention time, or Ct (concentration × time) is typically predicted for a 1-log (90%), 2-log (99%), 3-log (99.9%), or 4-log (99.99%) reduction in organism concentration. Detailed information on the impact of ozone on a number of freshwater and marine pathogens is presented in Table 1. While literature on effective inactivation rates is useful, pilot-scale work is generally necessary to determine the required dose or Ct.

Aquatic Animals

Lethal levels can be as low as 9.3 μg/L parts per trillion and sublethal effects have been observed below 5 μg/L parts per trillion (11). Under production conditions, ozone concentrations in the range of 10–20 μg/L parts per trillion (measured at the discharge from the contactor) have been found to have no impact on salmonid eggs and fry (12) because the chemical ozone demand from uneaten feed and waste products will quickly reduce the ozone residual to

Table 1. Values of Ct for a 99 and 99.9 Percent Inactivation for Various Pathogenic Organisms

| Pathogen | Temperature (°C/°F) | Salinity (g/kg) [ppt] | Ct (mg/L·min) | | | Reference |
			99% Kill	99.9% Kill	Design Value	
Enterococcus seriolicida	25/77	34.4	0.123	0.186	—	18
Vibrio anguillarum	25/77	34.4	0.056	0.084	—	18
Pasteurella piscicida	25/77	34.4	0.081	0.123	—	18
Mixed bacteria population	25/77	34.4	0.200	0.621	—	18
Infectious hematopoietic necrosis virus	4-16/39-61	0	—	—	2.0	19
Ceratomyxa shasta	12-17/54-62	0	—	—	1.0	12

nonsignificant levels. A general criteria of 10 µg/L parts per trillion should be protective of most species and life-stages; this criterion will be over protective for many culture animals that are reared under production conditions, and needs to be evaluated on a case-by-case basis.

OZONE CONTACTOR SYSTEMS

The most common ozone contact systems (a combination of gas mixing and detention time for inactivation) are the deep-tank contact basin and the injector system.

Deep-Tank Contact Basin

The deep-tank contact basin is conventional technology that has been used successfully in the drinking-water field for at least 40 years. The water depth is in the range of 5–7 m (15–21 ft). Commonly, the contact basin is divided by baffles into 3 or 5 separate chambers. The ozone-gas mixture is introduced into the first chamber by porous diffusers mounted on the bottom of the chamber.

Injector Systems

The most common type of injector system uses a number of venturi eductors or static mixers placed in parallel. Ozone gas is supplied to each eductor. The eductors require 170 to 200 kPa (25 to 30 psi) of pressure for operation, so a booster pump system is commonly needed. Static mixers operate best at lower water pressures

OZONE REMOVAL AND DESTRUCTION

Ozone removal and destruction is needed for both undissolved ozone gas from the contact system and for the residual ozone in the process water prior to use.

Gas Phase

For contact systems that do not result in 100% transfer into the water, the ozone gas in the off-gas must be collected and the ozone converted back into oxygen and vented to the atmosphere. This conversion and venting process is generally accomplished by passing the ozone-gas mixture through either a thermal ozone destruct unit or a catalytical destruct unit. Since 100% transfer does not always occur, a decision to leave out the destruction unit should be carefully considered.

Liquid Phase

Effective control of ozone residuals in the process water is necessary for protection of the culture animals. If effective control is not provided, the applied dose must be limited to levels that may not be effective for disinfection or for oxidation of the targeted organic.

Detention Time. The simplest process for ozone removal in the liquid phase is to provide enough detention time to allow the ozone to naturally decay back to oxygen gas. For large production flows, the required detention storage volume is significant; such storage offers the potential for reintroduction of pathogens from outside sources.

Air Stripping. Dissolved oxygen gas can be removed using diffused aeration, a cascade aerator, or an air-stripping column. This process will not remove ozone-produced bromide compounds. Air stripping is generally the most cost-effective way to remove residual ozone in a temperate climate. Careful design is important to prevent entrainment of air below the stripping column.

Granular Activated Carbon. In seawater applications, granular-activated carbon (GAC) can be used to remove both residual ozone, ozone-produced bromide compounds, and other organics. Carbon will be consumed by the reaction and spent carbon will need to be replaced or regenerated.

Ultraviolet Radiation. Ultraviolet radiation has been used to reduce residual ozone in the process water prior to its use in the rearing units. The primary application of ultraviolet radiation for ozone destruction has been in cold climates where air stripping would result in excessive heating costs. Ultraviolet radiation in the range of 250 to 260 nm catalyzes the decomposition of ozone to oxygen. An average dose of 90,000–150,000 µW·s/cm² is required to reduce an ozone residual of 0.3 to 1.0 mg/L (ppm) to a non-detectable concentration. Higher doses are required at lower temperatures.

Chemical Addition. Sodium thiosulfate will react with ozone-produced oxidants in seawater (13). The amount of ozone-produced oxidants removed per milligram of sodium thiosulfate ranges from 1.13 mg (1 hours of aeration) to 0.16 mg (48 hours of aeration).

GENERAL DESIGN CONSIDERATION

General design considerations that apply to all ozone systems are discussed in the following section.

Determination of System Capacity

Ozone output requirements depend on analytical testing to establish ozone demand [applied dose in mg/L (ppm)] and a knowledge of the flow requirements of the system. Ozone output is typically given in kg or lb/day of production. For example, a flow of 19 million liters (5 million gallons) per day, requiring 2.5 mg/L (ppm) of applied dose, would require 47 kg/d (104 lb/d). Assuming that the system would be operated at only 80% of capacity, a single ozone generator of 60 kg/d (132 lb/d) would be needed. Two units would be needed for critical applications where it was necessary to provide 100% standby duty.

System Control

Ozonators are controlled in several ways. The most common is to vary the power to the dielectrics. This can be accomplished either manually or by using an external signal (flow, ozone off-gas, or ozone concentration in the contactor). By using a programmable logic controller, the system can be automated and operated with constant attention if conditions vary.

Material Considerations

The extreme oxidation potential of ozone requires careful selection of construction materials to prevent corrosion and deterioration. Generally, the most serious problems occur with a mixture of ozone gas and water vapor. Fewer material problems are reported with dry or dissolved ozone gas.

Piping for dry ozone service should be stainless steel, AISI 316 or 316L, or better, and connection should be made with TIG welding and Teflon-filled gaskets. Valves should be 316 or 316L stainless steel or common steel with a Kynar body liner, 316 stainless steel disc, and Teflon seat and seals or 316 stainless steel, disc, and shaft, with TFE-filled seat and seal (14). Threaded pipe connections tend to leak with time and should be welded. However, flanges are necessary to remove fittings or connections. For small systems, Teflon tubing and fittings can be used. PVC should be used only after careful examination of the conditions and service computability. For example, in seawater applications, PVC may be preferable to 316 stainless steel due to chloride corrosion concerns.

Reinforced concrete has proven resistant to both dissolved ozone gas and ozone–water mixture in the head-space of contact chambers. The gas space concrete should be of Type 2 or Type 5 Portland cement using a low water/cement ratio (14). All fittings and seals should be stainless steel or Teflon.

Some fiberglass resins are resistant to dissolved ozone gas in the concentrations found in aquatic systems applications; the resistance of fiberglass to wet gas conditions depends very strongly on the specific resin used; fiberglass should be avoided for long-term critical applications.

DESIGN OF OZONE FACILITIES FOR AQUATIC SYSTEMS

Disinfection

Ozone has been shown to be effective at inactivating bacterial, viral, and protozoan agents at low dosages [0.5 to 1.5 mg/L (ppm) applied dose] in comparison to other chemical disinfectants. As discussed, the Ct for an ozone system is calculated based on the actual ozone residual [mg/L (ppm)] following the contact period, multiplied by the detention time of that mixing/contact unit. This approach provides a conservative method to establish the required ozone generator capacity.

General Improvements in Water Quality

Ozone has attracted a great amount of interest recently for the purpose of enhancing water quality in reuse systems for rearing shrimp and fish (15,16). These systems have generally not included effective ozone removal, so the applied ozone doses have been limited to prevent ozone toxicity problems. These systems have not been designed to provide a given level of disinfection, although some disinfection will occur (17). Improvements in water quality and solids removal have resulted from applied doses in the range of 0.025 to 0.045 kg ozone/kg of feed (16); but the difference between the required dose for water quality improvements and toxicity problems is very narrow. While this application may have the potential to improve general water-quality conditions in reuse systems, more focused research is necessary to rationally develop the design parameters and operational strategies for its use.

Applications to Aquaculture Design

Bibliography

Fish performance engineering consists of the application of environmental physiology and bioenergetics to fish production in aquaculture systems. Fish performance engineering is a primary consideration in aquacultural engineering, in which fish metabolism, feeding, and growth represent the primary processes for the benefit of which fish culture systems are designed and managed. The objective of this entry is to provide an overview of the methods and models used in fish performance engineering, with a focus on analytical tools suitable for practical application. The scope of the term 'fish performance' in this context includes (*1*) fish response to environmental variables and (*2*) quantitative aspects of fish metabolism, feeding, growth, and survival. The methods presented here are applicable to aquaculture facility design and management for the production of both finfish and crustaceans (together referred to hereafter as "fish") in all types of aquaculture systems.

FISH PERFORMANCE PRINCIPLES

The fundamental principles of fish performance engineering are based upon physiological energetics (1–3). Physiological energetics, commonly referred to as bioenergetics, concerns the rates of energy losses and gains and the efficiencies of energy transformation for a whole organism or group of organisms; this mid-level focus distinguishes it from cellular energetics (4) and ecological energetics (5). In this respect, fish and fish foods can be expressed in terms of their material composition or in terms of the energy equivalent of these materials. Fish gain energy through food ingestion (I), store energy as growth (G), lose energy through excretion (E), and expend energy through metabolism (M). To apply physiological

energetics to fish performance engineering, these energy sources and sinks are combined into a bioenergetic budget: $I = G + E + M$. In response to analytical objectives, this budget can be re-arranged to calculate energetic capacities (or scopes) for fish activity (6,7), growth (8–10), or feeding (11–13).

A flow chart of the sources, sinks, and pathways of fish bioenergetics is presented in Figure 1. For an individual fish, energy input begins with 'ingested energy' (I), and food conversion efficiency is the proportion of ingested energy incorporated as growth. In practical
Figure 1. Flow diagram of fish bioenergetics, showing energy sources and sinks, controlling processes, and distribution paths.

applications of bioenergetics, however, fish are managed and analyzed as populations (fish production lots), and the quantities of feed applied, feed wasted, and fish mortality are also included in food conversion efficiency values. As shown, metabolic energy demand consists of several components. Maintenance metabolism includes (1) standard metabolism, defined as the rate of energy use by a fasting fish at rest, and (2) additional demands such as those due to responses to environmental stress. Active metabolism consists of the energy demands of swimming, aggression, and feeding (locomotion). Heat increment (or specific dynamic action) represents the energy costs of processing and assimilating food. Metabolic energy demands are supported through the catabolism of food substrates, in which oxygen is consumed and metabolites (or catabolites) are produced. In practical applications of bioenergetics, components of fish metabolism are combined into total oxygen consumption and metabolite excretion rates, usually expressed as *g (compounds)/kg (fish)/day* (grams of compound per kilogram of fish per day) or *mg (compound)/kg (fish)/hr*.

Rates of fish metabolism, feeding, and growth vary diurnally, seasonally, and over the life of a fish, in response to changes in fish and in environmental factors (14). Fish performance is a graded response to temporally and spatially graded environmental conditions, and the effect of environmental variables on fish activity, appetite, and growth is mediated through metabolism. The variables driving fish performance include (1) fish rearing-unit shape and dimensions, hydraulic characteristics, and water velocity, (2) water quality, (3) length of day and exposure of fish to direct light, (4) disturbances due to human activity and to fish-handling practices (e.g., fish grading), (5) fish density, as it affects fish behavior and access to food resources, (6) fish development state and size, (7) the availability and quality of natural food resources, and (8) the quality, application rates, and application methods of prepared feeds. The response variables of fish performance include (1) disease resistance, stress accumulation and compensation, and mortality, (2) swimming capacity, behavioral aggression, and competition for limited food resources, (3) appetite levels, food ingestion rates, and food assimilation efficiencies, (4) sexual maturation and reproduction, and (5) somatic growth.

FISH PERFORMANCE MODELING

For practical application of bioenergetics to fish performance engineering, bioenergetic budgets are formulated into quantitative models of fish metabolism, feeding, and growth. Development of these models relies on the use of simplifying assumptions about the underlying mechanistic processes and on the use of empirical data for model calibration. Fish performance models consist of one or more equations and rules of application, defined equation inputs and outputs (independent and dependent variables), and equation coefficients and exponential terms (parameters). Fish performance models may be used to analyze historical production data (through regression) or to predict future fish production (through simulation).

Values are established for model parameters by using procedures of model calibration and validation (15). Calibration is accomplished by using regression procedures on empirical datasets to generate parameter values. Validation is accomplished by using additional, independent datasets to test predictive accuracy. Aquaculture production trials are used to generate these datasets, in which data are collected at regular time intervals for fish length and weight samples, feed application rates, water quality, and other fish and environmental variables. Calibrated models are specific to a given fish species or stock, and closely related species share similar parameter values. When independent variables that significantly affect fish performance are not adequately accounted for in the model, calibrated models may be specific to an aquaculture system type or site location. While these site-specific models are not generally applicable, they are often useful for the site at which they were developed, and they can take advantage of simplified methods and reduced requirements for input data. After formulation, calibration, and validation, model application requires that values be provided for independent (input) variables. For analysis of historical fish performance, input variables can be specified using historical, empirical data. To simulate future fish performance, input variables can be based on past, empirical data, using daily, weekly, or monthly mean values, or they can be predicted by the use of system-level simulation models (16).

Models of fish metabolism, feeding, and growth intended for practical application are found throughout the aquaculture literature. These models utilize simplifying assumptions and aggregation of processes, in terms of the specific driving and response variables considered and of the functions used to represent bioenergetic processes. All of the potential driving variables of fish performance (listed earlier) may be considered in the design and management of aquaculture facilities, but fish size, water quality, food quantity, and food quality normally receive the most attention. The response variables of primary interest are mortality, somatic growth, feeding, and total metabolic rates. Models intended for practical use generally calculate the effects of environmental factors on fish growth and feeding rates directly, then calculate metabolic rates as a function of feeding rates. Feeding and growth rates are related by the use of food conversion efficiencies or ratios, and the metabolic rates of concern are limited to oxygen consumption and metabolite excretion.

ENVIRONMENTAL CRITERIA AND RESPONSE

Within the stated scope of this discussion, the environmental criteria of interest are water quality and related fish and feed loading variables. For this purpose, the criteria values listed in Table 1 are intended as approximate guidelines. Criteria values are dependent on the nutrition status, stress level, life stage, body size, and environmental acclimation of the fish. In addition, criteria for a specific variable may depend on levels of other variables (e.g., minimum criteria for dissolved oxygen increase as carbon dioxide levels increase). Environmental criteria can be used as parameters in fish performance models, as design

Table 1. Fish Environmental Criteria, as Defined by Low and High Values for Tolerance ($C_{min}t$ and $C_{max}t$) and Optimum ($C_{min}o$ and $C_{max}o$) Ranges, with Respect to Fish Growth[a]

Physical Variables	Criteria				
Temperature (C)	Fish Species	$C_{min}t$	$C_{min}o$	$C_{max}o$	$C_{max}t$
	Brook trout	3	8	13	19
	Pacific salmon	3	9	14	22
	Rainbow trout	3	11	17	23
	Atlantic salmon	3	12	18	22
	Yellow perch	8	18	22	27
Basis: primary controlling	White sturgeon	6	19	22	26
factor of fish performance	Striped bass	7	20	25	31
	Marine shrimp	10	20	30	36
	Centrarchids	12	20	28	33
	Freshwater prawns	10	22	28	33
	Hybrid striped bass	10	23	28	33
	Common carp	5	24	30	35
	Channel catfish	12	25	30	34
	Tilapia	15	28	33	37

Salinity (ppt)	• *Basis*: primary physiological criterion, and highly dependent on fish species and life stage. • *Values*: narrow ranges for stenohaline species, wider ranges for euryhaline species; criteria range from near zero to >35.0.
pH	• *Basis*: primary controlling factor of fish performance. Exerts major impact on other water quality variables (e.g., un-ionized ammonia of total ammonia) and other facility processes (e.g., biofilter nitrifying bacteria). • *Values*: approximate $C_{min}t$–$C_{max}t$ range is 6.5–8.0 for trout, 6.0–9.5 for catfish and tilapia.
Alkalinity (mg $CaCO_3$/L)	• *Basis*: closely related to pH and water hardness criteria; used mainly as a measure of buffering capacity against decreases in water pH. • *Values*: approximate ranges are ≥20 for flow through systems, ≥50 for phytoplankton systems, and ≥100 for recirculation systems, but ≤500 mg/L for all systems.
Hardness (mg $CaCO_3$/L)	• *Basis*: calcium and magnesium are required nutrients for body composition and osmoregulation. • *Values*: approximate $C_{min}t$–$C_{max}t$ range is 50–350

Fish Biomass Loading	Criteria
Biomass density (kg/m^3)	• *Basis*: biomass support and fish behavior. Values range widely and depend on fish species, feeding rate, and type of culture system. Used for systems with known biomass capacities. • *Values*: expressed as biomass density index (kg/m^3/cm-length). Approximate $C_{max}t$ are 0.05 for extensive production, 1.5–3.0 for salmon hatcheries, and 3.0–20.0 for intensive production.
Biomass loading (kg/m^3/d)	• *Basis*: biomass support. Values range widely and depend on fish species, influent water quality, and production intensity. Used for systems with known biomass loading capacities. • *Values*: expressed as biomass loading index (kg/m^3/d/cm-length). Approximate $C_{max}t$ are for 0.1 for intensive trout production and 0.3 for intensive tilapia production.
Feed loading (kg feed/m^3/d)	• *Basis*: system capacity to digest feed; related to oxygen demand and metabolite production. Highly dependent on fish species and culture system. Used for systems with known feed loading capacities. • *Values*: approximate $C_{max}t$ are for 0.1 for intensive trout production and 0.3 for intensive tilapia production; these example values are equivalent to biomass loading criteria for a 33-cm fish fed 3.0% of bw/day.
Water-exchange rate (number/day)	• *Basis*: biomass support and water velocity, and other considerations similar to biomass loading. Used for systems with known water-exchange rate requirements. • *Values*: values range from zero, for makeup of water loss only, to three exchanges per hour (72/day) for intensive, flowing water culture.
Cumulative oxygen consumption (COC, mg O_2/L)	• *Basis*: metabolite stoichiometry and criteria in relation to oxygen consumption. Used for systems with known relationships between COC values, pH values, and metabolite concentrations. • *Values*: for a pH range of 6.0–9.0, approximate $C_{max}t$ values range from 14 to 25 for carbon dioxide constraints and from 0.5 to 100 for un-ionized ammonia constraints.

(continued)

Table 1. *Continued*

Dissolved Gases	Criteria				
Dissolved oxygen (mg O_2/L)	Fish Species	$C_{min}t$	$C_{min}o$	$C_{max}o$	$C_{max}t$
Basis: primary limiting factor of fish performance.	Salmonids	5	7	(Use percent saturation)	(Use percent saturation)
	Striped/hybrid bass	4	6		
	Catfish	3	6		
	Carp	2	6		
	Tilapia	2	5		
Dissolved oxygen (% saturation)	All species	30	50–70	200	300
Dissolved carbon dioxide (mg CO_2/L)	• *Basis*: primary limiting factor of fish performance; minimum criteria are zero in value, maximum criteria decrease as dissolved oxygen levels decrease below lower optimum levels. • *Values*: approximate $C_{max}t$ range is 20.0–50.0, but values $\geq$100.0 are reported to be tolerated for some species.				
Total gas pressure (TGP; % saturation, or mm-Hg pressure difference between TGP and local barometric pressure)	• *Basis*: gas supersaturation can cause gas-bubble formation in fish blood and tissues (gas bubble disease). • *Values*: approximate $C_{max}t$ range is 105–110% sat. or 38–76 mm Hg. Approximate $C_{max}t$ is 102–103% sat. for sensitive species and life stages (e.g., eggs).				

Metabolites	Criteria				
Un-ionized ammonia (mg NH_3-N/L)	Fish Species	$C_{min}t$	$C_{min}o$	$C_{max}o$	$C_{max}t$
Basis: primary limiting factor of fish performance and concentration is a function of total ammonia, pH, temperature, and salinity.	Salmonids	0.0	0.0	0.01	0.2
	Striped/hybrid bass	0.0	0.0	0.02	0.3
	Carp	0.0	0.0	0.02	0.5
	Crustaceans	0.0	0.0	0.05	0.7
	Catfish	0.0	0.0	0.05	0.9
	Tilapia	0.0	0.0	0.10	1.0
Nitrite (mg NO_2-N/L)	• *Basis*: primary limiting factor of fish performance; minimum criteria are zero, and criteria are highly dependent on species, life stage, water salinity, hardness, and dissolved oxygen. • *Values*: approximate $C_{max}t$ is 0.1 for trout, 2.0 for catfish, and 4.0 for tilapia. $C_{max}t$ may range from 10–20 for tolerant species when sufficient chloride is present as natural or added salts.				
Nitrate (mg NO_3-N/L)	• *Basis*: effect on fish is likely limited to impaired osmotic regulation at very high concentrations; this effect may occur in recirculating fish culture systems with low system exchange rates and no denitrification processes. • *Values*: approximate $C_{max}t$ range is $\leq$50–300 for all species.				
Particulate solids (mg dry wt./L)	• *Basis*: impaired fish ventilation and gill abrasion; tolerance to solids is highly dependent on fish species. Includes inorganic, organic, and phytoplankton particulate solids. • *Values*: approximate $C_{max}t$ is 10–80 for solids of feed and fecal origin — for example, $C_{max}t$ is 25 for salmonids, a species with low tolerance to particulate solids.				

[a]Values represent an approximate consensus of reported values in the aquaculture literature. Use of the terms "controlling factor" and "limiting factor" conforms to their standard use in bioenergetics (1).

criteria for fish culture systems, and as management criteria for assessing results of environmental monitoring. For modeling applications, a fish growth and feed model generally includes water temperature as an independent variable or makes clear that its use is restricted to a given temperature range. Water quality variables in addition to temperature need to be considered if their levels fall significantly outside of optimum ranges. Fish biomass and feed loading variables can be used as indicators of water quality, but only when relationships between the loading levels and the associated concentrations of dissolved oxygen and metabolites have been determined. Relationships between loading and water-quality variables are highly dependent on the specific aquaculture system.

Up to four criteria values are used for each environmental variable: the minimum and maximum values for the tolerance and optimum ranges. In the optimum range, maximum growth rates and food conversion efficiencies are supported with respect to the given variable. The width of the optimum range is related to the capacity for environmental acclimation by the fish. The tolerance range exists outside of the optimum range. Conditions here cause a reduction in growth rates and accumulation of stress, depending on the elapsed time and extent of deviation from optimum limits. The lethal range exists outside of the tolerance range. Conditions here do not support fish growth and, when sustained, may result in mortality. Specification of only the lower or upper criteria may

Table 2. Typical Functional Forms Used to Calculate Performance Scalars as a Function of Given Water-Quality Criteria and Variable Values

Parameters and Variables	Definition
$C_{min}t$	Minimum tolerance criterion
$C_{min}o$	Minimum optimum criterion
$C_{max}o$	Maximum optimum criterion
$C_{max}t$	Maximum tolerance criterion
V	Water-quality variable (same units as associated criteria)
S	Individual scalar value (0−1)
CS	Combined scalar value (0−1) = minimum of individual separable scalars or product of interactive scalars

Scalar	Condition	Function
All	$V \leq C_{min}t$ or $V \geq C_{max}t$	$S = 0$
Linear	$C_{min}t < V < C_{min}o$	$S = (V - C_{min}t)/(C_{min}o - C_{min}t)$
	$C_{min}o \leq V \leq C_{max}o$	$S = 1.0$
	$C_{max}o < V < C_{max}t$	$S = (C_{max}t - V)/(C_{max}t - C_{max}o)$
Exponential	$C_{min}t < V < C_{min}o$	$S = \exp\{-k1 * [(C_{min}o - V)/(C_{min}o - C_{min}t)]^{k2}\}$
	$C_{min}o \leq V \leq C_{max}o$	$S = 1.0$
	$C_{max}o < V < C_{max}t$	$S = \exp\{-k1 * [(V - C_{max}o)/(C_{max}t - C_{max}o)]^{k2}\}$
Polynomial	$C_{min}t < V \leq C_{max}o$	$S = a + bV + cV^2$
(second order and higher)	$C_{min}o \leq V < C_{max}t$	$S = d + eV + fV^2$

be sufficient, depending on the specific aquaculture practices in use and the environmental variable in question. For example, water temperatures and dissolved oxygen levels often vary below maximum optimum levels, and only maximum criteria need to be considered for fish metabolites.

Fish growth and feeding rates are scaled from zero to maximum rates on the basis of environmental conditions relative to specified criteria. Scalar values are calculated for each environmental variable considered, and the overall scalar is estimated as the minimum individual scalar value or scalar product. (The latter is used for interactive criteria such as oxygen and carbon dioxide.)

Normally, depth-averaged water quality is used in design and management, but, if the cultured organism is a bottom dweller (e.g., shrimp) and water quality is vertically stratified, then benthic water quality is used. Various equation forms can be used to calculate scalar values (Fig. 2; Table 2), and paired functions are often required to express fish response adequately over the full range of a given variable (12,17). This functional discontinuity complicates both the regression and use of these functions, but, for a given environmental variable, consideration of values both above and below the optimum range often is not needed under practical conditions. Criteria values used in scalar functions can be taken from the literature or can be determined by regression using fish production datasets, in which scalar functions are substituted into fish growth and feeding models.

EXPRESSIONS FOR FISH SIZE, GROWTH, AND FEEDING

The following expressions for fish size, growth rate, and feeding rate are used in fish growth and feeding models. All fish and feed weights used in this discussion are expressed in terms of wet weight (moisture content included), unless use of dry weights is noted. Specific rates and index values can be expressed as factors (e.g., 0.1) or as percents (e.g., 10%), and factors are often used to simplify equations. Mathematical operators used in this discussion include the following abbreviations: log (base-10 log); ln (base-e log); and exp (e to given power). For the sake of readability, conversions from metric will be left to the reader.[a]
Figure 2. Linear, exponential, and polynomial scalar functions used for modeling fish response to environmental conditions, applied to the response of tilapia to water temperature.

[a] 1 g = 0.0353 oz, 1 mm = 0.0394 in., 1 cm = 0.394 in., 1 kg = 2.205 lbs.

Table 3. Reported Values for Fish Condition Factor, where Le = 3.0 (18–20)

Fish Species	Fish Condition Factor (g/cm^3)
Northern pike	0.005013
Channel catfish	0.007964
Chinook salmon	0.008191
Steelhead	0.009425
Coho salmon	0.01034
Rainbow, brook, and brown trout	0.01122
Largemouth bass	0.01275
Blue tilapia	0.0233

Fish total length (L; cm) and body weight (W; g) are related by a length exponent (Le; range 2.5–3.5, typical value 3.0) and a fish condition factor (FCF; g/cm^3; Table 3). FCF varies with fish species, size, nutritional state, and water content (19,21). Parameters Le and FCF are established by linear regression, with log transformation (base 10 by convention) of geometric mean values (21):

$$W = FCF \times (L^{Le})$$

or

$$L = (W/FCF)^{(1.0/Le)}$$

or

$$FCF = W/(L^{Le})$$

where

$$\log(W) = \log(FCF) + [Le \times \log(L)]$$

Length growth rate (LGR; mm/day) is based on the change in fish length (L_o to L_t; cm) over a given time interval (t; days):

$$LGR = (10 \text{ mm/cm}) \times (L_t - L_o)/t$$

Absolute fish growth rate (GR; g increase/day) and specific growth rate (SGR; g increase/g fish/day or 1/day) are based on the change in fish weight (W_o to W_t; g) over a given time interval (t; days):

$$GR = (W_t - W_o)/t$$

and

$$SGR = [\ln(W_t) - \ln(W_o)]/t$$

Fish growth index (FGI; range 0–1) is based on the target or actual fish growth rate (GR) relative to the maximum growth rate obtained under satiation feeding (GRm) for a given growth interval:

$$FGI = GR/GRm$$

or

$$FGI = SGR/SGRm$$

For simulations of fish production over extended periods, in which it is desired to achieve a specified date and weight target (by control of feeding rates) but the varying of temperatures or other environmental scalars makes it difficult to predetermine GRm, FGI values can be adjusted over the course of iterative simulations by

$$FGInew = FGIprior \times [(W_{tt} - W_o)/tt]/[(W_t - W_o)/t]$$

where

$$FGInew = \text{FGI to be used in an iterative simulation;}$$
$$FGIprior = \text{FGI that was used in the prior simulation;}$$
$$W_{tt} = \text{target fish weight (g) to be achieved at target time tt (days);}$$
$$W_t = \text{fish weight achieved in prior simulation (g) at time t (days);}$$
$$W_o = \text{initial fish weight (g).}$$

Specific feeding rate (SFR; kg feed/kg fish/day or g feed/g fish/day) is based on the quantity of feed fed (FD; kg) over a given time interval (t; days) relative to total fish biomass (FB; kg) at the beginning or midpoint of the time interval:

$$SFR = FD/(FB \times t)$$

SFR may also be expressed as percent body weight per day (% bw/d). Fish feeding index (FFI; range 0–1) is based on the target or actual specific feeding rate (SFR) relative to the maximum (appetite satiation) specific feeding rate (SFRm) for a given growth interval:

$$FFI = SFR/SFRm$$

Food conversion efficiency (FCE; %) is based on the total feed applied (FD; kg) over a given time interval relative to the change in fish biomass (FB; kg) for this time interval (FB_o subtracted from FB_t; kg). The reciprocal value, food conversion ratio (FCR), is also commonly used. FCE and FCR values are typically calculated for fish populations, rather than for individual fish, so as to include losses due to applied feed that is not consumed and to fish mortality:

$$FCE = 100.0 \times (FB_t - FB_o)/FD;$$

$$FCR = FD/(FB_t - FB_o).$$

Interconversion of wet weight (ww) and dry weight (dw) values is based on the moisture contents of fish and feeds (FSmst and FDmst; range 0–1):

$$SFRdw = SFRww \times (1.0 - FDmst)/(1.0 - FSmst)$$

$$FCRdw = FCRww \times (1.0 - FDmst)/(1.0 - FSmst)$$

and

$$FCEdw = FCEww \times (1.0 - FSmst)/(1.0 - FDmst)$$

Typical moisture contents are 0.75 for fish, 0.10 for dry prepared feeds, 0.40 for moist prepared feeds, and 0.65–0.95 for natural foods.

FISH SURVIVAL

Fish survival is dependent upon a complex interaction among water quality variables, fish physiological status, and presence of pathogens. While aquaculture systems are designed and managed to avoid fish stress, disease, and losses beyond natural attrition levels, prediction of fish survival is necessarily an approximation. Nonetheless, some accounting of fish population numbers is required in order to generate fish biomass schedules based on mean fish weights. Assuming that fish mortality losses are proportional to population levels (i.e., exponential decay), predicted fish numbers over a culture period can be based on the expected fish number at the end of the culture period by

$$POP_t = POP_o \times \exp(SMR \times t)$$

and

$$SMR = \ln(POP_{tp}/POP_o)/tp$$

where

POP_t = fish number at elapsed time t (days),
POP_o = initial fish number at time zero,
SMR = specific mortality rate (1/day),

and

POP_{tp} = expected fish number after total period tp (days).

FISH GROWTH

The fish growth models presented in the aquaculture literature vary in their consideration of fish size, of the anabolic and catabolic components of fish metabolism, of food quality and quantity, and of water quality (21). Consequently, these models vary in their consideration of exponential, linear, and asymptotic fish growth stanzas (Fig. 3) and of profiles of predicted growth trajectories over time (Fig. 4). The transition from exponential to asymptotic fish growth is due to limits imposed by environmental variables and/or maximum (maturation) fish-size constraints. Reported growth models include (1) constant absolute weight growth rate (CAGR), (2) constant specific weight growth rate (CSGR), (3) length growth rate (LNGR; 18,22), (4) double-logarithmic specific growth rate (DSGR; 2,23), (5) von Bertalanffy growth function (VBGF; 24,25), and (6) anabolic-catabolic bioenergetic function (BIOE; 1,26,27). In reverse order, these models can be derived through successive levels of simplification of the fundamental bioenergetic equation of fish growth. A particular model is selected for use by choosing the model with the weight-time profile most similar to a plot of given weight-time data or by choosing the simplest model that adequately describes the data as indicated by regression analyses.

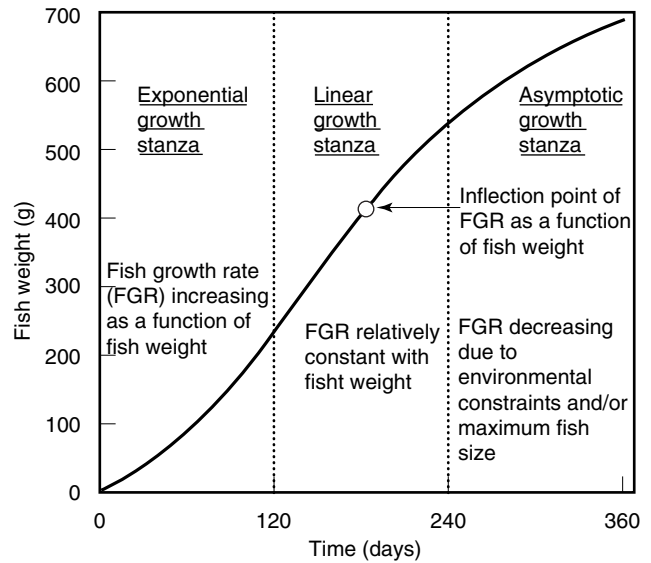
The LNGR and DSGR models are further described and applied here, because of their wide applicability and use in aquaculture and the ease of parameter calibration for them by linear regression. The LNGR and DSGR models are appropriate for exponential and


Figure 3. Idealized fish growth profile, including exponential, linear, and asymptotic growth stanzas.
Figure 4. Representative fish growth profiles for each of the fish growth models identified in the text, using equivalent starting and ending weights, growth periods, and environmental conditions for each profile.

combined exponential-linear growth stanzas. With the inclusion of environmental scalar terms, these models can also consider growth that is asymptotic because it is limited by environmental constraints. Environment-limited asymptotic growth, when found in aquaculture systems, is most commonly due to deteriorating water quality or food availability, as fish and/or feed loading rates achieve maximum system capacities. The LNGR and DSGR models do not consider size-based asymptotic growth, but, under typical aquaculture conditions, fish weights are normally two-thirds or less of maximum maturation weights and are not significantly constrained by maximum fish size. For example, the maximum size

of Nile tilapia (*Oreochromis niloticus*) is about 2.5 kg (5.5 lb) (28), but common harvest sizes are no more than 1.25 kg (2.8 lb), 50% of maximum size. For many other culture species, this differential between market size and maximum size is even greater (e.g., for channel catfish, rainbow trout, and sturgeon). When asymptotic growth may be due to maximum size, then the VBGF or BIOE model should be used. (Maximum fish-size scalars can be applied to the LNGR and DSGR models, but this approach complicates their use and is not covered in the current discussion.)

The LNGR model is based on the simplifying assumptions that length growth rate is constant with respect to fish length, length growth rate varies with water temperature, and water temperatures do not rise so high that growth is reduced. The LNGR model is well suited to fish growth in the exponential stanza and becomes increasingly less suitable as the linear stanza occupies an increasing proportion of the total growth profile. The LNGR growth model is

$$L_t = L_o + (k \times t)/10.0 \text{ mm/cm}$$

where

L_t = fish length (cm, total) at time t (days),
L_o = original fish length (at time = 0) (cm, total),

and

k = fish length growth rate constant (mm/day),

where

k = FGI × CS × [La + (Lb × T)]
La = temperature function y-intercept (mm/day),
Lb = temperature function slope (mm/day/C),
T = temperature (C),
CS = combined environmental scalar (in addition to temperature; 0−1),

and

FGI = fish growth index (0−1).

To convert fish lengths and weights, the fish condition factor function given earlier is used. Combining the equations above into one equation, and assuming that CS and FGI both equal 1.0 (or are comparable between the model calibration and the application studies), length growth rate is calculated by the following equation. Reported values for La and Lb are provided in Table 4. This equation can also be used as a regression equation for estimating La and Lb from fish growth and temperature data:

$$L_t = L_o + [(La + (Lb \times T)) \times t]/10.0 \text{ mm/cm}$$

The DSGR model is well suited to both exponential and combined exponential-linear growth stanzas, as demonstrated in Figure 5. As demonstrated in Figure 6, the DSGR model shows poor predictive ability when it is applied without scalar terms to fish growth profiles having asymptotic components. The SGR exponent (SGRe) is apparently based on intrinsic physiological characteristics

[a]Emphasis on salmonid species reflects availability of values in the literature.
Figure 5. Application of the DSGR model to channel catfish growout in ponds, including over-wintering of fingerlings; a constant fish growth index is used, and water temperatures are accounted for by using a polynomial function within the DSGR model.

common to all fish (2). Reported values for SGRe tend to be about 0.33 for the exponential growth stanza and to increase to about 0.45 as greater proportions of the linear growth stanza are included. If SGRe is equivalent to the reciprocal of Le in the fish length−weight expression (e.g., Le = 3.0 and SGRe = 0.33), then the DSGR and LNGR models are equivalent. In contrast, the SGR coefficient
Figure 6. Application of the DSGR model to tilapia growout under intensive culture; growth is limited at fish weights over 400 g, as a result of limited feeding rates that are due to maximum system constraints. Curves derived by regression used are as follows: (*1*) feeding rate scalar; (*2*) data to day 150 only; and (*3*) all data but no scalar terms.

(SGRc) is a function of species, of environment variables, and of food availability, for which reported values range from 0.02 to 0.2. The DSGR growth model is

$$SGR = SGRc \times W^{-SGRe}$$

or

$$GR = SGRc \times W^{1.0-SGRe}$$

and, by integration

$$W_t = [W_o{}^{SGRe} + (SGRc \times SGRe \times t)]^{(1.0/SGRe)}$$

where

SGR = specific growth rate (1/day),
SGRc = specific growth rate coefficient (1/day, constant or function),
SGRe = specific growth rate exponent,
GR = fish growth rate (g/day),
W_t = fish weight (g) at time t (days),
W_o = fish weight a time 0 (g).

Reported values for SGRe and SGRc are provided in Table 5. SGRe and SGRc can be determined by log-transform linear regression, when datasets are available. The simplest approach to this exercise occurs when water quality and feeding rate conditions are relatively uniform over time and are comparable between the model calibration and the application studies. In such cases, SGRc is a constant value. Alternatively, maximum growth rate data for fish under satiation feeding and optimum environmental conditions can be used to determine parameter values, and then the feeding and environmental scalar functions can be applied when the growth function is used. For a more rigorous approach, data for feeding rate and significant environmental variables must be included in the DSGR regression. For the latter two cases, SGRc is represented as a function of FGI, temperature, and additional water quality variables, as needed.

For all approaches, geometric-mean fish weight (Wgm, g) and SGR values are calculated for each growth interval of fish weight samples (W_i and W_{i+1}) and their natural

Table 5. Reported Parameters for the Weight Growth Model DSGR[a]

Fish Species	Temperature Range (C)	SGRc	SGRe	Reference

Nile tilapia	NA	0.836	0.713	(39)[d]

[a]SGRc and SGRe values are expressed for calculation of SGR in units of 1/day. SGRc may be expressed as a function of water temperature (T; C). emphasis on salmonid species reflects availability of values in the literature.
[b]Florida red tilapia: *Oreochromis mossambicus* × *O. hornorum* (seawater culture).
[c]Mixed species: *O. niloticus* and *O. niloticus* × *O. aureus*; DSGR parameters estimated from given data.
[d]The marked differences from the values typical in other entries reflect use of growth profiles consisting of linear and asymptotic growth stanzas under limited feed availability.

logs are used:

$$\ln(\text{SGR}) = \ln(\text{SGRc}) - [\text{SGRe} \times \ln(\text{Wgm})]$$

where

$$\text{Wgm} = \exp\{[\ln(W_i) + \ln(W_{i+1})]/2.0\}$$

If SGRc is a function of environment variables and food availability, for example, water temperature (T; using polynomial scalar function) and feeding rate (expressed as FGI), then

$$\ln(\text{SGR}) = \ln[\text{FGI} \times (k1 + k2 \times T + k3 \times T^2)]$$
$$- [\text{SGRe} \times \ln(\text{Wgm})]$$

where

$$\text{SGRc} = \text{FGI} \times (k1 + k2 \times T + k3 \times T^2)$$

As used in the LNGR model, a combined environmental scalar (CS) can be applied to SGRc, in addition to FGI and temperature.

NATURAL FISH PRODUCTIVITY

Food resources used by fish may consist of (*1*) natural (endogenous) food resources only, (*2*) natural foods plus supplemental prepared feeds, or (*3*) prepared feeds only. Possible natural food resources include bacterial-detrital aggregate, phytoplankton, zooplankton, invertebrates, and fish prey (polyculture). The contribution of natural foods, and the resulting level of natural fish productivity (NFP, kg fish/ha/day), is highly dependent on species (feeding habits), fish size (when feeding habits vary ontogenetically), biological productivity variables, and the type of aquaculture system. For herbivores and detritivores [such as carps, tilapia, and crayfish under extensive aquaculture production (500−5000 kg fish/ha)], natural foods can be a primary or sole food source. Natural foods may also be significant for fry and fingerling production of carnivorous species such as striped/hybrid bass, sea bass, and red drum, for which zooplankton food resources are utilized. Endogenous food resources can be indirectly managed by control of fish densities and by maintenance of nutrient levels for primary productivity.

Mechanistic models used to quantify natural food resources are relatively complex and are used mainly as research tools (17). For practical purposes, NFP can be approximated by empirically determined relationships between NFP and primary productivity (40) and between NFP and fish biomass density (FBD; kg/ha) (2). This method utilizes critical standing crop (FBDcsc) and carrying capacity (FBDcc) fish density parameters with respect to food availability. At fish densities less than FBDcsc, the availability of natural food resources exceeds maximum consumption rates by fish and does not limit fish growth rates. As fish density increases above FBDcsc (because of growth), natural food resources are utilized by fish beyond their sustainable yield and hence depleted; the result is a decline in natural fish productivity. When fish density achieves FBDcc, natural food resources are
Figure 7. Application of the algorithm for natural fish productivity described in the text, in which supplemental feeding is not used, fish over utilize and deplete their natural food resources, and asymptotic fish growth results.

depleted to such a level that net fish growth is no longer supported, and natural fish productivity is reduced to zero. The ratio of FBDcc to FBDcsc typically ranges from 1.5 to 3.0. Use of natural fish productivity without supplemental feeding yields sigmoidal fish growth curves, as natural food resources are initially nonlimiting, then overwhelmed, then finally exhausted.

The calculation of fish feeding and growth rate equivalents of natural fish productivity by this simplified, empirical approach is outlined here and is illustrated in Figure 7. For projections over time, this procedure is repeated at each simulation time step, so that fish weights and related values are updated at each simulation time step.

1. For single-day calculations, or for the initial step of a simulation, the current mean fish weight is a given. Otherwise, a new fish weight is calculated from the fish weight and the growth rate in the prior simulation step. Current FBD and NFP values are updated accordingly, using the mean fish weight, the growth rate, and the number of fish.

2. Maximum potential NFP (NFPm) either is calculated as a function of primary productivity or is specified as a constant value (e.g., 50 kg/ha/day). When the current NFP exceeds NFPm, FBDcsc is set equal to the current FBD, and FBDcc is calculated as a multiple of FBDcsc. These FBDcsc and FBDcc values are fixed and are not recalculated in subsequent steps.

3. Maximum fish growth rate (FGRm) is calculated by using the selected growth model, for the existing environmental conditions and for an unlimited feeding rate. If FBD ≤ FBDcsc, then fish growth is equal to the maximum fish growth rate. If FBD ≥ FBDcc, then fish growth rate is zero, and this procedure is terminated. Otherwise, for the case FBDcsc < FBD < FBDcc, the fish growth index
Figure 8. Application of the DSFR model to the calculation of feeding rates, where natural fish productivity is considered and a supplemental feeding schedule is determined that maintains a specified, constant fish feeding index (FFI).

(FGIn) and the growth rate (FGRn) supported by NFP are calculated by

$$FGIn = (FBDcc - FBD)/(FBDcc - FBDcsc)$$

and

$$FGRn = FGIn \times FGRm$$

4. If supplemental feeds are used, then the fish feeding index equivalent of natural fish productivity (FFIn) is calculated from FGIn, by use of the FFI–FGI function (given later). To achieve the target feeding index, as based on the target growth index, the FFI to be supplied by prepared feeds is equal to the target FFI minus FFIn (Fig. 8).

FISH FEEDING

Various calculation methods and management strategies for predicting and scheduling fish feeding rates are used in aquaculture. Feeding rates can be determined by the use of tables (which are indexed by water temperature and fish weight) or by the use of functions. For any method, the maximum feeding rates calculated for given environmental conditions must be corrected to actual feed application rates by the use of the fish feeding index (FFI) defined earlier, where FFI is based on target growth rates. The double-logarithmic specific feeding rate model (DSFR) is similar to the DSGR growth model in its functional form and in its parameter-estimation procedures, and these two models often share a calibration dataset. The DSFR feed model is

$$SFR = SFRc \times W^{-SFRe}$$

or

$$FR = SFRc \times W^{1.0-SFRe}$$

where

$$SFR = \text{specific feeding rate (1/day)},$$
$$SFRc = \text{specific feeding rate coefficient (1/day, constant or function)},$$
$$SFRe = \text{specific feeding rate exponent},$$
$$FR = \text{fish feeding rate (g/fish/day)}.$$

For parameter estimation by regression when SFRc is a constant, SFRc and SFRe are determined by this equation:

$$\ln(SFR) = \ln(SFRc) - [SFRe \times \ln(Wgm)]$$

where Wgm is defined under the DSGR model.

If SFRc is a function of environment variables and of food availability—for example, water temperature (T; using polynomial scalar function) and feeding rate (expressed as FFI)—then

$$\ln(SFR) = \ln[FFI \times (k1 + k2 \times T + k3 \times T^2)]$$
$$- [SFRe \times \ln(Wgm)]$$

and

$$SFRc = FFI \times (k1 + k2 \times T + k3 \times T^2)$$

Alternatively, feeding rates can be determined from the fish growth rate and food conversion efficiency (FCE), where FCE can be determined by the use of either tables or functions. For calculating FCE, the DSGR and DSFR models can be mathematically combined to give FCE as a function of fish weight (Fig. 9). In this derivation, if the DSGR and DSFR models use the same environmental scalar criteria and functions, then these scalars cancel, and the calculated FCE is not responsive to water quality. While this approach may be a suitable simplification for practical aquaculture, FCE normally shows a concave-down profile over the full tolerance range of a given
Figure 9. Food conversion efficiency as a function of fish weight, calculated by the methods given in the text. For larger fish sizes, it may be sufficient to represent this relationship with a straight line (i.e., FCE = a − b × W).

water quality variable, with a maximum achieved under optimum conditions. This example demonstrates that scalars for fish growth need to be somewhat more stringent than scalars for fish feeding, as controlled by the scalar criteria used. For the case where water scalars do cancel, FCE can be calculated as a function of fish weight (w; g) by

$$FCE = 100.0 \times FCEc \times W^{FCEe}$$

where

FCEc = SGRc/SFRc
(note that $FCEc < 100.0 \times [(1.0 - FDmst)/(1.0 - FSmst)]$)

and

FCEe = SFRe − SGRe
(note that $FCEe < 0.0$).

(See DSGR and DSFR models for additional definitions.)

FCE also varies with fish feeding rate for a given fish size (1,8,14). FCE first increases with increasing feeding rate above a maintenance ration (FFImnt, e.g., 10% or 0.1), then reaches a maximum efficiency at an optimum ration (FFIopt, e.g., 50% or 0.5), and finally declines as feeding rate is increased further to a maximum ration (FFImax: 100% or 1.0). The bioenergetic mechanisms underlying the response of FCE to feeding rate are complex. The shape of the FCE–FFI curve varies to some degree with fish species and with environmental conditions, and various functional approaches have been reported for expressing the FCE–FFI relationship. A somewhat simplified expression for the FCE–FFI relationship is given below and is illustrated in Figure 10. FFI is calculated as a function of FGI, and then FCE is calculated using this derived FFI value:

$$FGI = 1.0 - [(FFImax - FFI)/(FFImax - FFImnt)]^k$$

or

$$FGI = 1.0 - [(1.0 - FFI)/(1.0 - FFImnt)]^k$$
Figure 10. Fish growth rate (as FGI) and food conversion efficiency (FCE), as a function of fish feeding rate (as FFI), calculated by the methods given in the text.

and

$$FFI = 1.0 - [(1.0 - FGI)^{1/k} \times (1.0 - FFImnt)]$$

and

$$FCE = 100.0 \times (SGRm \times FGI)/(SFRm \times FFI)$$

where

k = exponent parameter used to adjust shape of FGI–FFI curve and region of optimum FCE (typical range 1.5 to 2.0; a value of 1.7 is used in Fig. 10),

SGRm = maximum SGR (1/day),

and

SFRm = maximum SFR (1/day).

The optimum feeding rate with respect to FCE is found at the highest point on the FCE–FFI curve; on the FGI–FFI curve, it is found where a tangent drawn from the origin intersects the curve. Feeding rates can also be optimized over the rearing period as a whole (41). However, feeding rates at which FCE is maximized can be two-thirds or less of maximum feeding rates (e.g., 50% FFI; 14) and can result in significantly slower growth rates and hence in longer growout periods. Especially for intensive aquaculture, the additional economic considerations of facility capacity utilization, fish biomass support, and production throughput for marketing objectives often overwhelm those of FCE optimization, and feeding rates well above FFIopt are normally used. As is evident in Figure 10, responses of FGI and FCE to feeding rates greater than FFIopt may be adequately represented with simple linear functions:

$$FGI = a + (b \times FFI)$$

and

$$FCE = c - (d \times FFI)$$

If feed quality is comparable between the model calibration and application studies, then feed quality can be ignored in calculating feeding rates and conversion efficiencies. If feed quality is a consideration, then feed quality scalars can be applied in a manner similar to that in which water quality scalars are. To accomplish this task, one assigns the prepared fish feed a nutritional quality scalar based on feed protein content (% dw), total gross energy (kcal/g), total metabolizable energy (kcal/g), or protein-energy ratio (mg/kcal) relative to nutritional criteria. This scalar is applied to FCE, so higher-quality feeds result in higher FCE values and hence lower SFR values. Corrections for differences in feed moisture content between the calibration and application studies may also be required, because the calculations presented here are in terms of wet weights.

FISH FEED DIGESTION AND METABOLISM

Fish oxygen consumption, metabolite excretion, and fecal egestion that occur in conjunction with food digestion

and catabolism are of primary interest in aquaculture design and management. Fish oxygen demand, and the production of dissolved and particulate compounds [particularly carbon dioxide, nitrogen and phosphorous compounds, organic solids, and BOD (biochemical oxygen demand)], are fundamental design variables of fish culture systems and of aquaculture waste treatment. Excreted metabolites, including carbon dioxide and dissolved nitrogen and phosphorous compounds, are end products of ingested, digested, and catabolized food. Fish excrete nitrogen mainly as ammonia (generally $\geq 75\%$), with the remainder usually as urea, which breaks downs to ammonia and carbon dioxide. Rates of fish oxygen consumption and of metabolite excretion (g/kg fish/day or mg/kg fish/hr) are a function of feeding rate, feed quality, water quality, and fish metabolic demands (1−3,14). Egested particulate solids result from undigested foods, and their production rates are a function of feed ingestion and digestion rates. Applied feeds that remain uneaten (waste feed) may be an additional source of particulate solids in rearing units. The composition of fish fecal material is dependent on feed composition and digestion efficiency and can include nitrogen, phosphorous, and BOD. Generally, ash content is increased and organic and caloric contents are decreased relative to feed composition (1). The BOD content of fish fecal material is approximately 1.0 kg ultimate BOD per kg dry weight solids (43).

Fish oxygen consumption and metabolite/fecal excretion rates represent terms in the mass balance equations used to design and manage fish culture systems. Two general cases are found in their practical application. For extensive fish culture practices with no or low application rates of prepared feeds (gross fish yields ≤ 3000 kg/ha), the impact of fish metabolism on water quality is normally overwhelmed by other processes, for example, by the phytoplankton and bacterial processes of solar-algae ponds. Under these conditions, fish may exert an indirect impact on water quality, by representing significant sources of nutrients for primary productivity, but this impact normally is a consideration only when fish are fed. In contrast, for semi-intensive practices (gross fish yields 3000−20,000 kg/ha) and intensive practices (gross fish yields >20,000 kg/ha), which rely predominantly or wholly on prepared feeds, fish metabolic processes are a dominant component of the combined physical, chemical, and biological processes in rearing units and have direct impact on water quality.

In addition to mass-balance modeling for the design of fish culture systems, mass-balance equations can be used to determine actual fish metabolic rates, by measuring changes in water quality (e.g., dissolved oxygen) from the influent to the effluent of a rearing unit. This approach is particularly applicable to rearing units with high water exchange rates and a minimum of processes in addition to fish processes; it represents a logical extension of the single-fish respirometer chambers historically used in bioenergetic research. Measured metabolic rates can be used to parameterize fish metabolism models and to estimate FCE values based on feed application rates. Elevated oxygen-food consumption ratios can be used as indicators of fish stress and excessive activity.

Oxygen consumption rate and metabolite/fecal excretion rates can be calculated directly as a function of fish weight and temperature (2,14), but, more typically, those rates are based on fish feeding rates and on the stoichiometry of food catabolism. Ratios of oxygen consumption and of metabolite/fecal excretion to a unit of food consumption (g compound/g feed) are available in the literature and are often based on empirical observations. Alternatively, such ratios can be calculated as functions of food composition and of feeding rates. The first task of this procedure is to calculate ratios for complete feed oxidation as a function of food composition and catabolic parameters. These ratios are then corrected for food digestion and conversion efficiencies, to account for the undigested and stored feed fractions that are not catabolized. It is generally accepted that food digestion efficiency declines with increasing feed ingestion rate, but the magnitude of this response apparently depends on fish species and environmental conditions (2,43,44). Finally, daily mean oxygen consumption rates and metabolite/fecal excretion rates (g compound/kg fish/day) are calculated by multiplying compound-to-food ratios by the predicted (or actual) daily feed application rate (g feed/kg fish/day).

The correction of compound-to-food ratios from feed composition to food catabolism illustrates an important concept regarding feed quality and the utilization of feeds. Metabolizable energy contents of feeds (kcal/g) depend on the feed composition and on species-specific digestion capabilities (1). Because energy needs for maintenance and activity must be satisfied before growth can occur, dietry protein will be used for energy when the diet is deficient in non-protein calories (lipids and carbohydrates). As the use of protein for energy increases, nitrogen excretion and the exothermic energy losses of amino acid deamination (heat increment) also increase. Accordingly, nitrogen loading by fish on their culture system is increased, and the net energy content of the feed is reduced. To minimize the use of protein for energy and to maximize its use for growth, fish feeds can be formulated to achieve protein-to-energy ratios that spare protein as an energy source. Such formulations normally are achieved by increasing the proportion of lipids.

An example calculation of food catabolism is summarized in Tables 6 and 7. The results of this exercise demonstrate the pronounced impact of fish feeding rates on compound-to-food ratios (Table 7.2), an effect due to the dependency of both food conversion and digestion efficiencies on feeding rate. These results are highly dependent on the values used for food digestion efficiencies, conversion efficiencies, and energy and protein contents. For example, higher digestion efficiencies would *increase* oxygen-to-food ratios, and higher conversion efficiencies would *decrease* oxygen-to-food ratios. The metabolizable energy content of fish feeds varies from 2.0 to 3.5 kcal/g or more, compared to the 3.3 kcal/g used in the example, with a directly proportional impact on compound-to-food ratios for oxygen and carbon dioxide. In addition, the protein content of fish feeds varies from about 25 to 55% of dry weight (dw), and fish protein contents typically range from about 50 to 70% of dw (42). To simplify the example exercise, it was assumed that the protein content of both fish and

[a]Undigested fraction—based on linear response of digestion efficiency to feeding rate.

[b]Growth fraction—equivalent to dry-weight food conversion efficiency, expressed as a fraction.

[c]Catabolized fraction = 1.0 – undigested fraction – growth fraction = digested fraction – growth fraction.

feed was the same, i.e. 50% of dw, and therefore, nitrogen-to-food ratios were a product of the catabolized fractions and the nitrogen content of the feed. In practical aquaculture, however, the protein level of feed is typically less than that of the fish, and feeds are normally formulated to allow protein sparing for growth. The resulting decrease in nitrogen-to-food catabolic ratios can be calculated by considering this protein differential in the nitrogen mass-balance of the fish. For example, if fish protein content is increased to 60% of dw in the example exercise, then the nitrogen-to-food ratio at the 80% FFI feeding level is

0.027 g N/g food (compared to 0.030). If feed protein content is reduced to 40% of dw in the example exercise, then the nitrogen-to-food ratio at the 80% FFI feeding level is 0.021 g N/g food (compared to 0.030), reflecting both the reduction in the nitrogen content of feed and the preferential nitrogen uptake by the fish. This concept of compound incorporation as a function of availability and body composition also applies to phosphorus and other feed minerals (ash content).

In the application of daily mean metabolic rates (from daily feeding rates) to facility design, it is critical to consider that over a 24-hour diurnal cycle, the hourly metabolic rates of a fish may vary by a factor of three or more; this variation is due to feed application events during daylight hours, diurnal temperature oscillations, and diurnal fish activity levels (1). Accordingly, peak biomass support demands on fish culture systems may exceed daily mean demands by a factor of two or more. To take into account peak metabolic demands, metabolic models can be expanded to include diurnal variations. More simply, daily mean metabolic rates can be multiplied by empirically based peak-to-mean ratios, ranging from 1.2 to 1.4 or higher (45). Diurnal variations can be significantly reduced by increasing the number of feedings per day and by lengthening the daily feeding period. Required peak-to-mean ratios for facility design also depend on management tolerance for short-term, suboptimal water quality. Depending on aquaculture management intensity, strategies used to address diurnal changes in fish metabolic loading differ on how closely hourly (say) levels of fish biomass support capacity are matched to demand. If biomass support capacity is maintained at a constant rate that satisfies peak requirements over a whole day, then biomass support capacity is not fully utilized during periods of low demand—but facility management is simplified.

Table 7.2. Example Budget for Deriving Compound-to-Food Ratios of Food Catabolism, Combining Feed Composition Values from Table 6 and Catabolic Fractions from Table 7.1 and Assuming that Fish and Feed Material Compositions Are Comparable (Other than in Moisture Content)

Feeding rate	Food Catabolism (g compound/g food)[a]					Total Metabolism[b]
FFI	Oxygen (O_2)	Carbon Dioxide (CO_2)	Total Ammonia (N)	Phosphorus (P)	Particulate Solids (dry wt.)	mg O_2/kg fish/hr
10.00	0.912	1.049	0.065	0.0153	0.100	114
20.00	0.675	0.777	0.048	0.0113	0.133	169
40.00	0.557	0.641	0.040	0.0094	0.200	279

Reported values[c]	0.20−0.60	0.25−0.70	0.025−0.040	0.005−0.050	0.30−0.65	50−500+

[a] Expressed as g compound/g food, for wet-weight food at 10% moisture content.
[b] Calculated at a feeding rate of 30 g feed/kg fish/day (equivalent to 3% body weight per day).
[c] Ranges are based on a wide review of aquaculture literature sources.

APPLICATIONS TO AQUACULTURE DESIGN

The fish growth, feeding, and metabolism models presented earlier in this entry may be used singly or in combination, for a variety of aquaculture design and management tasks. Analyses performed for one point in time may be accomplished with a calculator. Projections over time (simulations) require many calculations and are best performed with computer spreadsheets or programs. Simulations are used extensively in fish performance engineering to generate schedules for the following: fish weights, numbers, and biomass; feed application rates; biomass and metabolic loading; and water-flow and -quality management. On the basis of this information, rearing volume requirements and the water transport and treatment systems required to maintain water quality criteria can be determined.

A typical spreadsheet format has columns of given and calculated values. From left to right, a typical column order is the following: (*1*) time (e.g., days); (*2*) given environmental variables (e.g., water temperature); (*3*) calculated fish number, body weight, growth rate, total biomass, and biomass density; (*4*) feed application rate, feed conversion rate, and metabolic rates; and (*5*) required fish rearing-unit volume and water flow-rate of given quality. With time increasing down the spreadsheet, each row represents an increment of time equivalent to the simulation time step (e.g., one day). Cumulative values in each row (e.g., fish weight) are based on values in the prior row; the first row holds initial values.

The aquaculture design procedure outlined below is used to generate fish management schedules and culture system design requirements. This procedure normally requires some iteration in order to match production objectives with available facility resources. At any point in the procedure, usage levels of one or more resources may be found to be under- or over-utilized; such a condition requires the return to a prior design step and the adjustment of production objectives or culture system specifications. This procedure consists of multiple stages, organized by increasing levels of analytical scope and resolution. Under this approach, the basic feasibility of

rearing a given species and the target biomass of fish under expected environmental conditions is determined before the specific culture system, resource, and economic requirements necessary to provide this fish culture environment are developed.

1. Establish design objectives, specifications, and analytical tools, including the following:
    1.1. fish production targets: stocking and target release/harvest dates, weights, and numbers;
    1.2. fish environmental criteria: see Table 1;
    1.3. facility environmental regimes: historical (empirical) or predicted (simulated);
    1.4. facility specifications: tentative system design and management strategies;
    1.5. fish performance models: selection and calibration.
2. Assess the feasibility of production-trajectory objectives and generate associated schedules:
    2.1. Calculate the period mean FGI necessary to achieve the target fish weight, from the target growth rate relative to the maximum growth rate achieved under maximum feeding rate.
    2.2. Generate fish weight schedules on the basis of environmental conditions and FGI or on the basis of NFP (if prepared feeds are not used).
    2.3. Generate fish feeding schedules on the basis of environmental conditions, of contributions from NFP, and of the required FFI calculated as a function of FGI.
    2.4. Determine compound-to-food metabolic ratios from food quality and feeding rate.
3. Combine production trajectories and fish numbers in order to assess the feasibility of production-scale objectives, on the basis of rearing volume and water flow-rate requirements:
    3.1. Generate fish number schedules from initial numbers and survival estimates.
    3.2. Generate fish biomass schedules from fish number and weight schedules.

3.3. Generate use schedules for rearing units on the basis of biomass schedules (kg), of desired biomass density levels (kg/m^3), and of resulting rearing-volume requirements (m^3).

3.4. Generate rearing-unit water flow-rate schedules from desired water-exchange rates (no./day) or biomass loading rates (kg fish/m^3/day).

3.5. Generate feed application schedules for rearing units (kg feed/RU/day), on the basis of feeding rate (kg feed/kg fish/day) and biomass schedules.

3.6. Check on whether system capacity limits have been exceeded for water flow-rates and feed application rates.

4. Depending on the required rigor of design analyses, mass-balance analyses are applied to rearing units to better quantify biomass support requirements. These analyses are used to determine peak and mean capacity requirements for diurnal and seasonal periods. Objectives include the operational requirements of influent and effluent water systems and the scheduling of rearing-unit water flow-rates and of treatment processes performed within the fish rearing units (e.g., aeration).

4.1. Combine fish biomass density (kg/m^3) with metabolite/fecal production rates (g compound/kg fish/day) to get mass sources and sinks due to fish processes (g compound/m^3/day). Include any additional significant mass-transfer processes of the rearing unit, including (*1*) influent and effluent water flow rates and (*2*) passive and managed physical, chemical, and biological processes. Heat transfer between a rearing unit and its environment may also be an important consideration, especially for static ponds and at lower water exchange rates, where rearing unit temperatures may diverge significantly from initial or influent temperatures.

4.2. If the fish culture system is pre-defined in respect to rearing-unit water flow-rates, influent water quality, and in-pond treatment processes, then estimate fish impacts on water quality and determine whether water-quality criteria are maintained. If the fish culture system is to be designed, then determine the water flow-rates, the influent water quality, and/or in-pond water-treatment processes required to maintain water-quality criteria.

4.3. Assess management risk by determining the elapsed time between system failure and fish death (or excessive stress) due to deterioration in water quality past fish tolerance extremes. System failure includes loss of power or of critical components (e.g., water pumps and aerators) and is simulated by terminating all water flow through and treatment processes in the rearing unit.

PESTICIDES

ROBERT R. STICKNEY
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

Types, Uses, and Threats
Bibliography

Certain pesticides have found limited use in aquaculture for controlling predatory insects and certain types of pests. The major interest of aquaculturists with regard to pesticides, however, is with respect to accidental exposure, as most aquatic animals are highly susceptible to these toxicants.

TYPES, USES, AND THREATS

Two general categories of pesticides have dominated the market for the past few decades: chlorinated hydrocarbons and organophosphates. Chlorinated hydrocarbons are persistent in nature. They or their breakdown products can remain active and lethal for many years. The most widely used organophosphates, on the other hand, become inactive within a few days after application. DDT was taken off the market in the United States in the 1970s, and many other chlorinated hydrocarbons were later banned for public use, though some can still be applied by persons who are licensed to employ them. Yet, DDT and related compounds not generally available in the United States are being produced and employed throughout much of the world.

While herbicides are used to control aquatic vegetation (see the entry "Aquatic vegetation control"), there is little need for pesticide applications in conjunction with aquaculture operations, although pesticides have been used to control sea lice in salmon net pens (1).

Pesticides have sometimes been used to control burrowing crawfish and other pests between crops of the target aquaculture species. It is possible to control aquatic insects with pesticides, but, such use is uncommon, because of potential toxicity to the aquaculture species. Aquatic insect populations are often controlled by pouring sufficient diesel fuel over a pond to cover the surface in a thin film, which will cause the insects to suffocate when they surface to obtain oxygen.

The use of any type of chemical in aquaculture facilities is closely controlled in the United States, and few biocides of any type have been approved for use by foodfish (including shellfish) producers. However, this is not the case in many countries, particularly those in the developing world, where chemical use is largely or totally uncontrolled. That having been said, there have been few, if any, reports of pesticide-contaminated fish or shellfish from the aquacultured products that reach the markets of the world.

Since many aquaculture facilities are located in agricultural areas, it is not at all uncommon for pesticide applications to occur in the immediate vicinity of fish or invertebrate culture facilities. In many cases, pesticides are applied, at least in the United States, through aerial application. Misjudgment on the part of pilots or wind drift of the chemicals can lead to disastrous results. Ponds and other outdoor rearing chambers are particularly susceptible, though contamination of incoming water must also be considered. In addition to the possibility of direct contamination of facilities or their water supply, there is the chance that runoff of active pesticide during and after rain events will contaminate water being used for aquaculture.

As a part of site selection (see the entry "Site selection"), the aquaculturist should evaluate the potential of pesticide-contaminated water and soils and have sample tests performed if there is any indication of a potential contamination problem. Once a facility has been established, aquaculturists should avoid causing pesticide contamination from their own activities and ensure to the greatest extent possible that neighbors do not spray pesticides on their crops on windy days.

Much of what is currently known about pesticide toxicity to fish and shellfish comes from toxicity studies, which

have determined such things as LD_{50} concentrations. The LD_{50} (LD = lethal dose) is the lowest concentration of a chemical that will kill 50% of the animals exposed to the chemical in a given period. The periods used are usually 72 or 96 hours. While such acute toxicity information is useful, it is the chronic effects of pesticide contamination that are most worrisome for aquaculturists: If a pond happens to receive overspray or wind drift of pesticide from an aerial application, that fact will be apparent within several hours as fish begin to float up in affected ponds. Much less obvious is the cause of low-level, continuous mortalities over long periods, due to chronic exposure low levels of pesticide. Soil and waters tests should be virtually negative with respect to pesticides if the aquaculturist is to be assured that no chronic toxicity problem exists.

pH

Gary A. Wedemeyer
Western Fisheries Research Center
Seattle, Washington

OUTLINE

Definition of pH

Measuring and Reporting pH

Sources and Effects of Unfavorable pH in Aquaculture Systems

Management Recommendations

Bibliography

The pH of the aquatic environment indicates the degree to which the water is acidic or basic (alkaline). This information is important to aquaculture, because plankton, fish, and other aquatic life can survive and grow only within a relatively narrow range of acidity. Knowledge of the pH of an environment is important to many other aspects of aquaculture management as well. For example, the pH is important in alkalinity and carbon dioxide measurements and affects such diverse factors as chlorine disinfection and ammonia toxicity. Thus, pH is one of the most frequently employed water chemistry tests in aquaculture.

DEFINITION OF pH

Acidic substances liberate hydrogen ions (H^+) into the water, while basic (alkaline) substances can accept H^+. The more acidic the water, the greater the hydrogen-ion concentration and the lower the pH. On the other hand, the more basic the solution, the lower the H^+ concentration and the higher the pH. Strictly speaking, acidity is the capacity of a water supply to neutralize alkaline substances (hydroxyl ions, OH^-). It is measured by titration and is expressed as mg/L of equivalent $CaCO_3$. Thus, like alkalinity (see the entry "Alkalinity"), acidity is a capacity factor. In biological work, however, it is more relevant to express acidity in terms of its intensity (i.e., the hydrogen-ion concentration itself), rather than as a capacity factor. To do so, the concept of pH, defined as the negative logarithm of the hydrogen-ion concentration (in moles/L), was developed. The "p" stands for puissance (power), and "H" is the symbol for hydrogen. By convention, the pH range extends from 0 to 14. A pH of 7.0 is the neutral point, a pH greater than 7 indicates alkaline conditions, and a pH less than 7 is acidic. By way of illustration, freshwater supplies used for aquaculture usually have pH of 5 to 9. Soft waters normally have a slightly acidic pH, while hard waters usually are slightly basic, because they contain bicarbonate and carbonate minerals. Seawater is strongly buffered at about pH 8.2. Sodium bicarbonate added to ponds to correct low alkalinity problems also adjusts the pH of the water to about 8.2. The gastric acid of salmonid fishes is about pH 3; their urine is pH 7.2, and their blood is pH 7.8. For some purposes, it is important to take into account that the neutral point of water is temperature dependent and is pH 7.0 only at 25 °C (77 °F); it ranges from pH 7.5 at 0 °C (32 °F) to pH 6.5 at 60 °C (140 °F) (1). Thus, the normal blood pH of fish and other poikilothermic animals is not fixed, but varies inversely with the water temperature.

MEASURING AND REPORTING pH

The pH of a solution is most accurately measured with a glass electrode system that produces an electrical potential, which is converted from millivolts into a pH value by an electronic circuit. Such pH meters are calibrated with standardized buffer solutions and are usually accurate to at least 0.1 pH unit. For routine monitoring work, portable water chemistry test kits using pH sensitive paper strips or color standards may be entirely adequate.

When reporting pH monitoring results, it is important to remember that the average pH value cannot be determined by simply adding the individual numbers and dividing by the number of samples. The individual pH values must first be converted back to hydrogen-ion concentrations in moles/L and then averaged. The negative logarithm of this number gives the average pH. Alternatively, it may be just as meaningful to report the pH range and explain any unusual deviations (2).

SOURCES AND EFFECTS OF UNFAVORABLE pH IN AQUACULTURE SYSTEMS

Acidity in freshwater used for aquaculture is generally due to carbon dioxide (CO_2) dissolved from the atmosphere or produced by fish metabolism. However, mineral acids from pollution (e.g., acid precipitation and acid drainage from coal mines), naturally occurring organic acids from humus deposits, and the hydrolysis of salts leached into water supplies from mineral deposits can also cause acidity.

Mine drainage water becomes acidic because iron bacteria oxidize pyrites (FeS_2) and other sulfide impurities in the ore to sulfuric acid (H_2SO_4). In hatcheries supplied with hard, alkaline water (greater than 200 mg/L as $CaCO_3$), introduced acidic compounds such as acid mine waste drainage may be partly or completely neutralized by the natural carbonate content of the water. However, the dissolved CO_2 that is then produced can be as deleterious to fish health as the low pH of the acid mine waste itself. Carbonate rock can also be placed in the mine waste drainage stream to neutralize H_2SO_4, but doing so may result in the production of semigelatinous hydrated iron oxide [$Fe(OH)_3$], which may physically damage gills (3).

The CO_2 produced by fish respiration itself can substantially lower the pH in hatcheries that use water low in total hardness (less than 50 mg/L as $CaCO_3$). This condition is rarely of concern in raceways, but can be a problem in fish transport operations, where CO_2 concentrations of 20–30 mg/L can accumulate in the tanks, lowering the pH to 6.0 or less within 30 minutes of loading. In heavily stocked ponds, the pH can fluctuate by one or two units, even in well-buffered water (i.e., alkalinity greater than 100 mg/L), because of the CO_2 produced by fish respiration.

The photosynthesis and respiration of phytoplankton can also strongly affect water pH. Phytoplankton photosynthesizing in intense sunlight may remove CO_2 faster than it can be replaced, causing the pH to rise. At night, plant respiration adds dissolved CO_2, decreasing the pH. The resulting pH fluctuations can be quite severe, depending on the size of the phytoplankton community and the buffering capacity of the pond water. A large phytoplankton community, typical of fed-fish ponds in waters of low alkalinity (i.e., less than 50 mg/L as $CaCO_3$), may cause the pH to fluctuate from pH 5 at night to pH 10 or above during daylight hours (3).

Proper management of water pH is fundamental to protecting the health of aquatic animals in aquaculture systems. If the pH is too low (i.e., pH less than 5), ion transport at the gills of salmonid fishes is affected, leading to osmoregulatory failure and death. Ammonia toxicity is also strongly affected by pH, because the equilibrium between nontoxic NH_4^+ and toxic NH_3 shifts toward the toxic NH_3 form as the pH rises. Thus, water containing ammonia from uneaten food or from fish excretion may be completely safe for salmonid fish at pH 6, but the same ammonia concentration at pH 8.0 may be toxic. Another well-known deleterious effect of pH is that toxic heavy metals in soils and bottom sediments can be solubilized and leached into the water, where they may kill fish and invertebrates at sensitive life stages. Aluminum toxicity is an important example of this problem. At pH 6.6, 30-day aluminum exposures at concentrations up to 57 μg/L (ppb) are safe for the egg and fry stages of brook trout. At pH 5.6, however, the safe concentration decreases to only 29 ppb (4). Low pH levels also interfere with the normal development of smoltification in juvenile anadromous salmonids, even in the absence of metal toxicity. For example, the parr–smolt transformation of juvenile Atlantic salmon is normal at pH 6.4–6.7, but

seriously impaired at pH 4.2–4.7 (5). Spikes of acidity can occur during the spring runoff of freshwater streams when acid precipitation has accumulated in the snow pack. Finally, water pH strongly affects the metabolic activity of the nitrifying bacteria used in recirculating aquaculture systems to remove ammonia. Inhibition begins if the pH falls much below 7.0 and the alkalinity drops below about 80 mg/L (6).

MANAGEMENT RECOMMENDATIONS

The upper and lower limits for pH values that are safe for fish and invertebrates in aquaculture systems are not fixed values, but vary somewhat, depending on other environmental factors, such as temperature, metal and ammonia concentrations, and acclimation pH. Fish populations in natural waters can tolerate the pH extremes of 5–9 (without the effects of metal toxicity), but a more prudent range to protect the health of freshwater fish in aquaculture facilities is pH 6.5–9.0 (3). Fish in mariculture facilities, such as net pens, normally do not experience pH fluctuations, because seawater is strongly buffered at a pH of about 8.2.

PLAICE CULTURE

ROBERT R. STICKNEY
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

General Information on Plaice Culture
Bibliography

Plaice, *Pleuronectes platessa*, was one of the first flatfish to be developed as an aquaculture species. Culture and stocking of plaice in Norway goes back to the turn of the century, though the practice was nearly abandoned and not much interest existed until James Shelbourne with

the Whitefish Authority in Great Britain began making significant breakthroughs in plaice larval culture in the 1950s and 1960s (1,2). That work paved the way for development of culture techniques for such other flatfish species as Atlantic halibut; sole; turbot; Japanese flounder; summer flounder; southern flounder; and two species closely related to plaice: winter flounder (*P. americanus*) and yellowtail flounder (*P. ferrugineus*). The culture of most of those species is described in detail in other sections of this encyclopedia.

GENERAL INFORMATION ON PLAICE CULTURE

One of the first breakthroughs in plaice larval culture was the finding by Shelbourne that heavy losses in the hatchery occurred as a result of the growth of bacteria in hatchery tanks. The problem was controlled by adding a mixture of penicillin and streptomycin to the water. Since that time, techniques for sterilizing eggs prior to introducing them into hatchery tanks have been developed. For example, gluteraldehyde is an effective chemical to sterilize plaice eggs. In addition, advances in the technology associated with water filtration and ozonation, improvements in ultraviolet sterilization units, and the development of hatching chambers that allow constant water exchange without damaging eggs have reduced or eliminated the need to use antibiotics in many instances.

The technique for plaice culture that was developed by the early 1970s involved holding adults in ponds, where they were allowed to spawn naturally. The floating eggs were collected and placed in the hatchery. Incubation tanks were supplied with recirculated seawater that was exposed to ultraviolet light for sterilization.

Hatching and rearing troughs were $4.9 \times 1.2 \times 1.2$ m deep ($12.4 \times 3 \times 3$ ft). Each trough was stocked with 30,000 to 40,000 eggs, which were hatched after three weeks when the water temperature was maintained at $6\,^{\circ}$C ($43\,^{\circ}$F).

Brine shrimp nauplii were found to be a suitable first food for plaice larvae. It was also discovered that brine shrimp from different sources were slightly different in size, the difference being sufficient enough that nauplii from an inappropriate source were too large to be consumed by first-feeding larvae. Since the 1960s, many marine fish culturists have been producing rotifers, in particular *Brachionus plicatilis*, for first-feeding larvae. Rotifers are smaller than brine shrimp nauplii and have, in general, better nutritional quality. Larval fish quickly become too large to efficiently capture rotifers, so brine shrimp continue to be a food source for part of the larval development period.

Plaice, like other flatfish, are sight feeders. Research has shown that dark-colored, opaque tanks facilitate prey capture, as the brine shrimp nauplii could be clearly seen against the light that entered from the surface of the tank. Plaice larvae have been shown to feed successfully over a fairly wide range of illumination, unlike some other flatfish species.

After metamorphosis, plaice were, during the early years, fed chopped mussels or fish. Since then, prepared feeds have been developed. Live foods are still used, and a weaning period is required during which the fish are gradually adapted to prepared feeds by giving the feeds in combination with live or fresh food material initially and then gradually reducing the live or fresh food until it is eliminated.

Early nutritional work demonstrated that flatfish appear to have a high protein requirement. One study placed this requirement at 70% of a dry diet, but later research has suggested a lower apparent requirement of 57% (3). The protein requirement can best be met with animal protein sources, usually some type of fishmeal.

There are few other data available on the nutritional requirements of plaice. In addition to the aforementioned work on protein requirements, research has examined the vitamin C requirement of plaice

One problem with plaice and other flatfish has to do with pigment abnormalities, in particular the development of black pigment on the side that is down when the fish is swimming horizontally or lying on the substrate. Abnormal pigmentation reduces the value of fish and may even make them unmarketable. Early nutrition may play a role in the development of abnormal pigmentation. Incidence of the anomaly has been reduced by feeding enriched brine shrimp nauplii during first feeding. (Enriched nauplii are those that were fed a source of high-molecular-weight fatty acids prior to being offered to the plaice larvae.)

The initial work with plaice by the Whitefish Authority was aimed at producing fingerlings for enhancement stocking. Stocking of fjords has been ongoing for many years in the United Kingdom as a means of augmenting wild stocks. Once the techniques for larval culture had been worked out, interest in plaice culture within the commercial sector quickly developed, though that interest has since waned. Instead, other species have come into favor, for one reason or another. Much of the early and subsequent work with plaice has been of great importance to persons interested in other flatfish, which is the primary reason that a summary of the work with plaice is included here.

OUTLINE

INTRODUCTION

The aquaculture industry is considered the fastest growing segment of agriculture. However, the industry has been experiencing growing pains as a result of water quality deterioration, and poor water quality has in turn contributed to disease outbreaks. For example, the shrimp aquaculture industry has experienced numerous disease outbreaks worldwide and production has decreased as a result. Because of these water pollution problems, production in the aquaculture industry has been slowed.

Pollution is at the heart of the seafood industry's dilemma. There is growing concern over the safety of ingesting shrimp, catfish, and other aquatic life taken from polluted waters. The U.S. Centers for Disease Control (CDC) reported that because of continuous pollution of the coastal wetlands and bays, shellfish caught in those waters are 18,000 times more likely to cause illness than shellfish grown elsewhere. This entry discusses water pollution and its relation to aquaculture.

EFFECTS OF POLLUTION

According to the U.S. National Marine Fisheries Service (NMFS), over one-third of all commercial and recreational fish species have dramatically declined in population or have completely disappeared in the past 15 years. This is mostly due to overfishing but is partly due to toxic pollutants and urban development of the coastlines. The NMFS has reported the status of U.S. fisheries to the U.S. Congress for the second time, and that report can be accessed through their Web site, http://kingfish.ssp.nmfs.gov/sfa/98stat.

In Canada, waters in and around Quebec and Montreal have been contaminated for over 20 years, due primarily to pesticides, sewer runoff, and pollutants from the St. Lawrence River. The Provincial Environmental Department monitors water quality and pollution levels regularly and issues guidelines on fish consumption to keep the public informed about how often they can eat various types of fish caught in those waters.

In 1990, approximately 1,400 beaches in the United States were closed due to pollution and toxic waste hazards, with another 1,700 threatened, as reported by the CDC. Toxic medical supplies discarded from Mexico were found washed up on the shorelines of Corpus Christi, Texas, resulting in the closing of some beaches in Texas. In 1997, Gulf of Mexico king mackerel were found to have high levels of mercury, and the Texas Department of Health issued guidelines for public consumption.

Off and on in the past, alarmed scientists have been concerned about 7,000 square miles (18,130 km^2) in the Gulf of Mexico, called the "dead zone," because hypoxia occurs in this area. It does not occur every year, but sometimes seasonally, especially during drought years, these areas are rendered almost lifeless by a lethal combination of agricultural fertilizer, sewage runoff, and diminished oxygen. Most of this comes from the Mississippi River. The process kills the food chain from the bottom up, rendering the area virtually lifeless. Some scientists are concerned that if the ecology of the affected ocean becomes stressed over long periods of time, it might become permanently damaged. When this major change takes place, forms of bacteria that thrive under anoxic conditions replace fish, shellfish, and crustaceans that need oxygen. However, these dead zones seem to come and go and are not always predictable. According to the U.S. National Oceanic and Atmospheric Administration (NOAA, Department of Commerce), 53% of U.S. estuaries

experience hypoxia part of the year. The Gulf of Mexico is not the only water that suffers from dead zones. There are as many as a dozen dead zones in different areas of the world, all caused by some combination of pollution.

In certain cases, harmful algal blooms have resulted in fish kills, the deaths of numerous endangered West Indian manatees, beach and shellfish bed closures, threats to public health and safety, and concern among the public about the safety of seafood. According to some scientists, the factors causing or contributing to harmful algal blooms may include excessive nutrients in coastal waters, and other forms of pollution. There is a need to identify more workable and effective actions to reduce nutrient loading to coastal waters.

Since 1991, the Alabama Department of Environmental Management has been testing fish from major water bodies around the state for contaminants. In the latest round of testing, lab results showed that at some sites, polychlorinated biphenyls (PCBs) and mercury continue to be present in amounts exceeding the U.S. Food and Drug Administration (FDA) guidelines. As a result, consumption advisories for those areas have been issued. Even though the contaminant level may be very low in the water source itself, PCBs and mercury have a tendency to bioaccumulate. When a predator eats prey, the contaminants are deposited in the tissue of the predator. Over time, the contaminant can build up to unsafe levels.

As a result of growing health hazards, the Marriott Corporation (USA) placed a permanent ban, in all of its national hotel restaurants on the use of any shellfish caught in the Gulf of Mexico. Similarly, many more restaurants across the country make disclaimers warning of the possibility of food poisoning from the seafood they serve their customers. These problems are not isolated to the United States; in fact, they are often worse in other countries where laws are not as strict. One of the most prolific producers of cultured shrimp, Malaysia, has been plagued with a serious state of shrimp toxicity in polluted waters, which threatens their entire industry. China, the world's top producer in 1991 of pond-raised shrimp, was almost completely out of the shrimp business in 1995 due to pollution-induced diseases and the yellow head and white spot viruses. Indonesia and India have suffered similar fates of rapid aquaculture growth and near collapse as a result of pollution and water quality deterioration.

GREATER AWARENESS OF WATER POLLUTION

United States television broadcasts, Web sites, and published papers on public concerns about capture fishery policies and aquaculture development have increased the awareness of pollution problems. For example, CNN aired the program *Earth Matters* and included a segment titled, "Troubled Waters: The State of World Oceans." Worldwatch distributed a paper titled, "Rocking the Boat: Conserving Fisheries and Protecting Jobs." For more details on the press release, and ordering information, visit the Web site: http://www.worldwatch.org.

ACTIONS TAKEN TO COMBAT POLLUTION

Many countries with coastal aquaculture industries have enacted laws to address water pollution problems. However, legislative mandates can accomplish only so much toward a solution. The Food and Agricultural Organization of the United Nations (FAO) has published a set of guidelines for sustainable aquaculture, and most countries around the world are trying to adhere to them as they pass new laws to regulate their individual industries. More information on FAO and sustainable aquaculture can be obtained from their Web site http://www.fao.org/waicent/waicente.htm. An even greater alarm is the problem of radioactive leakage from the former USSR's decimated nuclear-powered naval fleet. Radioactive contamination of our oceans is going to continue to be a pollution problem in the future.

Aquaculture is important to the United States and to the world's fisheries. Both import and export markets for aquaculture products will expand and increase as research begins to remove physiological and other animal husbandry barriers. Overfishing of wild stocks will necessitate harvest regulations and replenishment through aquaculture. Future aquaculture development programs require an integrated public health approach to ensure that aquaculture does not cause unacceptable risks to public or environmental health and that aquaculture's potential economic and nutritional benefits are not harmed.

AQUACULTURE AND POLLUTION

Some aquaculture activities are considered pollution, but there are two aspects of water pollution in aquaculture. The first is the effect of pollution on aquaculture and the second is the pollution of the environment by aquaculture. Although aquaculture can pollute the environment, there are many other forms of pollution. Aquaculture requires high-quality water, and often the aquaculture industry suffers from other users' pollution.

Some of the pollution from aquaculture includes the misuse of therapeutic drugs, chemicals, fertilizers, and natural fishery habitat areas. As in agriculture, the use and misuse of antibiotics to control diseases is global and will probably increase as culturists move toward more intensive animal-rearing techniques and higher stocking densities. The illegal use of chloramphenicol in shrimp culture to control diseases may result in high levels in the harvested product, and this has been shown to cause liver damage in humans. Similarly, the improper or illegal use of chemicals (e.g., tributyl tin) to control pond pests such as snails can also result in human health hazards. The misuse of raw chicken manure as pond fertilizer may result in the transmission of *Salmonella* from manure to the cultured product.

Much attention has been given to the net-pen culture of salmon and to how that industry adds pollution to water in the form of feces, ammonia, and uneaten feed. It has been reported that one large salmon net-pen operation (exact size not given) can produce pollutants equivalent to untreated wastes from 10,000 people per

day. Stickney (1) listed issues concerning net-pen culture. Other aquaculture industries have raised public concerns over pollution. Some of those have been the trout industry on the Snake River (western United States), and shrimp farms around the world.

The tilapia aquaculture industry is also facing a pollution-related dilemma. Some producers have found the bacteria *Streptococcus* in their fish, and this bacteria can be transmitted to humans. There has been at least one highly publicized case in Canada where this bacterium was transmitted from fish to human, but for the most part these occurrences are rare. Diseases associated with the handling of fish occur more often than diseases associated with human consumption of fish.

One of the most common pollutants from aquaculture activities is solids (clay and other soil particles that may be suspended as a result of moving water, especially during drain-harvesting). Suspended solids may cause low light attenuation and negatively affect seagrass growth or even smother seagrasses as the solids settle below the discharge area. Suspended solids may affect the overall aesthetics of the area. Such loading, with the addition of other organics, uneaten feed, and feces, may result in low oxygen and/or elevated ammonia levels in effluent waters. For the farmer, controlling pollution often becomes a balancing act between effluent dissolved oxygen (DO), biological oxygen demand (BOD), and ammonia.

Ammonia is another one of the common forms of pollution from aquaculture, but it is a natural element, and bacteria break it down in the environment. Nitrogen is one of several elements essential to the survival of aquatic organisms. Bacteria consume nitrogen in specific compounds that they can use and later excrete, frequently in a different, less harmful compound. Nitrogen cycles through the ecosystem by being absorbed and excreted by bacteria, plankton, and other aquatic life. In a normal cycle, bacteria transform nitrogen in ammonia ions into nitrite and later, ions. Denitrifying bacteria turn the nitrogen to gas that is released into the atmosphere from the soil or the water. Coastal waters have the ability to assimilate the pollutants that are released into them, as long as the capacity of those waters is not exceeded.

Treatment of pollution is the subject of much technology and may involve increased water use in a flow-through system, increased recirculation of water in a closed or semiclosed system, concentration or settling of solids, aeration, addition of beneficial bacteria, or a combination of these techniques. Treatment of solids is often done by routing the effluent into a settling pond or created wetland. Most of the solids can be settled by using baffles in the discharge canal and only allowing the discharge water to move slowly through the canal. Another technique is to hold water in a settling pond for a minimum of 6 hours (see settling time of solids in Fig. 1). Prevention of soil suspension is also another method used to control pollution and is done through soil erosion control techniques.

Permitting approaches often involve concentration of solids and monitoring the loading of solids and ammonia. Ambient conditions such as total suspended solids (TSS),
Figure 1. Turbidity (NTU) versus settling time, in hours. *Source*: David R. Teichert-Coddington, Auburn University, Alabama.

volatile suspended solids (VSS), inorganic suspended solids (ISS), ammonia, and, in most areas, biological oxygen demand (BOD) and dissolved oxygen (DO), are usually recorded, and effluent waters may not exceed set threshold criteria and limits over ambient conditions. VSS refers to those solids that can be incinerated, such as algae. ISS are those solids such as clay particles that are inorganic in nature and will not burn away in an oven.

The most common additives to aquaculture ponds are feeds, fertilizer, lime, and sometimes Zeolite (a natural mineral used for ammonia removal or blue-green algae control and is not toxic to the environment).

REGULATIONS TO CONTROL POLLUTION

The U.S. Environmental Protection Agency (EPA) and local state agencies regulate aquaculture effluents in the United States For those persons following aquaculture and National Pollutant Discharge Elimination System (NPDES) permit and effluent issues, a fact sheet and draft permit can be downloaded from the EPA homepage. The Internet sites are http://www.epa.gov/ and http:www.epa.gov/r10earth/offices/water/ow.htm. In 1977, the EPA considered developing effluent guidelines for aquaculture facilities and recommended issuance of Best Practicable control Technology (BPT) limitations, but regulations were not implemented. The EPA had until recently left effluent issues and regulation up to the states. If the state's regulations are not as strict as the EPA's, then the state must follow EPA guidelines. If state regulations are more strict, then they are followed.

Aquaculture operations in the United States are now controlled by the EPA's authority to regulate under the Clean Water Act, as amended (33 U.S.C. 1251 *et seq.*). Section 402 of the Act requires that an NPDES permit be issued by the EPA prior to discharge. In May, 1998 the EPA published their effluent guidelines plan. See the entry "Regulation and permitting" for more details on aquaculture permitting. Also see the EPA criteria referred to throughout this entry.

Some countries have developed Best Management Practices (BMPs) and effluent limitations and requirements to establish a minimum standard of operating in order

to reduce pollution. Most monitoring involves sampling the discharge for flow solids (total and volatile), ammonia, and dissolved oxygen. Monitoring pH is sometimes done following the use of lime. Total residual chlorine monitoring may also be required following the use of chlorine.

ADDITIONAL SOLUTIONS TO POLLUTION

Control treatment technologies, which have been adopted by numerous industries, do reduce the pollutants of greatest concern at designated locations and can serve as a basis for BMPs. Improved feeding management practices, feed manufacturing, and diet formulations have contributed to gains in feed conversion efficiencies and reductions of solids and nutrient levels in discharges. New facility engineering designs and innovations have also refined solids waste reduction and removal for proper disposal.

POLLUTION AND TOXICOLOGY OF AQUATIC LIFE

The majority of available reports regarding pollution and invertebrate toxicology deal with penaeid shrimp, e.g., Overstreet (2). There have also been numerous studies by the EPA concerning the effects of pollution on commercially valuable penaeid shrimp of the United States, in the Atlantic States and Gulf Coast. Therefore, most of the information presented here is related to pollution and the following three species of penaeids: *Farfantepenaeus duorarum* (pink shrimp), *Farfantepenaeus aztecus* (brown shrimp), and *Litopenaeus setiferus* (white shrimp), all Atlantic and Gulf of Mexico species. References to other species of penaeids, nonpenaeid crustacea, and finfish are also made.

A brief discussion of the following pollutant categories follows: PCBs, organic chemicals other than petroleum and related compounds, petroleum, heavy metals, and other pollutants. Under each of these divisions some of the known toxicity levels are reviewed.

POLYCHLORINATED BIPHENYLS

PCBs are industrial pollutants that can influence aquatic ecology (3). They are a group of chlorinated hydrocarbons developed for commercial use as electrical transformer insulation fluids, hydraulic fluids, fire retardants, plasticizers, and extreme pressure oils and greases. For many years PCBs have been present in the aquatic environment as a result of waste effluents, disposal of dielectric fluids, and other industrial sources. It is a well-established fact that certain fresh and marine bodies of water are contaminated with various compounds of PCB. It is not as large a problem as it once was since laws controlling the discharge and burning of these waste products on offshore ships have been severely strengthened; however, PCBs are extremely stable and inert compounds. As a result, they have accumulated in native fish and wildlife in many parts of the world. Biphenyls may have anywhere from one to ten attached chlorine atoms, making possible more

that 200 compounds. The 1998 FDA Hazard Analysis Critical Control Point (HACCP) (4) action level for PCBs in fish is 2 parts per million (ppm, Table 1). Other important information about FDA and seafood can be obtained at the Web site http://vm.cfsan.fda.gov/~mow/intro.html, and more information about the NMFS HACCP Program can be obtained at http://www.nmfs.gov/iss/manual.html or http://www-seafood.ucdavis.edu/haccp/Plans.htm.

According to the EPA, concentrations of PCBs should not be above 0.002 parts per billion (ppb) in water, and residue in aquatic animals should not be above 0.5 ppb. The minimum concentration causing mortality in invertebrates was 0.9 ppb. Penaeid shrimp suffered the greatest mortality when exposed during premolt (just before molting) and during molt. Most exposed shrimp and fish became lethargic and stopped feeding, and shrimp did not dig into the substrate (digging is a normal activity for penaeids). Dramatic chromatophore changes in the cuticle of exposed shrimp and the skin of fish were more frequent and obvious than in unexposed control animals.

ORGANIC AND OTHER PESTICIDE CHEMICALS

If the aquaculture area or site is suspected of having pollution such as organic chemicals, an analysis of organic chemicals (pesticides and their derivatives) should be performed for the following: endrin; lindane; methoxychlor; toxaphane; 2,4-D; 2,4,S-TP; and DDT; plus any other pesticides known to be used in the area (3). A composite analysis for all chlorinated hydrocarbons should also be performed. The HACCP action level for 2,4-D is 1.0 ppm for all fish (4).

In the past 50 years, many kinds of chemical pesticides have been released into the environment and are considered pollutants. The world has many insects and it is understandable that these chemicals are being used to successfully carry on agricultural activities. If the agricultural activities in an area require pesticides, then pesticides do pose a possible pollutant source, most likely during the rainy season when runoff from farming may occur. Aquatic life is exposed to these compounds because the rivers, estuaries, bays, and oceans often behave as a "sink" or receptacle for these compounds. Some pesticides, such as certain organochlorines or their metabolites, are slow to break down and thus tend to accumulate in various compartments of the aquatic environment. Shrimp and fish have been found to accumulate certain pesticide compounds in the laboratory, and feral or wild shrimp and fish have possessed detectable levels of compounds when taken directly from contaminated waters. The EPA has found that over several years of testing, penaeid shrimp generally are far more sensitive to toxic and ecological effects of most pesticides than are fish or molluscs because of the shrimp's close relation to insects. Vogt (5) reported further work with monitoring pesticides in aquaculture. The new United States HACCP Program (4) deals with natural toxins, environmental chemical contaminants and pesticides, methyl mercury, aquaculture drugs, toxin formations, and metal inclusion in seafood. Table 1 gives the environmental chemical

Table 1. Environmental Chemical Contaminant and Pesticide Tolerances, Action Levels, and FDA Guidance Levels[a]

Deleterious Substance	Level	Food Commodity	Reference
Aldrin/dieldrin[b]	0.3 ppm	All fish	Compliance Policy Guide, sec. 575.100
Benzene hexachloride	0.3 ppm	Frog legs	Compliance Policy Guide, sec. 575.100
Chlordane	0.3 ppm	All fish	Compliance Policy Guide, sec. 575.100
Chlordecone[c]	0.3 ppm	All fish	Compliance Policy Guide, sec. 575.100
	0.4 ppm	Crabmeat	
DDT, TDE, DDE[d]	5.0 ppm	All fish	Compliance Policy Guide, sec. 575.100
Diquat[e]	0.1 ppm	All fish	40 CFR 180.226
Fluridone[e]	0.5 ppm	Fish and crayfish	40 CFR 180.420
Glyphosate[e]	0.25 ppm	Fin fish	40 CFR 180.364
	3.0 ppm	Shellfish	
Toxic elements			
Arsenic	76 ppm	Crustacea	FDA Guidance Document
	86 ppm	Bivalves	FDA Guidance Document
Cadmium	3 ppm	Crustacea	FDA Guidance Document
	4 ppm	Bivalves	FDA Guidance Document
Chromium	12 ppm	Crustacea	FDA Guidance Document
	13 ppm	Bivalves	FDA Guidance Document
Lead	1.5 ppm	Crustacea	FDA Guidance Document
	1.7 ppm	Bivalves	FDA Guidance Document
Nickel	70 ppm	Crustacea	FDA Guidance Document
	80 ppm	Bivalves	FDA Guidance Document
Methyl mercury	1 ppm	All fish	Compliance Policy Guide, sec. 540.600
Heptachlor/heptachlor epoxide[f]	0.3 ppm	All fish	Compliance Policy Guide, sec. 575.100
Mirex	0.1 ppm	All fish	Compliance Policy Guide, sec. 575.100
Polychlorinated biphenyls (PCB's)[e]	2.0 ppm	All fish	21 CFR 109.30
Simazine[e]	12 ppm	Fin fish	40 CFR 180.213a
2,4-D[e]	1.0 ppm	All fish	40 CFR 180.142

[a]*Source*: Reference 4.

[b]The action level for aldrin and dieldrin are for residues of the pesticides individually or in combination. However, in adding amounts of aldrin and dieldrin, do not count aldrin or dieldrin found below 0.1 ppm.

[c]Previously listed as Kepone, the trade name of chlordecone.

[d]The action level for DDT, TDE, and DDE are for residues of the pesticides individually or in combination. However, in adding amounts of DDT, TDE, and DDE, do not count any of the three found below 0.2 ppm.

[e]The levels published in 21 CFR and 40 CFR represent tolerances rather than guidance levels or action levels.

[f]The action level for heptachlor and heptachlor epoxide is for the pesticides individually or in combination. However, in adding amounts of heptachlor and heptachlor epoxide, do not count heptachlor or heptachlor epoxide found below 0.1 ppm.

contaminant and pesticide tolerances, action levels, and guidance levels suggested in the HACCP program. As can be seen, the deleterious substances of concern are aldrin/dieldrin, benzene hexachloride, chlordane, chlordecone, DDT, TDE, DDE, diquat, fluridone, and glyphosphate. Among the elements considered toxic and of concern are arsenic, cadmium, chromium, lead, nickel, methyl mercury, heptachlor/heptachlor epoxide, mirex, PCBs, simazine, and 2,4-D. Amazingly, some of the action levels are very high. Arsenic, for example, has an action level of 76 ppm for crustaceans and 86 ppm for molluscs. Nickel has an action level of 70 ppm for crustaceans and 80 ppm for molluscs. All deleterious substances and toxic elements have action levels in the ppm (not ppb); therefore, tolerance levels appear to be very high.

Herbicides and pesticides fall under the larger heading and category of insecticides. Fortunately, most of the herbicides and pesticides either are not water-soluble or have a short half-life. The organophosphate Malathion has a half-life of days in an estuarine system rather than months or years. Unfortunately, some of the new insecticides used are much more deadly and have such complicated structures that bacteria are not able to break them down as readily. Therefore, they do what they were designed to do more effectively, and that is to kill. Banana farms are using fungicides to stop black spot, and these are suspected to cause problems for aquatic life in the estuaries when runoff occurs. Areas of insecticide and fungicide use should be avoided during site selection of aquaculture facilities. One must see to it that there is no widespread agricultural activity in the area which would be a potential source of pesticides, fungicides, and herbicides. If this is not done, the effects of the chemicals would indeed most likely show up during the wet season and would negatively affect production.

ORGANOCHLORINES

The following organochlorine pesticides have been studied relative to their ecological effects on fish and shrimp: chlordane, DDT, dieldrin, endrin, heptachlor, hexachlorobenzene, lindane, mirex, and toxaphene (3). For example, the

HACCP action level for heptachlor in all fish is 0.3 ppm, 0.3 ppm for benzene hexachloride in frog legs, and 0.3 ppm for aldrin/dieldrin in all fish (4).

White shrimp that died as a result of DDT exposure (banned in the United States) accumulated up to 40 ppb DDT and DDE (a decomposition product) in the hepatopancreas after 18 days of exposure to 0.20 ppb in flowing seawater. Exposure to a DDT concentration greater than 0.01 ppb was lethal to pink shrimp in 28 days. Sodium and potassium concentrations in shrimp exposed to 0.05 ppb DDT for 20 days were lower than in those not exposed. Magnesium, however, was not significantly lowered. The significance of reduced cation in the hepatopancreas of shrimp for pathophysiogical behavior is not known, but a loss of ATPase activity in ion transport may be indicated. Blood protein levels have also been found to drop in shrimp exposed to DDT. In acute, high-concentration laboratory exposures, shrimp and fish showed tumors, hyperkinetic behavior, and paralysis. With DDT poisoning, shrimp did not become paralyzed but sank into lethargy, refused food, and then died (3). The HACCP action level for DDT in all fish is 5.0 ppm. Major problems have occurred mainly when inland ponds were located near row crops such as cotton. Ponds should not be located on land where DDT was used unless soil tests indicate that DDT is no longer there.

Some juvenile aquatic organisms died after laboratory exposure to low concentrations of mirex. However, all survivors from the test died after four days in mirex-free seawater, demonstrating a delayed toxic effect of this pollutant. Mirex poisoning in aquatic organisms produces loss of coordination and equilibrium, and finally, signs of lethargy and paralysis. The HACCP action level for mirex in all fish is 0.1 ppm.

The EPA conducted a detailed ecological monitoring study of the distribution of mirex in oysters, crabs, shrimp, and fishes from estuarine waters, from the Gulf of Mexico to Delaware Bay. Only shrimp in the Savannah, Georgia area had detectable concentrations of mirex (0.007 ppb in tissues). The Savannah, Georgia area has a long history of mirex usage. Mirex does not appear to be as widespread in estuarine regions as are PCBs and DDT. Mirex, usually applied as a particle-bait poison, would not be as directly available to many marine organisms as are broadcast liquids or powder formulations of other pesticides.

The EPA found that 25% of the pink shrimp tested died in the laboratory after seven days of exposure to only 1.0 ppb mirex. The EPA (3) also found that toxaphene affects the early metamorphic stages of pink shrimp and larval fish. The mysis stage of pink shrimp is most susceptible to toxaphene, particularly under various temperature and dissolved oxygen conditions.

ORGANOPHOSPHATES AND CARBAMATES

The organophosphate compounds tested have been shown to be approximately 1000 times more toxic to shrimp than most other pesticides tested, with penaeid shrimp showing greater sensitivity than fishes or molluscs (3).

Among compositions tested, baytex was toxic to penaeid shrimp in the laboratory. Naled (1,2-dibromo-2, 2-dichlorethyl phosphate) had little effect in field tests on shrimp. Malathion, at 14 ppb, caused hyperactivity, paralysis, and death in penaeids. Parathion's lethal concentration for 48 hours in pink shrimp was 0.2 ppb.

In the 1970s it was found that malathion, aerially applied to flooded marshes in Texas, caused from 14 to 80% mortality in brown and white shrimp held in cages. It was recommended that malathion not be applied to flooded marshes that maintained shrimp. It was also found that caged pink shrimp were killed when they received malathion via thermal fogging for mosquito control in salt marshes. In the 1980s Ralph Gouldy's hatchery in the Florida Keys had problems with aerial mosquito spraying of malathion and had to operate the facility as a closed system. The hatchery now operates under the name GMSB — Shrimp Culture, Inc., under the same conditions, producing postlarvae for a large Honduras farm. Additionally, the state of Florida will not allow them to draw directly from the bay system or to discharge directly into the bay system. They draw their water from wells, use a reverse osmosis system to eliminate hydrogen sulfide, and discharge into a series of settling ponds. The system is considered closed, and outside sources of pollution can therefore be avoided to some extent.

Both organophosphates and carbamates are reported to be potent growth inhibitors in the invertebrates and vertebrates. Inhibition as high as 75% was found in moribund shrimp experimentally exposed to malathion. Carbamate pesticides (e.g., sevin) were found to be quite toxic to aquatic animals in laboratory tests. Brown shrimp have a 96-hour LC_{50} (the concentration at which 50% of the organisms were killed) of 2.5 ppb, the lowest concentration of sevin reported to kill any crustacean tested.

Some naturally occurring insecticide chemicals such as pyrethrum, nicotine, rotenone, hellebore, ryania, and sabadilla could also be potential pollutants. Rotenone is a crystalline ketone insecticide extracted from roots of certain plant species in the bean family and is commonly used in ponds to kill fish (by blocking oxygen transport). Rotenone is a restricted use pesticide in the United States and could be considered a pollutant if not used properly because it may linger in cooler water for up to one month, it is commonly dissolved in diesel fuel for application, and this combination adds another pollutant to the environment.

PETROLEUM AS A POLLUTION THREAT TO AQUACULTURE

Annual spillage of oil and oil products into the world's oceans is over 4 million tons (not including the occurrence of occasional megaspills such as the Alaskan spill by Exxon). Most of these spills occur in estuaries or near coastal regions of significant biological value. Of particular importance is the fact that many coastal areas affected by oil spills (including potential spill areas) are in fish- and shrimp-producing regions and are prime sites for aquaculture activities. Detailed studies of ecological and

physiological effects of oil on many aquatic animals have been published (3).

Almost all boats, including many sailing vessels with either inboard or outboard motors, use petroleum products and are potential pollution hazards. There are usually one or more deep ports in every country with a coastline that handles petroleum products. Barge traffic and other shipping occurs off the coasts of all countries. Even small boats can cause problems with water pollution. It has been found that when fish and penaeid shrimp are experimentally exposed to oil-contaminated seawater, they accumulate hydrocarbons in their tissues. Brown shrimp (*Farfantepenaeus aztecus*), exposed to oil in seawater and then depurated in clean seawater, released accumulated hydrocarbons more rapidly than clams (*Rangia cuneata*) and oysters (*Crassostrea virginica*). Shrimp can metabolize the hydrocarbons whereas molluscs have a limited, if any, capability to do so.

Couch (3) presented results of tests using the water-soluble fractions and oil-in-water dispersions of four oils (South Louisiana crude, Kuwait crude, refined No. 2 fuel, and Bunker C residual), against brown shrimp postlarvae, for toxicity. The tests showed that fractions of refined oils were generally more toxic to penaeid shrimp and to other aquatic species than were the fractions of crude oils. The crustacean species tested, including brown shrimp postlarvae, were more sensitive to oil fractions than fish species tested (*Cyprinodon* sp., *Menidia* sp., and *Fundulus* sp.). The 24-hour median tolerance limit (the concentration at which the median number of shrimp survived) of juvenile brown shrimp exposed to components of No. 2 fuel oil (naphthalenes, methyl naphthalenes, and dimethyl naphthalenes), ranged from 0.77 to 2.51 ppm. The naphthalenes were the most toxic water-soluble components of fuel oils to shrimp.

Mills and Culley (6) determined acute toxicity of four oils and two oil-spill dispersants on shrimp and fish and found that the dispersants were actually more toxic than the oil, with the 48-hour LC_{50} for the four oils being 1–40 ppt and 40-hour LC_{50} for dispersants being 2.5–5,000 ppm.

HEAVY METALS IN WATER CAUSING POLLUTION

A variety of heavy metals are found naturally in freshwater and seawater environments. These metals may exist in several oxidation states, with different reaction potentials, depending on their specific properties. Certain heavy metals are pollutants generated by industry, and some may be acted upon by microbes to produce other compounds accumulated by organisms, and which are potent toxicants.

Heavy metals occur naturally in the aquatic environment as a result of weathering and land drainage. Additionally, the use of various pesticides and fungicides, which contain metals, has added large quantities of heavy metals to the aquatic environment. Excessive additions of heavy metals to the aquatic environment could have an adverse effect both on animals and on humans who use these animals as food. There are a number of reports on the toxicity of heavy metals to aquatic animals (7–13).

The biological effects of metals are complicated by their interactions with other metals (14) and by metal speciation (15). For example, zinc influences the toxicity of cadmium (16), and chelating agents such as tris, NTA, and EDTA reduce the toxicity of metals by sequestering reactive species (17–20). EDTA has been used for a variety of purposes (21), including as a chelator of heavy metals in aquaculture hatcheries to avoid toxic effects of metals to crustaceans during early stages of life.

Many studies have been carried out to determine the bioaccumulation and toxicity of heavy metals to aquatic organisms (e.g., 10,11,18,22,23). Chen and Liu (24) found that heavy metal concentration in *Artemia* nauplii increased linearly with an increase in the heavy metals in the water.

The heavy metals that can be methylated, such as mercury, tin, palladium, platinum, gold, and thallium, pose special threats as environmental pollutants. Other metals, such as cadmium, lead, and zinc, do not form stable alkyl-metals in aqueous solutions, but may have different modes of toxic action. The following is a description of various toxic metals that pose risks to aquaculture.

Cadmium

Biologically, cadmium (Cd) is generally recognized as a nonessential, nonbeneficial element with high toxicity potential. It is deposited and accumulated in various body tissues. Cadmium occurs chiefly as a sulfide salt, frequently in association with zinc and lead. Then EPA criteria are 0.01 ppm for domestic water supply, 0.04 ppm for freshwater aquatic life, and 0.05 ppm for marine aquatic life. This metal is a pollutant from several industrial effluents into aquatic systems. The HACCP action level for Cd is 3.0 ppm in crustaceans and 4.0 ppm in molluscs. Castille and Lawrence (19) found that Cd in a concentration of 0.2 ppm was lethal to *Litopenaeus stylirostris* nauplii.

The Cd concentration in seawater, at 35 ppt salinity, with a standardized nutrient level, is 1.1×10^4 ppm (Cd^{2+}) (25,26). Fujimura (27) reported hatchery water samples from Sabah, Malaysia with Cd levels of 0.05 ppm. Colt and Huguenin (28) recommend a Cd level of <0.005 ppm for aquaculture hatchery water. The Marine Products Export Development Agency (MPEDA) of India states that the 96-hour LC_{50} Cd level for postlarval shrimp is 0.42–0.8 ppm.

Iron

Dissolved iron (Fe) is not toxic to shrimp, but when it precipitates it can cause problems. Water treatment should be done by oxidizing the iron or by aeration of the water and filtering the precipitate before exposing animals.

Useful information concerning iron and other heavy metals in seawater can be found in Chen et al. (29).

Fe levels should be below 0.01 ppm to be in the optimum range for shrimp culture and below 1.0 ppm for any kind of shrimp production to occur. Fe combines with oxygen to give a rusty or orange color. This process uses up oxygen, and if not properly aerated, Fe forms a precipitate that can clog the gills of cultured organisms (Fe^{2+} is converted

to Fe^{3+} which precipitates as $FeOH_3$). The 96-hour median tolerance limit (TL_m 96) of Fe to aquatic insects, mayflies, stoneflies, and caddisflies is 0.32 ppm.

In another study, Fujimura (27) reported hatchery water samples to contain 0.23 ppm Fe from Sabah, Malaysia and 0.3 ppm from Guam water samples. Natural seawater has been reported to have 0.02 ppm trace metal Fe. Colt and Huguenin (28) recommended Fe levels of <0.3 ppm for hatchery water. Care must be taken when taking the water sample for analysis. When sediment is in the water sample, Fe can and will leach into the sample before it is processed; therefore, the results obtained may not be a true indication of Fe levels.

Copper

Couch (3) reported that a copper (Cu) concentration of 0.5 ppb was lethal to nauplii, protozoea, and mysis of *Farfantepenaeus aztecus* and *Farfantepenaeus duorarum* that were exposed in a seawater–brine mixture similar to that derived from desalination plants. The same larval stages were able to grow normally in seawater (35 ppt) containing 0.025 ppm Cu. Kumaraguru et al. (23) reported a 96-hour LC_{50} of 0.57 ppm Cu to *Meretix casta*. Cu is toxic to juvenile fish and crustaceans. Criteria (upper limits) are 1.0 ppm for domestic water supply, and 0.1 times the 96-hour LC_{50} for freshwater and marine aquatic life.

Normal seawater contains 0.04–0.1 ppm Cu. Fujimura (27) reported 0.03 ppm in hatchery water from Sabah, Malaysia and Yuan et al. (30) reported 0.3–2.1 ppm levels of Cu from Qingdao, China water. Colt and Huguenin (28) recommend a Cu level of <0.003 ppm for hatchery water. Cu occurs as a natural or native metal in various mineral forms. Oxides and sulfates of Cu are used for pesticides, algaecides, and fungicides. Cu is present in seawater at a concentration of approximately 3 ppb (26,31). Cu is toxic to oysters at concentrations above 100 ppb, and to clams at levels of 20 ppb. The minimum reported concentration of Cu that begins to exhibit toxicity to some agricultural vegetation is 100 ppb. The toxicity of Cu to aquatic life is dependent on the alkalinity of the water, as the Cu ion is complexed by anions present. At lower alkalinity levels, Cu is generally more toxic to aquatic life. Other factors affecting toxicity are pH and the presence of organic compounds.

Mercury

Mercury (Hg) is widely distributed in the environment, but it is generally considered to be a nonessential and nonbeneficial element to organisms. The EPA's criteria are 2.0 ppb for domestic water supply, 0.05 ppb for freshwater aquatic life and wildlife, and 0.1 ppb for marine aquatic life.

Hg itself (as a metal) does not appear to have toxic effects on organisms; however, mercuric salts and methylated Hg are extremely toxic, with both short- and long-term chronic effects (3). These mercuric products were partly responsible for the 1988 closing of the area to fishermen around the Alcoa bauxite plant on Lavaca Bay, Texas. The area eventually became an EPA superfund cleanup site which cost the U.S. government millions of dollars. The HACCP action level for methyl Hg in fish is 1.0 ppm (4).

Zinc

Zinc (Zn) in the water column has been shown to cause a decrease in the rate of oxygen consumption of the freshwater shrimp (32). Correa (10) reported a differential reduction in respiration and ammonia excretion in shrimp, with static 96-hour LC_{50} values for Zn at 0.2 mg/L (ppm). Normal seawater has a level of 0–0.1 ppm Zn (8). As a comparison, Fujimura (27) reported Zn levels in hatchery water from Sabah, Malaysia at 0.06 ppm and at 0 levels in Hawaii and Guam, and Yuan et al. (30) reported 0.9–3.2 ppm in Qingdao, China water samples. Colt and Huguenin (28) reported that Zn should be at <0.05 ppm in shrimp hatchery water.

Lead

In addition to its natural occurrence, lead (Pb) and its compounds may enter and contaminate the global environment at any stage during mining, smelting, or industrial use. Pb enters the aquatic environment through precipitation, fallout, erosion, leaching, and industrial waste discharge. Criteria are 50 ppm for domestic water supply, and 0.01 times the 96-hour LC_{50} values for aquatic species.

Forstner and Wittman (8) reported the Pb level in normal seawater was between 0.005 and 0.01 ppm. The HACCP action level for Pb is 1.5 ppm in crustaceans and 1.7 ppm in molluscs (4).

Magnesium

Riley and Chester (33), as well as other sources, have reported magnesium levels in normal seawater (35 ppt) between 1,090 and 1,350 ppm. The level of Mg is dependent upon the salinity level. Generally, the higher the salinity the higher the Mg. A low salinity site of 8 ppt showed a Mg level of 285 ppm, and another with salinity of 15 ppt had a Mg level of 607 ppm. However, Mg is rarely found at high enough levels to be considered a pollutant.

Aluminum

Spotte (26) reported that 0.01 ppm aluminum (Al) is found as a trace metal in normal seawater. Water in an area with much industrial development might have elevated Al levels and should be checked. Although high levels of Al may be toxic to animals, little is known regarding its toxicity to aquatic species.

Manganese

Manganese (Mn) levels of less than 0.05 ppm are recommended by Colt and Huguenin (28) for aquaculture hatcheries. This metal is a required nutrient for aquatic animals, but it can be toxic to aquatic animals at relatively higher concentrations.

Nickel

Colt and Huguenin (28) recommended that hatchery water contain <0.05 ppm nickel (Ni). However, the HACCP

action level for Ni is 70 ppm in crustaceans and 80 ppm in molluscs (4).

Chromium

Chromium (Cr) is a relatively abundant element in aquatic ecosystems. Fish are relatively tolerant to Cr, but some aquatic invertebrates are quite sensitive. The EPA's criteria are 50 ppm for domestic water supply and 100 ppm for aquatic life. Colt and Huguenin (28) recommended hatchery seawater levels at <0.025 ppm Cr. The HACCP action level for Cr is 12 ppm in crustaceans and 13 ppm in molluscs (4).

Silver

Biologically, silver (Ag) is a nonessential, nonbeneficial element recognized as causing localized skin discoloration in humans and as being systemically toxic to aquatic life. Criteria are 50 ppm for domestic oyster supplies, with a 96-hour LC_{50} of 0.01 ppm for many aquatic species.

Arsenic

Arsenic (Ar) has many diversified industrial uses such as hardening of Cu and Pb alloys, pigmentation in paints and fireworks, and the manufacture of glass, cloth, and electrical semiconductors. Arsenicals are also used in the formulation of herbicides. The EPA's criteria are 0.05 ppm for domestic water supply and 0.1 ppm for irrigation of crops. The HACCP action level is 76 ppm in crustaceans and 86 ppm in molluscs (4).

Barium

Barium (Ba) is a yellowish-white metal of the alkaline earth group and many of its salts are soluble in water or acid. It has various applications in the metallurgic, paint, and electronic industries. The EPA's criterion is 1 ppm for domestic drinking water. Experimental data show that soluble Ba concentrations in marine water would have to exceed 50 ppm before toxicity as opposed to nonlife would be expected.

Selenium

Biologically, selenium (Se) is an essential, beneficial element recognized as a metabolic requirement in trace amounts for animals, but toxic to them in amounts ranging from 0.1 to 10 ppm in food. The EPA's criteria are 10 ppb for domestic water supply, with a 96-hour LC_{50} 0.01 for sensitive resident aquatic species.

OTHER POLLUTANTS

Among metals, cyanides can be toxic depending upon the temperature, pH, and oxygen level in the water. Free cyanide can occur as hydrogen cyanide and is very toxic to fish if above 0.01 ppm in saltwater. According to the EPA, any cyanide level above 0.005 ppm can cause problems in freshwater.

Other forms of aquatic pollution that may affect aquaculture include urban usage of pesticides and petroleum products, commonly from storm water runoff, industrial pollution, and thermal pollution from power plants (34). Additionally, detergents containing phosphates can cause algal blooms that result in low dissolved oxygen.

Phosphorus appears to be more of a pollutant problem in freshwater than in saltwater. Phosphorus is the nutrient limiting algal growth and eutrophication in natural systems, and it is sometimes regulated in the freshwater aquaculture industry.

Further reading on the toxicology of aquatic pollution, especially the impact on fish biology of nitrite and oestrogenic substances, can be found in Taylor (35). Topics discussed are as follows: (*1*) water chemistry at the gill surface of fish and the uptake of xenobiotics; (*2*) bioaccumulation of waterborne 1,2,4,5-tetrachlorobenzene in tissues of rainbow trout; (*3*) dietary exposure to toxic metals in fish; (*4*) the physiology and toxicology of zinc in fish; (*5*) lethal and sublethal effects of copper upon fish: a role for ammonia; (*6*) the physiology and status of brown trout exposed to aluminum in acidic soft waters; (*7*) physiological and metabolic costs of acclimation to chronic sublethal acid and aluminum; (*8*) physiological effects of nitrite in teleosts and crustaceans; (*9*) metallothioneins in fish; (*10*) oestrogenic substances in the aquatic environment and their potential impact on animals, particularly fish; (*11*) the effect of genetic toxicants in aquatic organisms; (*12*) *in vitro* toxicology of aquatic pollutants: use of cultured fish cells; and (*13*) principles governing the use of cytochrome P-450 measurement as a pollution monitoring tool in the aquatic environment.

For additional information on aquaculture pollution, Ziemann et al. (36) characterized aquaculture effluents in Hawaii, Hastings and Heinle (37) discussed the effects of aquaculture in estuarine environments, and Piedrahita (38) and SEAFDEC (39) discussed managing environmental impacts in aquaculture. For additional information on pesticides, see (40).

POLYCULTURE

ROBERT R. STICKNEY
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

Historical Perspective
Animal Polyculture
Animal/Plant Polyculture
Bibliography

Polyculture is the rearing of two or more species in the same culture system. In most cases, it involves two or more species of aquatic animals, but it could also mean rearing aquatic animals in conjunction with terrestrial or aquatic plants.

HISTORICAL PERSPECTIVE

Polyculture is not a new concept. The traditional method of rearing carp in China involves the culture of several species. (See the entry "Carp culture.") If the proper mixture of fish species is stocked, all of the available natural food in a pond will be preyed upon by a fish that has value as human food. In China, polyculture has always involved carp species almost exclusively, at least until recently, when such fish as tilapias (see the entry "Tilapia culture") were introduced into polyculture ponds. The practice goes back millennia and continues to exist today. Several species of carp are stocked, each of which has different food habits. Mud carp or common carp are benthos feeders, silver carp feed primarily on phytoplankton, bighead carp feed on zooplankton, and grass carp feed on higher aquatic plants (e.g., macrophytes) or on plant material supplied by the fish farmers (e.g., agricultural wastes). Ponds are fertilized with livestock manure and night soil. Aside from the previously mentioned agricultural wastes, no supplemental feed is provided.

In recent years, polyculture has been a concept that has been extended to various aquatic species. In most cases, it involves rearing compatible species that do not compete for food and that have commercial value. It may, however, also involve rearing of a noncommercial species that provides a service to the fish farmer. For example, predators may be stocked in tilapia ponds to consume fry and reduce overcrowding. (See the entry "Tilapia culture.") In Norway, wrasses have been stocked to control sea lice on Atlantic salmon (1).

The practice of using culture systems for the culture of fish or invertebrates in conjunction with hydroponically grown vegetables is another form of polyculture. Rice–fish culture, the rearing of fish in rice paddies, has been practiced at least for decades in some countries and can also be considered a form of polyculture.

ANIMAL POLYCULTURE

Multispecies carp culture in China continues to be practiced, and while that approach has not been widely adopted elsewhere, some research has been conducted that involved polyculture of two or more species used routinely by the Chinese. In addition, aquatic animal polyculture of various species, sometimes in combination with carp, has been adopted in a variety of situations. Grass carp (*Ctenopharyngodon idella*), one of the species used in Chinese polyculture, have found their way into many other aquaculture situations. For example, since aquatic weeds are a nuisance and can lead to oxygen depletions in ponds (see the entry "Pond culture"), their control is often considered not only desirable, but also necessary. (See the entry "Aquatic vegetation control.") Grass carp provide one means of controlling aquatic plants in ponds. Catfish farmers often stock a few grass carp in each of their production ponds, as do the culturists of other freshwater fish species.

There have been many studies on polyculture, but how widely the results of those studies have been adopted by producers is not clear. Among the species that have reportedly been stocked in various types of polyculture situations are the following:

- carp and Australian red claw crayfish;
- channel catfish and fathead minnows in separate ponds with water exchange;
- channel catfish and tilapias;
- channel catfish with Asian clams;
- common carp and *Colossoma* sp.;
- common carp and walking catfish;
- grass carp and *Colossoma* sp.;
- Indian carp and various other carp species;
- mullets and carp;
- salmon and scallops in net pens;
- salmon and sea urchins in net pens;
- tilapias and various species of carp (carp singly or in combinations);
- tilapias, common carp, and walking catfish;
- tilapias, common carp, grass carp, and pacu;
- tilapias and walking catfish;
- tilapias and mullets;
- tilapias and *Colossoma* sp.;
- tilapias and snakehead;
- tilapias, common carp, and freshwater shrimp;
- tilapias and freshwater shrimp;
- tilapias and Australian red claw crayfish;
- crayfish and snails;
- freshwater shrimp, grass carp, and *Colossoma* sp.;
- freshwater shrimp and bighead carp;
- freshwater shrimp and various species of carp (including Indian carp species);
- freshwater shrimp with giant gouramis;

- freshwater shrimp and mullets;
- marine shrimp and mullets;
- marine shrimp and milkfish;
- marine shrimp and rabbitfish;
- marine shrimp of various species;
- marine shrimp, abalone, and mussels;
- marine shrimp and clams;
- marine shrimp and scallops;
- marine shrimp, oysters, and clams;
- scallops and sea urchins;
- oysters and sea squirts.

ANIMAL/PLANT POLYCULTURE

There are significantly fewer examples of aquatic animals being polycultured with seaweeds than of aquatic animals being cultured with other aquatic animals. The following are a few examples of the former:

- marine fish with bivalves and seaweed;
- marine shrimp and seaweed;
- scallops, sea urchins, and seaweed.

More common is the culture of aquatic animals with higher plants and the use of plants for water treatment in aquatic animal culture systems.

One of the most widely used polyculture systems involving higher plants and aquatic animals is rice–fish culture. The practice of culturing rice and fish together is not new; it has been practiced for decades, if not centuries, in various parts of the world. Rice is a terrestrial plant that is routinely grown in flooded fields (paddies). Fish can also be reared in rice paddies. The most common species reared in rice–fish culture are in the group of species commonly referred to as tilapias (see the entry "Tilapia culture"), though other species, including various types of carp, also lend themselves to the practice.

In recent years, there has been a good deal of interest in the development of fish or aquatic invertebrate culture in conjunction with hydroponic fruit and vegetable production. Lettuce, tomatoes, cucumbers, and other fruits and vegetables have been reared in water that is also used for aquatic animal production. Tilapias are commonly used as the aquatic animals in such systems (2).

The waste from aquatic animals is not very rich in nutrients in comparison with organic wastes obtained from birds and mammals, so some augmentation of nutrients is often necessary. Water from aquaculture systems can also be used to irrigate and provide partial fertilization for row crops and ornamental plants, but that approach stretches the definition of polyculture. Sea lettuce (a type of marine algae), water hyacinths, and marsh grasses are among the plants that have been used to reduce the nutrient loads in aquaculture effluents before the water is released into natural environments. Some plants can be used as livestock food, though because of their high water content, they should be fed at a location immediately adjacent to the aquaculture

facility, as hauling them any distance can be inordinately expensive.

POMPANO CULTURE

STEVEN R. CRAIG
Texas A&M University
College Station, Texas

OUTLINE

Recent interest in culturing Florida pompano (*Trachinotus carolinus*) commercially has resulted in renewed efforts to predictably spawn the species in captivity. Although pompano were the subject of many studies beginning in the early 1960s, several failed attempts at culture on a commercial level were experienced in the 1970s. Several factors are behind the renewed interest in the species. First, there has been a recent desire to culture more highly valued marine fish. Pompano is considered one of the most desirable and valuable table fish from tropical U.S. waters and sells in the United States for $2.00–3.50/kg ($4.00–8.00/lb) in the round, among the highest prices accorded any marine fish (1,2). Additionally, the U.S. pompano fishery has declined dramatically in recent years, the total catch in 1988 being just one tenth that of 1976 (3). Finally, pompano are hardy animals, able to tolerate a wide range of salinities, low dissolved oxygen concentrations, and high turbidity (1). These characteristics make them appealing candidates for the high-density recirculating systems that are becoming increasingly popular. Reliable and predictable spawning of Florida pompano has not yet been attained, although renewed efforts are underway by several major universities as well as enterprises in the private sector.

LIFE HISTORY

A member of the carangid, or jack, family, the pompano is found in an area ranging from North Carolina to Brazil. It is a small fish, with maximum length and weight of approximately 63.5 cm (25 in.) and 3.5 kg (7.7 lb), respectively (4). Pompano are found in the surf zone along beaches on the Gulf coast of the United States, and the appearance of juvenile fish throughout spring, summer, and fall indicates a prolonged spawning season (5). Additionally, spawning is believed to occur offshore, and in Florida, mature fish move to the shore in mid-April to mid-May. "Waves" of larvae appear about one month later and continue to show up through late October (4,6). Pompano generally spawn from April to October, with a peak in April and May (7), although spawning seasons vary according to geographic location. Shorter spawning periods are observed in the northern parts of the range, with potentially year-round spawning in the tropical parts of the range (8). Based on those observations, it appears as if pompano are continuous spawners, as is the case with many subtemperate and tropical marine species. Continuous-spawning fish are desirable in aquaculture, because they can potentially produce fry for stocking growout systems year-round (9).

Juvenile pompano are easily caught on the beaches of the Gulf coast of Mexico from late April until October, with fish staying in the surf zone until they reach approximately 60–80 mm (2–3 in.) in length (6), after which they migrate into deeper, offshore waters (4). Juvenile pompano are thought to be opportunistic feeders. As adults, they become more selective, consuming small fish, crustaceans, and clams, especially coquina clams (5).

Growth rates of pompano in the wild have been difficult to estimate. Several studies have investigated length-to-weight relationships (5,6,10). For example, Fields (6) and Finucane (5) estimated growth rates in wild fish at approximately 22 mm (0.8 in.) per month, while Bellinger and Avault (10) observed somewhat higher rates ranging from 27 to 42 mm (1.0 to 1.7 in.) per month, with a mean of 36 mm (1.4 in.).

Environmental Requirements

Pompano are tolerant of a wide range of environmental conditions. They thrive in salinities ranging from 0 to 35 g/L (ppt) (1) and adjust well to lower salinities if acclimated properly (4). Higher salinities are necessary in a hatchery application for the release, buoyancy, and survival of their eggs.

Temperature is a major constraint on pompano culture, as the species is relatively cold intolerant (1,4,5,11), with thermal stress and mortalities occurring in the range of 10–12 °C (50.0–53.6 °F) (5,11). This factor restricts the potential for outdoor culture to areas with winter temperatures higher than 12 °C (53.6 °F), but cultured pompano have recovered from temperatures as low as 9.7 °C (49.5 °F) (4). Growth and survival appear to be maximum at temperatures ranging from 26–30 °C (78.8–86.0 °F), although juveniles have been observed to thrive at a temperature of 34 °C (93.2 °F) (11).

In terms of their dissolved oxygen and pH requirements, pompano appear to be similar to other marine species currently being cultured. They can survive dissolved oxygen levels as low as 3.0 mg/L (ppm) for short periods of time, although levels at or below 2.5 mg/L (ppm) are lethal. Pompano can survive in water with pH ranging from 5–10 (4,11) and would likely survive any pH commonly encountered under culture conditions. Pompano also are known for their ability to survive in waters of high turbidity. These environmental characteristics make pompano an attractive candidate for commercial culture. Their capability to thrive in a wide range of environmental conditions also makes them a promising candidate for high-density recirculating systems. However, the major constraint on the development of such a system is the large capital outlay necessary to build and equip a commercial facility of this type. However, the ability to produce a product that commands such a traditionally high market price as pompano would be of great value to the aquaculture industry. Additionally, the use of indoor, high-density systems to culture pompano commercially would negate their relatively cold-intolerant nature as a factor limiting the development of an aquaculture industry focused on the species.

SPAWNING IN CAPTIVITY

Despite the attractiveness of pompano from a marketing and culturing standpoint, as of this writing, there has been little or no success in producing these fish economically via commercial aquaculture, a situation that is due primarily to the limited availability of young fish and to reduced growth efficiency of fish at advanced sizes (1). There were several commercial attempts at rearing pompano under aquacultural conditions in the 1960s and early 1970s in Florida and in the Dominican Republic (1). Those attempts generally met with failure, although McMaster (3) reported success with the culture of pompano by Oceanography Mariculture Industries in the Dominican Republic. That business reportedly developed reliable hatchery techniques, using gonadotropin injections and strip-spawning (i.e., manually expressing eggs from the female and fertilizing the eggs with milt from the male), but the growout stage had problems related to the design of the culture system and drastic declines in feed conversion as fish approached a size of 200 g (0.4 lb) (2). None of the techniques used by that venture have been published.

Numerous reports of spawning with the aid of human chorionic gonadotropin (HCG) injections by researchers in the 1970s (7,8,12) helped maintain interest in pompano culture. To date, however, there have been no published reports of successful spawning and culturing of pompano on a commercial level, and there have been no reports of a spawning regime for pompano that does not include hormone injections or implants. Several research institutions associated with universities, as well as a few enterprises in the private sector, have renewed attempts to close the life cycle of pompano. At the time of this writing, several laboratories in Texas, Louisiana, and Florida have pompano undergoing manipulation of photoperiod and temperature, in an effort to naturally spawn the fish, as is routinely done with red drum (*Sciaenops ocellatus*) (13).

Broodstock and Hatchery Conditions

Broodstock are collected by hook and line from the wild. Adult pompano are very active in the surf zones in the spring and summer. However, the fish are very nervous, and great care must be taken to transfer them to the hatchery without harm. Normal procedures for the hauling of any marine broodstock should be followed, including the use of oxygen to maintain dissolved oxygen levels above saturation and an anesthetic such as tricaine methane sulfonate (MS-222) at a level of 1–2 mg/L (ppm) to aid in calming the captured fish. By using these procedures, pompano can be transported for extremely long distances with little stress and minimal mortality. The fish are relatively hardy once relocated to spawning tanks and adapt well to the hatchery environment. They are voracious eaters and will begin to consume frozen squid or penaeid shrimp within two weeks of being brought into the hatchery. Typically, circular tanks 2.5 to 3.6 m (8 to 12 ft) in diameter are best for the hatchery system. Very little is known about proper male-to-female sex ratios or even how many broodfish to include in tanks of various diameters. Presently, 10–16 adult pompano in a tank 3.0 m (10 ft) in diameter appears to be an adequate stocking rate. The fecundity of pompano has been estimated to be between 400,000 to 650,000 eggs per female fish (12). A 1 : 1 or 2 : 3 male : female sex ratio should be sufficient to obtain adequate amounts of fertilized eggs. If significant numbers of eggs are observed as being unfertilized, the number of males in the hatchery tank should be increased.

Environmental Parameters

The hatchery system should include adequate biological filtration for the removal of nitrogenous wastes. Although no specific research on this issue has been conducted, hatchery systems designed for red drum have worked well with pompano. Levels of total ammonia and nitrite nitrogen of more than 0.5 mg/L (ppm) at pH 7.8–8.2 should not be sustained for prolonged periods of time. With proper sizing of the biological filter, and strict maintenance of pH through the addition of sodium bicarbonate, water quality should not pose a problem for the hatchery system. Although pompano are able to live and thrive in waters ranging widely in salinity, the preferred salinity for the hatchery system is 32–35 g/L (ppt), to ensure adequate floatation of the fertilized eggs for collection out of the spawning tank. Typically, water temperature is controlled using a heater and chiller combination, or, more effectively, by ambient-air control. The water temperature must be controlled within ±0.5 °C. Illumination should be provided by three separate banks of fluorescent lights, each connected to an individual digital timer, enabling the simulation of dawn, full daylight, and dusk, as well as precise control of photoperiod regimes.

Temperature and Photoperiod Spawning Regime for Pompano

Cycling of pompano in a hatchery may be achieved by techniques previously developed for the successful spawning of red drum. Because the beginning of the natural spawning season for pompano occurs in early spring, the cycle used for pompano should begin in summer and end the following spring. Spring-spawning fish typically respond to increases in temperature and photoperiod by beginning final oocyte maturation (9). The spawning cycle described next is presently being evaluated at Texas A&M University.

The cycle begins with conditions simulating summer and progresses through fall and winter, ending in conditions simulating spring. The environmental conditions for summer are 26–30 °C (78.8–86.0 °F) and 15 hours of daylight. The temperature is adjusted daily through the 30-day simulation of summer to temperatures resembling fall [20–24 °C (68.0–75.2 °F), 12 hours of daylight], winter [17–19 °C (62.6–66.2 °F), 9 hours of daylight], and, finally, spring conditions [21–25 °C (69.8–77.0 °F), 12 hours of daylight]. Due to the precise nature of the environmental controls, the changes occur on a daily basis, with each "season" represented by approximately 30 days. Once spring conditions are reached, the temperature and photoperiod are held constant until spawning begins. Minor alterations in temperature and photoperiod are enacted to induce spawning during the final 30-day period.

Other research laboratories are currently exposing groups of adult pompano to a natural year-long cycle, and as of this writing, they also have failed to produce successful spawning. Still other research laboratories are experimenting with hormonal implants. Implants typically are inserted into the broodfish, and the hormone is slowly released over time. Unfortunately, the method is relatively new in the field of aquaculture and has met with limited success. However, it is highly desirable over older manual injection techniques, due to the simplicity of the single event of inserting the hormone implant. Further, the technique greatly reduces stress on broodstock, and there are claims that it promotes more reliable and predictable spawning behavior. Still, there are substantial costs and labor involved with inserting the implant.

Successful Hormone-Induced Spawning

Early attempts to spawn pompano in captivity have met with varied degrees of success, with most methods involving the use of hormonal (gonadotropin) injections, followed by strip-spawning (3,7,8,12). Several successful attempts at spawning pompano occurred in Florida in the 1970s (7,8,12), using HCG injections ranging from 0.176 IU to 0.55 IU/g body weight. Higher dosages appeared to inhibit oocyte growth in response to the injections. The studies involved pompano that had been conditioned with photoperiod and temperature regimes, as well as unconditioned fish. Several successes were reported for techniques using both strip-spawning and seminatural spawning (i.e., allowing the injected female to return to the spawning tank to release eggs naturally). The use of hormone injections to spawn many different species of fish is fairly common, although natural spawning is far less labor intensive, less expensive, and, of course, far less stressful to the broodstock. However, problems associated with the methods used in the aforementioned studies are evident. For example, stress associated with the capture and injection of the broodstock is inevitable, and death of broodstock after strip-spawning is frequent and unavoidable. Clearly, it is desirable to spawn marine fish naturally, but so far that approach has met with no success with pompano. The future success of pompano culture is dependent upon reliable and predictable spawning procedures by any means. Until such procedures can be determined, pompano culture is destined to fail, as it did in the 1960s and 1970s.

CULTURE IN CAPTIVITY

Almost all research involving pompano has been carried out with wild-caught fingerlings, due to the unreliability and unpredictability of spawning adult pompano in captivity. Young juveniles have been easily caught with seine nets along the beaches of the Gulf coast of the southeastern United States (11). In the early 1970s, juvenile pompano were reared in 1-m^3 (35.3-ft^3) aluminum cages in Florida with some success (15). That effort concluded that juvenile pompano could be successfully reared to market size [approximately 454 g (1 lb)] in 47 to 51 weeks, starting with 7-g (0.02-lb) animals. Concrete tanks and wooden cages were used in Venezuela in the late 1970s, with mixed results. The cages were in an area of high salinity and temperature, which resulted in disease outbreaks and high mortality. Both growout studies concluded that several major constraints remained to be overcome before pompano culture could succeed on a commercial level. Included among the constraints were lack of a reliable source of fry and juveniles, lack of a formulated feed that would provide maximum growth, and lack of adequate disease control (1,15).

Diets for the culture of juvenile pompano have been problematic. Attempts in the 1960s to culture pompano involved primitive diets, mostly trout and salmon feed and fresh fish by-products (14). Those early attempts at growout studies, as well as commercial production, all documented a decrease in the feed conversion ratio as the fish approached market size. In some cases, feed conversion ratios went from 2:1 to over 6:1 in growout trials (1). The failure of previous commercial attempts to raise pompano was due primarily to the use of inferior diets that were not specifically formulated for pompano (1).

Pompano are relatively hardy fish and well suited for culture, even in high-density systems (1); however, disease outbreaks in early studies were prevalent. Protozoan parasites such as *Trichodina, Scyphidia* sp., and *Oodinium* sp. are the major external parasites found on wild pompano, while *Vibrio anguillarum* is the primary causative agent of bacterial disease outbreaks involving fin rot and skin ulcerations (16). Under good culture conditions, the most prevalent disease problem encountered in pompano

culture is *Oodinium* sp. That gill parasite is exceedingly deadly and will rapidly spread throughout the culture system if the outbreak not controlled (17). *Oodinium* sp. can be easily diagnosed through observation of the fish and microscopic examination of gill filaments. When infected with *Oodinium* sp., pompano "flash" noticeably, by swimming on their sides near the bottom of the culture tank. Gill filaments of infected fish have noticeable brownish–blackish ovoid spots when observed at relatively low (400×) magnification. Although not approved for use as a chemotheraputic for food fish by the U.S. Food and Drug Administration (FDA), copper sulfate and chelated copper have been successfully used to treat pompano stocks by laboratories, which have found these chemicals to be extremely effective for control of *Oodinium* sp. outbreaks. Treatment levels for juvenile and adult pompano should not exceed 0.25 mg free copper/L (ppm). Higher doses irritate the gills of pompano, as evidenced by exaggerated opening and closing of the pompano's mouths and flaring of their gill opercula.

The second most prevalent disease problem with pompano is secondary bacterial infections resulting from wounds obtained in the culture tank. Pompano are very skittish fish, and sudden movements or noises lead to rapid and frenzied activity in tanks, often resulting in bruised or cut heads and other incidental scrapes. Under hatchery conditions with excellent water quality, such wounds normally heal in two to three weeks. However, under more intensive culture conditions, there is a paramount need to prevent secondary infection by bacteria present in the environment. Pompano broodstock have been successfully treated for bacterial infections with oral application of oxytetracycline (OTC). This course of treatment involves dissolving OTC in a gelatin solution (4–5 g OTC/mL of gelatin solution) and injecting this mixture into shrimp, which are then fed to the broodstock. Treatments continuing for four to five days have successfully controlled bacterial infections. If the infection persists after one week, the treatment may be repeated. Experimental treatment of juvenile pompano with OTC at a concentration of 55 mg/kg (ppm) body weight has been successfully achieved by coating commercial feed with OTC in gelatin and feeding it to the fish for one week. The use of drugs in aquaculture is an exceedingly important issue, and FDA approval (in the United States) of safe, therapeutic treatments to aid in the culture of fish is necessary for the future of the industry.

CONCLUSIONS

The three main constraints on pompano culture in the past currently remain: (*1*) The predictable and reliable spawning of broodstock in captivity has not been documented; (*2*) the quantitative nutritional requirements of the species have not been determined; and (*3*) the problems associated with disease have not been suitably addressed. With the current renewed interest in the species, it should not be long until the life cycle is truly closed on pompano and the predictable spawning

of pompano becomes a reality. The well-documented nutritional problems, especially those relating to the increase in feed conversion rates, should not be a problem, given the steady advances in fish nutrition over the years. Diets formulated specifically for pompano would not only result in increased production efficiencies, but also aid in resistance to disease and reduction of stress. Additionally, the use or ultraviolet irradiation and, more recently, ozone for the oxidation of known pathogens in culture systems is increasing in the aquaculture community; these procedures may aid in the prevention and control of the disease outbreaks and mortalities that were so devastating to commercial ventures in the past. The price for pompano has historically been one of the highest for any marine fish, and that trend appears to be continuing. As long as the price for the species remains high and the public desires to consume this delectable fish, there will be a strong interest in commercial pompano culture.

Ponds as Culture Chambers

Siting and Configuration

Water Inflow and Drainage

Pond Preparation and Stocking

Management of Ponds

Harvesting

Bibliography

Ponds were the first type of culture system developed and continue to be much more widely used than any other type of culture unit (Fig. 1). A primary reason for the global popularity of ponds for culture is that under most circumstances, ponds are the least expensive way to produce aquatic animals.

Ponds can produce surprisingly high levels of aquatic animals if the ponds are properly managed. Management usually includes increasing the amount of food that is naturally available to the culture species, which can be done by fertilizing the pond to promote the growth of algae, zooplankton, and benthic organisms. Prepared feeds may also be provided, with or without fertilization.

Most aquaculture ponds are fairly shallow, although they vary widely in size and shape. A well-designed pond will not have side slopes that are so steep that they will easily erode and make access difficult or that have such a low angle that large amounts of shallow water, which promotes aquatic vegetation growth, are present. Ponds should have a reliable water supply, be fitted with a drain, and have a bottom that slopes toward the drain. They should be constructed in soils that have a high clay content, to prevent excessive seepage. Various types of liners may be used when facilities are constructed in

Figure 1. A typical fish culture pond, showing an inflow pipe to the left of the drain structure.

porous soils. Ponds need to be carefully managed to avoid stressing the animals contained within. Additional details may be found in (1–4).

PONDS AS CULTURE CHAMBERS

Ponds are relatively small, man-made water bodies that are employed to water livestock, control flooding, and produce aquatic animals. In the United States, it is common practice for farmers to employ ponds for multiple uses, by using them for both livestock watering and recreational fishing, and to have ponds provide an alternative source of food for livestock.

The first aquaculture production facilities in China consisted of ponds, and ponds continue to be the predominant culture chamber employed throughout the world, particularly in conjunction with freshwater aquatic animal husbandry. It has been estimated, for example, that over 75% of the freshwater aquaculture production in China comes from ponds. Carp production in China currently exceeds seven million tons annually. Most tilapia culture is conducted in ponds. Catfish farming in the United States is conducted primarily in ponds, and throughout the world, shrimp farming is dominated by pond culture. Trout, which we commonly think of as being reared almost exclusively in raceways (see the entry "Tank and raceway culture"), have been satisfactorily reared in ponds as well. This brief list could be expanded to include many additional species.

The steps taken by the fish culturist to enhance the production of species being reared range widely, but, in general, involve the provision of more food for the species than would be available under natural conditions. If we take a farm pond as a baseline, we might expect that the annual production of stocked fish is around 100 kg/ha (100 lb/acre). If the pond is fertilized, either with chemical or organic fertilizer (manures), productivity can be increased severalfold. Sometimes, natural productivity is increased without direct assistance by humans. For example, fertilizers applied to cropland can run off into ponds and lead to increased productivity. Similarly, farm ponds in pastures may receive organic fertilizer inputs from the livestock in the pasture. If the pasture is fertilized, the ponds may also receive chemical fertilizers from runoff.

Options for growing aquatic animals in ponds include the following, where the production figures (in parentheses) are the range typically observed for channel catfish, in kg/ha (lb/acre) (4):

1. Stocking only (50 to 100);
2. Stocking and fertilizing (200 to 300);
3. Stocking, fertilizing, and providing supplemental feed (not a technique used with catfish);
4. Stocking and feeding (1,500 to 2,500);
5. Stocking, feeding, and providing supplemental management (4,000 to 15,000).

In the last option, supplemental management may include providing aeration when necessary, exchanging water, or

both. If only aeration is provided in addition to stocking and feeding, the lower production level (4,000 kg/ha) may be achieved. Production can be improved somewhat with continuous aeration and can jump to the higher level (15,000 kg/ha) when high rates of water exchange are also employed.

To control the amount of nutrients that enter a pond, the aquaculturist must apply fertilizer in known amounts directly in the water. Fertilizers enhance plant growth, which, in most cases, means increased phytoplankton production. For some species, such as milkfish, fertilization techniques aimed at encouraging the growth of benthic algae have been developed. In most cases, promotion of the growth of rooted aquatic vegetation is not desirable. Phytoplankton provide food for zooplanktonic organisms, aquatic insects (in freshwater), and benthic organisms, all of which, in turn, may be directly fed upon by the species being cultured. In some cases, algae may be consumed directly by the culture species (for example, molluscs, such as clams and oysters, and some larval animals).

To further enhance productivity of the species being cultured, prepared feed may be provided, in the presence or absence of fertilization. Supplemental feed provides additional protein, fat, and energy for the culture species, but may not provide all of the required nutrients. The most sophisticated form of pond culture involves providing the culture animals with complete feeds. Complete feeds are feeds whose formulation is based on the known nutritional requirements of the animals. Complete feeds supply the proper levels of protein, fat, energy, vitamins, and minerals.

It has been said that no two ponds are alike. This statement does not refer to the general size or shape of a pond, as it is relatively easy to construct two ponds that share all of the same physical dimensions. What sets one pond apart from another relates to biology and chemistry. Even when ponds are stocked identically (i.e., with the same numbers of the same-size animals of the same species) and managed in the same fashion (e.g., the same amount of feed is given at the same time each day, the ponds share the same fertilization schedule and rate, etc.), there will be differences in the amount and type of biota present and in the water chemistry. Different species and concentrations of algae frequently grow, and differences in the zooplankton and benthos communities develop naturally in any pond. In many instances, bird's-eye examination of a group of ponds of the same size and shape will reveal distinct differences in water color that underscore the inherent variation that can occur. Because the biota vary, so will nonconservative water quality parameters, such as pH and levels of dissolved oxygen, carbon dioxide, ammonia, nitrite, and nitrate. As a result, management of individual ponds may vary considerably on any given aquaculture facility. Other culture systems, such as tanks and raceways, tend to be more uniform with respect to both their biota and water chemistry, because high water-turnover rates make physical factors more important than biological factors in controlling the culture environment.

SITING AND CONFIGURATION

Three types of ponds are recognized by aquaculturists and vary depending on hydrology (4). Levee, or embankment, ponds are the most common type of pond. They are made by constructing levees around the perimeter of the area that is to impounded. The original ground level becomes the pond bottom. Since the tops of the embankments are above the original ground level, water must be pumped into levee ponds. The source of water can be well water or surface water (such as lakes, streams, estuaries, or the ocean).

Excavated ponds are the second type of pond used for aquaculture. Earth from the pond-bottom area is used to construct the levees. In many instances, the tops of the levees are above the original ground level, and it may even be necessary to haul off excess earth (which may be used to construct levee ponds). If the bottom of an excavated pond is below the water table, it may be partially filled by seepage. Water may have to be pumped into excavated ponds to completely fill them, though rainfall sometimes is sufficient to maintain the water level. If the levee tops are at the same level as the elevation of the original land, there may also be some runoff to help keep the ponds full.

Both levee and excavated ponds can be of any shape. The shape of ponds may vary, because of the shape of the property on which they are constructed, but in most cases, rectangular ponds seem to be the most common type constructed.

The third type of aquaculture pond is the watershed pond. Watershed ponds are formed by damming a watercourse to impound runoff water. The ponds tend to be of irregular shape, though it is possible to construct rectangular ponds below a dam and distribute runoff water to them through canals or pipelines. Many catfish grown commercially in Alabama are raised in watershed ponds.

The location of an aquaculture facility is often based on the general locale, opportunity, or land availability, rather than suitability of the area for construction of ponds. Ideally, the land should be level to gradually sloping and have soil that has a high percentage of clay (a minimum of 25% clay is recommended). The soil should be free of toxic chemicals. Competition for space with other user groups, land costs, existing ownership by the prospective aquaculturist, proximity to markets, availability of suitable volumes and quality of water, and other factors may influence the choice of location (see the entry "Site selection").

Many coastal regions have sandy soils, which do not hold water well. In fact, some coastal sediments may be almost entirely composed of sand and shell material. However, in order to construct a facility in proximity to saltwater, it may be necessary to construct ponds in such soils. Inland sites may also have soils that do not hold water. There are various methods that can be used to prevent seepage, but all of them will add to the cost of construction. For example, bentonite, a clay mineral, can be mixed into the soil. When wet, bentonite expands greatly and is thought to help seal pond bottoms. However, many aquaculturists who have tried bentonite have experienced more frustration than success, so impermeable membrane liners have become

more popular. Plastic and fabric lining materials, available from various sources, can be spread over the sides and bottoms of ponds to provide an impermeable layer. Liners vary greatly in cost, depending on the material they are made of and their thickness.

Ponds can be of virtually any size, though they typically range from less than 0.2 ha (0.5 acre) to 8 ha (20 acres). Sixteen-ha (40 acre) ponds were common in the catfish industry several years ago, but they were difficult to manage, and if a disease or water quality problem led to high levels of mortality, the economic consequences were disastrous. Most of the large ponds have now been divided into two or more smaller ponds.

Small ponds are often used for holding broodfish, for spawning, and for fingerling production. Large ponds tend to be used for growout. Large ponds also tend to be more common in areas where mechanized harvesting (e.g., seines pulled by trucks or tractors) is conducted. Where human power is used to harvest, smaller ponds are more practical. Also, when the culture species is fed from the bank by hand (as opposed to using boats or feed blowers towed behind tractors or trucks), it is easier to distribute food evenly from the bank of a small pond than a large one.

Prior to construction, surface vegetation, including grass, should be removed. Topsoil can be set aside for use on the completed levees in areas where grass will be encouraged to grow. It is extremely important to remove stumps, roots, and any other type of organic debris from the site and not to place any such material in the levees: As organic matter decays, it will create voids in the levees that water will eventually find. Breaches in levees and other catastrophic failures can result.

Levees should be constructed with slopes of 1:2 or 1:3 [i.e., 1 m (ft) high for every 2 or 3 m (ft) wide] (Fig. 2). Ponds have also been constructed with much steeper slopes; 1:1 is not uncommon, and even vertical walls—typically of wood or concrete—are sometimes used (Fig. 3). However, steep slopes make entry and exit from ponds by personnel difficult, unless stairways are provided. Also, the shallower the slope, the more shallow water that is available. This condition limits total water volume in the pond, but, more importantly, provides increased area where undesirable rooted aquatic vegetation can become established. Pond
Figure 3. Ponds with vertical sides constructed of wood. This approach allows for the construction of narrow between pond levees, but will add to the cost of construction.

bottoms should gradually slope toward the deep end. A 1:100 slope is sufficient for the bottom.

Most aquaculture ponds have a maximum depth of no more than about 2 m (4 ft). Shallow ponds are less expensive to construct than deep ponds, since less earth must be moved. Also, shallow ponds utilize less water, which may be important economically. In addition, it is much easier to seine a shallow pond than a deep one. Seines are used to harvest various species of fishes, and, at least in relatively small ponds, seines are often pulled manually. People who pull seines do not want to have to swim while pulling the seine; they should be able to walk along the banks without experiencing water depths much over waist high.

Deep ponds have greater volumes per unit of surface area than shallow ponds and tend to stratify during warm weather. If you were to wade into a pond out to a chest-deep level in a temperate region during summer, you might find that your upper body is in warm water while, from your waist down, the water becomes progressively and noticeably colder. The change in temperature, called a *thermocline*, can be several degrees in a typical pond. In shallow ponds, such as used in aquaculture, the thermocline goes to the bottom. In a deep pond, another zone, called the *hypolimnion*, will form below the thermocline. Water in the upper layer (the *epilimnion*) is mixed by the wind, but the thermocline forms a barrier that prevents mixing in the hypolimnion. Over a period of time, due to the respiration of living organisms and the decay of organic matter, the dissolved-oxygen level in the hypolimnion can be reduced to lethal levels. Thus, the aquaculture species will avoid the deep water, if possible. (Immobile species are not able to move to shallower, more oxygen-rich water). As a result, the effective volume of the pond is reduced to that of a shallower pond that does not have a hypolimnion. Therefore, there is no advantage to building a deep pond rather than a pond that, at its deepest, is about 2 m (6 ft).

Levees should be wide enough to allow for easy mowing. If they are too narrow, the chance that erosion will occur increases. One levee, usually the one at the drain end of the pond, should be wide enough to drive on and should be

Figure 2. Cross-sectional diagrams of ponds with different side slopes.

Figure 4. An antiseep collar (this one fabricated from metal) being placed around a drain line that will be installed through the levee of a pond under construction.

Figure 5. Water flowing by gravity into a culture pond in Jamaica.

topped with gravel, to provide all-weather access. It will be necessary to drive along at least one side of each pond for harvesting and, in most cases, for feeding. The levees should be planted with grass, to prevent erosion.

Drain lines should be fitted with antiseep collars imbedded in the middle of the levee (Fig. 4). An antiseep collar is a device that prevents water from working through the levee along the drain line over time and eventually leaking from the pond. When water reaches an antiseep collar, it will be distributed laterally instead of being able to follow the pipe. Antiseep collars can be constructed of metal, concrete, or any other sturdy and nondegradable material.

Orientation of ponds with respect to prevailing winds is a sometimes a consideration, particularly in small ponds. Wind mixing will provide aeration and limit the time during which a thermocline can form, so the long axis of small ponds should line up with the direction of the prevailing wind if the culturist wishes to encourage mixing. At the same time, if the prevailing winds tend to be strong, it may be better to orient ponds with their narrowest aspect to the prevailing winds. This configuration will reduce the size of waves that form and thereby reduce bank erosion. In large ponds, wind mixing tends to be acceptable no matter what the orientation, so erosion prevention becomes the major consideration in pond orientation. Orientation is also often dictated by the configuration of the land on which the ponds are constructed.

WATER INFLOW AND DRAINAGE

Each pond should have plumbing to provide for inflow and drainage. While this requirement seems intuitive, there have been instances in which moveable pipe has had to be maneuvered into place each time a pond was to be filled. Inflow may also be diverted surface runoff, as mentioned previously for the case of watershed ponds. When water is diverted from a stream, reservoir, or irrigation canal, it may be routed into culture ponds by gravity through surface channels or through pipes (Fig. 5). Pressurized systems require pipelines and valves to each pond, to control inflow locations and volumes. When water under pressure is available, spraying the water into ponds may help improve the culture conditions during periods when levels of dissolved oxygen are low.

Pipelines should be sufficiently large to allow a pond to be filled within several days. Small ponds can often be filled in no more than three days, while it may take one to two weeks to fill large ponds. The smallest practical pipes and valves should be used to keep costs down. Splash blocks (concrete pads) are useful at inflow locations to avoid eroding pond bottoms during the early stages of filling.

Inflow pipes can be located anywhere, though they tend to be at either the upper (shallow) or lower (drain) end, or there may be one inflow line at both ends. If only one inflow line is used, the culturist needs to decide whether to place it at the upper end, where attempts to flush water through the entire pond will be facilitated, or at the drain end, where new, high-quality water can be added during periods when the pond is being drained for harvesting and the fish are concentrated in a small volume of water near the drain. Clearly, having water available at both ends of the pond is optimal.

Once a pond has been filled, the water level needs to be maintained. During dry periods, evaporation may require that water be added intermittently to maintain the level of the pond. A good management practice is to keep the water level somewhat below the top of the level or overflow pipe. A few centimeters (a little over an inch) of freeboard will allow additional free water to be obtained and retained when it rains.

The simplest and least expensive drain is a simple standpipe that is elbowed into a drain line. The water level can be controlled by the elevation of the standpipe above the pond bottom, since the standpipe swivels on the elbow. The standpipe can be located inside the pond or, if a drainage ditch is available, outside the pond (Fig. 6). Standpipes and drain lines of this nature can be made from metal pipe, which is recommended particularly for large ponds, because of its strength. Polyvinyl chloride (PVC) pipe is light in weight, nontoxic, will not corrode, and is much easier to cut and plumb than metal pipe. PVC

pipe is commonly used for both inflow and drain lines in small ponds.

When funding is not limiting, more elaborate drain structures are a better choice (Fig. 7). Such structures may have stairways, to provide easy access for personnel. They are usually constructed of concrete and are called *kettles*, or *monks* (Fig. 8). A typical kettle has a back and two sides made of concrete, with a concrete floor. Kettles are constructed in front of or within the levee at the deep end of the pond, with the top of the concrete walls extending above the maximum water level. A screen (or preferably a pair of screens) is fitted into slots at the front of the kettle

Figure 8. A simple kettle design has two sets of boards set in slots to control the water level. Dirt is packed between the two sets of boards to deter leakage. Valves are not required in conjunction with this type of kettle, but a good deal of labor is needed to put the dirt in place and then remove it. The third pair of slots show the location of the screen.

so that water may enter, but fish are screened out. The dual-screen configuration (one screen behind the other) allows the culturist to remove one screen for cleaning if it gets fouled with debris, without allowing the culture animals to enter the kettle.

Concrete harvest basins are often constructed in front of kettles. Harvest basins of this type are particularly useful when harvesting freshwater or marine shrimp. Featuring concrete bottoms and side walls, harvest basins may be 30.5 cm (1 ft) or less in depth and of varying dimensions, though usually not more than a few meters (yards) on a side. Harvest basins provide a collection point for the animals being harvested to congregate when pond draining is nearly complete. By flowing new water into the harvest basin at the time of harvest, the level of dissolved oxygen can be maintained and excessively high temperatures due to radiational heating can be avoided.

POND PREPARATION AND STOCKING

It may be necessary to make some adjustments in water quality prior to stocking. Iron, carbon dioxide, and hydrogen sulfide may be present in the incoming water, particularly if it is from wells (see the entry "Water sources"). All of those undesirable substances can be removed, or chemically altered to reduce their toxicity, through aeration. If the soils in the pond bottom are acidic, it may be necessary to apply lime or crushed

Figure 7. A concrete kettle with a catch basin in front. Note the stairway to the left, the valve that can be opened to completely drain the pond, and a moveable (up and down in this case) standpipe to control the water level when the pond is in use or being drained. The pipe on the right side of the kettle is an inflow line. The screens have been removed in this photograph.

limestone to control the pH. Limestone (CaCO₃) can also be used to increase hardness and alkalinity if the water is deficient in one of these conditions (see the entries "Water hardness" and "Alkalinity"). The dissolved-oxygen level and temperature should be checked prior to stocking, to ensure that they are within the optimum range for the animals that will be introduced. If well water is used, the temperature of the incoming water may be different from that in ponds that have been allowed to come to ambient temperature, which may require several days.

Salinity, if too low, can be adjusted by adding salt, though this technique is not frequently practiced in ponds, because it is expensive. More commonly, the salinity is too high (or become too high as evaporation concentrates salts in the water), and refilling the pond with additional saltwater will not reduce the salinity to its original level. The solution for maintaining the desired salinity in marine ponds is to dilute the pond with freshwater.

Once a pond is filled, it may be fertilized to induce a plankton bloom or to encourage the growth of benthic algae, depending upon the species being cultured (see the entry "Fertilization of fish ponds" and specific information in contributions on individual species). Fry and fingerling ponds, as well as ponds in which filter feeders, milkfish, and tilapias are reared, are commonly fertilized to provide supplemental feed or the sole source of food. A well-established plankton bloom will shade out many of the rooted aquatic plants that might otherwise become established.

If an aquaculture facility runs its own hatchery, the amount of time between the capture of fish or invertebrates from the hatchery or early rearing facilities to the placement of the animals in growout ponds can be very short. On the other hand, if young animals are purchased from a distant hatchery, the amount of time between collection and stocking may be several hours. Further, the water temperature in hauling tanks will increase or decrease more rapidly than that in a pond. If the animals being stocked have been hauled for a period of at least several hours, the temperature may have changed significantly from what it was when the animals were put in the hauling tank. Also, the water source in which the animals are hauled may be of a temperature somewhat different from that of the water in the receiving pond. If the temperature of the hauling water is more than a few degrees different from that in the pond, it will be necessary to temper the animals. This can be done by pumping pond water into the hauling tank at a rate that will reduce the temperature by a few degrees per hour, until the water in the tank is the same temperature as that in the pond. When the temperatures have been equalized, the animals may be safely stocked.

MANAGEMENT OF PONDS

Day-to-day management of fish ponds involves feeding, evaluating and managing water quality, observing the culture animals for signs of disease and treating the animals if necessary, and keeping good records. The last item is sometimes neglected, but should be a primary management practice. Having accurate records for each pond is important to management decision making and for tracking performance from one pond to another. In many instances, information from pond records can be used to anticipate problems.

Feeding is a daily activity for aquaculturists. Some fish farmers feed six days a week, and some have even made statements to the effect that the fish will perform better if they go one day a week without feed. There is no validity in that opinion, but there is probably a lot of truth in the notion that the farmer wants to take off at least one day a week from performing farm duties. When prepared feeds are provided, the animals are typically fed once or twice daily, though when automatic or demand feeders are used (exclusively for fish), the animals may feed at their own volition. The number of daily feedings will vary to some extent, depending on the species being cultured, the water temperature, and other water quality conditions.

When sinking feeds are used, it may be necessary to subsample the animals periodically to determine growth rates and any changes that need to be made in the amount of feed offered. Floating feeds, which are appropriate for species that surface to obtain feed, provide a means by which the culturist can monitor the amount of feed being consumed and increase or decrease the daily ration, based on feeding activity. The use of floating feeds also provides the culturist with the opportunity to observe the animals and perhaps detect the onset of diseases before they become significant problems.

Water quality should be monitored in each pond, because of the intrinsic differences that exist between ponds. Feeding rates may be varied as a function of temperature. The amount of feed and supplemental aeration should be provided based on the level of dissolved oxygen, which should be measured at about dawn each day, particularly during warm, cloudy weather (see the entry "Dissolved oxygen"). The temperature need not be measured daily, though periodic measurements should be made, as is also the case for pH. Hardness and alkalinity measurements should be taken at least annually. Levels of ammonia, nitrite, hydrogen sulfide, and carbon dioxide may be measured when conditions warrant. An analysis of the water and soils for trace metals, pesticides, and herbicides may be desirable, or necessary prior to construction or after incidents that may have caused contamination. An example of such an incident might be suspected spray drift from pesticide application upwind of aquaculture ponds.

The water quality dynamics in a pond can be complex. As the rate of fertilization and/or use of prepared feeds increases with increased intensity of culture, there may be concomitant responses in terms of which water quality variable becomes first limiting. The first-limiting factor in ponds that are heavily fertilized and fed is usually the level of dissolved oxygen. Careful daily monitoring of oxygen is important, with measurement at dawn, as mentioned previously, being of particular importance for detection of dangerously low levels. Controlling the amount of oxygen through water pumping or aeration may allow other limiting factors to become dominant, including ammonia, nitrite, and, perhaps, carbon dioxide.

Ameliorating those factors when they become limiting is more difficult than simply providing aeration to deal with oxygen depletions.

Stress associated with low levels of dissolved oxygen, high levels of ammonia, rapid changes in temperature, handling, and various other factors can lead to the onset of disease in aquatic animals. The culturist should be particularly observant after any stressful incident. Epizootics typically occur after 24 hours, about three days, or two weeks following a stress event. Cessation of feeding is one of the first signs of a pending disease outbreak, so careful observation of the animals at feeding time is important, as mentioned previously.

In addition to maintaining grassy pond banks to avoid erosion, it may be necessary to perform intermittent routine maintenance on the portions of ponds that are underwater when the ponds are full. Uneaten feed, feces, and decaying organic matter from various sources can accumulate on pond bottoms, creating anaerobic areas that will reduce the water volume suitable for the culture species and may lead to overall oxygen depletion in the pond. Unavoidable erosion of banks, sometimes accelerated by the activities of culture species, such as rooting in pond banks by carp and digging into the banks by crawfish, may mean that repairs will become necessary.

After draining, ponds can be allowed to dry for a period of several weeks. The bottom may be disked to accelerate decomposition of organic matter, or pond bottoms contaminated with disease organisms or resting stages of parasites may be limed (such as with CaO) and disked to sterilize them. If slopes need to be repaired and reshaped, or if the bottom sediments need to be removed, it will be necessarily to employ tractors, bulldozers, backhoes, or draglines. In most cases, ponds can be in production for several years before needing extensive renovation.

Bird predation is a problem for many pond culturists. Noisemakers will work temporarily to ward off birds, but the birds will eventually ignore them. Netting can be installed over ponds to keep birds away from the water, but that solution is economically feasible only for small ponds. Patrols by dogs or humans will help keep birds away, but such patrols are not effective on large fish farms unless a large number of dogs or people are used, which may not be economical. Lethal means of dealing with birds are often employed as well.

In most instances, the animals stocked in ponds are allowed to roam freely within the pond, though there are cases in which cages of one species are used in conjunction with a second, free-roaming species. This type of polyculture (see the entry "Polyculture") may be employed if the two species are not compatible. In most cases, polyculture involves two or more compatible species that are allow to interact freely in an open pond.

HARVESTING

Ponds may be harvested one or more times a year to remove an entire crop, or they may be partially harvested periodically and restocked, a technique known as the "continuous harvest" method. Shrimp ponds will produce one crop a year in low temperate regions, such as South Carolina and Texas, and may produce two to three crops a year in tropical regions. The standard practice is to completely drain ponds during harvesting. The same technique is used for various other species as well.

The channel catfish industry once employed annual pond draining and harvesting almost exclusively, but has now gone to a continuous harvest approach. Fingerlings are stocked and fed for several months, then the pond is seined with a large mesh net, and marketable fish are removed, while submarketable fish escape through the seine. Periodically—perhaps as often as monthly—the pond is seined again. Restocking with additional fingerlings to replace market-size fish that were removed may follow each seining event or be done less frequently, depending on the availability of small fish. Some catfish ponds have been undergoing the continuous harvest regimen for over a decade without having been drained completely. One result of this technique is that water is conserved, and environmental damage associated with effluents from aquaculture ponds can be avoided.

Eventually, there may be an accumulation of stunted fish in ponds subject to continuous harvesting. Such fish consume feed, but do not reach market size, and end up being an expense, rather than a source of profit. Also, over time, pond banks may erode, and organic material will accumulate in the pond sediments and can impair water quality and negatively affect fish growth. Therefore, it may be wise to completely drain and harvest all ponds at least once every several years.

Continuous harvesting is desirable in that seine crews can spread their activity not only throughout the year, but also on a rotational basis, so that only one or a few ponds on a fish farm will be harvested on any given day. Continuous harvesting also ensures that there is a dependable year-round supply of fish for the market.

The technique of continuous harvesting may not always be the most economical way to raise fish. The problem of stunting has already been mentioned as a negative economic factor. Also some fish may reach market size, but escape the seine for extended periods of time. These fish will continue to grow and may reach sizes that are not particularly desirable, thereby bringing reduced prices at the processing plant. By harvesting an entire pond at one time, the farmer can, to some extent, time harvesting to take advantage of periods when prices are high, though timing is critical and may not always fit even the best planned growout schedule. Continuous harvesting spreads out and lessens the risk of bad timing, to some extent. For the catfish industry, in which off-flavors have been a major problem (see the entry "Channel catfish culture"), having several ponds containing harvestable fish virtually all of the time also helps ensure that at least some fish of suitable quality can be sold periodically.

A pond may be allowed to remain full, or it may be partially drained at the time of harvest. Seines should be of the proper mesh size to retain marketable animals, and they should be sufficiently deep to hold the bottom with the lead line while the float line reaches the surface, without stretching the seine tightly in the vertical direction. Having ponds no deeper than about 2 m (6 ft) reduces

to reach the processor alive and in good condition. Shrimp and other invertebrates may be removed from ponds and placed directly on ice, but they, too, need to be in good condition when harvested, as they rapidly spoil after death when exposed to high temperatures.

Predators on aquaculture facilities are at best a nuisance and at worst an economic disaster. Many predatory species are in small enough numbers or prey upon so few culture animals that, while being a nuisance, they cause little economic loss. On the other hand, some insects, birds, and a few other predators can decimate an entire crop, causing economic hardship for the aquaculturist.

Included in this discussion are animals that, while not predators, are pests on aquaculture facilities. Pests include burrowing mammals such as the muskrat, nutria, and beaver.

Figure 9. Tilapia culturists seine a pond in the Philippines.

the necessary amount of netting, and thus the expense, of seines of any given length. The length of a seine should be $1\frac{1}{3}$ as long as the pond is wide. Having ponds of uniform size is desirable in that the number of seines required can be small relative to what would be needed if ponds of various sizes are used.

For small ponds, seines can be pulled by hand (Fig. 9). For large ponds, trucks and tractors are routinely used to pull seines. Seines usually have a bag in the middle where the harvested animals are concentrated. The fish or invertebrates may be herded from the seine bag into a live car (basically a net pen staked to the pond bottom), from which they are netted and moved to the trucks that will take them to the processing plant.

When ponds are totally drained during harvest, it is common practice to pull a seine through each full or partially drained pond, lower the pond level, seine again, and so forth in three or four steps until the majority of the animals have been removed and the water level has been reduced by perhaps 75 to 80%. Thereafter, the pond can be completely drained and the remaining animals captured from the harvest basin and the bare pond bottom.

There are many variations on the theme just presented. If harvest basins are sufficiently large, the pond may be drained all at once or after only one or two passes through it with a seine. If the drain line from a pond flows into an open drainage canal, it may be possible to put a net over the end of the line, to collect animals as they are flushed from the pond (in that case, the screens over the kettle would be removed). Shrimp are sometimes harvested in this manner.

It is important to avoid having the pond water become too warm during harvesting. For that reason, harvesting activities often take place as early in the morning as possible. A pond may be partially drained overnight, and seining will commence when there is sufficient daylight and be completed before the hottest part of the day. During the last stages of harvesting, when there is very little water in the pond and the animals are concentrated in one area, the water temperature can rise precipitously. Having a plentiful supply of new, cool water to add will greatly reduce stress and subsequent mortality, which are important considerations, even when the animals are on their way to market. For example, many fish are expected

LOCATION AND DESIGN OF FACILITIES

Location and design of aquaculture facilities can significantly influence some predation problems. Aquaculture facilities located near rivers, major creeks, bays, marshes, or other wetlands, or known predatory bird roosting areas will increase the likelihood of significant predator interactions and problems. However, factors such as soil type and water availability critical to the production of the cultured species may override the problems associated with locating the facility within major predator corridors.

Facility design can also discourage predators or enhance predator control methods. For example, if a site is suitable for raceway culture, then it is more easily covered and protected from most predators than ponds. Small ponds are more easily protected than large ponds. Design of the facility to place fry, fingerlings, or other highly vulnerable life stages in areas nearest to human activities and where they can be easily observed is advantageous. Ponds and raceways at least 1 m (3 ft) deep with steep sides or band slopes and control of vegetation around facilities can discourage some types of predators. Finally, designing ponds or raceways that are covered or fenced, without disrupting normal production activities, can discourage many vertebrate predators.

INVERTEBRATES

Invertebrate predators include insects, crustaceans, molluscs, starfish, and leeches.

Insects

Certain aquatic insects prey on small fish (larvae and fry) and, in some cases, cause significant losses. Predatory insects include members of the following orders: Coleoptera, Hemiptera, and Odonata. The coleopterans and the hemipterans breathe air and must return to the surface periodically to replenish their supply, while odonates have gills. All of these insects colonize ponds as adults that fly in from other aquatic sites. Then they mate and lay eggs. Usually only after successful reproduction do they achieve numbers sufficient to cause serious damage.

The coleopterans are beetles and include several species of diving beetles (*Cybister*, *Dytiscus*, *Hydrophilus*, and *Dineutus* spp.) that prey on fish as larvae and adults. Diving beetle larvae resemble large segmented worms with large pincers or fangs. The fangs are modified mouth parts that pierce and hold prey, then suck out the body fluids. Adult diving beetles can reach 2 to 3 in. (5–8 cm) in length; they capture and kill prey with mouth parts that crush and tear the prey into pieces (1).

Hemipterans are true bugs and include predacious aquatic insects like the giant water bugs, water scorpions, water boatmen, and backswimmers. Hemipterans carry air bubbles trapped under their wings when they dive underwater and have mouth parts that are modified into beaks that pierce the prey. They inject their prey with digestive enzymes and then suck out the fluids. Typically it takes hemipterans 6 to 9 weeks to develop from eggs to adults and achieve numbers sufficient to cause major losses.

The giant water bug is among the largest insects, attaining a length of up to 4 in. (10 cm). The giant water bug swims by using its flattened hind legs, captures prey with modified front legs, then kills its prey and sucks the body fluids out using its piercing beak. Water bugs are seldom numerous enough to cause severe losses in aquaculture ponds.

Water scorpions are sticklike insects 1 to 2 in. long (2.5–5 cm). They are called water scorpions because the shape of their front legs resembles those of true scorpions. Prey is captured with the front legs, then pierced and consumed using the beak. Water scorpions are poor swimmers and usually cling to vegetation at the surface where they can breathe through their tubelike abdomen. Like water bugs, water scorpions are usually not numerous enough to cause severe losses of fish larvae and fry.

Water boatmen (Corixidae) are small bugs (less than 0.5 in.) that are not considered an important predator on fish larvae or fry, but compete with them for available natural food.

Backswimmers (*Notonectidae*) are small bugs (less than 0.5 in.) that swim upside-down by using their hind legs as oars. Backswimmers, although small, can inhabit ponds in such large numbers that they can severely impact larvae and fry. Backswimmers prey heavily on fish larvae, fish fry, and invertebrates.

Odonates include the damselflies and dragonflies. Large dragonflies (up to 5 in.) can prey on fish that they catch at the surface. The naiads (the aquatic larval stage) of dragonflies and damselflies have gills and do not need to come to the surface to breathe. The naiad stages of the dragonfly and damselflies are serious predators on fish larvae, fry, and also invertebrates like crayfish.

There are several methods to prevent and/or control aquatic insects. The most common method is to fill ponds immediately before stocking larvae or fry. This helps suppress the numbers of predatory insects by limiting the time for them to colonize, reproduce, and develop in the pond. However, immediately filling a pond before stocking may not be acceptable with certain fertilization and plankton development regimes (2).

Another common method is to treat ponds with chemicals to kill aquatic insects. In the United States, the following insecticides have been used to treat nursery ponds prior to stocking: trichlorfon, fenthion, and methyl parathion. However, insecticides may suppress zooplankton populations that are essential to the natural food chain of the larvae or fry being cultured. Insecticides are regulated by government agencies (e.g., in the United States, the Environmental Protection Agency or the Food and Drug Administration) and some "special local needs" (SLNs) exceptions have been granted. Current regulations should be checked before using any insecticides and the label followed explicitly (3). In most cases, insecticides cannot be used in ponds where foodfish will be cultured.

Probably the most common method for chemical control of insects is the use of diesel or kerosene. Vegetable oils (e.g., cottonseed oil) will also work but are more expensive than petroleum products. These products will form an oil slick on the surface of a pond. As air-breathing

insects (hemipterans and coleopterans) come to the water's surface to get air, the petroleum coats or plugs their air passages, causing them to suffocate. Usually application rates are between 1 and 4 gal/ac (9.5 and 38 L/ha). Often motor oil is mixed with diesel at a ratio of 1 part oil to 3 parts diesel. These should be applied upwind on the pond and a slick will need to be maintained for at least an hour. Aquatic vegetation and high winds will reduce the effectiveness of these treatments.

Controlling aquatic vegetation will also reduce insect populations by denying the insects good habitat and breeding areas.

Crustaceans

Crayfish and crabs may prey on slow-swimming fish larvae and small fry that they can catch. They can also severely impact ponds where fish are spawned by preying upon the eggs (e.g., minnows) and often cause muddiness in ponds through their foraging activities. Muddiness reduces the effectiveness of fertilization regimes and can thereby diminish the natural food chain in the pond. Generally, crayfish are controlled by draining and drying out the pond. Burrows can be treated with calcium hypochlorite (HTH) at 200 ppm (4).

Crabs can prey heavily on molluscs. Control for crabs usually involves screening intake water to remove planktonic larvae, baited traps to capture adults, or placing molluscs in cages or baskets so crabs cannot get to them.

Molluscs

Oyster drills are marine conches (gastropods) that prey upon oysters and other molluscan shellfish. They can cause serious losses, in some cases as much as 85–90% (5,6). Some oyster drills are reported to secrete a toxin that paralyzes their prey. As the name suggests, the oyster drill drills a hole through the shell of its prey by using its radula (toothed tongue). After penetrating the shell, they extend their proboscis (tubular mouth) into the shell, cut up the soft tissues with the radula, and suck out the flesh. Conches have pelagic larvae that allow them to disperse and colonize over a wide area. This pelagic dispersal makes control of oyster drills difficult.

Oyster drills have been controlled physically by divers with vacuum devices and with underwater plows that bury them before seeding the shellfish. Exposing oysters to air and treating their surfaces with a strong salt solution has been effective in controlling oyster drills, as has moving the oysters to less saline water.

Snails can be a pest in aquaculture because they are an intermediate host for several species of parasitic flukes. They can also decimate beneficial aquatic vegetation. Drying pond bottoms and disking in hydrated lime at 1,500 to 2,000 lb/ac (1680–2240 kg/ha) can eliminate snails. Also, copper sulfate can be used to kill snails in ponds. However, the concentration of copper sulfate will depend on total alkalinity of the water (4). Eliminating rooted and filamentous aquatic vegetation can also reduce snail populations.

Starfish

Starfish are predators of oysters, clams, scallops, and mussels. Like conchs, starfish have pelagic larvae that can settle directly on spat (young molluscs) and start preying upon them (7).

Starfish have been controlled using the same methods as those for oysters drills. Starfish have also been controlled physically with "starfish mops." Mops are made of rope-yarn bundles attached to iron bars, which entangle starfish when they are dug over shellfish beds. Applying hydrated lime to shellfish beds at a rate of 270 lb/ac (300 kg/ha) also has been effective (2).

Leeches

Leeches can be simple external parasites or true predators. Different species of leeches can inhabit freshwater and marine ecosystems and vary in size from less than 1/2 to 8 in. (1–20 cm) (8). Predatory leeches feed only on invertebrates. Fish leeches are external parasites that suck blood from the host fish. In aquaculture, leeches seldom cause major problems, but can harm fish if their populations are high and can cosmetically damage the product (e.g., fillet), making it unacceptable to the consumer.

Control of freshwater leeches has been accomplished by using salt baths of 1–3% for up to 30 minutes. Masoten has also been used in ponds at 1–2 ppm, depending on temperature. As this chemical may not be legal in some countries, check the label.

FISH

Unwanted or wild species of fish compete with or prey upon cultured species. Wild fish can also introduce diseases into the culture system and increase harvest costs because of the need to separate them from the cultured species.

Preventing wild fish from entering ponds is the first step in controlling them. Prevention methods include filtering surface water that is used to fill ponds, constructing overflow spillways with at least a 3 ft (1 m) vertical drop, constructing levees and drains so that floodwaters cannot enter ponds, and not transferring wild fish into culture ponds during seining and stocking operations. Draining and drying ponds between crops and filling ponds just before stocking can also help control wild fish. Completely draining the pond and treating any puddles (and holes in levees that could contain puddles) will eliminate many species that can survive by keeping their gills moist for long periods of time. Filter boxes or socks can be used to screen out wild fish and their eggs (2). Screening drains during draw-downs can keep wild fish from entering the ponds through drains from drainage ditches. Seines that are not thoroughly dry can transfer unwanted fish eggs from one pond to another. Carefully checking shipments of fish for unwanted species is always prudent.

Once unwanted species of fish have contaminated a pond, they may be controlled biologically or chemically. Biological control usually involves stocking a predator fish in the pond. The predator must be smaller than the

cultured species so that it cannot prey on them. This practice has worked in catfish and tilapia culture with the use of a variety of predatory species (9,10).

The most commonly used chemical to remove or kill fish is rotenone. Rotenone is a naturally occurring pesticide derived from the roots of certain plants (*Derris* and *Lonchoncarpus* spp.). Rotenone kills fish by blocking cellular respiration, but is not very toxic to mammals. Rotenone is best applied at temperatures above 60 °F (15 °C) and is more effective in acidic to neutral waters with low hardness (11). Rotenone comes in liquid and powdered formulations, usually with 5% as active ingredient. Rotenone is applied at 0.5 to 5 ppm, depending on water temperature and target species. Many times, after a pond is drained following harvest, rotenone is applied to the remaining water. Rotenone is detoxified rapidly by warm temperatures and intense sunlight. Usually rotenone is completely degraded in 3 to 14 days during warm weather. Rotenone is a restricted-use pesticide in the United States and many other countries.

Antimycin, chlorine, cyanide, tea seed cake, oil cake, and anhydrous ammonia have also been used to kill unwanted fish (12).

AMPHIBIANS

Frogs, particularly bullfrogs, are predators of larvae, fry, small fish, and crustaceans. Tadpoles compete for food and space with larvae and fry of some cultured species. The control of frogs and tadpoles includes drying ponds between crops and filling them just before stocking. Keeping pond levees and sides closely mowed and aquatic vegetation controlled will reduce the habitat that frogs prefer. Removing the frogs' floating egg masses can also help reduce their numbers. Encircling ponds with small meshed netting or solid fencing (e.g., sheet metal) to a height of 2 ft can keep out frogs. Finally, frogs can be physically removed by hunting them.

REPTILES

Snakes, turtles, alligators, and crocodiles can all prey on aquacultured species. Snakes can be discouraged by keeping pond levees and sides closely mowed and aquatic vegetation controlled. Bird netting and solid fencing around ponds can also discourage snakes and turtles. Turtles can be live trapped from ponds by using several different trap designs (13). Snakes and turtles are often hunted around aquaculture facilities.

Alligator and crocodiles (crocodilians) can be problematic. Crocodilians are usually more nuisance than major predator, although they have been known to prey on valuable brood fish. These animals migrate from surrounding areas, so a 6-ft (1.5-m) high chain-link fencing that is partially buried or has galvanized sheet metal buried to 18 in. (45 cm) deep can keep them out of most facilities. All crocodilians are protected by international treaty and special permits must be obtained before they can be captured or killed. Many states have animal damage personnel that will trap or remove nuisance crocodilians.

BIRDS

Undoubtedly, the most problematic predators around most aquaculture facilities are birds, as they can cause significant economic losses. In North America alone, more than 60 species of birds have been described as predators or pests on aquaculture facilities (14). Open water and a concentration of cultured aquatic animals attract predatory birds. Accurate identification and determination of the damage is critical to understanding potential impacts of a particular bird species (15). However, many species are attracted to aquaculture facilities without interfering with, or impacting, aquaculture production and profitability.

Predatory birds are highly mobile, efficient, and adaptable predators of aquatic organisms. Aside from preying directly on cultured organisms, birds also injure them (often leading to secondary diseases), spread diseases and parasites, and disrupt feeding and breeding activities. Common types of predatory birds that cause most problems on aquaculture facilities include cormorants, anhingas, pelicans, herons, kingfishers, gulls, terns, certain ducks, and particular hawks and eagles.

Cormorants, anhingas, and pelicans all belong to the same order (Pelecaniformes), which are characterized by having a pouched throat area, devoid of feathers, and highly webbed feet.

Cormorants (family Phalacrocoracidae) are major predators at aquaculture facilities around the world. Worldwide there are more than 30 species of cormorants (16). In North America, the double-crested cormorant is the most problematic predator on the majority of pond aquaculture facilities. Cormorants have long, flexible necks, and a straight, hook-tipped beak that efficiently captures slippery prey. They typically land and swim on the water's surface, then dive and swim through the water rapidly by using their feet for propulsion. Cormorants consume between 0.5 and 1 lb (0.25 and 0.5 kg) of fish per day (15). Cormorants do not have water-repellent feathers and, therefore, are often seen perched near the water with wings outspread, drying themselves after diving for food.

Anhingas (family Anhingidae), often called snake birds or water turkeys, are sometimes mistaken for cormorants. Anhingas also do not have water-repellent feathers and often swim with just their head out of the water. Like cormorants, they dive and swim to capture prey and perch with outspread wings while drying after diving. However, anhingas have a straight bill, not a hooked one, with which they spear prey. Anhingas are thought to consume about 0.5 lb (0.23 kg) of fish per day.

Pelicans (family Pelecanidae) capture fish near the surface with their scooplike pouch. All but one of the seven species of pelicans are predominately white and capture prey while swimming. The American and Eurasian white pelicans often fish cooperatively by swimming in lines while splashing the water with their wings and driving fish into the shallows, where the birds encircle them and capture them in their pouches. White pelicans are among the largest birds in the world and consume approximately 1 lb (0.5 kg) of fish per day. The brown pelican of North America can plunge-dive into

the water from a soaring position and capture fish. Brown pelicans are typically only in marine habitats, while white pelicans inhabit both marine and freshwater environments.

Herons, egrets, bitterns, ibises, and storks (order Ciconiiformes) all prey to some extent on fish and shellfish. Members of this order are long necked and relatively long legged. They stalk their prey, often by wading through shallow water, then striking with a rapid thrust of the bill. Large herons and egrets (e.g., great blue heron and great egret) consume between 0.3 and 0.75 lb (0.14–0.35 kg) of fish per day, while smaller varieties consume from 0.15 to 0.3 lb (0.07–0.14 kg) per day. Some members of this group, like the great blue heron and the night herons, feed at dusk or at night, especially when harassed during the day. Ibises are common predators of crustaceans such as crayfish (17). Storks tend to prey on invertebrates and sick or weakened fish. Wading birds often collect around aquaculture facilities in large numbers and can cause heavy losses (18).

Kingfishers (family Alcedinidae) are small birds that are territorial and solitary daytime hunters that plunge-dive to catch prey. Worldwide there are more than 80 species of kingfishers. Because of their territorial nature, kingfishers seldom cause major fish losses, but can be problematic around ornamental and tropical farms consuming from 0.05 to 0.15 lb (0.02–0.07 kg) of fish per day (15).

Worldwide there are more than 80 species of gulls and terns (family Laridae). Gulls have hooked beaks, while terns have straight and pointed ones. Terns are solitary daytime hunters that feed by hovering above the water, then dive headfirst into the water to capture prey. Gulls feed in a similar manner, but also capture prey while swimming and can scoop prey from the water without plunging. Gulls usually feed in flocks, scavenge readily, and will consume aquaculture feeds off the surface of ponds or raceways. Gulls will consume between 0.15 and 0.3 lb (0.07 and 0.14 kg) per day, while terns consume only about 0.1 lb (0.05 kg) per day. Large feeding aggregations of these birds can cause serious economic losses of fish, crustaceans, or feed.

Certain species of ducks (family Anatidae), loons, and grebes will prey on fish and shellfish. Loons, grebes, mergansers, and other diving ducks capture prey by diving and swimming underwater. Many diving ducks feed extensively on molluscs and can cause heavy losses in cultured species of oysters, clams, and mussels. Mergansers and other diving ducks do prey on small fish and crustaceans and can become problematic for farms if in large flocks. Grebes are not usually considered a problem, except in crustacean culture (19).

The osprey and some eagles are fish predators and can catch large fish. Normally these solitary hunters are not a major concern for fish farms, but have been know to cause problems by preying upon brood fish.

Prevention and Control Methods

Most birds that cause problems on aquaculture facilities are considered migratory and are protected by either federal and state laws or international treaties. In some countries, as well as some states in the United States, permits can be obtained for lethal control of depredating birds, but these are relatively rare. In the United States permits to kill depredating birds can be issued by the U.S. Fish and Wildlife Service (USFWS) after assessments of the damage created by the birds have been confirmed by the U.S. Department of Agriculture — Animal and Plant Health Inspection Service — Animal Damage Control (USDA — APHIS — ADC). Lethal permits are never issued until nonlethal methods have been used correctly and damages were verified.

Methods to discourage or prevent bird depredation have included completely enclosing the facility, perimeter fencing, overhead wires or lines, automatic cannons or exploders, pyrotechnics, scarecrows, alarm or distress calls, water sprays, lights, ultralight or radio-controlled model aircraft, and adapting new management strategies. In some cases, harassment of roosting areas has been effective in moving entire colonies away from aquaculture facilities. The methods utilized depend on factors such as type and size of the facility, extent of the problem, the bird species involved, cost of the prevention method, and management implications (20–22).

Complete enclosure is the only method to entirely prevent bird depredation, but is usually limited to raceways and ponds smaller than 5 ac (2 ha). All other methods that have been employed have had mixed results, depending on the species targeted and the tenacity of the manager. A combination of methods has generally worked best.

Birds quickly adapt or habituate to scaring devices. Any device that is automatic or stationary, such as automatic gas cannons, scarecrows, electronic noise makers, distress calls, and strobe or flashing lights, must be moved every few days and, if possible, set so that they go off at random intervals and varying intensities.

Table 1 summarizes the techniques commonly used to harass and discourage predatory birds around aquaculture facilities.

MAMMALS

A few mammals, not excluding humans, can be serious predators on aquaculture facilities, including otters, seals, and sea lions. Sea otters, seals, and sea lions are protected in most countries and cannot be killed without special permits. They are usually problems only around sea cages. Generally, exclusion nets surrounding individual netpens or the entire sea cage complex has been used to control these predators. Harassment techniques for these species have involved underwater sonic devices, but their effectiveness has been questionable.

River otters can be serious predators of freshwater aquaculture facilities, especially brood fish. These otters are usually most problematic during the winter months when natural food becomes scarce. River otters can be controlled by trapping. Minks also predate fish but do not usually cause severe losses.

Many mammals around aquaculture facilities are more pest than predator. These include beaver, muskrats, nutria, rats, and mice (2). Beaver can dam up water

Table 1. Harassment Methods Frequently Used on Various Bird Predators[a]

Bird Species	Control Method[b]								
	AC	CE	DC	L	OW	PF	P	WS	SC[c]
Cormorants	X	X			X		X		X
Anhingas	X	X			X		X		X
Pelicans	X	X			X		X		
Herons, egrets, etc.[d]	X	X	X[e]	X[f]	X[g]	X	X		X
Kingfishers	X	X					X	X	
Gulls and terns	X	X	X[h]		X		X	X	X
Ducks	X	X					X		X
Hawks and eagles	X	X			X		X	X	

[a]Effectiveness is highly variable and a combination of methods are often utilized.

[b]Control methods are automatic cannons (AC), complete enclosure (CE), distress or alarm calls (DC), lights (L), overhead wires (OW), perimeter fencing (PF), pyrotechnics (P), water sprays (WS), and scarecrows (SC).

[c]Scarecrows can include human effigies, raptor models (e.g., owls), and reflective strips. Moving or animated scarecrows work better than stationary ones.

[d]This group includes herons, egrets, bitterns, ibises, and storks.

[e]Distress calls work only with some species (e.g., black-crowned night heron).

[f]Lights are only effective with night-feeding species (e.g., black-crowned night heron and great blue heron).

[g]Overhead wires are only somewhat effective on larger species (e.g., great blue heron and great egret) that fly in to land in shallow water.

[h]Distress calls are somewhat effective on gulls, but not on terns.

supplies, especially creeks. The burrowing activities of beaver, muskrats, and nutria can severely damage pond levees, causing ponds to leak and making vehicular access dangerous. Rats and mice can consume and contaminate aquacultural feeds. Prevention measures include proper storage of feeds and elimination of access points (i.e., "rat proofing") and alternative food sources (e.g., garbage). Control of all these pests usually involves trapping and/or poisoning.

Aquaculture, with its intensive confinement of aquatic organisms, is attractive to predators. Losses are often difficult to quantify. Hoy et al. estimated that wading birds could cause losses of up to $10,000 per week on some bait fish farms during fall migration (18). Stickley and Andrews estimated catfish losses in 1988 of $3.3 million due to double-crested cormorants (23). They also estimated that in the same year, bird depredation control efforts were costing the catfish industry $2.1 million. It is prudent that the aquaculturist work with regulatory agencies, be aggressive with prevention and harassment techniques, keep good records, and work with other local producers to combat predators.

PROBIOTICS AND IMMUNOSTIMULANTS

WENDY M. SEALEY
Texas A&M University
College Station, Texas

OUTLINE

Immunostimulants

Immunostimulation of Specific Host Defense Mechanisms

Immunostimulants and probiotics are two promising options to aid in disease control. Interest in the use of immunostimulants and probiotics in aquaculture to improve aquatic animal health and prevent disease has increased rapidly in the last 10 years, due, in part, to limitations associated with the treatment of disease outbreaks in foodfish. Immunostimulants increase disease resistance by causing up-regulation of host defense mechanisms against pathogenic microorganisms. These substances are often grouped by either function or origin and consist of a heterogeneous group that includes vitamins and minerals; animal-, bacterial-, and fungal-derived compounds; and several synthetic compounds. Probiotics decrease the frequency and abundance of pathogenic or opportunistic pathogenic organisms in the environment. Probiotics are live microorganisms that are often introduced into the food chain to shift the microbial balance from disease-causing microorganisms to beneficial microorganisms.

IMMUNOSTIMULANTS

The immune system of fish and other cold-blooded vertebrates is similar to that of mammals in that it is divided into both specific and nonspecific branches. The immune system of invertebrates differs from that of all three of the former in that the immune system of invertebrates lacks a specific branch. An immunostimulant may stimulate the specific immune system when given along with an antigen, or it may stimulate the nonspecific immune system when given alone. The immunostimulatory effects of certain vitamins and minerals in aquatic species have been reviewed previously and will not be addressed here (1,2).

Immunostimulation of Specific Host Defense Mechanisms

A specific immune response is dependent upon the host having prior exposure to an antigen and requires recognition and subsequent activation of the immune response through a coordinated effort of antigen-presenting cells, B lymphocytes, and T cells. Vaccination is the best known method of specific immunostimulation. (See the entry "Vaccines.") Immunostimulatory products other than vaccines have also been effective at improving specific immune responses, by acting as adjuvants. Adjuvants are compounds that are used in conjunction with a specific antigen to increase intensity and duration of the specific response

against that antigen. Classically, adjuvants were injected with vaccines to intensify antibody production by holding the antigen in tissues for slow release; most oil-based adjuvants intensify antibody production in this manner. Other products, such as dextran sulfate, act as adjuvants by protecting the antigen from rapid clearance, which could lead to a decreased response to the antigen.

Oil-based products, such as Freund's complete adjuvant (CFA) and various modifications of CFA, were initially used in fish and have been shown to increase antibody production in multiple species. When salmonids are injected with CFA or a modified version of incomplete Freund's adjuvant (MIFA) containing bacterins (whole-killed bacteria), an increase in antibody production is generally observed (3). Oil-based adjuvants also have been shown to increase protection against bacterial infections in fish. For example, injections of oil-based adjuvants combined with *Aeromonas salmonicida* bacterins increased protection of rainbow trout (*Oncorhynchus mykiss*), coho salmon (*O. kisutch*), and brook trout (*Salvelinus fontinalis*) against furunculosis (4,5).

Adjuvants also can increase the action of cell types involved in the specific immune response by attracting them to the injection site, thus allowing greater numbers of specific cell types to be exposed to the antigen. Compounds with mycobacterial components, such as CFA, bacille calmette guerin (BCG), muramyl dipeptide (MDP), and the synthetic drugs levamisole and FSK-565, function in this way by stimulating the attraction and subsequent increased production of T cells in terrestrial mammals. These compounds have also been used in aquatic species, with similar results.

Due to the damage of tissues surrounding the injection site often encountered with many of the classical compounds, newly developed adjuvant products focus on increasing cell activation. Recently, studies have examined the ability of β-glucans, polysaccharide derivatives from yeast and fungi, to increase antibody responses in fish and have turned up varied results (6−8). Glucans are believed to function as nonclassical adjuvants by increasing macrophage activation, thus, theoretically, increasing antigen presentation to T cells, resulting in a more vigorous antibody response. A positive aspect of glucans as adjuvants is their ability to be administered not only by injection, but also orally or by immersion; the latter two methods do not cause substantial tissue damage.

Immunostimulation of Nonspecific Host Defense Mechanisms

Most immunostimulatory compounds examined in fish have been shown to have immunoenhancing potential through improvement of nonspecific immune responses of fish. The nonspecific branch of the immune response, in contrast to the specific branch, does not require prior exposure to an antigen and consists of barriers, such as skin, scales, lytic enzymes, and phagocytic cells. The nonspecific immune response is also considered to be the first line of defense against invading organisms. It has been hypothesized that fish and invertebrates are more reliant on this branch of the immune response. For these

reasons, a large portion of the research on immunostimulation has focused on up-regulating the nonspecific immune response. Mononuclear phagocytes and granulocytes are the key components of the cellular nonspecific response of fish. Hemocytes and the prophenoloxidase system are the primary defense mechanisms of shrimp. The activation states of these cells and enzyme systems are often used as measures of nonspecific immunostimulation. Other measures employed for this purpose include cell migration, phagocytosis, and bactericidal activity, as well as changes in numbers of leukocytes and the activation potential of cells upon stimulation, as measured by oxidative radicals and enzymes.

Common Immunostimulants Used in Aquaculture

Immunostimulants that have been examined most frequently for their ability to increase the nonspecific immune responses of aquatic animals include glucans (9–14) and the synthetic drug levamisole (15–18). Additionally, animal-derived products, such as chitin (19,20) and abalone extract (21); bacterial-derived products, such as MDP; and plant-derived alginates, such as k-carrageenan (22,23) and spirulina (24), have been examined.

Glucans appear to show the most promise of all immunostimulants thus far examined in fish and shrimp. β-glucans are insoluble polysaccharides consisting of repeating glucose units that can be joined through β1–3 and β1–6 linkages when derived from yeast and mycelia fungi (10), and β1–3 and β1–4 linkages when derived from barley (25). The source and extraction process by which these glucans are produced can greatly affect their immunostimulatory capacity. Engstad et al. (26) have suggested that the mechanism through which these agents induced protection in Atlantic salmon (*Salmo salar*) was by increasing lysozyme and complement activation; results observed in other fish species seem to support these results (27,28). Increased oxidative capacity of phagocytic cells also has been suggested as the mechanism through which β-glucans enhance nonspecific resistance (29,30).

In vitro studies have attempted to further examine the potential of glucans to stimulate the phagocytic cells of aquatic animals and the mechanisms by which the glucans exert their effects (31–33). When macrophages were cultured in the presence of glucans, they underwent spreading and membrane ruffling, which are indicative of activation. In addition, these cells demonstrated increased pinocytosis, increased superoxide anion, and elevated acid phosphatase levels. However, studies indicate a suppression of response at the highest glucan levels examined.

The immunostimulatory potential of levamisole in fish is of considerable interest in the United States and elsewhere, because it has approval by the U.S. Food and Drug Administration for treatment of helminth infections in ruminants (3). Levamisole, which is a synthetic phenylimidazothiazole (21), has been shown to have the ability to up-regulate nonspecific immune responses in carp (Cyprinidae) (20), rainbow trout (3), and gilthead seabream (*Sparus aurata* sp.) (21).

Certain animal products and extracts also have nonspecific immunostimulatory potential. For example, injections of abalone extract and chitin increase phagocytic response and natural killer cell activity in fish (23–25). Increased protection against *A. salmonicida* has been observed when brook trout were injected with chitin (34). Products derived from various algal species, such as carrageenans, linear sulfated poly-d-galactans composed of repeating disaccharide units (26), and the blue-green algae *Spirulina platensis*, (28) also show nonspecific immunostimulatory potential. Unfortunately, this up-regulation of the nonspecific response does not always correlate with resistance to bacterial infections.

The foregoing information provides a brief coverage of common immunostimulants used in aquaculture and their effects on the nonspecific immune response of fish. Many other immunostimulants have been tested for the ability to increase immune function in aquatic species (3,35,36).

Research on Immunostimulants in Disease Resistance of Aquatic Animals

Although the scientific literature on immunostimulants seems to indicate that they have a positive effect on nonspecific immune responses, their effect on disease resistance is less clear. Immunostimulation of disease resistance appears to be dependent on the type of aquatic species and disease agent. β-glucans have been the most studied immunostimulant in terms of disease resistance (3,35,36). β-glucans have been reported to increase protection against *Vibrio anguillarum*, *A. salmonicida*, and *A. hydrophila* in a variety of salmonid species, as well as in carp, gilthead seabream, milkfish (*Chanos chanos*), tilapia (*Oreochromis niloticus*), and turbot (*Scophthalmus maximus*). β-glucans also have been shown to increase protection against *Edwardsiella tarda* in carp, milkfish, and tilapia, as well as against *Streptococcus* sp. in yellowtail (*Seriola quinqueradiata*). However, β-glucans have not been shown to be effective at increasing protection against *Edwardsiella ictaluri* in channel catfish (*Ictalurus punctatus*) *Pasteurella* sp. in yellowtail (*S. quinqueradiata*) or *Yersinia ruckerii* in Atlantic salmon.

β-glucans have also received attention in recent years for their ability to increase disease resistance in shrimp, largely because the limitations of the shrimp immune response and the nature of the disease agents make the development of effective vaccines impractical. β-glucans have been shown to increase resistance of both kuruma (*Marsupenaeus japonicus*) and tiger shrimp (*Penaeus monodon*) to *Vibrio* infection (37).

Other Considerations

Certain types of immunostimulants appear to have potential for incorporation into disease prevention and control regimes — in particular, the β-glucans and levamisole. However, some concerns about immunostimulants must still be addressed. Many factors contribute to the success or failure of an immunostimulation regime, including the type of immunostimulant, the dosage (level, route, and application), the fish species, and the disease organism(s) against which protection is sought.

The type of immunostimulant chosen to be incorporated into an immunostimulation protocol is of obvious importance, due to the large variation of responses. The proper dosage of the immunostimulant also is critical, because failure to administer a sufficient amount could result in no enhancement of response, while excessive quantities can lead to immunosuppression. In addition, considerable variations in immunostimulant effectiveness have been noted with different routes of administration. Injection protocols clearly have produced the best results. However, injections are problematic, due to the considerable effort necessary for their administration, the excessive stress they cause on the fish, and the fact that they are often cost prohibitive. Bath immersion has also been shown to be somewhat effective, but is generally not practical for larger size fish. Oral application of immunostimulants therefore appears to be the route of choice. Unfortunately, oral applications also have the most varied success rates. In addition, to date, much of the research performed has focused on using immunostimulants to prevent disease by applying the compound prior to infection. Further research addressing dosage and timing of prophylactic and therapeutic oral treatments, and further investigation of the adjuvant activity of many of these compounds, seem warranted.

PROBIOTICS

Probiotics may be defined as live organisms that beneficially affect the microbial balance of the host (38). A variety of mechanisms have been proposed to explain the actions of probiotics, including their production of antimicrobial substances, competition for adhesion receptors, and the provision of nutrients and direct immunostimulatory effects (39).

Administration Strategy

The strategy often followed for administering probiotics includes isolating bacteria from mature fish and including these favorable bacteria in the feed of juvenile fish of the same species (40). Lactic acid bacteria, such as *Carnobacterium* sp., which produce bactericins, are often used in this manner (41). Lactic acid bacteria have been isolated from the intestine of Atlantic salmon and can inhibit the growth of pathogenic bacteria, such as *V. anguillarum*, *A. salmonicida* (42), and *A. hydrophila* (43). Challenge experiments have shown that feeding larval turbot with rotifers enriched in lactic acid bacteria (44) and giving cod (Gadidae) fry dry feed containing lactic acid bacteria (39) improved their resistance to mortality due to *Vibrio* infection. However, no effect on the protection of salmon fry against *A. salmonicida* was noted when lactic acid bacteria were added to dry feed (42).

Mechanisms

The mechanism(s) through which probiotics infer protection remain speculative. Gildberg et al. (39) were unable to demonstrate growth inhibition of *V. anguillarum* in an *in vitro* mixed culture of *V. anguillarum* and *Carnobacterium divergens*, even though the lactic acid bacteria had elicited disease protection when included in the diet. This

observation seems to rule out the production of antimicrobial agents as the mechanism behind increased protection in Atlantic cod (*Gadus morhua*).

Considerations

One concern of including probiotics into the food chain or environment of larval fish is that the probiotics's colonization and proliferation within the host must remain under control. Gatesoupe (44) observed a negative correlation between high concentrations of lactic acid bacteria and survival in turbot larvae fed greater than 2×10^7 colony-forming units, indicating the need for careful determination of inclusion levels of lactic acid bacteria in order to obtain beneficial, not detrimental, effects of probiotics. In addition, these organisms have limited scope in their application to commercial aquaculture production. The successful isolation and cultivation of probiotic bacteria is a labor-intensive effort that seems best suited to larval fish culture when the environment or feed provided to mass quantities of fish may be treated with less probiotics and less labor.

CONCLUSIONS

Immunostimulants and probiotics appear to be useful tools to include in the arsenal of disease control and prevention. However, these compounds will not replace vaccines, proper nutrition, or good management techniques. The strength of these compounds appears to lie in their ability to enhance larval fish culture when the specific immune response has not yet developed and to improve nonspecific immune function against a variety of pathogens when a disease-causing agent has not been identified. Through such functions, the compounds may significantly aid the aquaculture industry, although some caution in their use is urged until dosage rates are optimized. Additional research is needed to define the specific dosage rates and efficacy of various compounds for a variety of aquatic species and their pathogens, to decrease costs of the immunostimulant or probiotic used and negate losses that could be encountered with improper supplementation levels.

PROCESSING

Russell Miget
Texas A&M University
Corpus Christi, Texas

OUTLINE

Aquaculture can be broadly divided into the categories of subsistence food production (i.e., food production that relies on aquatic plant production as well as low-density production of animals that feed near the bottom of the food web, such as carp, tilapia, and milkfish), and commercial production of relatively high valued food commodities (food production that relies on high density monoculture of animals that generally feed at a much higher trophic level on prepared feeds). This practice can also be thought of as the conversion of food of low economic value (i.e., grains and fishmeal) to food of high economic value such as shrimp, salmon, and sea bass. In some countries both subsistence and commercial production are utilized; many of the commercial products are often exported. Of the thousand-plus species of aquatic plants and animals consumed by humans, only about five percent are cultured, and of this five percent, less than one percent have their entire life cycle under control. This system results in a reliable supply of "seed stock" year round, similar to that used in agricultural production.

This entry focuses on the processing of the relatively high-value molluscs, crustaceans, and finfish that are raised in captivity for domestic consumption and/or international trade. This approach will not include processing

associated with subsistence aquaculture. Likewise, many traditional processes associated with seafoods, such as salting, curing, and mincing in surimi production, are not addressed, since these processes have historically relied on a relatively inexpensive supply of fish and shellfish in order to be profitable. Such products will continue to be economically supplied by the wild harvest fishery for the foreseeable future.

SPECIES

Molluscs

Aquacultured species consist principally of bivalves — oysters, mussels, clams, and scallops. Unlike finfish or crustacean aquaculture, which is most often carried out in monoculture ponds, molluscs are generally hatchery-reared and then raised to a size at which they can be placed in open waters for growout. Gastropods, such as abalone, queen conch, and certain species of whelks, are harvested primarily from the wild; however, these animals are in high demand, and there are active research programs underway to develop culture techniques for them. Cephalopods, which include squid, cuttlefish, and octopus, have thus far proven to be too expensive to raise in captivity, except in the specialty medical-research and ornamental markets.

Market Forms. Live bivalve molluscs are consistently the most valuable market form, but they require special handling and shipping procedures, and have a limited shelf life. Oysters (*Crassostrea virginica*, *Crassostrea gigas*, *Ostrea edulis*) are commonly consumed raw and therefore must be grown in waters that are certified by state shellfish authorities as meeting requirements to be (statistically) free of introduced human pathogens. Still, naturally-occurring pathogens which are concentrated by these filter-feeding animals can pose a health risk to people who consume them raw. Immunocompromised individuals are at the greatest risk. Unlike oysters, mussels and clams are generally cooked before consumption; the cooking effectively kills any pathogens which may be present.

Bivalve molluscs can survive for several days out of water simply by closing their shells tightly. However, in order to survive in that state, their metabolism must be significantly reduced through cooling. Most bivalves can survive for up to two weeks without significant mortality when stored at about 4 °C (40 °F). The exceptions to this rule are certain clam species for which 4 °C (40 °F) is lethal. The animals are stored dry in a cool, moist room. If stored in water, they will open up and begin pumping, and will eventually foul their own water and deplete the oxygen. Animals that die during live storage will open slightly (gape) and should be discarded. One exception to dry storage is soft-shell clams (*Mya arenaria*). These clams are routinely placed in clean seawater for a few hours to allow the discharge of grit and sand from the intestine, after which they are placed back in dry, cool storage.

There has been some thought given to wet holding (not storage) of oysters in order to improve their flavor. Because oysters are osmoconformers, shell stock placed in higher salinity waters will, over several hours, conform to the salinity of the surrounding water and result in a product some consumers find more flavorful. However, if such a process is employed, rigorous water quality standards (similar to those required for oyster depuration) would have to be adhered to. This process involves continuous filtration and disinfection of the recirculating high-salinity water.

More commonly, however, processing bivalve molluscs for the live market consists simply of breaking up clumps, washing, sorting to size, and packaging in breathable material like onion sacks. Mussels (*Mytilus edulis*) destined for the live market usually have their byssal threads (beard) removed first. The preferred mussel size is about 5 centimeters (2 in.) long.

Cultured mussels supply the live market. These, and marinating mussels, are the only types that have brought profit in the western hemisphere. Increasingly large quantities of green-lipped mussels (*Perna canaliculus*) are being imported to the United States from New Zealand. Korea, another significant exporter of mussels, ships mostly canned product to the rest of the world.

The live bivalve market has a few marketing idiosyncrasies of which one should be aware. The halfshell oyster market prefers medium-sized animals 7 to 9 centimeters (3 to 3.5 in.), whereas small hard clams (*Mercenaria mercenaria*) about 4 to 7 centimeters (1.5 to 3 in.), sold live, are more expensive than the larger animals, which are all wild-harvested and are usually processed further into soups and chowders.

The second most valuable market form for bivalves is the fresh market. Unlike many crustaceans and finfish that freeze exceedingly well (i.e., that make it difficult for the consumer to discern the difference between a fresh and a frozen product once it is prepared), certain bivalves (oysters and clams in particular) tend to diminish significantly in flavor and texture once frozen. Thus, considerable effort is made to develop and maintain fresh markets for these products.

Oysters are mechanically or hand-shucked to remove the meats for the fresh market. The entire animal, not just the muscle holding the shell together, is consumed, hence the public health concern discussed earlier. Mechanical shucking is faster but does not yield as uniformly intact a product as hand shucking and is therefore often employed when the product is going to be processed further, for example, breaded. Hand-shucked oysters are sorted by size as they are shucked, and are packed in gallon (3.8 L) containers (in the U.S) according to the number of meats (animals) per gallon (3.8 L): very small, over 500 meats; small (standard), 301 to 500; medium (select), 211 to 300 meats; large (extra select), 160–210; and extra large, less than 160. However, standards of identity for size no longer apply, so the aforementioned sizes are now voluntary grades. Unlike the live market, which prefers select size animals, the price for shucked oysters increases with size (except for *C. gigas*). After shucking and sorting, oysters are cleansed of shell fragments and other debris from the outside of the shell through a process of "blowing." This process consists of literally blowing the oyster meats around inside a container, using jets of air that enter

from the bottom. This allows grit and shell attached to the shucked meats to fall to the bottom. After 10 to 15 minutes the air is shut off and the meats are bathed in running water for another 20–30 minutes, after which they are removed and allowed to drain. The oysters are then packed "dry" (without additional water) in appropriate containers–increasingly, plastic tubs vs. traditional metal cans. Plastic is less expensive, is easily imprinted with company logos, recipes, and nutritional information, and allows the consumer to see the product through the translucent material. Although packed without water, a certain amount of liquid leaves the oysters after they are packed. This is referred to as "free liquor" and may amount to between 5 and 30% of the weight of the packed oyster meats, depending on the season and harvest location (there is generally more loss from summer-harvested oysters), and the condition (post-spawn oysters tend to be more "watery").

Cultured scallops (*Pecten maximus* in Europe, *Patinopecten yessoensis* in Japan) are hand-shucked for the fresh market. It is interesting to note that, in the U.S., only the adductor muscle of the scallop is eaten, whereas in Europe the entire shucked animal is consumed.

Certain molluscs maintain their original texture and flavor much better than others after being frozen and stored for a period of time. Product quality depends not only on species differences, but on the rate of freezing and packaging, and the temperature while in frozen storage.

The freezing of oysters may result in a loss of up to 30% of internal fluids (free liquor) upon thawing. Oysters also tend to darken once frozen; the degree of color change is proportional to how slowly the product is frozen. Oysters are rarely frozen in traditional metal cans, since the relatively slow freezing rate results in excess liquor loss as well as flesh darkening. However, oysters that are rapidly frozen in flattened plastic bags in which all air is evacuated, and that are then stored at $-18\,°C$ ($0\,°F$) maintain excellent quality for 10 months, (1). However, clams that are packaged, frozen, and stored similarly have a storage life of only four to six months before they become noticeably tough and rancid. Thus, most clams are destined for either the live or further-processed (chowder) markets.

Crustaceans

Tropical saltwater shrimp of the family Penaeidae are cultured worldwide in subtropical and tropical climates. Various species are grown in shallow coastal ponds, and reach market size in four to five months. Although large shrimp continue to command higher prices than small shrimp, aquaculture producers have determined that a medium-size animal [30–40 tails per pound (per 0.45 kg)] generally brings the best investment return. Growing animals appreciably beyond this size results in a lower feed-conversion ratio, increased mortality, additional operating costs, and, in climates where shrimp can be grown year-round, fewer annual crops.

Aquacultured shrimp have a distinct advantage over their wild-captured counterparts in that they generally fall within one or two size counts at harvest. This is a distinct advantage for companies that supply restaurants that are concerned with providing customers a consistent year-round "plate coverage" (i.e., number of shrimp per serving) at a specified cost.

Count size refers to the number of shrimp tails per pound (per 0.45 kg), beginning with the largest, which are simply classed as under 10, then grouped as 10–15s, 16–20s, and so forth until the smaller shrimp become classed by tens, beginning with 51–60s, 61–70s and so forth. It is unusual to find cultured shrimp smaller than 51–60s, since only larger warmwater shrimp are valuable enough to make a shrimp farming operation profitable. Many of the wild-harvested small shrimp (both warm- and coldwater species) are automatically peeled and subsequently breaded (popcorn shrimp) or used for value-added products like gumbo, or canned shrimp.

It is common to treat wild-harvested shrimp with a chemical to retard the darkening of pigments in the skin directly beneath the shell, a condition that is known as blackspot. While this blackening is esthetic and does not necessarily reflect the quality of the shrimp, it is perceived as a defect by the consumer and should thus be avoided. Shrimp vessels must use some type of chemical to retard blackspot formation, since they often remain at sea for a month or more, giving the enzymes that are responsible for the reaction plenty of time to work. On the other hand, due to the short period of time between harvest and processing (a matter of hours) some shrimp culturists have opted to eliminate the use of anti-melanosis agents (generally sodium bisulfite) as part of a chemical-free marketing strategy. While this has apparently worked well for some producers, others have been disappointed to find their untreated shrimp with a severely limited fresh shelf life (relative to blackspot development), or more commonly, turning black within hours after being thawed (following several months of frozen storage).

Unlike that which exists for bivalve molluscs, only a minuscule market exists for live shrimp. Only extremely upscale restaurants and a few specialty seafood shops offer live animals. Shrimp are considerably more difficult to ship and to subsequently maintain in aquaria than are live bivalves, which need only to be refrigerated. Thus, the cost for live shrimp becomes prohibitive for most consumers.

Although the market for fresh shrimp demands a premium price over similarly sized frozen product, the price difference in most retail settings is not great. This is because shrimp freeze extremely well, making it difficult for all but the most discerning consumers to tell the difference between fresh and previously frozen product. Shrimp are sold either whole (European market), head-off or tails (United States and Asian markets), peeled tails (worldwide market), fantail (peeled but leaving the uropod attached), or pieces (less than five of the six tail segments). Fantail shrimp are used for cocktail or specialty breading products whereas pieces are usually incorporated into salads or further processed products where shape is less important.

Since most of the world's production of cultured shrimp takes place in tropical countries for export, it is generally graded and then frozen in 425-kg (5-lb) waxed cardboard boxes with plastic bag inserts containing enough water to form a protective glaze around the entire block.

Increasingly, however, the largest customers (restaurants and supermarkets) are demanding individually quick frozen (IQF) shrimp which can be portioned by the piece while still frozen, and can then be rapidly thawed for either restaurant use or retail display.

Cultured crawfish include the red swamp (*Procambarus clarkii*), which is native to the United States, as well as the three Australian species, the marron (*Cherax tenuimanus*), the yabbie (*Cherax albidus-destructor*), and the red claw (*Cherax quadricarinatus*) These freshwater crustaceans survive well out of water and therefore bring the best price when sold live. Crawfish placed in high-humidity cool storage (8–9 °C or 46–48 °F) will survive for five to seven days. However, if storage temperatures fall below 3 °C (38 °F) the gills will frost over and the animals will suffocate. Likewise, crawfish should be transported in well-ventilated bags like onion sacks, never in tightly-sealed ice chests or plastic bags, or the animals will suffocate. Also, bags or other containers should not be so large as to impede the circulation of air to animals in the center. Crawfish intended to be sold live should be treated as gently as possible; i.e., sacks should not be thrown on and off trucks.

Some crawfish producers routinely "purge" live animals immediately after harvest by allowing them to remain in a shallow trough continuously supplied with clean water for 24 hours. This allows the animals to eliminate most of the content of their digestive tracts, which may contain gritty materials. Purged crawfish are reported to survive handling and cold-storage conditions better than untreated animals, and they also bring a better wholesale price, particularly from restaurateurs.

One relatively new market form that is increasing in popularity is that of soft-shell crawfish. Like all crustaceans, crawfish must molt in order to grow. Through manipulation of the water temperature and feeding of captive animals, they can be induced to molt, after which they are harvested, packaged and frozen. Prior to consumption, the head, which contains "stones," is removed.

Crawfish for the fresh market are generally sold as peeled tail meat. All tail meat is produced through hand peeling and is packed with or without the fat (i.e., digestive gland/hepatopancreas) attached.

Crawfish meat freezes extremely well; excess production can be frozen and stored for several months. However, if long-term storage is anticipated, the fat-laden hepatopancreas should be removed during the peeling process or the product will likely become rancid and result in a bitter taste. Dipping in 1.25% citric acid solution will retard discoloration during frozen storage. Until recently, most excess production was frozen and subsequently used in value-added products like bisque and etouffee. However, there is a developing market in both the U.S. and Europe for whole, boiled, frozen crawfish. In cooking, the live animals are added to boiling water, which is then allowed to come back to a boil. The crawfish are then removed, and immediately cooled and packaged for frozen storage.

Freshwater shrimp (*Macrobrachium rosenbergii*) culture developed rapidly in Hawaii during the 1980s, primarily to supply the local ethnic Asian market with live product. Animals can be live hauled in cool (21 °C, 70 °F) water at up to metric (0.5 lb/gal) for up to 24 hours with minimal mortality. The technology was soon introduced to the mainland U.S., but the demand for live animals was not sufficient to generate the high prices realized in Hawaii. To counter this economic problem, producers expanded the size of their farms to reduce production costs. This expansion necessitated the freezing of excess production. Most producers have subsequently found that only by selling a head-on product will they have a profitable operation. Freshwater shrimp (*M. rosenbergii*) lose 60% of their whole-body weight when deheaded, whereas saltwater shrimp suffer only a 40% loss. Thus, competing in the generic "shrimp tail" market is difficult. However, with their extremely long, slender-clawed appendages, whole animals provide attractive and sufficient "plate coverage" to consumers seeking an exotic menu alternative.

In the past, freezing head-on shrimp in conventional freezers resulted in a mushy texture. Recent work, however, has shown that whole animals that are individually quick-frozen (IQF) in cold tunnels and then stored at −18 °C (0 °F) have a shelf life of several months. Extreme care, however, must be taken when packaging IQF animals for shipping, to prevent breakage of the delicate long claws.

Alligators

Hide Processing. Since, in the recent past, alligators (*Alligator mississippiensis*) were considered an endangered species, each state regulatory agency restricts their processing to approved sites in order to assure that the animals were farm raised. Skinning, scraping, and curing must be carried out carefully to assure a top-quality product. Hides that are cut, scratched, or stretched, particularly the belly scales, have a greatly reduced value. Chilling prior to skinning makes this process easier. Hides are then scraped to remove fat and meat, and are then washed repeatedly to remove the remaining meat and blood residue. Fine-grained mixing salt is used to preserve the hide. Salt is rubbed thoroughly into the skin, which is then covered with about an inch of salt and rolled tightly to begin the curing process. Skins are allowed to drain and dry in a well-ventilated, cool enclosure. Hides are checked and resulted after about five days.

Meat Production. Alligator meat is cut in chunks and placed in waxed cartons (some states regulate the maximum amount of meat per carton) and sold either fresh or frozen. Deboned alligator meat comprises about 35–40% of the live weight.

Finfish

The culture of freshwater finfish species preceded marine species culture by several hundred years. There are two explanations for this: First, inland freshwater ponds, lakes, and streams offered relatively sheltered and controlled conditions conducive to the controlled production of aquatic plants and animals. Second, freshwater finfish generally produce much larger (but fewer) eggs which subsequently hatch into relatively large

fry, which experience a relatively high survival rate to adulthood (all compared with marine finfish species).

It has been generally observed that freshwater finfish yield a somewhat longer fresh shelf life than their marine counterparts. This is thought to be due to a relative lack of osmoregulators in their body fluids. Osmoregulators organic compounds of low molecular weight that help keep saltwater fish from losing too much body fluid to their salty external surroundings via osmosis. However, these compounds are easily metabolized by spoilage bacteria once a fish dies. Freshwater fish, of course, have just the opposite problem, because they have body fluids that are saltier than the surrounding water. They deal with this problem by producing fewer organic osmoregulators and by excreting copious amounts of dilute urine.

Another general observation for any aquacultured finfish species, fresh or saltwater, is that the dark-colored flesh (usually beneath the lateral line) is inordinately oily and will likely become rancid if the product is stored for several months, in which case the dark flesh should be removed during processing.

The most common market forms of finfish include whole (small fish only), gilled and gutted (gills and entrails removed), dressed (head, intestines, and fins removed), steaks (cross-sections of dressed fish), or fillets (the sides of the fish cut away from the backbone). Fillets can be either boneless (i.e., rib cage bones removed) or not. In the United States, the preference tends toward a boneless piece of meat, which can significantly reduce yield depending on the species cultured.

As stated earlier, many of the more traditional processing treatments for finfish (i.e., canning, mincing, etc.) are not applicable to aquacultured products, due to the relatively high cost of production. The majority of these products are marketed fresh or frozen in one or more of the forms described in the previous paragraph. Although butchering and freezing are common to all aquacultured finfish, a few "preprocess" procedures which are unique to certain species will also be described.

Catfish (*Ictalurus punctatus*), one of the most commonly cultured freshwater finfish species, may acquire a muddy flavor in spring and summer, making it unacceptable to the consumer. Initially thought to be due to ingestion of sediment while feeding, further investigations revealed that the off-flavor is actually due to the uptake (through their gills and/or epithelial tissue) of one or both of the organic compounds geosmin and 2-methylisoborneal. These compounds are produced by blue-green algae and filamentous bacteria, which thrive in warm waters enriched with nutrients from uneaten feeds and fish excreta. Fortunately, these off-flavors can be "purged" from fish in a matter of days if the fish are transferred to an unaffected pond or if the algae/bacteria bloom subsides in the culture pond.

Net-pen-raised salmon (principally *Salmo salar*, the Atlantic salmon, and *Oncorhynchus kisutch*, the coho salmon) should be taken off their feed a week prior to harvest. The fish should be carefully removed from the cages with a minimum of struggle. This reduces the production of lactic acid, which is responsible for subsequent softening of the flesh. Fish should then be tranquilized in 1000-liter (263 gal) vats of chilled seawater through which carbon dioxide is bubbled. Individuals are then bled by severing the gill arch or by direct incision into the aorta. After bleeding, the salmon are returned to chilled seawater (below 8 °C; 46 °F), graded by size, gutted, and boxed with ice for the fresh market or for further processing or freezing.

A small percentage of cultured catfish find their way into the live market, both in restaurants and increasingly in upscale retail grocery stores. In contrast, the majority of cultured tilapia (*Oreochromis* sp.) are sold live. Metropolitan areas with substantial ethnic Asian populations have been largely responsible for the growth of this aquaculture industry. Both of these species can be easily raised in high-density culture (often in indoor recirculating systems close to metropolitan areas), and live-hauled for up to 24 hours with minimal mortality.

Other species of fish which have been profitably raised include rainbow trout (*Oncorhynchus mykiss*), hybrid striped bass (*Morone saxatilis* × *M. chrysops*), red drum (*Sciaenops ocellatus*), gilthead bream (*Sparus aurata*), sea bass (*Dicentrarchus labrax*), sole (*Solea vulgaris*), and turbot (*Scophthalmus maximus*).

HANDLING FRESH AQUATIC PRODUCTS

When one considers the complex process of getting wild-harvested aquatic products, particularly seafood items, from harvest to the consumer, it is understandable that it is conservatively estimated that approximately 50% of the product's remaining shelf life is lost before the product even reaches the processor (with the exception of processing on-board factory trawlers). Compared with other meat items, which reach the processing plant live, one can see how the post-processing shelf life of seafoods is severely reduced (Fig. 1). The captive production of aquatic products has greatly increased their post-processing shelf life, since the trauma of capture is reduced and the lengthy refrigerated storage on-board a vessel is eliminated. Much like other muscle foods, aquacultured products can be harvested to meet market demands. However, unlike beef, which may be "aged" under controlled conditions to improve its texture, aquatic products are naturally
Figure 1. The shelf life timetable for wild-harvested, refrigerated seafood products. (in hours)

tender, and aging only serves to diminish their textural quality, due to catabolic enzymes which are active at lower temperatures than those in warm-blooded animals. Likewise, as previously mentioned, all aquatic animals (and seafoods in particular) contain compounds of low molecular weight that are readily metabolized by spoilage bacteria upon the death of the organism. Therefore, immediate chilling and subsequent maintenance of low temperature storage [near 0 °C (32 °F) or slightly cooler] of fresh product throughout processing and distribution is essential.

How long an aquacultured product can remain in prime freshness or acceptable quality under iced storage depends largely on its species. As a general rule, fatty fish[a] have an 8- to 10-day acceptable quality life, whereas lean species can be kept on ice for 14–18 days. Flatfish and tropical shrimp have been shown to maintain acceptable quality after more than 20 days.

Prime freshness and acceptable quality are not synonymous. Certain species of finfish which are highly sought after because of their extraordinary sensory quality (and are quite often consumed raw) are graded on their degree of freshness rather than degree of spoilage. Freshness can be numerically determined (and is referred to as the K-value) by measuring the chemicals released as a result of enzymatic (vs. bacterial) breakdown of cellular nucleotides in the first hours after death, well before bacterial spoilage takes place. Also, a fish in prerigor is considered fresh, whereas one which has resolved the stiffness of rigor mortis no longer displays the attributes of prime freshness that are demanded by raw fish connoisseurs. Following resolution of rigor, microbial inhibitors present in live animals are exhausted, allowing spoilage bacteria to outgrow on the abundant low-molecular-weight compounds that are naturally present in cellular fluids and resulting in the noticeable "off" odors that are associated with stale or spoiled fish.

For certain species of finfish, spiking the brain after chilling in ice water, or immediate slaughter (i.e., removing the brain), prolongs the onset of rigor by several hours. Aquacultured species have the potential to meet this market niche since, unlike for wild-captured animals, post-harvest operations (including shipping) can be carried out in a matter of hours rather than days.

The ideal cooling medium for fresh products is melting ice. Not only is the temperature of the meltwater 0 °C (32 °F), but the intimate contact between water and product results in efficient heat transfer. Ice storage prevents dehydration, while the washing action of meltwater has been shown to reduce the surface (skin) bacterial load. Flake ice is most often used to chill products because its large surface area leads to rapid delivery of meltwater over the product. Chunk and crushed ice tend to melt more slowly, and are more likely to damage the flesh

during handling. Filleted or skinned products, however, should not be stored in melting ice, as the washing action tends to suck out soluble flavor components (freshwater has a lower osmotic pressure than body fluids), and may diminish the textural quality.

A downside to the use of ice for shipping fresh product is its weight. Adequate icing can increase shipping charges by as much as 50%, a significant cost if products are being transported by air. The use of cryogenic chemicals (like those found in gel packs) to maintain low temperature during shipment offers some cost savings. Also, borrowing from the poultry industry, some shippers have begun blowing "snow" dry ice into master cartons of fresh seafood. Although this forms a frozen crust on products, if they are adequately packaged in moisture-proof materials the textural quality loss is negligible for most items.

Except for food safety and marketing concerns, the choice of packaging materials for the fresh market is not nearly as critical as it is for frozen products (which will be discussed later). Packaging, in general, should address three critical functions: those of protecting, selling, and ensuring convenience. Most fresh seafood items are simply overwrapped in styrofoam trays, using absorbent pads to soak up lost moisture. Such packaging for self-service cases is familiar to both meat/seafood store personnel as well as to the public, and has been readily accepted into the mix of fresh meat items. Grocery chains that have installed full service seafood display cases simply place unwrapped products on a cosmetic bed of ice and maintain a case air temperature between 2 and 4 °C (35 and 40 °F) to maximize shelf life. Shucked oysters packaged in sealed plastic tubs may be displayed in the seafood case, and/or in free standing ice only gondolas.

Modified atmosphere packaging (MAP) is a process in which air is evacuated from a gas-impermeable package and replaced with a gas mixture which inhibits growth of spoilage microorganisms, thereby increasing the shelf life of fresh products by as much as 8–10 days. The replacement gas is typically a mixture of nitrogen, carbon dioxide and/or oxygen. The goal is to find the appropriate gas mixture: one which will inhibit outgrowth of aerobic (oxygen-requiring) spoilage microorganisms while simultaneously preventing outgrowth of *Clostridium botulinum* microbes which require an anaerobic environment. Public health professionals are most concerned about elevated temperature abuse by the consumer, which could allow botulism toxin production without typical spoilage odors and could result in consumption of a highly toxic product. Vacuum packaging is a type of modified atmosphere (i.e., no atmosphere) and has been used successfully to display fresh seafood products, but usually only after they have been treated with a chemical such as potassium sorbate to inhibit outgrowth of *C. botulinum* in the event of temperature abuse.

FREEZING AQUATIC PRODUCTS

Freezing aquacultured products effectively eliminates bacterial spoilage, but it does not completely prevent lipid oxidation or other enzymatic activities which can also alter texture. However, proper packaging, freezing

---

[a] Fatty fish are defined as those that have greater than 5% fat, whereas 2–5% is considered moderately fat, and less than 2%, lean. Most marine invertebrates are considered lean, because they have less than 2% fat. The remainder of the edible portion of aquatic animals is 18–20% protein and 75–78% water — along with trace amounts of carbohydrates, vitamins, and minerals.

rate, and storage temperature can minimize quality losses associated with freezing. Initial freezing may destroy 50 to 90% of the bacterial flora on a product; the others remain viable but dormant: that is, slowly dying off as frozen storage time increases. However product is never held long enough to kill all spoilage microorganisms which, when thawed, will begin to spoil the product.

Another factor that influences finfish quality is related to rigor mortis. Basically, fish should not be allowed to go into rigor at warm temperatures (above 20 °C; 68 °F) because the stiffening will be excessive, the product will experience excessive drip loss when thawed, and the texture may toughen. Most wild-caught finfish go through rigor while iced, after which they are offloaded, processed and frozen. Aquacultured finfish, on the other hand, can easily be processed (i.e., filleted or dressed) and then frozen before rigor is resolved. In certain species of fish, a tough texture and a change in color from white to gray occurs if rigor is resolved during frozen storage. If the product is then cooked before frozen rigor is resolved it may contract and become tough and bland. In the industry, this is referred to as thaw rigor. Thus, if aquacultured finfish are going to be processed and then frozen, trials should be run to determine the best time (i.e., pre- or post-rigor) for product processing, prior to freezing. It may be advantageous to condition the fish prior to thawing and filleting by holding them at a relatively high frozen storage temp to induce and resolve rigor.

Species

In general, fatty fish have approximately half the frozen storage life of lean fish when all other conditions are similar (i.e., harvest method, rate of freezing, and storage temperature.) Thus, for example, small mackerel would remain at acceptable quality after three months at −18 °C (0 °F,) whereas flounder could be stored at the same temperature for up to six months. Moderately fat to fat species can be treated with approved antioxidants, such as sodium erythrobate, ascorbic acid, BHA, and BHT prior to freezing, to slow the rate of lipid oxidation. Species that contain a pronounced area of fatty tissue, such as that found beneath the lateral line of many finfish, should have this meat cut away in preparation for long term storage. Particularly bloody species should be carefully rinsed, because blood accelerates rancidity.

Frozen lean products have less of a rancidity problem, but tend to become tough and lose excessive water upon thawing due to protein denaturation during storage. Pigmented fish, such as salmon, should be stored at as low a temperature as economically possible, to prevent muscle color bleaching from red/pink to yellow/orange due to the oxidation of carotenoids.

Packaging

Gas-impermeable packaging is imperative for products that will be held in frozen storage. Nylon and polyvinylidine chloride (Saran) are excellent gas barrier materials, whereas polyethylene, polyvinyl chloride (PVC), and polypropylene allow gas transmission. Under prolonged frozen storage the oils in even moderately fat fish will enzymatically react with oxygen and become rancid. Therefore, wrapping product in materials which prevent oxygen transfer will improve storage life.

Another critical aspect of packaging for frozen storage is the reduction of freezer burn, a condition which leads to unacceptable visual and organoleptic (tough and dry) attributes. Freezer burn is the dehydration of tissues that occurs as moisture migrates from product (80% moisture) to a drier atmosphere (the storage cooler). This is particularly pronounced in freezers that cycle frequently, as the relatively warmer air in the cooler during the defrost cycle, which is attempting to reach a new humidity equilibrium, tends to draw moisture from the product.

Skintight moisture-proof packaging will not only slow the rate of freezer burn, it will also eliminate frost buildup on the inside of the package material. This visually unappealing condition occurs in loosely packaged products when moisture migrates (sublimates) from the product, condenses on the inside of the packaging, and then refreezes.

Lean fish fillets are often dipped in a 5% brine solution for 20–30 seconds prior to packaging. This treatment solubilizes surface proteins on the cut surfaces, forming a kind of skin to further help prevent moisture loss. Such a treatment should not be applied to fatty products because it will accelerate rancidity. Instead, various phosphate dips have been recommended to help retain moisture for these species.

Finally, "packaging" may consist of encasing the product in ice, which forms an effective skintight seal. This is one of the least expensive techniques and is employed with products which "freeze well." These products include shrimp, as well as many species of finfish. Three major drawbacks to this process have been as follows: (1) eventual sublimation of the ice coating, which results in exposure and freezerburn, (2) the brittle nature of ice, resulting in loss of portions of the glaze with moderate or greater handling, and (3) the slower rate at which the product can be frozen due to the addition of the water glaze.

Each of these problems has been addressed, the first by freezing the "block" inside a moisture impermeable plastic bag, which is usually contained in a waxed or plastic coated cardboard carton. The second is solved by layering products using dividers inside master cartons. The third is solved by glazing only products which "freeze well," and/or altering the freezing mechanism to increase the rate (i.e., cryogenic tunnel vs. blast air).

Rate of Freezing

The recommendation for rate of freezing is not dependent on species, size, or product form. It is always "as rapidly as economically possible." It is essential that muscle temperature pass through the "critical freezing zone" (CFZ) of 0 °C to −5 °C (32 °F to 23 °F) rapidly to reduce the size of ice crystal formation within the tissue. Slow freezing promotes the formation of relatively few, but large, crystals, which tend to disrupt cell tissue, and lead to excessive moisture loss upon thawing. Rapid freezing, on the other hand, results in numerous small crystals which are much less damaging. As water within the tissue begins

to freeze, the remaining naturally salty fluid becomes even saltier (concentrating enzymes and catalysts) and, if left in this state for several hours, can denature proteins and result in a tough, fibrous texture and loss of water holding capacity.

There are three generally recognized freezing rates: *Slow*, in which the product remains in the CFZ for more than two hours (generally a freezer room or cabinet with little air circulation); *Fast*, where the product passes through the CFZ in less than two hours (blast or plate freezers brine immersion); and *Ultrarapid*, where products are frozen within minutes rather than hours (insulated tunnels where liquefied nitrogen, carbon dioxide, or Freon 12 are allowed to expand into their natural gas state creating very cold temperatures [$-195\,°C$ ($-320\,°F$) nitrogen, $-78\,°C$ ($-109\,°F$) carbon dioxide, and $-30\,°C$ ($-22\,°F$) Freon]).

Frozen Storage Temperature

Storage temperature is critical, not so much for bacteria spoilage, but to reduce the rate of fat oxidation, other chemical reactions and certain enzymatic actions. These deteriorative processes require a certain amount of free water. At $-1.1\,°C$ ($30\,°F$) only 32% of the water is frozen; at $-7.8\,°C$ ($18\,°F$) 89% is frozen. Even at $-18\,°C$ ($0\,°F$) and below a small amount of water still remains unfrozen. Maintaining seafood products at $-18\,°C$ ($0\,°F$) is adequate for short term (1–2 months) storage, but for longer-term storage a temperature of $-29\,°C$ ($-20\,°F$) is recommended. As a general rule, frozen storage at $-20\,°F$ ($-28.9\,°C$) will typically increase the "high-quality shelf life" of product stored more than 2–3 months by two to three fold. Storage temperatures colder than $-29\,°C$ ($-20\,°F$) generally have not been shown to result in quality maintenance noticeable enough to warrant the added expense. Maintaining uniform temperature during frozen storage minimizes moisture migration (freezer burn) and accretion (enlargement of ice crystals as they melt and slowly refreeze).

Thawing

Frozen products can be thawed by processors who wish to repackage or to produce value-added products. Although seafoods may be thawed in air or water, at the same temperature they will thaw faster in water due to its more efficient transfer of heat. As with freezing, as products are thawed they should be moved through the critical zone [$-5\,°C$ to $0\,°C$ ($23\,°F$ to $32\,°F$)] as rapidly as possible, to prevent protein damage and subsequent excessive drip loss. When thawing in air or water, the temperature should be kept below $18\,°C$ ($65\,°F$). Thaw rate can be increased by keeping the air or water moving across the frozen surface. If the product is not sealed in moisture-proof packaging, the air should be humidified to prevent dehydration. Also, unwrapped products should not be thawed in water or they will become waterlogged and lose flavor through leaching of water-soluble components. Increasingly, both industry and consumers are employing microwave ovens to thaw products. Industrial use of microwaves is referred to as ohmic thawing.

HACCP

As of December 1997, all seafoods in the United States are required to be processed under a safety program entitled "Hazard Analysis Critical Control Point," or HACCP. In essence, this program requires that a hazard (biological/chemical/physical) analysis be completed for each processing operation and/or species, and any potential food safety concern(s) be addressed through establishment (and subsequent monitoring) of one or more critical control points in the operation(s). This program presupposes a continuation of existing Good Manufacturing Practices (GMP) which include such things as potable water, employee cleanliness and a work environment sanitation program.

PROCESSING TRENDS

Certain relatively inexpensive aquacultured products like catfish are now being incorporated into school lunch programs. Aquacultured products offer such programs a portion-controlled product of defined nutritional content at a forecasted price. Cultured products have also found increasing acceptance in fast-food restaurants for many of the same reasons.

Certain relatively bland products have successfully entered the meat mix through the incorporation of spices during processing. Enrobing is a process in which skinless fillets are coated with an oil or oil/water mixture containing spices such as lemon-pepper, cajun, or blackened flavorings. Phosphates may be injected to aid in the retention of moisture as well as to allow a means to carry flavors and spices into the core of the fillet. The process of vacuum marination, in which fillets are gently tumbled in a drum containing spices and flavors in an oil or oil/water base, also allows for good penetration of added ingredients.

A deboning machine can be used to remove meat that adheres to fish frames after filleting. This minced product can be reformed into patties and breaded for portion-control markets such as school lunches and military contracts. Incorporating boneless fillets of cultured species into the gourmet frozen dinner market as well as supplying specialty processors, such as airline catering services, have been suggested as means to increase the value of cultured products, which, unlike most wild-caught competitors, have a defined quality, shelf life, and year round supply.

Many molluscan products, as well as finfish and crustaceans, are battered and/or breaded as part of a value-added process. The United States is the world's largest consumer of breaded seafood products. Products are breaded to improve appearance and taste, increase portion size with relatively low-cost ingredients, and improve moisture retention while cooking. Batters are liquid mixtures of water, flour, starch, and seasonings into which the seafood item is immersed. The product is then cooked to set the batter, resulting in a batter-fry product. Alternatively frozen products can be coated with a dry breading mixture and cooked. Prior to battering, seafood products are usually given a light dusting with flour or dry batter mix to increase the uniformity of batter adhesion.

In order to retain optimal texture and flavor of high value seafood products, a process in which products are processed minimally was developed. Referred to as "sous vide," a French term which translates to "under vacuum," products are portioned, individually vacuum-packaged in plastic pouches or rigid containers which are impermeable to oxygen and moisture, and cooked in a water bath or high humidity oven. Cooking time and temperature are generally lower than those required for pasteurization. Extreme care must be taken to insure that the products are kept under constant refrigeration following processing, as the heat treatment is not sufficient to kill *C. botulinum*, which may subsequently produce toxins if temperature is abused.

Hagerman, Idaho

OUTLINE

Although nearly all feedstuffs contain protein, only those that contain 20% or more crude protein are considered to be protein feedstuffs in animal diets. However, in diets for carnivorous fish species (e.g., salmon and trout), only ingredients containing at least 35% crude protein are considered protein feedstuffs. Protein feedstuffs generally are classified based on their origin as either animal or plant proteins. Animal proteins that are used in fish diets are marine products or by-products, by-products from livestock or poultry processing, or dairy by-products. The primary plant protein feedstuffs used in fish diets are products of oilseeds, such as soybean meal and cottonseed meal. Animal proteins (e.g., fish meal) are generally considered to be of higher quality than plant proteins, primarily because of their superior profiles of essential amino acids. Compared to animal proteins, most plant proteins are deficient in lysine and methionine, the two limiting amino acids in fish diets. Also, certain plant proteins contain toxins and antinutritional factors that may or may not be inactivated during processing of the meal. In this contribution, an overview of protein feedstuffs used in fish diets is presented.

PROTEIN FEEDSTUFFS

Animal Proteins

Marine Products or By-Products

Fish Meal. Fish meal is prepared from dried, ground tissues of whole marine fish, such as menhaden, anchovy, and capelin, or from fish-processing waste. Fish meal contains 55 to 75% protein, depending on the species of fish used. Fish meal protein is of excellent quality, both in terms of amino acid profile and apparent digestibility, and is highly palatable to most fish. It contains 5 to 10% oil, making it rich in energy and essential fatty acids, and it also contains bones and other sources of essential minerals. Due to their high ash content, fish meals made from fish-processing waste and residues of canning plants are of lower quality than fish meals prepared from whole fish. High levels of fish meal are used in starter diets for most cultured fish and in growout diets for carnivorous species, such as eels, salmon, and trout. However, because of its high cost relative to that of plant protein feedstuffs, fish meal is used sparingly in diets for omnivorous fish species.

Fish Solubles, Condensed or Dried. Condensed fish solubles, which contain a minimum of 30% crude protein, are semisolid (50% solids) by-products obtained by evaporating water from "press water" produced during the processing of cooked fish in the manufacture of fish meal. Dried fish solubles are composed of the same material as condensed fish solubles, only then are dried to powder, and contain about 60% crude protein. Fish solubles are a highly palatable protein feedstuff for use in fish diets.

Shrimp Meal and Crab Meal. Shrimp meal is produced from the waste of shrimp processing and includes the head, shell, and/or whole shrimp. The exoskeleton is primary chitin and has limited nutritional value. Chitin may account for 10 to 15% of the total nitrogen in the meal. Shrimp meal contains approximately 32% crude protein and 18% ash and is a good source of *n*-3 fatty acids, cholesterol (essential for crustaceans), and astaxanthin (a red pigment). Astaxanthin is desirable in salmonid diets, because it gives the flesh the pink color favored by consumers; it also is used in the diets of some tropical fish to enhance their color. Astaxanthin is highly palatable and may serve as an attractant in diets for some species.

Crab meal is the by-product of the crab-processing industry and includes the shell, viscera, and flesh. It contains about 30% crude protein and 31% ash. Its high ash content limits its use in fish diets.

Fish Silage. Fish silage is prepared by grinding whole fish or fish-processing waste and then adding an acid, usually formic acid or a combination of sulfuric acid and formic acid, to prevent microbial spoilage. Well-prepared fish silage can be stored for years without spoilage. Good-quality silage made from fresh fish contains about 18% crude protein and 74% moisture. Because of their high content of free amino acids and short-chain peptides, which are absorbed and metabolized too quickly following a meal, fish silages do not appear to be as effective as whole-fish meals.

Rendered By-Products

Meat and Bone Meal. Meat and bone meal is the rendered product from beef or pork tissues and should not contain blood, hair, hoof, horn, hide trimmings, manure, or stomach and rumen contents, except in amounts as may be unavoidable during processing. Meat and bone meal contains approximately 45 to 50% crude protein, the quality of which is inferior to that of whole-fish meal, because meat and bone meal contains less lysine. In addition, protein quality may vary considerably among products. Meat and bone meal is a good source of minerals, but high ash content limits its use in fish diets, because of the possibility that a mineral imbalance may occur in the diet and because its phosphorus content is high, making it difficult to include in diets designed to have limited environmental impact. Research with channel catfish (*Ictalurus punctatus*) has shown that meat and bone meal can completely replace fish meal in growout diets (1,2). A level of 18% meat and bone meal can be used to partially replace fish meal in the diets of Japanese flounder (*Paralichthys oliverus*) (3). Meat and bone meal can replace 40% of fish meal in practical diets for sea bream (*Sparus aurata*) (4). However, including more than 20% meat and bone meal in place of fish meal lowers growth of rainbow trout (*Oncorhynchus mykiss*).

Meat Meal. Meat meal is similar to meat and bone meal, except that there is no added bone. It contains approximately 50 to 55% crude protein, and its ash content is lower than that of meat and bone meal. Meat meal can be used as a substitute for fish meal in channel catfish feeds.

Blood Meal. Blood meal is prepared from clean, fresh animal blood, excluding hair, stomach belchings, and urine, except in trace quantities that are unavoidable. Blood meal contains about 80 to 85% crude protein and is an excellent source of lysine, but is deficient in methionine. Research with palmetto bass (*Morone saxatilis* × *M. chrysops*) has shown that blood meal could replace 25% of the protein supplied by fish meal (5). A level of 10% blood meal can be used in diets for Nile tilapia (*Oreochromis niloticus*) (6). Trout diets typically contain 5 to 8% blood meal.

Blend of Meat and Bone Meal and Blood Meal. Special products are available for use in fish diets that consist of a mixture of meat and bone meal and blood meal. The two feedstuffs are mixed to mimic the nutritional profile of menhaden fish meal and to provide 60 to 65% protein. Blends of meat and bone meal and blood meal can completely replace fish meal in channel catfish (*I.*

punctatus) diets (1,2), but apparently not in diets for species requiring higher levels of dietary protein.

Poultry Wastes

Poultry By-Product Meal. Poultry by-product meal is made of ground, rendered, or clean parts of the carcass of slaughtered poultry. It contains heads, feet, underdeveloped eggs, and visceral organs, but does not contain feathers. The product contains approximately 58% crude protein and 16% ash. Poultry by-product meal can replace 100% of fish meal in the diet of India major carp (*Labeo rohita*) (7), 25% of the protein supplied by fish meal in the diet of silver seabream (*Rhabdosargus sarba*) (8), and 50% of fish meal in the diet of Australian snapper (*Pagrus auratus*) (9). Poultry by-product meal is often used in limited amounts in rainbow trout diets.

Poultry Feather Meal, Hydrolyzed. Hydrolyzed poultry feather meal is prepared by the high-pressure treatment of clean, undecomposed feathers from slaughtered poultry. At least 75% of the protein should be digestible, as measured by pepsin digestion. It is high in protein (85%), but the quality of the protein is not as good as that of other animal protein feedstuffs. As a partial replacement of fish meal, a level of 25% can be used in the diet of Japanese flounder (10) and 20% in the diet of Indian major carp (11). Apparent protein digestibility coefficients for feather meal range from 75 to 86% for rainbow trout, depending on the source of the feather meal (12).

Plant Proteins

Oilseed Meals

Soybean Meal. Soybean meal is prepared by grinding the flakes that result after removal of the oil from soybeans by solvent extraction or by the expeller process. There are three types of soybean meal that can be used in fish diets: dehulled and solvent extracted, solvent extracted, and expeller processed. These types of soybean meal contain 48, 44, and 42% protein and 1, 0.5, and 3.5% oil, respectively. Soybean meal is the major protein feedstuff used in aquaculture diets. It has the best amino acid profile of all common plant proteins. Based on the requirement values published by National Research Council (13), dehulled, solvent-extracted soybean meal has a sufficient amount of all essential amino acids for, and highly palatable to, channel catfish. Antinutritional factors in soybeans, mainly trypsin inhibitor, are destroyed or reduced to insignificant levels by heating during oil extraction and are further inactivated by heating during extrusion of channel catfish diets. Additional heat treatment is beneficial for soy products used in salmon and trout diets.

Soybean meal is well utilized by many warmwater fish and is typically included in their diets at levels up to 60% or so. For example, soybean meal can be used at levels of about 50% in channel catfish diets (2,14), 55 to 60% in tilapia diets (15,16), 45% in common carp (*Cyprinus carpio*) diets (17), 44% in palmetto bass diets (18), 21% in silver seabream diets (8), and up to 66% in the diet of red drum (*Sciaenops ocellatus*), as long as 10% of the protein is supplied by fish meal (19). Soybean meal

has been extensively studied as a trout diet component, and the consensus is that diets for postjuvenile trout can contain 25% soybean meal without reducing growth performance in carefully formulated diets. Juvenile trout are less tolerant of dietary soybean meal, and feed intake is reduced at levels of 10 to 15% soybean meal in the diet, depending on the other constituents of the diet.

Heated, Full-Fat Soybean Meal. Heated, full-fat soybean meal is prepared by grinding heated, full-fat soybeans. The meal contains 39% protein and 18% fat. It is rarely used in channel catfish diets, because of its high fat content, but a limited amount can be used as long as the total fat level in the diet does not exceed 6%. Nile tilapia can use up to 58% heated, full-fat soybean in the diet; however, the body fat of the fish increases when they are fed the full-fat meal (20). Growout-stage chinook salmon (*Oncorhynchus tshawytscha*) grow normally when up to 30% of dietary protein is supplied by full-fat soybean meal (21).

Cottonseed Meal. Cottonseed meal is obtained by grinding the cake remaining after the oil has been removed from cottonseeds, either hydraulically, by screw-press extraction, prepress solvent extraction, direct solvent extraction, or expander solvent extraction. The products generally contain 41% protein, but must not contain less than 36% protein. They are highly palatable to channel catfish, salmonids, and tilapia, but are deficient in lysine. Cottonseed meal contains free gossypol and cylcopropenoic acids, which can be toxic to monogastric animals. The amount of free gossypol in cottonseed meal depends on the processing method. The free gossypol contents of five types of cottonseed meal are as follows: screw press, 0.02 to 0.05%; hydraulic, 0.04 to 0.10%; prepress solvent, 0.02 to 0.07%; expander solvent, 0.06 to 0.21%; direct solvent, 0.10 to 0.50% (22). Currently, the expander solvent method is the method of choice for processing cottonseed into meal. Channel catfish can tolerate a dietary free-gossypol concentration of 900 mg/kg (ppm) (23). The levels of cottonseed meal should not exceed 30% of the channel catfish diet, unless supplemental lysine is used (2). A level of 35% cottonseed meal [free-gossypol concentration of 300 mg/kg (ppm)] can be used in the diet of Mozambique tilapias (*Oreochromis mossambicus*) (24).

Peanut Meal. Peanut meal is obtained by shelling peanuts, removing the oil, either mechanically or by solvent extraction, and then grinding the peanuts. Solvent-extracted peanut meal contains 48% protein, and the mechanically extracted product contains 45% protein. Peanut meal is highly palatable to fish and contains no known antinutritional factors; however, it is deficient in lysine. Without lysine supplementation, the levels of peanut meal used in channel catfish diets are restricted to 15 to 20%.

Sunflower Meal. Sunflower meal is prepared by grinding the residue remaining after mechanical or solvent extraction of the oil from sunflower seeds. Dehulled sunflower meal is prepared from sunflower seeds after the hulls are removed. Solvent-extracted, dehulled sunflower meal contains about 44% protein. As the hulls are not easily removed, the meal contains around 13% fiber. In fact, higher levels of fiber are found in meals that are not dehulled. Consequently, its low lysine content and high level of fiber limit its usefulness in fish diets. A level of 15 to 20% sunflower meal without lysine supplementation is acceptable for channel catfish diets (25). A level of up to 70% sunflower meal can be used in the diet of Mozambique tilapias (*O. mossambicus*) (24). Growth reduction was observed in rainbow trout fed diets in which 25% of the dietary protein was supplied by sunflower meal.

Rapeseed Meal and Canola Meal. Rapeseed meal is prepared by removing the oil from rapeseeds, using the solvent extraction method, and then grinding the remaining residue. Rapeseed meal contains glucosinolates (antithyroid factor) and erucic acid, which may be detrimental to fish growth. It can be included at a level of 28% in the diet of common carp without causing adverse effects (26). A level of 15% rapeseed meal can be used in the diet of Mozambique tilapias (with an initial size of 0.3 g/fish) (27). The level of rapeseed meal can be increased to 41% in the diet of larger Mozambique tilapias (with an initial size of 13 g/fish) without negatively affecting fish performance (24).

Canola meal is prepared from a selected variety of rapeseeds by solvent extraction to remove the oil. Compared to typical rapeseed meal, canola meal is low in glucosinolates and erucic acid. Canola meal contains about 38% protein and is relatively low in lysine as compared with soybean meal, but is higher in lysine than are other oilseed meals. Canola meal is palatable to fish and can be used at levels of up to 36% in channel catfish diets (29–31) and 32% in the diet of hybrid tilapia (*Tilapia mossambica* × *T. aurea*) (32).

Other Plant Proteins

Distillers' Dried Grains with Solubles. Distillers' dried grains with solubles are the primary residues from the fermentation of yeast in cereal grains and after the removal, by distillation, of the alcohol in the grains. The product contains approximately 27% protein and is highly palatable to fish. Levels up to 35% can be used in channel catfish diets (33). If higher levels are used, supplemental lysine may be needed.

Brewers' Dried Grains. Brewer's dried grains are residues obtained during the brewing of beers and ales after the removal of the starches and sugars of the grains, such as malted barley, corn, rice grit, and hops. This product contains about 28% crude protein and 12% fiber. It can be used in fish diets, but is deficient in lysine.

Corn Gluten Meal and Corn Gluten Feed. Corn gluten meal is the dried residue from corn after the removal of most of the starch and germ and after the separation of the bran by the process of wet milling of corn starch and corn syrup, or by enzymatic treatment of endosperm. There are two types of corn gluten meal, which contain 41% and 60% protein, and 4% and 2.5% fiber, respectively. Corn gluten meal is a good source of methionine, but contains high levels [200 to 350 mg/kg (ppm)] of the yellow pigment xanthophyll, which imparts an undesirable yellow color in the flesh of trout and catfish. This effect limits the use of corn gluten meal in rainbow trout and

channel catfish diets. However, a dietary xanthophyll level of 11 mg/kg (ppm) can be used in channel catfish diets without accumulation of the yellow pigment (34), and supplemental astaxanthin can mask the yellow color in rainbow trout (35). A level of 20% corn gluten meal can be used in the diet of yellowtails without amino acid supplementation and without negatively affecting growth (36).

Corn gluten feed is the part of the corn that remains after most of the starch and gluten have been extracted by the process of wet milling of corn starch and corn syrup. Corn gluten feed contains about 21% crude protein and 10% fiber, as well as a low level of xanthophyll [approximately 11 mg/kg (ppm)]. A level of about 20% corn gluten feed can be used in the diet of Nile tilapia raised in cages without leading to a reduction in growth (37).

Alfalfa Meal. Alfalfa meal is prepared by grinding dried alfalfa plants. It contains 15 to 20% crude protein and 20 to 30% fiber. It is deficient in lysine. A level of 15 to 20% can be used in grass carp diets (38,39). A level of 5% in the diet reduced growth in blue tilapias (*T. aurea*) (40).

Miscellaneous Plant Protein Feedstuffs. Several other plant protein feedstuffs can be used in fish diets and may be important proteins in certain parts of the world. These include coconut or copra meal (about 25% protein) (24,41), groundnut meal (about 60% protein) (24,41), leucaena meal (about 30% protein) (24,41), linseed meal (about 38% protein) (41,57), mustard meal (about 35%) (41,42,57), salicornia meal (about 35% protein) (43), and sesame meal (about 50% protein) (41,57). These protein feedstuffs are generally low in lysine; some contain antinutritional factors, and some are high in fiber, which may limit their use in fish diets.

Plant Protein Concentrates. Plant protein concentrates are prepared by various methods that extract protein from plant feedstuffs. The concentrates contain high levels of protein, and several of the products have been tested in fish diets. Alfalfa leaf protein concentrates can be used at levels up to 35% of the dietary protein in Mozambique tilapias (44). Rapeseed protein concentrate can be used to replace 39% of the fish meal in the diet of gilthead seabream (*S. aurata*) (45) and all of the fish meal in rainbow trout diets if palatability is enhanced by adding betaine (28). Cowpea protein concentrate can replace up to 30% fish meal in the diet of Nile tilapia fry (46). A level of 20% Bermuda grass protein isolate can be used in channel catfish diets (47). However, these products are not generally available and may be too costly to be economical for use in diets of cultured fish.

Soybean protein concentrate (SPC) is commercially available, albeit at a relatively high cost compared with that of fish meal. SPC protein is highly digestible (95%) and highly palatable to rainbow trout. While some researchers have reported no reduction in growth at 100% fish meal replacement with SPC, optimum replacement levels are 45 to 50%, as measured by growth responses and feed efficiencies. Concentrates from other oilseeds, including sunflower, have been evaluated in trout diets and generally can replace 25% of dietary fish meal without reducing fish growth (48).

NUTRITIVE VALUE OF PROTEIN FEEDSTUFFS

The nutritive value of proteins, or protein quality, is based on the amino acid composition of the protein, particularly the concentration of essential amino acids and the biological availability of the amino acids. Several criteria can be used to determine the nutritive value of protein feedstuffs, including protein digestibility, amino acid availability, protein efficiency ratio, net protein utilization, percentage protein deposited, and essential amino acid index. These criteria are described in more detail elsewhere in this encyclopedia.

Protein Digestibility

The apparent protein digestibility coefficients of several commonly used protein feedstuffs by various species of fish are listed in Table 1. The apparent protein digestibility coefficients are defined as the percentage of protein consumed by the fish that is not excreted in the feces. They can be determined by direct or indirect methods (see other contributions for details). Some variations exist in the reported values, due to differences in fish species, experimental methodology, fecal collection methods, and diet composition. Processing of dietary ingredients also affects protein digestibility. For example, overheating reduces protein digestibility of soybean meal and fish meal. Protein digestibility coefficients can be used to estimate the value of a particular feedstuff or of a finished feed, and may also be used to estimate the availability of amino acids when these data are unknown. However, the availability of individual amino acids is variable and does not always correlate to the protein digestibility coefficient.

Amino Acid Availability

Values of the apparent amino acid availability of several commonly used protein feedstuffs by channel catfish, common carp, rainbow trout, and yellowtail are listed in Tables 2−4. Apparent amino acid availability is defined as the percentage of a specific amino acid consumed by the fish that is not excreted in the feces. It can be determined by direct or indirect methods (see other contributions for details). Factors affecting the protein digestibility coefficients also affect the availability of amino acids of the protein sources.

Protein Efficiency Ratio

Protein efficiency ratio (PER), which is defined as the grams of wet-weight gain per gram of protein consumed, is widely used as a measure of feed quality, because it is rather simple to calculate and does not require chemical analyses: PER = g wet weight gain/g crude protein fed. The major criticism of the assay is that it assumes that all of the protein is used for growth and makes no allowance for maintenance. Diet composition, fish size, and other factors that affect growth may also have an impact on the results. The protein efficiency ratio should be determined

by using single-protein diets that contain a suboptimal level of protein. If a high level of protein is fed, the amino acid deficiency may be masked. Protein efficiency ratio values for selected protein sources, determined by using channel catfish, are shown in Table 5.

Essential Amino Acid Index

The essential amino acid index is based on comparison of the essential amino acid content of the protein with the essential amino acid requirement values of the fish. The

use of the index in predicting limiting amino acids (the amino acids present in the protein at a level below that required by the fish) is illustrated in Table 6. Soybean meal contains adequate amounts of each of the essential amino acids to meet the requirements of channel catfish. Cottonseed meal and peanut meal are deficient in lysine. This method, however, does not consider the availability of amino acids in the diet.

Table 5. Protein Efficiency Ratio Values for Selected Protein Sources, Determined with Channel Catfish

Protein Source	International Feed Number	PER[a] Reference (66)	Reference (67)
Fish meal, menhaden	5–02–009	2.48	2.41

ALL-PLANT PROTEIN DIETS

Feedstuffs of animal origin, especially marine fish meals, are generally considered to be of higher quality than feedstuffs of plant origin. However, because animal protein is expensive and its availability is often limited, efforts are being made to reduce or eliminate animal protein in diets for some species. Diets for coldwater fish such as salmon and trout traditionally contain relatively high levels of animal protein, especially fish meal, making it more difficult to completely replace fish meal with plant

proteins. Warmwater carnivorous fish, such as striped bass (*M. saxatilis*) and largemouth bass (*Micropterus salmoides*), also require high levels of animal protein in their diets. Animal protein appears to be required for normal growth and survival in the diets of omnivorous fish, such as channel catfish, carp, and tilapia, during their early life stages, and research with channel catfish showed that fry and fingerlings require fish meal for maximum growth (49). However, under typical culture conditions, all-plant protein diets composed of soybean meal, cottonseed meal, corn, and wheat middlings are satisfactory for normal growth of channel catfish from fingerling to marketable size in ponds (2,14,50–52). A laboratory study with fingerling blue catfish (*Ictalurus furcatus*) indicated that fish meal cannot be totally replaced by soybean meal in the diet (33), but can be totally replaced by soybean meal plus supplemental methionine (53). There is also evidence that tilapias (15,16,37) can be fed a soybean-meal-based, all-plant diet without reduction in weight gain. Common carp (*C. carpio*), reared in plastic tanks, cages, or ponds and fed soybean-meal-based, all-plant diets with supplemental lipid and lysine grew as well as fish fed diets containing fish meal (17). When they can be used, all-plant protein diets are generally more economical and are also generally lower in phosphorus than are diets containing animal proteins. The lower level of phosphorus inherent in soybean-meal-based diets may be beneficial in that those diets can be supplemented with a highly digestible source of phosphorus, thus potentially reducing phosphorus loads in rearing waters.

SUMMARY

Although many protein feedstuffs have the potential to be used, relatively few of them are used in the commercial diets of various fish species, essentially for three reasons: Not many feedstuffs are available at a reasonable cost; not many feedstuffs contain the essential nutrients sufficient for optimum fish growth; and antinutritional factors are absent. Generally, proteins of animal origin are of higher quality, but more expensive than those of plant origin. Soybean meal has been the major protein feedstuff used in aquaculture diets worldwide, mainly because it has the best amino acid profile among all plant feedstuffs. Fish meal is the major protein feedstuff for coldwater and marine species, because the replacement of fish meal with plant proteins has not been successful, even though small amount of plant proteins can be used in diets for these species. Research efforts should continue to explore the use of less expensive alternative feedstuffs in aquaculture diets.

PROTOZOANS AS DISEASE AGENTS

S.K. Johnson
Texas Veterinary Medical Diagnostic Laboratory
College Station, Texas

OUTLINE

Many kinds of protozoa are harmful to aquaculture animals. In some aquacultures, parasitic protozoa are the most important disease agents. This contribution emphasizes important protozoan associates of fishes, crustaceans, and molluscs. It aims to give a sufficient description of protozoans without using complex terminology and taxonomy that are unfamiliar to most readers.

PROTOZOA

Protozoa are unicellular organisms that live individually or in small groups. The membrane, or pellicle, that encompasses the nuclear material and cytoplasm is more or less flexible, and in some species, it secretes a hard covering. Individual size is usually less than 1 mm (0.039 in.), but giant forms up to 5 mm (0.195 in.) are known. The intake of nutriment at any or some

specialized surface location is by permeation of the pellicle or by active engulfment of liquid or solid portions. A specialized cytostome functions in some protozoa for the consumption of small food particles, or, in the case of gulpers, swallowing of large prey. Reproduction is commonly accomplished by fission, either binary or multiple, and some groups produce new individuals by external or internal budding. Fertilization and sexuality are known to occur in many protozoa. Cyst formation occurs in some free-living types, and some cysts can resist harsh environments.

Structurally distinct stages of development are typical of entirely parasitic groups. They usually have complex developmental cycles, and a few involve alternate hosts. Some produce spores that are able to live for long periods in the water environment.

Protozoologists commonly include certain unicellular algae among protozoa, especially those capable of both animal-like and plantlike nutrition. Thus, parasitic algae are often considered protozoa. One encounters a similar inclusiveness with regard to certain microscopic organisms with undetermined taxonomic status. The myxosporans produce multicellular spores and other multicell stages in their developmental cycle, but for the sake of convenience and convention they are commonly discussed as protozoa.

PROTOZOA AS PARASITES OR HARMFUL ASSOCIATES

Many protozoan species are obligatory parasites, requiring a host for completion of the life cycle. Others, as facultative parasites, do not require this essential host connection, but have the capability for a parasitic life in relationship with suitable hosts. Some protozoan parasites gain nourishment by absorption of tissue and cellular fluids, while others use excretions or digestive content. Some feed directly on host tissue. Protozoan parasites inflict a broad array of structural damage, toxicity, and functional disturbance during their life on body surfaces, within tissues, or within cells. The potential to quickly increase in numbers upon a general deterioration of the host is common to many protozoan parasites. Inherent system characteristics, such as a stage of host development, reduction of water exchange, and host density, may also permit a rapid increase of a particular parasite. The intensity of protozoan parasitism usually determines its importance in aquaculture. The mere presence of a limited parasitism, which may be common, does not equate to a state of disease.

Certain free-living or otherwise benign protozoan associates have the ability to transform into facultative parasites. These protozoa may begin to invade and feed on tissues if susceptible hosts become vulnerable due to inadequate nutrition, exposure to overly stressful conditions, or internal access brought by abrasions and lesions. Some otherwise free-living forms are noninvasive, but colonize surfaces of weak hosts, causing irritation, host dysfunctions, and general burdens to the host.

Terms useful in distinguishing protozoan relationships are endoparasite (the protozoa exist in body lumen, tissues, and blood), ectoparasite (the protozoa exist on body surfaces), endocommensal (the protozoa consume the host's diet, but not the host's tissue), and ectocommensal (the protozoa affix to the host's body surfaces, but do not consume the host's tissue).

AMOEBAE

Amoebae use protoplasmic flow to produce body extensions useful in movement. Depending on the kind of amoeba, the retractable extensions are threadlike or blunt, but in some cases are branching. These simple, naked cells feed on bacteria and reproduce asexually by binary or multiple fission. Amoebae produce cyst stages, and some of the important aquatic animal associates also produce a flagellate stage. Though some species have a solid external cover or an internal skeleton, most amoebae that parasitize aquatic animals lack such hard parts (see Fig. 1).

Amoebae parasitize gill and skin surfaces, the intestine, and, occasionally, tissues of many aquaculture animals. Amoebae that invade internal tissues directly from the aquatic medium or the digestive tract are thought to be opportunistic pathogens. We know little about the biology of amoebae that exist within tissues of aquatic animals, but some harm results from the accumulation of large numbers of amoebae in body spaces and the structural disruption that occurs as amoebae move between cells. Infections are mostly noticed in tissue squashes and smears and in histological preparations. Plates of nonnutrient 1.5% agar that support "lawns" of bacteria are useful for isolation of amoebae from tissues and the amoebae's subsequent identification. Histology is essential in the determination of pathology.

A low prevalence of amoebae is sometimes found in normal fish populations. The occurrence of heavy infections in fish is sporadic and possibly relates to the presence of eutrophic water, abundant bacteria, and higher temperature. Aside from the benefits of maintaining sanitary systems and general animal health, we know little about specific interventions for the control of amoeba infections in aquatic animals. For chemotherapy of external infestations of gills and skin, formalin is commonly applied as a bath treatment of 150 to 200 ppm of water for 0.5 to 1 hour.

Amoebae have not shown great importance in molluscan or crustacean aquaculture. Blue crabs (*Callinectes sapidus*) are known to host *Paramoeba perniciosa* along the east coast of the United States. The intensity of infection becomes greater in warmer months, and more deaths occur at that time. Other *Paramoeba* spp. (possibly all *Paramoeba pemaquidensis*) are known to colonize and damage gills of salmon (Salmonidae), rainbow trout (*Oncorhynchus mykiss*), and turbot (*Scophthalmus maximus*).

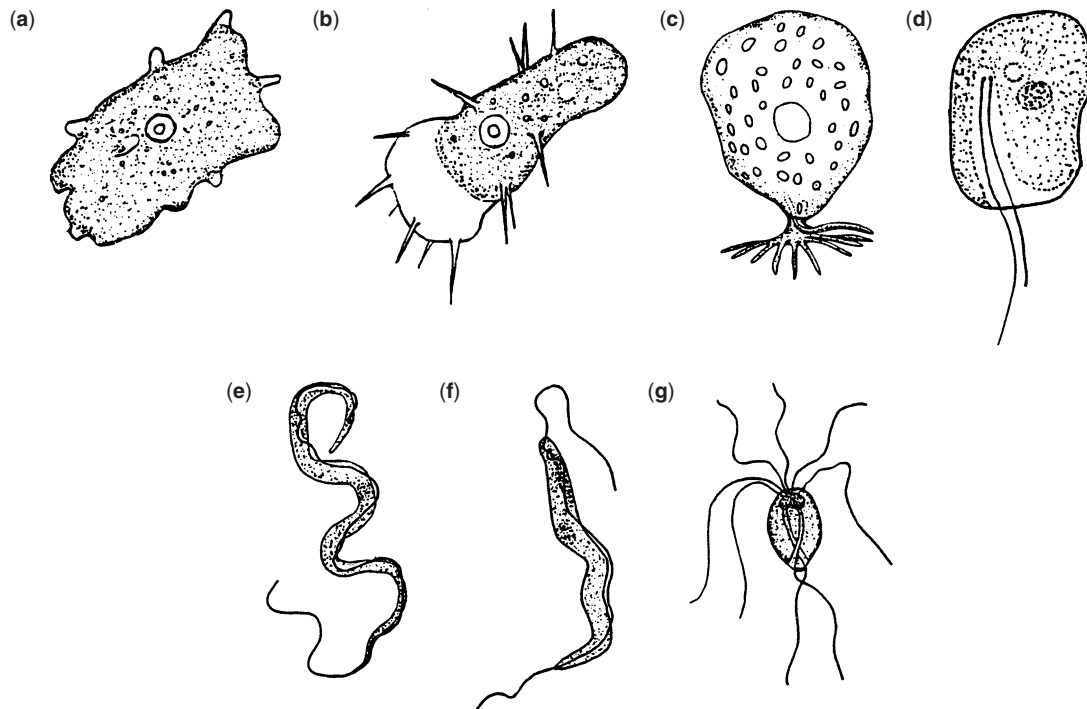
Members of several genera of free-living amoebae opportunistically invade tissues or colonize surfaces of freshwater fish species. Not surprisingly, these genera are the same ones that externally invade tissues and cause eye infection of terrestrial animals, including humans. *Naegleria* spp. and *Vahlkampfia* spp. colonize gills and skin surfaces. *Acanthamoeba* spp. are also found on gills and surfaces, but with some regularity invade body tissues.


Figure 1. Examples of amoebae and flagellates. (**a**) *Paramoeba*; (**b**) *Acanthamoeba*;
(**c**) *Amyloodinium*; (**d**) *Ichthyobodo*; (**e**) *Trypanosoma*; (**f**) *Cryptobia*; (**g**) *Hexamita*.

Relative to other fish species, tilapia (Cichlidae) have a greater history of *Acanthamoeba* infections. *Hartmanella* spp. are less commonly found in tissues of fish. Several fish, including the grass carp (*Ctenopharyngodon idella*), are known to host *Entamoeba* spp. within the intestine, but the importance of these amoebae to aquaculture is not understood.

FLAGELLATES

Possession of one to several locomotory flagella distinguishes the flagellates. Both plant and animal flagellates parasitize aquatic animals (see Fig. 1). Binary fission is the most common means of reproduction, and usually there is encystment.

Plant Flagellates

Among the plant flagellates, the dinoflagellates and euglenids have parasitic members. Much documentation exists about their parasitism of copepods, wherein they locate in gut, hemocoel, eggs, or general tissues and then influence the condition of the host (1). Such organisms have not become a nuisance in invertebrate aquaculture, but weak and dying larval animals often succumb to the invasion of opportunistic flagellates. In natural waters, *Hematodinium* spp. cause disease in lobsters, crabs, and pandalid shrimp during their molting season.

Parasitic plant flagellates of fishes are dinoflagellates, most of which are ectoparasitic. More important to aquaculture is *Amyloodinium ocellatus*, an ectoparasite of a variety of marine fish, and *Piscinoodinium* spp., parasites of freshwater aquarium fish. Unlike other dinoflagellates, *Amyloodinium* has lost its chloroplast, making it an obligate parasite. It is perhaps the greatest threat to the successful hatchery and nursery aquaculture of coastal fish species. At the optimal temperature of around 25 °C (77 °F), asexual multiplication is rapid, forming 256 infective dinospores in three days. The dinospores, whose structural features are responsible for taxonomic placement in the flagellates, must quickly find a host to continue the cycle. From there, the dinospore transforms into the harmful feeding stage. A penetrating and flexing organelle called the *stomopode* and the attachment base are important in inflicting pathology to epithelial cells that underlie the affixed parasite. This feeding stage, which is 80 to 100 μm (0.0031 to 0.0039 in.) in length, later detaches and transforms into the stage responsible for production of infective dinospores, which are about 8 × 12 μm in length. Under optimal conditions for the parasite, a cycle takes about a week to 10 days.

Controlling *Amyloodinium* is difficult. Chemical control with copper compounds (0.15 mg/L of water as free copper) has some advantage in the destruction of dinospores, but has the disadvantage of accumulating copper in systems. Other chemical approaches, such as chloroquine baths, have practical applications only in small systems. This is true also of rapid water exchange. Sudden exposures to freshwater results in some dislodgement, but the parasite is tolerant of salinities down to 1 ppt. Oestmann found that in small systems, a degree of dinospore reduction results from consumption by brine shrimp (2). Methods to enhance immunity have potential, but their validation requires much future work.

Certain dinoflagellates and other algae produce toxins that are harmful to aquatic species, especially fish. Toxic

effects are occasionally seen in closed and recirculating systems, but the dynamics of these events are largely unknown. The exclusion of water entry is a normal practice when a farm's natural surface-water supply experiences a nuisance bloom. In marine cage culture, fish are moved to new areas when such conditions arise.

Two groups with members that parasitize molluscs and crustaceans are subjects of an occasional report, but do not have established importance in aquaculture: *Ellobiopsidae* and *Thraustochytridae*. Ellobiopsids are mostly seen with the unaided eye as dangling protrusions on the surfaces of pelagic crustaceans. They affix themselves on hosts through structures that penetrate and spread out like roots in the host's tissue. They produce biflagellate spores that resemble dinoflagellates. Ellobiopsids usually receive taxonomic treatment as a distinct group.

Perhaps because members of the thraustochytrids consume and parasitize plant cells, thraustochytrids receive more consideration as slime fungi than as protozoa. They are usually given a separate status when considered among the protozoa. In the past, some were grouped with amoebae. *Labyrinthula*-like thraustochytrids and *Labyrinthuloides* invade abalone, cephalopods, and probably other molluscs and may destroy tissue and cause death in only a few days. A free mobile stage with flagella and a parasitic amoeboid stage are part of the development cycle. After entering a host cell, the parasitic stage divides, forming a network. Apparently not so confined as in the cell walls of plants, the network expands throughout tissues of animal hosts. Parasite invasions into animals apparently favor young and poorly resistant individuals, but there is little understanding of the host-to-parasite relationships for this group, and the economic importance of such relationships to aquaculture is basically unknown.

Animal Flagellates

Ichthyobodo spp. (possibly all *Ichthyobodo necator*) are ectoparasitic on a wide variety of freshwater and marine fishes. The swimming form, which is 5 to 18 μm in length, has two flagella and is round to oval in shape. It attaches to skin and gill epithelium by its anterior end and assumes a tear shape. Several may attach to a single cell in heavy infections. The epithelial mucous cells produce in excess, and qualitative changes in skin cell type accompany infection. Some surface tissue is lost as fish rub on solid surfaces in response to irritation. Swelling of gill tissues constricts blood flow, and cell death is common.

The prevalence of *Ichthyobodo* infection of fish in aquaculture, particularly in salmonids, is relatively high. Young and malnourished fish are more vulnerable to heavy infestations. Damage to surface tissues affects the performance of salmon during transition to seawater. Application of a formalin bath (150−250 ppm for 0.5−1 hr) is probably the most common method of chemical control. Bithionol may have promise for tank application (3).

Hexamita and *Spironucleus* species are found in the digestive tract of freshwater and marine fish that are present in many climates. The round to tubular cells of less than 20 μm in length possess four anterior flagella. The flagellates feed on bacteria and particulate matter, and their cysts pass into the water medium with feces. A primary living site, depending on species, usually exists somewhere from the rectum to anterior intestine. Smaller and weaker fish are often the host to larger numbers of these parasites. Fish with many parasites show a deterioration in condition and become vulnerable to infections by opportunistic microbes. On occasion, the flagellates pass through the protective lining of the gut and invade various body tissues. *Hexamita* and *Spironucleus* commonly infect salmonids, cyprinids, cichlids, and a variety of aquarium fishes. *Hexamita* spp. are also known to exist in the intestines of oysters in aquaculture and as in fish, can cause disease when they bypass intestinal barriers of weak hosts and generally invade their tissues. Methods for controlling *Hexamita* and *Spironucleus* infections aim primarily at disinfection and removal of predisposing conditions. Therapy with metronidazole is used with aquarium fish.

Cryptobia spp. (including *Trypanoplasma*) parasitize a variety of aquatic animals, including freshwater and marine fish. Those that parasitize fish are typically ectoparasites or act in combination as ectoparasites and blood parasites. Intestinal forms of these parasites are also known. Depending on species, transmission is direct from fish to fish or involves a blood-sucking leech vector wherein the parasite multiplies between blood meals.

Cryptobia spp. are elongated protozoa with length-to-width ratios of 2 : 1 to 10 : 1. The anterior end is rounded, and the posterior end tapers. Two flagella extend from the anterior end; one projects forward and the other toward the back. The latter is attached for most of the protozoan's length until it extends freely beyond the posterior end. Along the attached portion, the pellicle stretches to accommodate flagellar movement, giving the false appearance of an undulating membrane.

A variety of clinical signs and pathogeneses accompany *Cryptobia* infections. For the blood forms, the sheer accumulation of large numbers of parasites due to multiplication promotes a wide array of pathology and dysfunction, not to mention a drain on immune potential and the general condition of the host. Infected and anemic fish generally do not respond well to environmental challenges. *Cryptobia* that infest gills also cause disease and mortality when present in excessive numbers.

Chemical control of ectoparasitic *Cryptobia* is possible in some circumstances. Leeches are not easily controlled in aquaculture water, especially when fish are present. Dehydration of systems to kill cocoons has shown promise. Vaccines have produced variable results, and selection of resistant fish strains shows promise.

Trypanosoma infect the blood of all vertebrate groups. In fish, parasite transmission is by blood-sucking leech vector. *Trypanosoma* species are elongated protozoa, typically with a length-to-width ratio of 10 : 1 and lengths of 20 to 50 μm. The cell tapers at both ends. The single flagellum typically originates near the posterior end and from there extends anteriorly affixed first to an undulating membrane and then becomes free. In contrast to what was previously thought about trypanosomas, there may be less host specificity and, due to structural variation, fewer species.

Though a degree of pathology is expressed in cyprinid infections by *Trypanosoma carassii* = syn. *T. danilewskyi* (4), overall, the trypanosomas have relatively little importance in aquaculture. Aside from protection of fish from leeches, there is little known about means for controlling *Trypanosoma*.

APICOMPLEXANS

Apicomplexans represent a taxonomic assemblage of parasitic protozoans whose kinship is based on a set of organelles located on the anterior end of the protozoan cell, called the *apical complex* (see Ref. 4 for illustrations). This complex is visible with electron microscopy and is important to penetration of the host by the infective stage. Important to aquaculture are the perkinseans, which infect bivalves and abalone, and the sporozoans, which infect fish, molluscs and crustaceans (see Fig. 2).

Perkinseans

Perkinseans are very important parasites of molluscs. Several species of *Perkinsus* are able to harm oysters, clams, scallops, and abalone. Densely set oysters rapidly succumb to infections of *P. marinus* in conditions of warm water temperature and high salinity. The parasite spreads and infects easily at salinities above 10 ppt in the warm season. Efforts to raise oysters in ponds and other confinements of warm regions have been largely unsuccessful, due to *P. marinus*. Areas with cooler water have less of a problem with the oyster parasite than do areas with warmer water, such as the Gulf of Mexico.

The mollusc host ingests the swimming infective stage, and parasitic development begins. Several multiplications increase the number of parasites. The parasite spreads throughout the body, inflicting severe damage to tissues as it locates within or outside of the host cells. When the parasite damages adductor muscle cells, the mollusc's shell opens (gapes) somewhat. Sick or dead oysters release cells, which divide and release new infective stages. Both swimming and multiplying stages are infective. *P. marinus* is generally endemic to growing areas, and disease occurs when conditions favor its expression.

Except for possession of a rudimentary apical complex, perkinseans do not have much in common with other apicomplexans. Perkinseans have a flagellated infective stage, and, information about their sexual reproduction is unknown. The round, mature "spore" is characteristic of infections. It is 5 to 20 (most likely 10) μm in diameter, and because of the large transparent vacuole and the smaller refractive cell content therein, it appears as a ring with a small inverted crown.

The vulnerability of molluscs in open aquaculture beds or suspensions presents a challenge for control of parasites. The growth period usually lasts two years in an unpredictable climate. The use of sites selected for stable and favorable conditions and the use of genetically resistant organisms have promise.

The work toward a consensus over the true taxonomic home for perkinseanlike organisms still continues today. Nowadays, some perkinseanlike organisms are considered as either apicomplexans or dinoflagellates. For many years, perkinseanlike organisms were discussed as fungi, mostly as *Dermocystidium* spp. Reports of work on this sort of parasite in fish continue to refer to it as a *Dermocystidium* species or as a *Dermocystidium*-like species. Parasitologists attribute importance to these parasitisms in the freshwater or marine aquacultures of salmon, eels, trout, and carp.

Sporozoans

Sporozoans are represented primarily by the coccidia, the piroplasmia, and the gregarinia. Coccidians of fishes are of two general types: (*1*) those that typically infect and produce oocysts in the intestinal lining—the common
Figure 2. Examples of apicomplexans and microsporan. (**a**) *Perkinsus* (spore); (**b**) *Goussia* (oocyst containing infective stages, the sporozoites); (**c**) a blood-infecting coccidian within a red blood cell, with the parasite to the periphery of the cell nucleus; (**d**) *Nematopsis*; (**e**) *Haplosporidium* (spore); (**f**) microsporan (spore).

coccidia, and (2) those that typically infect fish blood cells with formation of oocysts in a second host, usually a blood-sucking leech. Piroplasmians also involve a leech and infect fish blood cells in the life cycle.

The dynamics of the fish–parasite relationship and the economic importance of parasitism by piroplasmians and blood-infecting coccidia are poorly known in natural environments and aquaculture systems.

The importance of the common coccidia is better known. In fish aquaculture, coccidian disease occurs in carp, goldfish, eels, red drum, (*Sciaenops ocellatus*) and tilapias. Most disease is caused by *Goussia* and *Eimeria* species. Infective stages enter and develop within the epithelial cells that line the intestine, eventually causing cell death. Many such cellular infections thus lead to disease. Oocysts pass with the feces and transmission normally occurs when the infective stages they contain are eaten by a new host. Upon release from the host, the oocyst of some species contains stages that are not yet infective. Depending on the species, the parasite must undergo further maturation in the oocyst after its release or after some transformation in the gut of a small organism that has eaten the oocyst.

Important coccidian infections of fishes occur in culture ponds. The traditional method for control is a disinfection that combines dehydration with a broadcast application of quicklime or chlorinated lime. Application of coccidiostat and other drugs to fish food has had some success, but the practical benefit of such chemotherapy is poorly understood. Coccidian infections of mollusc kidneys are apparently common and are possibly important to molluscan aquaculture.

Human infection by a coccidian, *Cryptosporidium*, via drinking water is a subject of current public-health interest. Attempts to transmit *Cryptosporidium* and comparable fish-infecting species, *Piscicryptosporidium* spp., between fish and people have been unsuccessful.

Most gregarinians are single-host parasites, but the ones important to crustacean aquaculture have alternate invertebrate hosts. Gregarinians locate in the gut of commercially important crabs, lobsters, and shrimp. There, a slender infective stage of approximately 30 μm in length emerges from the spore and initially attaches to a cell's surface, rather than entering the cells, as in the case of coccidians. The parasite then forms into a cigar-shaped structure that contains distinct components and expands greatly in size to 0.1–1.0 mm as it absorbs nutrients (see Fig. 2). Most parasites remain attached, but some glide about the intestinal lumen either as detachments or as parasites that did not make an initial attachment. Eventually, the parasite moves to the rectum, where it attaches and forms an encystment by coiling up and secreting a wall. Following multiplication therein, stages release into the water that are capable of being taken up and infecting a second host. In that host, the gregarinian apparently parasitizes a single cell and, without multiplication, transforms into a spore that contains the infective stage. This spore is consumed by a crustacean that eats the second host or some of its parasite-containing releases.

Crustacea show little pathology from gregarinians, except when very heavy parasitisms result in epithelial damage to the gut, a physical blockage of the gut, or, possibly, predisposing tissues for bacterial infection. *Nematopsis* spp. are common in crustaceans and occur widely in bivalves, which are often alternate hosts. In bivalves, the parasites have little or no reputation as important pathogens. Control efforts in aquaculture focus on elimination of the alternate hosts during system dryouts.

MICROSPORANS

Microsporans commonly parasitize insects and crustaceans. Other invertebrates and members of all vertebrate classes also host microsporans. Some species are important in aquaculture when exceptionally heavy infections cause disease or when obvious masses in skin and musculature degrade the market-ready product. Diseases of reproductive tissue affect the reproductive potential of some hosts.

The foremost defining and obvious structural feature of this group is a small (usually less than 10 μm in length) spore containing an extrusion apparatus (see Fig. 2). The extrusion apparatus appears as a coiled filament packed to the periphery of the spore. Also within the spore is a small infective agent. Transmission occurs upon consumption the infective agent within the spore. In some cases, infection is possible only if the spore first passes through the gut of another appropriate animal. Certain insect microsporans are known to involve a distinctive cycle in alternative, totally unrelated hosts. Perhaps future study will show such life cycles to be characteristic also of some aquatic animal microsporans.

Once a microsporan is inside the gut of its host, the filament bursts out from within the spore. The extruded filament is stiff enough to penetrate a cell. The infective unit passes through its hollow core and gains entry to the host's tissues. Once inside the host's tissue, it somehow associates with susceptible tissues and begins to grow and divide. Larger ameboid cells containing multiple divisions may grow to around 50 μm in length before their smaller internal units release to infect additional cells. As parasite cells continue to develop, some cells multiply to produce spores. These spores are eventually released in various ways, including release from a dead and disintegrating host.

Microsporan species are more or less specific in the selection of tissues to infect. Infection of musculature is common in crustaceans, and, due to transparency of the cuticle, many with infections give hosts a whitish appearance. During heavy parasitism of a fish's intestinal linings, the fish's gut appears completely displaced by opaque masses of the parasite. Skin infections may show discoloration, lumps, or nodules. *Enterocytozoon salmonis* infects the blood cell nuclei of chinook salmon which manifest a leukemic condition (5), but the chinook disease called plasmacytoid leukemia may have a viral cause (6). Some microsporans develop in great numbers within a host cell, causing the cell to enlarge greatly. In some species, these cystlike xenomas expand to the millimeter or centimeter range, with the infected cell membrane still intact.

Control of microsporans in most aquaculture systems is difficult. The effectiveness of oral medicines remains unclear, and the practice of their application has not been adopted by aquaculturists. Spores may survive for more than a year, and the efficiency of disinfectants is not sure. Facilities with troublesome infections may benefit most from species changes and general sanitary practice.

HAPLOSPORANS

Haplosporans parasitize invertebrates. Much of their importance in aquaculture comes from parasitism of oysters. The genus *Haplosporidium* is most important. *Haplosporidium nelsoni* has been responsible for many epidemics in eastern oysters along the eastern coast of the United States. Other *Haplosporidium* spp. cause disease to oysters and clams worldwide, but species assignments are seldom made, because of the rarity of spore stages in many infected hosts. Infected individuals grow poorly, show emaciation, and may die.

Spores are easily noticeable in infected tissues through use of using light microscopy, but except for their size of 5 to 7 μm in length, there is little to distinguish them as haplosprans (see Fig. 2). *Haplosporidium* spp. have a flat "cap" on one pole of their oval spore, and other genera may have peculiar surface structures. Electron microscopy is needed to determine a cellular part known as a haplolsporosome, the presence of which suggests the inclusion of otherwise ambiguous spores among the haplosporans.

The haplosporan infective stage enters a host oyster at the gills and develops into larger cells that contain multiple divisions. These cells eventually infect their hosts throughout the body, some associating with tissues next to the digestive tract and gonads. This process may be important to subsequent production of spores in the intestine, especially of young animals. A portion of the parasites that multiply in the gills release into the mantle cavity and from there are swept to the outside. This process may be important in the rapid development of the parasite in oyster beds. Details of the sexual reproduction of these oyster parasites are unknown in spite of long study of the subject. This suggests that a second host may be involved in the developmental cycle.

H. nelsoni lives best in salinities of 10 to 30 ppt. Culturing oysters below 10 ppt may have an advantage for controlling the parasites. The use of resistant strains in recent years has also shown promise.

The taxonomy of haplosporans is somewhat confusing. Many authors continue to write about haplosporans as part of a group known as the ascetosporans. Others treat haplosporans as a distinct and separate group, as is done in this text. Paramyxans of importance to aquaculture are generally considered among the haplosporans, but differ in the manner of spore formation. *Bonamia* spp. usually receive separate treatment as a taxon, but they have many haplosporan features.

Paramyxans

Paramyxans of *Martelia* spp. cause disease to young European flat oysters, mussels, scallops, and a variety of other molluscs. These parasites infect the stomach and move to the digestive gland. The number of parasites increase in the tissues of the digestive organs, where dividing stages of 6 to 30 μm in length may seen in histological preparations. A disruption of the digestive gland tissues during the formation and release of spore stages is probably important in the development of disease. The diameter of a spore is around 3 μm. Heavily infected populations of molluscs may become greatly reduced by *Martelia* infections. The best known paramyxan is *Martelia refringens*, a parasite of the flat oyster and mussels.

Bonamia and Mikrocytos

Bonamia ostrea is a small (2 to 3 μm in length) parasite found worldwide in populations of the flat oyster, *Ostrea edulis*. It is of major importance to aquaculture of this species. *B. ostrea* infects blood cells. On an occasion of disease, it is unclear whether oyster loss is due directly to the parasite or to its predisposing effect for bacterial infection. The disease occurs most easily at temperatures between 12 and 20 °C (54 and 68 °F). Newly exposed stocks are particularly vulnerable to mortality. *Bonamia* spp. infect several oyster species in a number of growing regions.

Mikrocytos spp. are small (2 to 3 μm in length) organisms that cause a winter disease of oysters. More is known about *Mikrocytos mackini*, which causes disease in Pacific oysters (*Crassostrea gigas*). Various superficial tissues and adductor muscles show greenish lesions in infected oysters. These parasites apparently do not develop when temparatures are above 15 °C (59 °F).

CILIATES

Ciliates possess rows of cilia that are useful in mobility and also in directing food bacteria toward their cytostomes. Structurally, cilia and flagella are basically identical. Cilia are, of course, more numerous and proportionally smaller in respect to the individual protozoan. Ciliate motion is gliding, whereas flagellates dart and wiggle. Ciliates range in size from 10 μm to around 3000 μm in length, but the ones that occur on and in fish are typically 30 to 100 μm in length (see Fig. 3). An obvious exception is the large feeding stage of *Ichthyophthirius*, which may grow to 1000 μm. Asexual reproduction occurs by simple or multiple fission and by budding. Some ciliates produce cysts.

Most internal and external associations of ciliates with hosts are not harmful. When conditions stressful to the host or system favor excessive ciliate proliferation, otherwise harmless ciliates may cause tissue irritation, asphyxiation if on gills, and, in larval animals, immobility. Only a few ciliates feed on tissue or have the ability to invade tissue.

Ectoparasitic and Ectocommensal Ciliates

Mantle cavities of molluscs harbor a number of commensal and parasitic ciliates. The genera *Ancistrocoma*,
Figure 3. Examples of ciliates. (**a**) *Trichodina*; (**b**) *Epistylis*; (**c**) *Ambiphrya*; (**d**) *Chilodonella*; (**e**) *Tetrahymena*; (**f**) *Ichthyophthirius*; (**g**) *Cryptocaryon*.

Sphenophrya, and *Trichodina* are common, but cause little harm to cultured molluscs.

The crustacean cuticle, or exoskeleton, is the habitat for apostome ciliates. There, apostomes are found within encystments or as newly excysted feeding stages. After feeding occurs, internal division produces more infective stages, which settle on a new host. Some of the parasites feed on nutriment associated with the exoskeleton after it is shed at molting. Other types merely consume the unshed exoskeleton or excyst when there is a break in it and consume internal tissues. Apostomes have not become important in crustacean aquaculture.

Crustaceans and fish host a variety of sessile ciliates on their gill and body surfaces. Many associate with inanimate objects as well as the aquatic hosts. Others favor direct associations with aquatic animals, and some form even more specific associations with a host group or a species. A variety of structural types occur on crustacean hosts. The basic feeding cell of some is borne on the terminus of a long stalk or its branches. While this type dangles freely into the water, other kinds attach directly and snugly to the surface of the host. Suctoreans, with their obvious needlelike tentacles, make up part of this array of ciliates, though they do not normally possess obvious cilia during host attachment. Certain bacteria and algae also attach among and upon the ciliates. All organisms together contribute to a general burdening of the animal. Sessile ciliates fare better during periods of poor host condition and higher system eutrophication.

Sessile ciliates become important in crustacean aquaculture when heavy infestations occur. Species of *Zoothamnium*, *Ephelota*, and *Epistylis* are able to debilitate mobility of very small early larval stages in hatchery tanks. Excessive infestations by these and other sessile ciliates reduce marketability, because they mar the appearance of the whole product. Heavy infestations of the gills may impair respiration and promote disease during conditions of low levels of dissolved oxygen.

Ambiphrya, *Apiosoma*, *Capriniana*, and *Epistylis* species attach to gill and body surfaces of a great variety of marine and freshwater fish. Heavy infestations may contribute to host asphyxiation. *Epistylis* spp. are often the direct or indirect cause of lesions at attachment sites.

Mobile parasites of gill and skin surfaces are more harmful than sessile species. *Chilodonella pisciola* and *Chilodonella hexasticha* infest a great variety of freshwater fish. *Brooklynella* spp. infest a variety of marine aquarium fishes, but do not match *Chilodonella* spp. in terms of importance. Cells of these species vary around dimensions of 60×40 μm and have shapes similar to a fingerless human palm. Aside from ciliary rows covering the pellicle, there is a conspicuous structure called the pharyngeal basket that is associated with the cytostome. Heavy infestations of most *Chilodonella* cause parasitic disease to fish in aquaculture systems. *Chilodonella* is common on cyprinids and often infests all fish in mixed populations where cyprinids are grown as forage species.

Trichodinid ciliates are the most common mobile ectoparasites of marine and freshwater fish. Heavy trichodinid infestations, especially in hatchery fry, are responsible for fish mortalities in aquaculture. Large numbers of trichodinids can damage the gill epithelium and subsequently feed on cellular debris. This damage may derange functions associated with gill excretion and provide a portal of entry for infective bacteria. Some trichodinid species are found in urinary bladders. *Trichodina* is by far the most common trichodinid genus.

Bowl-shaped trichodinids are generally around 25 to 75 μm in length. Obvious cilia fringe the cell and also coil toward the cytostome. Characteristic denticles, which

appear as jagged skeletal needles blunted to the periphery and pointed toward the cell center, overlap as a circular fan around the cell's relatively flat ventral surface. The height of the bowl-like cell differs according to species. Some are short like a frisbee, and others are tall like a bell jar.

Most methods to control ciliates that infest the surfaces of aquaculture animals usually rely on adjusting environmental conditions or adding mild toxicants that are safe for the aquaculture animal but are destructive to the protozoans. Adding sodium chloride to provide a concentration of 0.3% for indefinite periods is effective in ridding freshwater fish of ciliates. Dips for several minutes in concentrations of 1 to 3% salt in water are also effective against ciliates and are tolerable by fish of all but the smallest sizes. Applications of formalin, copper sulfate, potassium permanganate, and other chemicals are also effective at levels that are nontoxic to fish when used as baths or static treatments of indefinite duration. Water replacement to restore a lower level of organic content and microbial flora to the culture medium is effective in reducing ciliate burdens on the cuticular surfaces of crustaceans.

Invasive Ciliates

Fish and crustaceans of poor health in aquaculture systems succumb to invasions by certain free-living or commensal ciliates that possess an invasive potential. Better-known examples of this type of invasiveness are *Tetrahymena corlissi* of poecilid fishes, *Mesanophrys maggi* of Dungeness crabs, *Anophryoides hemophilia* of lobsters, and *Uronema marinum* of marine fish. These ciliates are generally oval shaped and measure near 50×30 μm.

The ciliate of greatest importance to aquaculture is *Ichthyophthirius multifiliis*, an obligate parasite of freshwater fish. Known as "Ich," this parasite goes through several development stages. The infective stage contacts a host's skin or gill and burrows into the epithelium, where it begins a stage of growth while feeding on the host's tissue. Upon gaining a considerable size that approaches 0.5 mm (even up to 1.5 mm in cold water) in length, it abandons the host, secretes a fragile cyst wall, and divides therein into several hundred to more than a thousand individuals. Upon the last division, the individuals are released into the water as infective stages. The complete life cycle of the parasite is as short as three to four days at 25 to 28 °C (77 to 82 °F). Seasonal influence encourages polycyclic infection. Ich disease in pond fishes typically follows the arrival of warmer weather, when the duration of the ciliate's life cycle decreases from weeks to a few days. Water temperatures of below 5 °C (41 °F) slow the cycle to as long as three months. Above 30 °C (86 °F) development does not take place.

These ciliates invade only superficial, epithelial tissues of skin and gills. Much mechanical damage to tissue is the result of parasite movement. Epithelial thickening occurs at first, and later the epithelium becomes detached, exposing the dermal layer of the skin to the water. Heavily infected fish with respiratory and osmoregulatory problems become listless and, when

stocked in ponds, begin to accumulate at edges or leeward shores.

A low prevalence of subclinical infection must be normal for natural systems, but epidemics in streams during times of low flow and fish crowding have been observed. Populations of scaleless fish possessing a thick epithelium may be more susceptible to Ich. Infectivity obviously benefits from higher fish densities. The presence of the parasite in unnatural systems, such as fingerling ponds, during periods when the temperature is optimal for the parasite is a sure set for an epidemic. Acquired immunity has an influence on infection dynamics. Exposure of naive fish to infected, partially immune fish usually results in quick and severe infection of the former. Fish in live markets often acquire severe infections in this way, due to continual introduction of fish.

Ich epidemics often occur soon after fish holding or transport. Such handling crowds the fish, and if some are infected, a window of opportunity is given the parasite to massively infect. Fish are lost in large numbers two or three days later, usually at some new destination. Keepers of tropical ornamental fish often attribute outbreaks to a sudden lowering of temperature. In such cases, successful infections probably result from new conditions that are optimal for Ich and too cool for the fishes.

Approaches for avoidance of Ich disease include not consolidating stocks, using ground water rather than infected surface water for system supply, and using seed stock that is known to be Ich free. Periodic checks of fingerling stocks for infection are helpful for early detection. Control of the parasite in fish stocks is difficult. Chemical treatments must be directed to the postemergence stages and therefore require multiple applications to culture water. Success with chemical treatments in pond systems occurs only during transitional seasons, when temperatures favor a short parasite cycle. If conditions permit, such as in small growing and handling systems, continual exposure of fish to a salt concentration of three ppt of water results in control of new infections and eradication of the parasite within a few days to weeks, depending on water temperature.

Cryptocaryon irritans, a parasite of marine fish, produces a parasitism very similar to that of *I. multifiliis*. The developmental stages and host damage are essentially the same. The parasite lives better at warmer temperatures and higher levels of salinity. The preventive approaches previously mentioned are suitable for *Cryptocaryon*, and for active infections, a drop in salinity to levels below 20 ppt effectively controls the parasite.

Endoparasitic ciliates of fish are found in the digestive tract, urinary tract, and oviduct. The pathological importance of these ciliates is probably small in aquaculture, though a report on grass carp (7) describes a detrimental invasion of intestinal tissues by *Balantidium ctenopharyngodonis*.

MYXOSPORANS

Myxosporans are parasites of fish, amphibians, reptiles, and some invertebrates. They occur in fresh, brackish,
Figure 4. Examples of myxosporans (spores). (**a**) *Myxobolus*; (**b**) *Hoferellus*; (**c**) *Myxidium*; (**d**) *Ceratomyxa*; (**e**) *Henneguya*.

and marine water systems. Many are found in gall bladders, but species more important to aquaculture parasitize muscle, skeletal, gill, intestinal, kidney, and skin tissues. Some species are very important in aquaculture. Myxosporans may be the most important cause of fish disease in natural populations.

Myxosporans produce unique and characteristic multi-cellular spores, with dimensions usually between 10 and 20 µm in length (see Fig. 4). The spore's rigid shell and easily recognizable sporoplasm and polar capsules are representative of different cells. The shell formation results in portions known as valves. Spores and their valves have certain variability of size and shape, but the structure is distinctive enough to determine genus and species. The polar capsules contain filaments that extrude in appropriate conditions and act as holdfasts. Concurrent with filament extrusion is a release of the sporoplasm through open valves.

The means of entry into a new host differs according to species (e.g., via gut or body surface), but once entry is made, the sporoplasm migrates to the susceptible body site. Following further development, and depending on parasite species, the now small or large multinuclear and multicellular plasmodium of a few µm in length to more than 2 µm in length undergoes production of spores. Depending on species, one, two, or many spores will form in a plasmodium. The large plasmodia of some species contain many fully developed spores and have a cystlike appearance within gill, epithelial, or other tissue. The small plasmodia (pseudoplasmodia) of other species produce only one or two spores and are not visually apparent, unless perhaps in an assembly.

As previously mentioned, spores occur in various tissues of their hosts. They are released from the host at death, through excretions, ruptures of cysts, and after transport by blood to release sites. A second host is involved in some myxosporan development cycles. Transmission and infectivity studies show that some myxosporan species that infect aquatic worms (oligochaetes) also infect fish. In fish, the worm's myxosporan parasite transforms its appearance to that characteristic of a fish myxosporan. In other words, what was previously thought to be two distinct and structurally dissimilar spore-forming species is really one species with a development cycle that uses second hosts.

Many myxosporans do not cause disease when present in aquaculture. Those that do produce a varying degree of pathology, whether in the kidney tubules, digestive tract, gills, skin, or other tissue. Sometimes, damage is due merely to the intensity of the parasitism and the inability of the host to heal. Nevertheless, under certain aquaculture conditions, myxosporans have great potential for harm.

Several myxosporan diseases are notable in aquaculture. *Myxobolus cerebralis* causes "whirling disease" in young salmonids. The cartilage of fry is infected, and spores form a number of weeks later, depending on the water temperature. Erosion of cartilage by the parasite affects the nervous system, causing a whirling, or tail-chasing, behavior. This process and structural abnormalities may eventually lead to death. *Sphaerospora* and *Hoferellus* spp. have very small pseudoplasmodia that multiply several times prior to formation of spores. This proliferation of parasites results in an enhancement of infection. As numerous parasites locate in tissues, swelling and other tissue reactions become manifest, and disease occurs. Such parasites cause gill and kidney diseases in carp, catfish, salmonids, and other fish. Examples are proliferative gill disease of channel catfish and proliferative kidney disease of salmonids. *Ceratomyxa shasta* causes generalized infections in salmonids following parasitism of the intestinal epithelium. After causing serious lesions in the intestine, the parasite moves further into the host, affecting a variety of tissues.

Some important aquaculture diseases may result from harm done to "wrong" hosts by prespore stages of yet-unidentifiable myxosporans. According to this hypothesis, massive numbers of infective stages of myxosporans somehow become present in the culture system, and subsequent invasion of the abnormal fish host produces a pathology sufficient to cause disease.

Muscle-invading myxosporans produce milky-white, streaky, wormy-looking, or spotted flesh that is unacceptable in the market. Flesh heavily infected by developing stages of some myxosporans becomes soft, jellylike, or liquefied a few hours after death at ambient temperatures, due to postmortem release of proteolytic enzymes by the parasites. Skin-infecting myxosporans, such as some members of *Myxobolus*, *Henneguya*, and *Myxidium*, may alter fish appearance to a degree that the fish are unmarketable.

The application of sterilants to pond sediments and dehydration are the favored approaches for controlling myxosporans in aquaculture. The use of preventative drugs for myxosporan infection has some history of experimentation, but has not been adopted in aquaculture practice. The development of control methodologies for myxosporans is largely lacking.

Recent reviews of protozoan parasites of aquatic animals are helpful for their study. Important references that discuss fish (4,8,9) and molluscs and crustaceans (1) are available.

PURE OXYGEN SYSTEMS

JOHN COLT
Northwest Fisheries Science Center
Seattle, Washington

OUTLINE

The use of pure oxygen can increase the carrying capacity of an aquatic culture system when dissolved oxygen is the most limiting factor. The actual increase in carrying capacity will depend primarily on temperature, pH, and alkalinity. Pure oxygen systems can economically saturate or supersaturate water with dissolved oxygen. Supersaturated dissolved oxygen in the absorber effluent significantly reduces the volume of water that must be treated to satisfy a given oxygen demand. Unlike air contact systems, pure oxygen systems have the capability of reducing dissolved nitrogen to or below saturation for the purposes of controlling gas bubble disease.

SOLUBILITY OF OXYGEN IN PURE OXYGEN SYSTEMS

The solubility of oxygen depends on its temperature, salinity, gas composition, and total pressure (1):

$$C^* = (1{,}000 K \beta) \chi \left(\frac{P - P_{H_2O}}{760} \right) \qquad (1)$$

where K = ratio of molecular weight to molecular volume (1.42903 mg/mL); β = bunsen coefficient L/(L·Atm); χ = mole fraction of oxygen in dry gas (%/100) (dimensionless); P = total system pressure (mm Hg); and P_{H_2O} = vapor pressure of water (mm Hg).

This equation can be used to compute the solubility of a gas of arbitrary gas composition and pressures. Tabular values of β and P_{H_2O} can be found in standard references (1,2). At 15 °C (59 °F) and 1 atm pressure, the air solubility of oxygen ($\chi = 0.20946$) is equal to 10.07 mg/L (ppm), while the solubility of pure oxygen ($\chi = 1.0$) is equal to 48.09 mg/L (ppm). Oxygen solubility may be further increased by increasing the total system pressure, P in Equation 1. Compared to air contact systems, increased solubility in the pure oxygen systems increases both the rate of oxygen transfer and the potential maximum effluent dissolved oxygen concentration.

SOURCES OF PURE OXYGEN

Standard conditions for the reporting of volume are 20 °C (68 °F) and 1 atm for gas and the normal boiling point for liquids. Useful physical data for oxygen gas and liquid are presented in Table 1.

Enriched oxygen may be obtained from three sources: high-pressure oxygen gas, liquid oxygen (LOX), and on-site oxygen generators. In many facilities, at least two sources of oxygen are used.

Table 1. Physical Properties of Oxygen Gas and Liquid

Parameter	SI Units	English Units
	Gas Phase	
Density	1.331 kg/m^3	0.08309 lb/ft^3
Specific volume	0.7513 m^3/kg	12.04 ft^3/lb
Selling units	1.331 kg/m^3	8.31 lb/100 ft^3
	Liquid Phase	
Density	1.141 kg/L	9.52 lb/gal
Specific volume	0.877 L/kg	0.105 gal/lb
	Gas–Liquid Relations	
Volume of gas/volume of liquid	0.857 m^3 gas/L liquid	115 ft^3 gas/gal liquid

High-Pressure Oxygen Gas

High-pressure oxygen gas (98–99%) can be obtained in cylinders containing 3–7 m^3 (100–250 ft^3) at 17.6 MPa (2550 psi). A number of cylinders can be connected together using standard manifold assemblies to increase the total capacity. The use of large numbers of gas cylinders is expensive and, therefore, commonly restricted to small transport or backup systems.

Liquid Oxygen

Liquid oxygen (98–99%) is produced on a large-scale basis by distilling liquefied air. Liquid oxygen (LOX) is generally trucked to the use site in bulk, then pumped into the storage tank. At 1 atm pressure, liquid oxygen boils at −182.96 °C (−297.3 °F). To reduce the amount of oxygen converted to gas, liquid oxygen must be stored in an insulated container. Liquid oxygen containers range from 100 L (30 gal) to greater than 40,000 L (10,000 gal). A liquid oxygen supply system will consist of a storage tank, evaporator, filters, and pressure regulator (Fig. 1). The maximum gas pressure in these containers is generally in the range of 1000–1400 kPa (150 to 200 psi). If the pressure exceeds these values, gas is vented to the atmosphere through a safety valve. Approximately 0.25% of the liquid will be lost per day, even if no oxygen is used. With the exception of direct impact from bullets and vehicles, there are few things that can go wrong with a LOX supply. It is common to lease the LOX tank and evaporator from the company supplying the LOX.

Pressure Swing Adsorption Oxygen Generators

Manufacturers have adapted industrial pressure-swing adsorption (PSA) systems for aquaculture applications. Single units are available to produce 0.50 to 10.0 m^3 oxygen/hour (15 to 400 ft^3 gas/hour) and may be connected in parallel to produce larger quantities. These units require a source of 600–1000 kPa (90–150 psi) filtered air and generate enriched oxygen gas of 85 to 95% oxygen. Oxygen generators work on a demand basis, so oxygen is produced only when needed. When used as a primary source of oxygen, a standby electrical generator is generally needed.

Production Oxygen Systems

For production systems, more than one source of oxygen may be required. Selection of the oxygen source(s) will depend on a number of site-specific conditions and the biases of designers and hatchery managers. Isolated production facilities may find PSA systems to be more economic due to high LOX transport costs. Sites near LOX production plants may find LOX more attractive due to reduced capital and maintenance costs. A LOX supply is much more reliable than a PSA.

Steel pipe and copper tubing are recommended for oxygen lines. Special care must be used in construction and installation of pure oxygen piping and fittings to remove grease and oil which may present a fire hazard when in contact with pure oxygen. It is possible to order specially cleaned and packaged valves and fittings for pure oxygen applications.
Figure 1. Major components of a LOX supply and regulation system that incorporate auxiliary compressed gas cylinders as an emergency source of oxygen.

TYPES OF AERATORS USED FOR PURE OXYGEN SYSTEMS

When compared to air, pure oxygen is relatively expensive, and only systems with high absorption efficiencies are generally economical. At least seven types of oxygen absorption equipment are being used.

U-Tubes

The u-tube aerator consists of a vertical shaft 10–45 m (30 to 150 ft) deep, either partitioned into two sections or consisting of two concentric pipes (3). Oxygen is sparged at the top of the down-leg of the u-tube and transferred into the water as the gas–liquid mixture is carried through the contact loop. Some commercially available u-tubes may include proprietary modifications to increase mixing and oxygen transfer. If 2 to 3 m of head are available, the system can be operated without pumping (Fig. 2a). To increase the oxygen absorption efficiency, the oxygen-rich off-gas may be collected and recycled (Fig. 2b) (4).

Packed Columns

A pure-oxygen packed column consists of a sealed column packed with a high specific-surface area medium (Fig. 3). Water is distributed uniformly over the upper surface of the medium by a perforated plate or spray bar. Pure-oxygen packed columns are efficient nitrogen strippers, and most production columns are designed to both increase dissolved oxygen and strip out nitrogen (5,6).

"Michigan" Spray Columns

A spray column is similar to a packed column except it does not contain media, and the size of the discharge is reduced (Fig. 4). This type of column may be required in reuse systems due to problems with media fouling. The reduced discharge produces a vacuum of 50–120 mm Hg (7) and results in excellent degassing of nitrogen.

Low-Head Oxygenator

The low-head oxygenator (LHO) is a proprietary oxygen transfer unit that can be readily retrofitted into serial
Figure 2. U-tube (**a**) gravity system and (**b**) pumped system with off-gas recycling.
Figure 3. Packed column mounted in rearing unit.
Figure 4. "Michigan" spray column mounted in rearing unit.

Figure 5. Low-head oxygenator (LHO) system. Water falls vertically through the perforated distribution plate into the oxygen-enriched gas zone and then flows out the bottom and down the raceway. The pure oxygen gas is introduced on the left side and exits on the right side (top view). The unit is divided into seven compartments, so there is minimal backmixing of the gas as it moves from the first compartment to last compartment. Within each compartment, the gas phase is well mixed.
Figure 6. Aerator cone (downflow bubble contact aerator).

raceway systems. The unit consists of a distribution plate positioned over seven rectangular chambers (Fig. 5). Water flows over the dam boards at the end of a raceway, through the distribution plate and then falls through the rectangular chambers. All of the pure oxygen is introduced into the outer rectangular chamber, flows through the series of individual chambers, and is finally vented to the atmosphere. Each of the rectangular chambers is gas tight, and the orifices between the chambers are constructed to reduce back-mixing between chambers (8). The LHO is most efficient when the required change in dissolved oxygen is in the range of 3–5 mg/L (ppm) (9).

Aeration Cones

The aeration cone, bicone, or downflow bubble-contact aerator (DBCA) consists of a cone-shaped cylinder with a high turbulence zone at the top of the cone (Fig. 6). Oxygen is injected into the high-turbulence zone, resulting in efficient gas transfer. As the bubbles are carried down toward the large end of the cone, the downward velocity of the water is reduced until it equals the upward buoyant velocity of the bubble and the bubbles are trapped inside the cone. Some of the gas may be vented for nitrogen gas control (10). These units are commercially produced and have been widely used in Europe.

Oxygen Injection

The most widely used form of oxygen injection injects oxygen through a venturi on the discharge side of a high-pressure pump (Fig. 7a) or into a high-pressure supply line. Relatively high pressures and contact times are required to achieve satisfactory absorption (11). This method can achieve 100% absorption of oxygen, but total gas pressure will also be elevated. A number of proprietary contact systems are available (11,12). These systems generally treat only a portion of the total flow and require a pressurized water supply.

Diffused Aeration

Pure oxygen diffused aeration generally has a low-absorption efficiency and has been limited to emergency use in production systems or for transport systems. Some recently developed fine-bubble diffusers have absorption
Figure 7. High-pressure oxygen injection. (**a**) High-pressure absorber; (**b**) pressurized side-stream unit.

Figure 8. Definition sketch for gas and liquid composition relationships in pure oxygen systems.

efficiencies in the range of 40 to 60% when submerged at 1–2 m or more.

MODELING OF GAS TRANSFER IN PURE OXYGEN SYSTEMS

The rate at which a slightly soluble gas such as oxygen is transferred into water is proportional to the area of the gas-liquid interface and the gradient between the saturation and existing concentration of the gas in the water as in the following model (13):

$$\frac{dC}{dt} = (K_L)(a)(C^* - C) \qquad (2)$$

where

$\dfrac{dC}{dt} =$ Rate of mass transfer (kg/hr)

$K_L =$ Overall liquid phase mass-transfer coefficient (m/hr)

$a =$ Area of interfacial contact between gas and liquid (m^2)

$C^* =$ Saturation dissolved gas concentration at a given temperature, pressure, and mole fraction (mg/L)

$C =$ Dissolved oxygen concentration (mg/L).

Substitution of Equation 1 into Equation 2 results in the following:

$$\frac{dC}{dt} \propto (K_L a)\left\{(1000 K\beta)\chi\left(\frac{P - P_{H_2O}}{760}\right)\right\} \qquad (3)$$

For a given system and temperature, $K_L a$, $1000 K\beta$, and P_{H_2O} are constants. The rate of oxygen transfer can be increased by increasing the mole fraction of oxygen (χ) and the system pressure (P). The pressure may be increased by (*1*) pressurizing the entire aeration unit or (*2*) increasing the depth of the contact system. The value of χ can be

increased by increasing the gas-flow rate (or gas-to-liquid ratio), but at increased gas costs.

A generalized sketch for the gas and water composition relationship in pure oxygen systems is presented in Figure 8. To model the performance of a general pure oxygen system, it is necessary to write the simultaneous mass transfer equations for oxygen, nitrogen + argon, and carbon dioxide. At any time and place, these three transfer equations are coupled by the following relationship:

$$\chi_{O_2} + \chi_{N_2} + \chi_{CO_2} + \chi_{H_2O} = 1 \qquad (4)$$

In well-mixed systems, a single value of both C^* and C can be determined. For other systems, both C^* and C may vary both temporally and spatially within the aeration device. These variables are written with a tilde—$\tilde{\chi}_{O_2}$ in Figure 8.

In general, the modeling of pure oxygen systems has involved an iterative solution. Published mass-transfer models are available for the u-tube (4), jet aerator (14), and packed column (15). A noniterative model has been developed for the packed column aerator (8).

PERFORMANCE OF PURE OXYGEN SYSTEMS

Important measures of performance for a pure oxygen system include the following:

ΔDO Change in dissolved oxygen through the contact system

ΔP_{out} Effluent ΔP from the contact system

DC_{out} Effluent dissolved carbon dioxide concentration from the contact system

COC Cumulative oxygen consumption

AE Absorption efficiency (% of oxygen transferred into water)

Each of these parameters will be discussed shortly. It is important to note that important trade-offs may be required among certain parameters. For example, it may not be possible to simultaneously produce a high ΔDO, a high-absorption efficiency, and a low-variable cost.

Based on the transfer model developed for the packed column aerator, the performance of a typical pure-oxygen absorber system is presented in the following sections. Specific parameters used in this model are water temperature = 15 °C (59 °F), barometric pressure = 760 mm Hg, pressure inside column = 760 mm Hg, media type = 2.54-cm (1 in.) pall rings, $G = 2.0$, oxygen purity = 100%, DO_{in} = 10.07 mg/L (saturation), DN_{in} = 17.18 mg/L (105% of saturation), and a well-mixed gas phase inside the column. This model is used only to illustrate many of the complex interactions between the different operating parameters. Other types of pure oxygen systems may have significantly different characteristics and constraints.

ΔDO (Change in Dissolved Oxygen)

One of the major advantages of pure oxygen systems is that the effluent DO concentration can be varied by changing the G/L ratio (Fig. 9). In contrast, the effluent DO concentration from typical surface or gravity aerators used in aquaculture cannot exceed the air saturation concentration. Adjustment of the gas-flow (and G/L ratio) can be used to vary the capacity as a function of the (*1*) time of day, (*2*) production cycle, or (*3*) operational requirements. While it is possible to adjust the ΔDO value, it does affect absorption efficiency.

ΔP_{out} (Effluent ΔP)

The allowable ΔDO from the absorber is also a function of the criteria for ΔP. For a raceway, the allowable ΔDO is computed from

$$\Delta DO = \frac{\Delta P_{out} - \Delta P_{in}}{\left| F_{O_2} + \dfrac{F_{N_2}}{\Delta DO/\Delta DN} \right|} \qquad (5)$$

where

$$
\begin{aligned}
\Delta DO =\ & \text{Allowable change in dissolved oxygen} \\
& \text{through the contact systems (mg/L)} \\
\Delta P_{out} =\ & \text{Maximum allowable } \Delta P \text{ in the raceway} \\
& \text{(mm Hg)} \\
\Delta P_{in} =\ & \text{Influent } \Delta P \text{ in the contactor (mm Hg)} \\
F_{O_2} =\ & \text{Conversion factor between gas} \\
& \text{concentration and pressure for oxygen} \\
& \text{(mm Hg)/(mg/L)} \\
F_{N_2} =\ & \text{Conversion factor between gas} \\
& \text{concentration and pressure for oxygen} \\
& \text{(mm Hg)/(mg/L)} \\
\Delta DO/\Delta DN =\ & \text{Change in dissolved oxygen/change in} \\
& \text{dissolved nitrogen + argon (mg/mg).}
\end{aligned}
$$

The allowable ΔDO is controlled by the oxygen:nitrogen stripping ratio, influent ΔP, and effluent ΔP. The F values are a constant at a given temperature.

The allowable ΔDO as a function of $\Delta DO/\Delta DN$ for a plug-flow reactor is presented in Figure 10a for the following conditions: temperature = 15 °C, (59 °F) ΔP_{out} =
Figure 10. Limitation in maximum dissolved oxygen due to gas supersaturation considerations. (**a**) Allowable ΔDO for raceway and (**b**) conditions where nitrogen stripping is needed in a circular tank.

Figure 9. Change in ΔDO as a function of the gas-to-liquid ratio.

76 mm Hg $\Delta P_{in} = 29.5$ mm, influent DO = saturation, and influent DN = 105% of saturation).

In a pure oxygen aeration application, the operating conditions should be in the second quadrant ($+\Delta DO$, $-\Delta DN$, $-\Delta DO/\Delta DN$). At large positive and negative values of $\Delta DO/\Delta DN$, the ΔDO approaches a horizontal asymptote equal to 2.99 mg/L (ppm), which depend only on $\Delta P_{out} - \Delta P_{in}$. The value of $\Delta DO/\Delta DN$ also approaches a vertical asymptote at $-\{F_{N_2}/F_{O_2}\}$. The maximum positive ΔDO (second quadrant) is limited to 42.3 mg/L (ppm) due to conservation of mass considerations for nitrogen gas. At this point, all of the nitrogen gas has been stripped out and replaced with oxygen gas. For maximum ΔDOs, the absorber should be operated with $\Delta DO/\Delta DN$ slightly less than $-\{F_{N_2}/F_{O_2}\}$. If the value of $\Delta DO/\Delta DN > -\{F_{N_2}/F_{O_2}\}$, the value of ΔDO must be reduced to prevent problems with gas-bubble trauma. The value of $\Delta DO/\Delta DN$ can be adjusted by changing the system pressure and gas composition (8).

The allowable ΔDO across the absorber for a circular tank can be several times larger than for the raceway due to the rapid mixing of absorber effluent with process water in the rearing unit. The maximum allowable DO in the circular tank as a function of total gas pressure (TGP) (%) and nitrogen saturation (%) are presented in Figure 10b. Over typical operating conditions, stripping is required when the influent nitrogen saturation exceeds 106 to 126%. Therefore, if the influent water is degassed below these limits, no nitrogen stripping is needed in the oxygen absorber units.

DC_out (Effluent Dissolved Carbon Dioxide Concentration)

Due to the high solubility of carbon dioxide, little dissolved carbon dioxide gas will be removed in the off-gas from the absorber unit. Other types of aeration equipment will be needed to remove carbon dioxide gas.

COC (Cumulative Oxygen Consumption)

The utilization of oxygen produces both carbon dioxide and ammonia. The depletion of oxygen may not always be the most limiting parameter; and when ammonia or carbon dioxide is more limiting, aeration will have little effort on carrying capacity (16). Maximum cumulative oxygen consumption ($DO_{in} - DO_{out}$) based on pH, carbon dioxide, and un-ionized ammonia limitations are presented in Figure 11 for water quality criteria typical of salmon and trout culture.

AE (Absorption Efficiency)

The absorption efficiency is an important operating parameter and has a significant impact on operating costs. Over the range of 25–82% absorption efficiency, the G/L ratio decreases from 8 to 0.5% (Fig. 12a). The highest absorption efficiencies occur at low values of the G/L ratio. Over the range of absorption efficiencies modeled, the ΔDO decreases from 26.6 to 5.4 mg/L (ppm) (Fig. 12b). Therefore, the system can produce either high ΔDOs at low absorption efficiencies or low ΔDOs at high absorption efficiencies. Over the range of absorption efficiencies modeled, the ΔP_{out} decreases slightly from 21.0
Figure 11. Maximum cumulative oxygen consumption (mg/L) as a function of equilibrium pH_e (pH of a solution in equilibrium with the atmosphere). At low pH_es COC is limited by the pH criteria, at intermediate pH_es by the carbon dioxide criteria, and at high pH_es by the un-ionized ammonia criteria (8).

Table 2. Operational Advantages and Disadvantages of Different Pure Oxygen Systems

Type	Advantages	Disadvantages
U-tube	May be operated with no external power input if adequate head is available	Excavation may be expensive under some conditions; not an off-the-shelf device
Packed column	Simple to build or retrofit to existing hatcheries; good nitrogen stripping characteristics; can be ordered off the shelf	Fouling may be a significant problem in reuse applications
Spray column	Very resistant to fouling; good nitrogen stripping characteristics when operated at a vacuum (Michigan columns)	Moderate transfer efficiency
Pressurized packed column	Can be designed for 100% oxygen transfer efficiency	Poor nitrogen stripping characteristics
Low-head oxygenator (LHO)	Operate with 12–24 inches of drop; can be retrofitted into existing raceways	Poor nitrogen stripping characteristics
Aeration cones		Will require special basin; difficult to retrofit existing facility; limited commercial availablity in some parts of the world
Oxygen injection	Available from several vendors; simple to install in new or existing facility	Moderate transfer efficiency
Diffused aeration	Very simple to install; transfer efficiency has improved in the fine-bubble diffusers	High head losses; clogging can be a problems in fine-bubble diffusers

to 13.5 mm Hg, while the effluent N_2 increases from 32.9 to 87.8% (Fig. 12c). If the column was operated at 100% absorption efficiency, the ΔP_{out} would be equal to 473 mm Hg at a G/L ratio equal to 2%. Therefore, the absorption efficiency must be limited to allow stripping of nitrogen gas to prevent gas supersaturation problems. Increasing the absorption efficiency from 25 to 82% decreases the transfer efficiency from 2.49 to 0.51 kg O_2/kwh (4.09 to 0.84 lb O_2/hph) (Fig. 12d). Therefore, at high absorption efficiencies, both the transfer efficiencies and ΔDOs are low (Fig. 12a).

SELECTION OF PURE OXYGEN SYSTEMS

Some common advantages and disadvantages of different types of pure oxygen systems are presented in Table 2. Due to differences in site conditions, operational modes, and specific absorber units, it is impossible to suggest a single design procedure (17).

OUTLINE

Approaches to Culture
Bibliography

Rabbitfish (family Siganidae) are Indo-Pacific fish that are economically important in capture fisheries, particularly of a subsistence nature. Rabbitfish can also be found in the Red Sea and the Mediterranean Sea. Aquaculturists have expressed some interest in rabbitfish culture since the 1970s. Various species have reportedly been cultured in Tanzania, the Middle East, the Philippines, Indonesia, Guam, and elsewhere, but total production is limited, so rabbitfish are currently considered to be a minor contributor to total world aquaculture production. There are presently 27 species of rabbitfishes recognized by fish taxonomists.

APPROACHES TO CULTURE

In addition to being a popular foodfish in the regions of the world where they dwell, rabbitfish can tolerate the high densities required of fish under culture. They also efficiently utilize a variety of natural and prepared feeds and tolerate handling stress, low levels of dissolved oxygen, a wide range of salinity, and water temperatures up to 34 °C (93 °F) (1). However, there have been reports of ciguatera poisoning associated with the consumption of rabbitfish in some parts of the world, and the spines of rabbitfish are sharp and venomous (2), making handling somewhat dangerous for humans.

Rabbitfish can be spawned naturally in ponds (3) or in the laboratory (4) through injections of human chorionic gonadotropin and other hormones. (See the entry "Reproduction, fertilization, and selection.") Natural spawning typically occurs during the new moon, from about midnight to dawn (2). The eggs of most species are demersal and slightly adhesive, though at least one species, *Siganus argenteus*, lays pelagic eggs (4).

The eggs tend to be smaller than 0.7 mm (0.03 in.) in diameter and will hatch between 18 and 35 hours after being deposited (2). The time taken from fertilization to hatching varies as a function of such factors as water temperature and fish species.

Because of difficulties associated with captive spawning and rearing of the very small larvae produced by rabbitfish, the capture of juveniles near beaches provides an alternative source of fish for stocking. Rabbitfish have been reared in captivity from eggs through adulthood, but mass production of juveniles in hatcheries continues to be a major problem. Thus, capturing wild juveniles and placing them in growout ponds or cages is an attractive approach. This is particularly the case in developing nations, where suitable hatchery facilities and the associated technology need to spawn adults in captivity are lacking. (Capturing wild juveniles for growout has been practiced with various other aquaculture species — for example, milkfish in southeast Asia and shrimp in Ecuador. However, as an aquaculture industry develops, the sustainability of natural populations can be affected by the removal of large numbers of fry or juveniles, so the practice may become severely regulated or even be banned.)

Strictly herbivorous fish are the exception rather than the rule, but rabbitfish consume primarily filamentous algae as adults, though they have been observed to be omnivorous in culture (2). Algal diets are not suitable for young rabbitfish. Larval and early juveniles may, like such other herbivores as grass carp (see the entry "Carp culture"), require animal protein in their diet for rapid growth and as a source of essential amino acids.

A critical stage in the life cycle of rabbitfish, as is the case with many other marine fish species, is associated with the time of first feeding. At that time, the fish must make the transition from obtaining their nutrients from the yolk sac to feeding on exogenous sources of energy and nutrition. Suitable prey must be available to the larval rabbitfish at the proper time and in the proper density. Starvation can occur very quickly if food is not available. The food needs to be present in sufficient quantity, so that the larvae do not have to swim far to capture prey. Larvae are such weak swimmers that they can exhaust their energy reserves quickly if they have to exert themselves in seeking food. Food particles need to be of the proper size so that the fish can engulf them, and the food items must be recognizable; that is, they must have a shape, color, and behavior (movement in the water column) that allows the larval fish to identify the particles as food. Texture may also be an important factor. If a food item does not have the proper texture, it may be ignored. Odor can be an important factor associated with food recognition, though in larval fishes that sense may not be well developed at first feeding. For many species, first feeding is often facilitated by a well-developed visual sense, which may be the case with rabbitfish. In such cases, the fish must be able to see the food particles in order to know to approach and consume them. Thus, light, water clarity, and background color may be important factors in helping the larvae proceed through the critical first feeding stage.

First feeding rabbitfish will accept brine shrimp (*Artemia* sp.) nauplii, copepods, rotifers, and other natural foods. Larval rabbitfish have also been successfully fed with prepared feeds under laboratory conditions.

Older rabbitfish, including adults, will also accept prepared feeds, and while there is little information available on the nutritional requirements of rabbitfish at any stage of life, their food habits indicate that they might

grow as well on a diet formulated for tilapias (many species of which are herbivorous or omnivorous and are able to grow well on diets high in plant proteins; See the entry "Tilapia culture") as on one formulated for trout or salmon. In the limited amount of nutritional research that has been conducted, the protein requirement, the protein-energy requirement, and the effect of dietary lipids on growth and egg quality have been investigated, though definitive information has yet to be developed on some of those subjects, as well as on many other topics of interest to fish nutritionists. There have also been a number of feeding trials conducted in various types of culture systems. At least one review paper has been published on the subject of rabbitfish nutrition (5). The ability of rabbitfish to digest various types of carbohydrates has been confirmed through examination of enzyme activity (6).

A limited amount of information exists on the diseases of rabbitfish. One survey of metazoan parasites in wild rabbitfish off Kenya (7) found incidences of monogenetic and digenetic trematodes, copepods, isopods, acanthocephalans, and nemaodes, but the impacts of parasites on cultured rabbitfish have yet to be determined. There appears to be very little information available on other diseases that affect rabbitfish.

RAFT, POLE, AND STRING CULTURE

ROBERT R. STICKNEY
Texas Sea Grant College Program

OUTLINE

Raft Culture
Long-Line Culture
Pole Culture
Bibliography

Molluscs, such as oysters, mussels, scallops, and clams, are often cultured on sediments in appropriate locations. To take advantage of the entire water column for increased shell growth and to reduce predation, many culturists have elected to rear molluscs, and, in some cases, algae above the sediments. When suspended culture systems are employed, it is necessary for the aquaculturist to have control over the area in which the animals are being grown. Boat traffic, for example, could be highly disruptive. The culture animals are reared by suspending them on ropes or in cages from rafts, on long lines strung between floats, or attached to poles driven into the sediments. Some species of macroalgae can be grown on nets. This contribution introduces the concept of this alternative means of culture, but is not meant to be a comprehensive treatment of mollusc or algae culture.

RAFT CULTURE

Mussels and oysters can be cultured on ropes suspended from floating rafts. Spain pioneered the development of raft culture for mussels and continues to be a leading producer of raft-cultured molluscs. Oyster raft culture was developed in Japan and continues to be widely used in that country and, to a lesser extent, elsewhere.

Both oysters and mussels attach to substrates in the larval stage, initially planktonic, when they settle to the bottom. The mechanism of attachment is different for the two types of molluscs.

Aquaculturists can provide a suitable substrate (cultch material) for the settling oyster larvae (spat). Suitable cultch materials on which to capture spat include oyster and scallop shells. The shells can be placed in the natural environment or, if the molluscs are being produced in a hatchery, in the tank or raceway into which the spat are introduced. Once the oyster spat have attached to the cultch material, the shells are strung on ropes that are suspended below rafts in a suitable environment.

For mussels, the technique is somewhat different. Juveniles are collected from natural beds and are tied in clumps around ropes 12 to 25 mm (0.5 to 1 in.) in diameter. A wooden peg is inserted into the ropes at intervals of 30 to 45 cm (12 to 18 in.) to keep the clumps of mussels from sliding down the ropes (1).

The ropes may be quite long, though they should be located in the photic zone (above the 1% light level), where phytoplankton live. The depth of the photic zone will vary as a function of turbidity caused by suspended inorganic particles and organic materials, including the phytoplankton upon which the molluscs feed. The length of the ropes used will depend on water clarity and available depth. The ropes, sometimes called strings, should remain above the bottom at all tidal stages, to prevent benthic predators such as starfish and oyster drills from attacking the crop.

Rafts should be located in an appropriate environment. Requirements include proper water quality conditions and a good supply of phytoplankton. The environment should also be free from sewage and other types of pollutants that could concentrate in the molluscs and make them unfit for human consumption.

Figure 1. A net bag containing small scallops and attached to a long line.

LONG-LINE CULTURE

A modification of the raft culture technique is called *long-line culture*. Instead of hanging from surface rafts, the ropes are strung horizontally between floats. The long lines may be many hundreds of meters long. Oysters can be reared attached to cultch material and suspended on a secondary rope that hangs vertically from the main string. Mussels can be attached to secondary ropes in the manner described previously for raft culture.

Long-line culture of scallops, which is well developed in Japan, involves rearing young scallops in net baskets suspended from the main line, since scallops do not attach to substrates (see Fig. 1). When the scallops become sufficiently large, they can be hung individually. At that time, a hole is drilled in one of the so-called wings of each scallop, and a monofilament line is strung through the hole. Individual scallops are then hung from the lines until they reach harvest size.

POLE CULTURE

Poles have been used to suspend oysters above the bottom of ponds and other water bodies in the Philippines and have been used for mussel culture in the Philippines and France. The French grow mussels on poles in a system known as *bouchet culture* (1). In this system, ropes are placed in locations where natural settling of mussels occurs. Once the ropes are covered with young mussels, they are taken to culture locations and are wrapped around oak poles. The poles are then driven into intertidal sediments. Plastic is placed around the base of each pole

to prevent benthic predators from climbing up to attack the mussels.

Poles are also used in conjunction with algae culture in Japan. Thousands of poles may be employed to anchor nets, upon which such seaweeds as nori (*Porphyra* sp.) are grown (see Fig. 2). Spores obtained from reproducing nori are collected on nets in indoor tanks (see Fig. 3). When the nets are covered with spores, they are placed into the environment and attached to the poles. The nets float at the surface and move up and down the poles with the tide. When the plants reach the appropriate size [about 15 cm (6 in.) long], they are harvested by being cut off. The nets are allowed to remain in place after the first harvest, and the plants then produce a second crop. Half of the colonized nets are kept in cold storage until the second
Figure 2. Koroshima Bay in Japan is devoted to pole culture of nori, a seaweed.

Figure 3. Indoor nori settling tanks.

cutting occurs, after which they are used to replace the first batch of nets. The result is four crops of nori per year.

OUTLINE

Rainbow trout are members of the genus *Oncorhynchus*, which also includes Pacific salmon, and members of the family Salmonidae (e.g., Atlantic salmon, trout, char, graylings, whitefish, and several other groups). Rainbow trout are native to cold-water environments in the north temperate zones and are distributed from southern California through Alaska, the Aleutians, and the western Pacific areas of the Kamchatka Peninsula and Okhotska Sea drainages. Rainbow trout are thought of as freshwater fish, but in the eastern Pacific, seawater forms called steelhead trout exhibit an anadromous life history, meaning that they spend a part of their life in the ocean, but return to lakes and rivers to spawn. Rainbow trout have been widely transplanted around the world and are established in South America, Japan, China, Europe, parts of Africa, Australia, and New Zealand.

The Kamchatka rainbow trout was originally named *Salmo mykiss* by Walbalm in 1792 (1) and was later named *S. gairdneri* by Richardson, regarding fish taken from the Columbia River at Fort Vancouver in 1836 (2). Rainbow trout appear to have survived glaciation in two refuges: the Pacific coast, south of ice-age glaciers; and the
Figure 1. Two rows of serial raceways used for trout production in Idaho.

Bering area, north of the Alaskan peninsula. From there, they became reestablished in western North America as glaciers receded. For many years the rainbow trout native to North America (*S. gairdneri*) was thought to be a different species than the trout native to Kamchatka (*S. mykiss*), but they are now considered to be the same species. Prior to 1989, rainbow trout were considered to be part of the trout genus, having the scientific name *S. gairdneri*, but they are now classified as *O. mykiss* (3).

Rainbow trout is by far the most widely farmed trout in the world, mainly because it is a prized food fish and because it is relatively easy to culture (see Fig. 1). Rainbow trout can survive a variety of environmental conditions, such as water temperatures from 0 to 28 °C. They spawn successfully in water temperatures from 2 to 15 °C and grow in water up to 25 °C. Depending upon their diet, rainbow trout can have pigmented (red) or nonpigmented (white) flesh. Once they have reached a certain size, they can be farmed in freshwater or in seawater. In North America, Britain, Denmark, France, and Italy, most trout farming occurs in freshwater facilities, using flow-through water-supply systems. In Chile and Scandinavian countries, rainbow trout are initially grown in freshwater farms followed by growout to harvest in marine cages. Total production of rainbow trout was 358,456 metric tons in 1995, making it the second largest production segment of the salmonids, behind Atlantic salmon (4). Until 1994, global production of rainbow trout exceeded that of other salmonid species. Top trout producing countries are France, Chile, Denmark, and Italy, which accounted for 48% of global production in 1995. The United States accounts for slightly over 7% of global trout production and in 1997 produced 25,777 metric tons, 74% of that in the state of Idaho. Other top trout producing states were North Carolina, California, and Pennsylvania.

LIFE HISTORY AND FARMING SYSTEMS

Rainbow Trout Life History

Rainbow trout live in lakes, streams, and rivers. They consume zooplankton as fry, followed by insects, crustaceans, and other fish as they grow. Spawning

occurs in spring, with rising water temperatures, although considerable variability is found, with coastal rainbow trout spawning in late December. Females deposit anywhere from 500 to 2,500 large eggs (50–150 mg per egg) in nests dug in gravel, while the males fertilize the eggs as they are deposited. The time required for fertilized eggs to develop and hatch depends upon water temperature. At 4.5 °C (40 °F), rainbow trout eggs require 80 days to hatch; at 10 °C (50 °F), 31 days to hatch; and at 15 °C (60 °F), 19 days to hatch (5). Eggs are extremely sensitive to handling and shock from 2 days postfertilization until the blastophore is completely closed, 9 days at 10 °C. Once the eggs become pigmented (about 16 days at 10 °C), the period of sensitivity is over, and the eggs can be handled up until just before hatching. At hatching, the fry still have large egg yolks attached to them and resemble small fish on beach balls. These fry are called yolk-sac fry, or alevins, and they burrow into spaces within the gravel, where they continue to develop and grow, utilizing their yolk sac for energy supply and nutrients. When the yolk sac is nearly gone and has been surrounded by skin on the ventral side of the fish, they are said to be "buttoned-up" fry. The time needed for alevins to reach this stage depends on water temperature, but is approximately 20 days at 10 °C and 10 days or less at 15 °C from hatching. The fry are then ready to feed and emerge from the gravel to seek food on the water's surface. At this point they are said to be "swim-up" fry. The entire sequence from spawning to emergence from the gravel is timed such that the fish emerge when natural food is abundant in spring. Since streams differ in water temperature and food abundance throughout the geographical range of rainbow trout, local populations are adapted to local conditions, and spawning and fry emergence are timed appropriately.

Rainbow trout growth rates depend on water temperature and food abundance, and wild fish generally reach maturity at three to four years of age. Most spawning trout are first spawners, but a small proportion of spawners, mainly females, survive to spawn again. Growth and maturation in rainbow trout is indeterminate, meaning that there is no set rate or age. Rather, environmental factors determine growth and maturation, with fish in cold, harsh environments generally living longer than those in warmer, more benign environments. Maximum size is variable, with 17–23 kg rainbow trout sometimes captured in Kooteney Lake, British Columbia. These fish would be five to six years old (1). However, rainbow trout in streams typically weigh 100 g at one year of age and 300–450 g after three years.

Rainbow Trout Farming

Rainbow trout farming in the United States was described in 1872 in a paper presented to the American Fish Culturists' Association by Livingston Stone (6). In the paper, Stone calculated the economics of trout farming, figuring four years to market, and a sales price of $0.50 to $1.25 per lb. In 1879, a trout spawning station was established on the McCloud River in California, and after various problems, the station produced 179,000 eggs in 1881. In subsequent years, the station shipped eggs throughout the country to state and federal agencies

and private individuals interested in undertaking rainbow trout rearing (6). Rainbow trout culture became a farming business in the early 1900s, with a third of farms being fee-fishing operations, at least until the early 1950s. In Idaho, the first commercial trout farm was started in 1909, near Twin Falls. This area contains many suitable trout farm sites supplied with abundant, constant temperature (14.5 °C) springwater from the Eastern Snake River Aquifer, over 23 m^3/sec in flow (7). Trout farming expanded greatly in the early 1950s, supported in part by the development of pelleted feeds, which reduced the cost of production by eliminating the need for farms to prepare their own feed. Production was about 500 MT in the early 1950s, but increased sixfold by 1960, doubling by 1970, and doubling again to 12,000 MT by 1975. Current production in Idaho is about 19,000 MT, or 74% of U.S. production (see Fig. 2).

Several characteristics of rainbow trout contributed to the expansion of its culture. First, rainbow trout are easy to spawn, and their fry are large at first feeding compared with most other freshwater fish. Thus, they can thrive on prepared feed from first feeding. Second, they grow rapidly and are in demand as a food fish. Third, as mentioned earlier, they tolerate a wide range of water temperatures, and there are numerous water sources in temperate regions in which they can be grown. A final characteristic of rainbow trout that contributed to their success as a farmed fish was that their spawning time could be manipulated by selection and by photoperiod adjustment to make eggs available year-round. This allowed farms to supply rainbow trout to markets throughout the year, hence increasing sales.

Farming systems for rainbow trout are similar everywhere in the world. Fish are raised in flowing water in earthen or concrete raceways, with rearing densities depending upon water flow and water quality (e.g., temperature and dissolved-oxygen content). In Idaho, springwater flows by gravity through a series of raceways, each usually no more than 30–40 meters long, with five to seven raceways receiving water in series. Rearing density varies with water quality, which is higher in upper raceways than in lower raceways. Typical rearing densities are 1.8 kg per liter/min water flow (15 lb/gpm) in raceways receiving first-use water, and up to 9.6 kg/lpm (80 lb/gpm) when all raceways in a series are combined (7; see also
Figure 2. Annual production (metric tons) of rainbow trout in the United States.

Fig. 1). In Italy, long earthen raceways, sometimes more than 1,000 meters long and resembling wide, shallow streams, are used to raise trout.

Fish are hatched indoors, usually in hatching jars with upwelling water sufficient to cause the eggs to slightly roll (see Fig. 3). Hatching success is typically 95%. When fish hatch, they float out of the hatching jars into troughs, where they remain through yolk absorption and first feeding. Feed is provided nearly continuously during the first 7–10 days. Fish are moved to larger troughs or circular tanks as they grow, and are stocked into outdoor raceways when they reach 3–4 inches in length. They remain in raceways until harvest, and often are moved as they grow to raceways receiving third to last-use water (see Fig. 5).

The first limiting factor for rainbow trout in raceways and ponds is usually the oxygen content of the water. Rainbow trout can survive in water containing as little as 3 ppm oxygen, but 5 ppm is considered the minimum oxygen content for fish to thrive. The oxygen saturation level of water depends upon water temperature and elevation. At sea level, for example, dissolved oxygen at saturation is 11.3 ppm in 10 °C water and 10.0 in 15 °C water. At 910 m (3000 ft) elevation (the approximate elevation of most Idaho trout farms), the oxygen levels at saturation are 10.1 ppm and 8.9 ppm for 10 and 15 °C water, respectively. Activity associated with feeding, cleaning, or harvesting lowers the dissolved-oxygen content of trout raceways, and raceways are stocked and managed accordingly. Some oxygen is added by splashing water from one raceway to another, but this rarely restores dissolved-oxygen levels to saturation levels.

Other dissolved gases can be a problem for rainbow trout, particularly nitrogen under conditions of supersaturation, such as occurs downstream from large dams. If air is sucked into a pipe supplying a hatchery, and if the head (vertical distance between the source of the water and the farm) is sufficient, nitrogen supersaturation can occur, resulting in gas-bubble disease. This condition results from nitrogen gas coming out of solution in the blood of fish. Subcutaneous bubbles are visible in fins and around the eyes of affected fish. Other dissolved gases, including hydrogen sulfide (H_2S) and hydrogen cyanide (HCN), are toxic to trout, but farms avoid water sources containing such gases (8).

The second limiting factor for rainbow trout is ammonia, the excretory product of protein catabolism. In flow-through rearing systems, dissolved ammonia rarely reaches toxic levels (0.0125 ppm as un-ionized ammonia, NH_3), but in farms using recycled water, ammonia buildup must be monitored, and nitrification through the use of biological filters or ion-exchange must be employed.

In the United States, most rainbow trout are harvested at 450–600 g, a weight achieved after 10–15 months of rearing, depending upon water temperature (see Fig. 4). A significant proportion of U.S. trout production provides fish for recreational fishing, and these fish are delivered

at nearly all sizes up to harvest size. In Europe, rainbow trout are harvested at 1–2 kg, while in Chile, Norway, Sweden, and Finland, rainbow trout are harvested at 3–5 kg after being grown in marine cages. Trout in the United States are expected to have white meat, so they are fed diets lacking the carotenoid pigments that give trout and salmon fillets their typically red color. In nature, these pigments are naturally present in their food. Trout raised in Europe and Chile to larger sizes are expected to have pigmented meat, so the feed for these fish is supplemented with astaxanthin, the carotenoid pigment found in wild fish. In trout feeds, astaxanthin can be supplied by natural sources, such as krill, yeast, or algae or by astaxanthin produced by chemical synthesis.

RAINBOW TROUT FEEDS AND FEEDING

Rainbow trout are carnivorous fish, consuming zooplankton, insects, crustaceans, and other fish. They have a relatively short digestive tract, consisting of an acid stomach, a pyloric cecae (where digestive enzymes are released), a small intestine (where most nutrient absorption occurs), and a large intestine for water and electrolyte reabsorption. The total length of the digestive tract, from mouth to anus, is barely the length of a trout, in contrast to humans (three to four times body length). Embody and Gordon (1924) conducted the first survey of the natural food of trout, finding that it averaged 45% protein, 16–17% fat, and 12% ash. Trout feeds were similar to that until the development of high-energy feeds within the last several years. In general, feeds for fry and fingerlings are higher in protein than feeds for growout or broodstock trout. The requirements of trout for essential dietary nutrients have been estimated, and trout are known to require about 40 nutrients, similar to other animals. They can obtain most minerals directly from water if rearing water levels are sufficient. Trout feeds contain adequate amounts of most essential minerals to meet their needs directly, regardless of rearing water supplies.

The first trout feeds were prepared by hatchery staff for each hatchery, and contained materials that could be obtained in the vicinity of the hatchery. The materials used in these feeds included slaughterhouse, fish, dairy, and other by-products. These were ground and mixed together to form a wet mixture that was hand-fed to fish in ponds. These feeds dissolved in water quite rapidly, lowering water quality, limiting stocking densities, and contributing to disease. Wet–dry mixtures were the next step in trout feed production. Wet products were combined with flour or other milling by-products to extend the wet products and to produce a mixture that formed a pellet. Pelleting technology was crude, often consisting of a meat grinder or noodle maker. In the mid-1950s, compressed, steam pellets were first produced by Clark Co. for trout; other feed companies soon followed suit. These feeds were based upon formulations developed by the Cortland Fish Nutrition Laboratory in New York State and contained 36% protein and 5% fat. By 1961, all trout farms used compressed pellets, a development that was critical to growth of the industry. In the mid-1990s, cooking–extrusion was introduced as a pelleting method in

trout feed production. Pellets made by cooking–extrusion are harder, but less dense. They absorb high amounts of added fish oil and permit the production of high-energy trout feeds (i.e., those over 16–17% fat). Dietary protein levels in trout feeds have increased from 35% to 45% over the last 35 years, and dietary fat levels now exceed 22% in high-energy feeds. These feeds are more nutrient dense, and thus support more growth per unit feed than earlier feeds. In the 1960s, feed conversion ratios (amount of feed/fish weight gain) were about 2.0, meaning that for every 2 lb of feed fed to trout, 1 lb of gain resulted. Today, the best commercial, high-energy feeds yield feed conversion ratios of 1.2 : 1 to as low as 0.8 : 1, when their use is combined with good feeding practices.

Feed formulations for rainbow trout utilize fish meal, fish oil, grains, and various by-products derived from production of food oils and other food products, (e.g., meats and poultry) (Table 1). Efforts have been made to lower the percentage of fish meal used in rainbow trout feeds, substituting other protein sources such as soybean meal, poultry by-product meal, and small amounts of blood meal and feather meal. In the past decade, the amount of fish meal used in trout feeds has decreased by about 50% as a result of the use of alternate protein ingredients.

Rainbow trout fry are fed frequently, as often as every 15–30 min. Feeding frequency decreases as fish grow and their ability to consume more feed at each feeding increases. Feed can be delivered by hand, by demand feeders, or by mechanical feeders. Hand feeding simply involves the broadcast of feed over the surface of a raceway or pond. Automatic and demand feeders are devices that deliver feed to troughs, tanks, and raceways. Each contains a feed hopper and a delivery system, the difference being that automatic feeders operate according to a program containing the number of feedings and the duration of feed delivery at each feeding, while demand feeders only deliver feed when the fish activate the feeder. Automatic feeders are electrically, mechanically, or pneumatically driven, using vibration, a motorized belt, a chamber or

Table 1. Generalized Feed Formulations Used for Rainbow Trout Reared in Seawater and in Freshwater

Feed Ingredient	Seawater Feed (g/kg)	Freshwater Feed (g/kg)
Fish meal	550	300
Poultry by-product meal		100
Blood meal		0–50
Soybean meal	50	50–100
Wheat grain and by-products	144	170–300
Vitamin premix	10	10
Trace mineral premix	1	1
Choline chloride (60%)	4	4
Ascorbic acid	1	1
Fish oil	240	120–210
Proximate composition		
Moisture	8%	8%
Crude protein	43%	45%
Crude fat	28%	18–26%

solenoid system, or air pressure to deliver feed to the fish. Automatic feeders are very useful for feeding fry, and some farms use them throughout the production cycle. Demand feeders are simply tapered feed hoppers, open at the bottom, with a rod extending from the hopper through the bottom into the water. An adjustable platform is fitted on the rod within the tapered bottom, and can be moved up or down the rod, thus changing the clearance between the outside edges of the platform and the tapered sides of the feeder. Fish bump the rod, causing the platform to move and feed to fall off into the water. The amount of feed falling off with each bump depends on the clearance between the platform and the sides of the feeder. The advantage of demand feeders in rainbow trout farming is that feed is only delivered when the fish want to feed. This eliminates feeding when fish are not interested, ensuring that fish, not the water, are being fed. Trout using demand feeders tend to feed intensively in the morning and evening, but also feed intermittently nearly all day (see Fig. 6). Fish move in and out of the feeding area. Reductions in dissolved-oxygen content associated with broadcast feeding and the frantic feeding that accompanies it do not occur. The disadvantage of demand feeders is that the clearance must be properly set to avoid feed delivery associated with wind or water movement.

The appropriate quantity of feed for a given size and number of fish is determined by using feed tables that contain recommended amounts of feed for different water temperatures and fish weights. Generally, the daily feed ration is divided into several feedings, with the aim being to feed between 0.75% and 1.0% of total biomass in a tank or raceway per feeding. The amount is chosen to minimize the range in size within a group of fish. If a lower amount is fed, aggressive fish will consume most of the feed, thereby increasing size variation within a group of fish. The idea is to feed enough at a feeding to satiate aggressive fish, allowing less aggressive fish the opportunity to eat. Many farmers fill demand feeders with a programmed amount of feed per day, determined from feed tables or farm records, in an effort to feed the amount needed to support rapid, but economical growth. Maximum feed efficiency (lowest feed conversion ratio) occurs at about 75% of maximum feed intake in trout, but maximum growth occurs at or near maximum feed intake. Trout farmers strike a balance between maximum growth and maximum feed efficiency by feeding between these levels at the growout stage, when most feed is fed during the production cycle.

RAINBOW TROUT HEALTH MANAGEMENT

Disease is one of the most important problems facing aquaculture, including rainbow trout farming. Disease organisms are frequently present in water or in fish, and when fish are stressed or exposed to suboptimal environmental conditions, disease outbreaks occur. Crowding, low dissolved-oxygen content, high particulate levels in water, and stress associated with handling are examples of conditions that can result in a disease outbreak in rainbow trout. Fish health management in rainbow trout farming is based upon prevention; once a disease outbreak occurs, it is very difficult to treat or control. Elements of prevention include sanitation (clean raceways), high-quality feed, prevention of overcrowding, elimination of disease vectors, and vaccination. Vaccination has been extremely effective in preventing some important diseases in rainbow trout. Treatment of disease in rainbow trout with antibiotics delivered via the feed is relatively uncommon. There are only two antibiotics approved for use in the United States to treat fish, and they are not effective against many trout disease strains. There are strict regulations about using antibiotics in trout farming that, in combination with the cost of adding antibiotics to feeds, limits their use. Health management by prevention is a more economical approach in rainbow trout farming. Birds are a major disease vector in trout farms because they move from farm to farm and eat diseased fish. Disease organisms pass through the gut of birds and remain pathogenic. Most farms in Idaho use netting to restrict bird access to trout raceways (see Fig. 5). Vehicles, equipment, and boots should be disinfected when moved between farms. Buildup of uneaten feed and feces in raceways should be avoided, and dead fish should be promptly removed.

ENVIRONMENTAL CONSIDERATIONS IN TROUT FARMING

Most forms of trout farming are not a consumptive use of water, but water from the farms is enriched with nutrients that in turn, enrich lakes and rivers receiving farm water flows. These nutrients reduce water quality and increase growth of algae and aquatic plants. Thus, rainbow trout farms are subject to regulations limiting the levels of solids and nutrients in hatchery water effluents. Phosphorus is one nutrient of concern in hatchery effluents. Unassimilated nutrients originate in uneaten feed, feed dust, feces, and metabolic excretions (urine and gill wastes). Many farms create quiescent zones at the ends of raceways where fish are excluded and particles settle without being disturbed. Settled material is regularly removed and applied to fields, sometimes after composting. Phosphorus in hatchery effluents is present in two forms: solid particles (e.g., bones and other insoluble forms) and soluble phosphorus excreted by fish in urine. Solid phosphorus can be collected and removed, but soluble phosphorus cannot be removed economically

Figure 6. Outdoor raceways. Note the demand feeders.

because it is present in very low concentrations in very large quantities of water. Thus, limiting the amount of digestible phosphorus in feeds to the amount needed by the fish is the approach used in rainbow trout feed formulation. By the use of this approach, the amount of soluble phosphorus excreted by fish has been reduced to very low levels. Reducing the amount of insoluble phosphorus in rainbow trout feeds requires two approaches: (1) using low-phosphorus feed ingredients and (2) increasing the bioavailability of phosphorus in feed ingredients. This is an area of active research.

RAINBOW TROUT PROCESSING AND PRODUCTS

Rainbow trout are processed within minutes or hours after harvesting and are supplied to markets either as fresh or frozen products. Kept on ice, their shelf life is 10–14 days or more. As is the case with all fish, storage of fresh fish at higher temperatures shortens shelf life rapidly. Trout are marketed as gutted fish, as fillets (often boneless), or as value-added products, such as smoked trout. Trout fillets typically contain 19% protein and 5–7% fat, with the remainder being water (∼70%) and ash (2%). The omega-3 fatty acid content of trout fillets depends upon the feed, but averages 22% of fillet fat. In the United States, 60–70% of food-size trout production is sold as head-on, gutted fish, with the remainder sold as portion-sized fillets, while in Europe, most trout are sold as whole fillets from larger fish, sufficient to feed several people (see Fig. 7).

RAINBOW TROUT FARMING INDUSTRY STRUCTURE

The U.S. trout farming industry was dominated by individual entrepreneurs during its growth phase in the 1950s and 1960s, but industry consolidation and vertical integration have characterized the trout farming industry over the past decade. The industry was composed of trout egg producers, growers, fish processors, distributors and brokers, and feed manufacturers. Businesses that combine trout farming, processing, and sales are most common. Egg production has remained a specialized business, as has feed manufacturing, although businesses that combine

Figure 7. Hand filleting rainbow trout. Note the butterfly fillet in the foreground.
Figure 8. Percentage of rainbow trout production costs by category (7).

these sectors with production do exist. Some companies engage in contract rearing by small farmers, whereby the companies provide fingerlings, feed, and management advice to small growers who produce trout for the company, thereby expanding their production. The general impression of the U.S. trout farming industry is of a stable, maturing industry that has concentrated on lowering the cost of production and markets fish products that are less expensive than most other seafood products. The cost of producing trout varies from company to company, but in general, feed constitutes the largest single operating expense (Fig. 8). Increasingly, regulatory compliance (e.g., water testing and treatment) and HACCP compliance, constitute a rising share of operating expenses.

Complete utilization of available groundwater supplies in many trout rearing areas of the United States, particularly in Idaho, limits expansion of trout farming as it is currently practiced. New approaches and techniques will be necessary for trout production to increase. As mentioned earlier, oxygen concentration is the first limiting water-quality parameter for trout. Increasing the oxygen content of raceway water will increase the carrying capacity of raceways, thus increasing production from a given quantity of water. Simple filtration and even partial recirculation of water within farms offers the potential of increasing the productivity of existing trout farms, assuming that the economics of such approaches merit their use. Other innovative approaches to trout farming include the use of cages or pens to rear trout within large rivers and the use of irrigation water before it is applied to fields. Large fingerlings stocked into pens in the Columbia River as water warms in spring reach harvest size of 3–5 kg within 12–18 months, which is similar to the growth rates of rainbow trout reared in marine cages off the coast of Maine or in Chile.

FUTURE OUTLOOK

Worldwide, farmed trout production is increasing, but at a lower rate than Atlantic salmon production (4).

Trout are an efficient fish with respect to converting feed ingredients not consumed by humans into human food. Currently, the conversion of trout feed into trout weight gain is about 1 : 1, meaning that for each ton of feed, a ton of trout is produced. Feeds are composed of by-products of edible oil production (soybean meal), fish meal, grain by-products, and recovered protein from poultry and meat production. Trout yield more than 50% of edible product after processing, and this product is high in essential fatty acids and protein and low in saturated fats relative to animal proteins. Trout production is predicted to increase by 5% per year for the foreseeable future and will likely maintain its place in the top 15 finfish and crustacean aquaculture species produced in the world, as well as remain in the top 10 species, with respect to total value.

RECIRCULATING WATER SYSTEMS

R<small>OBERT</small> R. S<small>TICKNEY</small>
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

INTRODUCTION

Recirculating or closed water systems continue to be used primarily for experimental work and for the rearing of larval organisms in commercial and research facilities, though increasingly, profitable commercial applications are being demonstrated. They are also used in public aquaria. The typical home aquarium is one type of a closed system. The popular press and aquaculture trade magazines have published many articles about systems that, their developers claim, work effectively and profitably. Such systems often do work. One can produce fish that demonstrate good growth rates and feed conversion ratios (wet weight increase divided by dry weight of feed offered) and that are acceptable to consumers. However, entirely closed commercial systems producing food-size aquatic animals in the United States are the exception rather than the rule. The exceptions tend to be associated with the availability of free heat (geothermally or industrially heated effluent used to provide increased temperature to the aquaculture facility through heat exchangers) or with the production of early life stages or high-priced ornamental species.

Given increasing land prices, water shortages that are occurring and are projected to occur in the future, and the increasing governmental regulation on the effluents from aquaculture facilities, there are many who feel that closed water systems will be needed if aquaculture is to continue growing in developed countries. Closed systems for marine species are currently being advocated as a means of avoiding the opposition that exists for conducting culture activities in coastal waters. Such systems may also be used to produce fingerlings for stocking in marine enhancement programs and may, at least for now, be more economical than net-pen or cage systems placed far offshore where they are exposed to storms.

Many innovations have occurred as a result of research and development, and ultimately, increasing numbers economically viable systems will be put into operation. In the meantime, claims of economic success should be looked upon with some skepticism until all the data are made available for close scrutiny.

The standard closed-water system is typically housed in a building to help maintain a constant environment, though outdoor systems have been designed and operated. Recently, shrimp farmers in Texas have converted from pond systems that relied upon enormous supplies of continuously flowing water to recirculation (achieved by setting aside some pond area as settling basins). When classical closed systems using tanks or raceways are placed outdoors, operators tend to experience problems with the growth of unwanted algae throughout the system. Covers over the various components of the system will reduce or eliminate the problem by drastically reducing the level of incident light. Such problems may be avoided through

increasing the scale of the operation as indicated by the Texas shrimp culture example. Indoors, light levels are usually insufficient to support significant amounts of algae growth, although plants may be purposefully grown in hydroponic chambers for tertiary treatment (described in the next section).

BASIC COMPONENTS

Some of the components of recirculating water systems are unique to closed and semiclosed systems (water systems where some percentage of total water volume is replaced on a continuous basis), while others have broad application in aquaculture. Recirculating systems are generally comprised of three basic types of components: one or more settling chambers, a biological filter (or biofilter), and the culture chambers (1). The appearance of the various components and auxiliary types of equipment that have been added to recirculating water systems vary considerably, but most systems operate in basically the same manner. As discussed by Lucchetti and Gray (2), the functions of such systems include ammonia removal, disease and temperature control, aeration, and particulate removal.

Water leaving the culture chambers usually, but not always, is allowed to enter a primary settling chamber where solids are removed. The water is then passed into a biofilter, where bacteria detoxify ammonia and nitrite. The biofilter is typically followed by a secondary settling chamber, where bacteria that sloughs from the biological filter is removed. After secondary settling, the treated water is returned to the culture chambers. Some systems use mechanical filters in place of, or in addition to, one or both settling chambers.

Well-designed systems pump the water only once and utilize gravity as much as possible. If water is pumped more than once, it is necessary to balance the pumping rates precisely to keep portions of the system from being either pumped dry or caused to overflow.

Biofiltration is a form of secondary waste treatment, where the settling of solids represents primary treatment. Tertiary treatment, which removes nutrients like nitrates and may reduce the levels of trace elements and dissolved organics, has been added to some recirculating systems. Supplemental aeration is generally provided in closed systems. Sterilization with ozone or ultraviolet radiation, foam removal, and other auxiliary components have also been used. Backup systems for all motors and pumps are critical.

The various components may be quite large or rather small, depending on the purpose for which the system has been designed. A closed system designed to produce 0.5 kg (1.1 lb) for rainbow trout (*Oncorhynchus mykiss*) or channel catfish (*Ictalurus punctatus*), for example, would in all likelihood have larger components than one designed for the rearing of shrimp larvae. In the same vein, research facilities are typically much smaller than commercial growout operations.

Components may be physically separated or, at least some, may be combined (e.g., a settling chamber and biofilter could be placed within a single unit). A single biofilter and associated settling tanks may service a number of culture chambers, or each culture chamber may be served by its individual biofilter and settling chambers. Various configurations have been designed for both freshwater and marine use. Some designs, such as those employed for research, have employed materials as readily available as plastic pails and garbage cans, while others, including most commercial facilities, have been fabricated from concrete or fiberglass. The use to which a system is to be put, the space into which the system is to be placed, and the resources available play roles in the materials chosen.

Materials used for construction of not only the culture chambers, but also the other components of closed systems and other types of water systems should be nontoxic to the culture animals. The same applies to paint used on any of the components. Metal should be avoided as much as possible because of potential toxicity. In saltwater systems, corrosion of metal can be a significant problem. Pumps with plastic impellers are recommended, although if operated continuously, metal impellers will hold up in salt water, but can still cause elevated levels of trace metals in the water.

Plumbing in modern aquaculture systems usually comprises plastic pipe, typically polyvinyl chloride (PVC). PVC pipe comes in various sizes and strengths. Pipe designed for drains should not be used in pressurized parts of the system. Pipe labeled "Schedule 40" or "Schedule 80" can be placed under pressure and can carry hot water. PVC made for drains should not be used outdoors in climates where freezing temperatures occur, unless it is buried. Drain PVC will shatter when water standing in it freezes.

Culture Chambers

Closed, semiclosed, and open culture systems typically employ relatively small culture chambers compared with ponds. Typical culture chambers are circular tanks (also called circular raceways), linear raceways, and silos (tall circular raceways). The material used for construction of culture chambers can vary widely, depending on such factors as the preference of the culturist, the availability of materials, the cost, and in some cases the species to be cultured. The most commonly used materials are concrete, wood, fiberglass, various types of molded plastic, and sheet metal (usually aluminum or stainless steel, and usually used only in freshwater systems because of the corrosion problems associated with salt water). Stainless steel is expensive and galvanized metal should be avoided because of zinc toxicity. Glass aquaria have been popular with some researchers and represent yet another type of construction material that can be employed.

Culture-chamber dimensions are quite variable, although most circular and rectangular tanks used in conjunction with closed systems are less than 10 m (30 ft) in diameter and seldom exceed 1 m (3 ft) deep. (The sides may be somewhat higher to provide freeboard above the waterline.) Commercial tanks are generally larger than those used in research.

Circular tanks have an advantage over rectangular culture chambers. When water inflow and drainage are properly designed, circular tanks are characterized

by uniform water flow throughout. Raceways tend to have areas of static water in the corners where waste accumulates; however, linear raceways with rounded ends have been designed to help reduce the problem. Circular tanks usually have center drains and water is typically introduced tangentially to the surface, causing it to move clockwise or counterclockwise in the tanks. The motion concentrates waste feed and fecal material around the drain, where it can be automatically removed if the proper type of drain is used. Some self-cleaning will occur in linear raceways that are equipped with venturi drains, which are very efficient in removing particulate matter from circular tanks. A venturi drain involves an inner standpipe that controls water level, with a larger standpipe surrounding the internal one. Holes at the bottom of the larger standpipe pull water in at the tank bottom from where it rises to exit at the top of the smaller internal standpipe. Waste material tends to collect between the two standpipes. Some of the material will flow out through the overflow and down the drain, and the remainder can be removed periodically by pulling the inner standpipe and allowing sufficient water to exit to remove the accumulated waste. The self-cleaning action is facilitated, particularly as the diameter of the tank increases, if the bottom of the tank slopes toward the drain. Venturi drains can also be placed on the outside of culture tanks through some modifications in plumbing design.

Circular tanks usually drain either into pipelines or into a channel imbedded in the floor of the building containing the system or ground on which an outdoor system is constructed. Pipes are typically used when gravity is depended on to carry water to the next component in a recirculating system. Either pipes or floor drain channels can lead to a sump in which a pump moves the water to the next component.

In linear raceways, water typically enters at one end and is discharged through a standpipe at the other. A venturi drain can be used in conjunction with a linear raceway and will help in waste removal. As previously indicated rounded corners can be used in conjunction with linear raceways to avoid dead spaces, but solids will tend to settle throughout much of the long axis of such chambers unless the flow rate is quite high. Screens are often placed in front of the standpipe in linear raceways to keep fish from being lost down standpipes that are not protected with an outside venturi pipe.

In tanks and raceways that have standpipes associated with the drains, water level is maintained in the event of a loss of inflow. Some designs employ bottom or siphon drains with balanced inflow. Depending on the design, such culture chambers may lose all their water in the event of a pump or power failure.

The exchange rate and manner in which water is introduced into raceways influences current velocity. Maintenance of some current not only is important in helping flush waste products toward the drain; it may also benefit the culture species by accommodating normal behavior in the case of species that tend to orient themselves with respect to a current, such as trout. There are some who feel that the exercise associated with constant swimming into a current is beneficial in terms of final product quality and may stimulate more active feeding and growth, although scientific evidence is scanty. Too much current can exhaust the culture species, or in the case of larval and early juveniles, may push them into screens and lead to heavy mortality. Employing a screen in front of the standpipe in a linear raceway will prevent the loss of animals down the drain. In circular tanks, large areas associated with the outer standpipe can be screened, which will avoid concentrating the effluent into small areas through which accelerated flow will occur. The size of the screen mesh in linear raceways and in association with outside standpipes used in circular tanks should be sufficiently fine to prevent escapement of the animals, but as large as possible to reduce clogging and the restriction of flow.

Culture tanks and raceways that employ venturi drains should be small enough to allow those drains to function properly. While the diameter of the standpipes can be increased as the size of the culture chamber is increased, in practice, outside standpipes larger than about 30 cm (1 ft) and inside standpipes larger than 10 cm (4 in.) in diameter are not normally used. Circular tanks larger than about 20 m (60 ft) in diameter may be impractical. Most are no larger than 10 m (30 ft) in diameter.

Raceways with screens placed in front of the standpipe area to prevent escapement can be quite large and can be fitted with two or more standpipes at the drain end if necessary to accommodate the flow. Indoor raceways used in hatcheries and research facilities tend to be relatively small. They are usually no more than 3 to 5 m (9 to 15 ft) wide and 25 to 50 m (75 to 150 ft) long. Many are less than 1 m (3 ft) wide and only 2 to 3 m (6 to 9 ft) long.

It should be possible to drain and refill culture tanks rapidly during harvesting and stocking. These processes are facilitated when oversized inflow and drain lines are used. During normal operation, inflow lines can be fitted with flow-regulation devices to control the amount of water entering. When the raceways are being filled, the flow regulators can be removed or bypassed to allow much higher flow rates. Similarly, while a large internal standpipe and drain lines may not carry anything like their design capacity during normal operation of the raceway system, when culture chambers are being drained, the job can be accomplished quite rapidly by having oversized plumbing. Also, it may be possible to drain several raceways simultaneously without exceeding the capacity of the drains to handle the increased water flow.

For large outdoor raceways, flow is generally controlled with valves alone. In the laboratory and in the hatchery, it may be necessary, or useful, to maintain constant, limited, and equal flow rates in a number of raceways. Homemade flow regulators have been produced for that purpose, but economical commercially produced flow regulators are also readily available through plumbing and irrigation supply houses. A flow regulator can be made by drilling a hole of the desired size through a PVC cap that is then glued onto the end of an inflow pipe. The flow rate through this type of flow regulator will vary if water pressure fluctuates.

Commercial flow regulators are designed to provide constant flow as long as reasonable water pressure is

maintained. They adjust to changes in water pressure above some specified minimum. Such changes occur when the amount of water being used is changed, which occurs very commonly when raceways are being filled or cleaned, or when water is diverted to other uses such as filling hauling tanks or washing down the floor.

Some of the most effective commercial flow regulators are made from stainless steel and plastic. The metal ones can be screwed onto the end of a threaded PVC pipe, while the plastic ones are disc-shaped and can be placed into a fitting that will screw onto a faucet (also available in PVC). When stainless-steel flow regulators are used, it is helpful to place a valve in the water line upstream from each flow regulator so that water supply to the individual raceways can be independently turned on and off. Either type of flow regulator can be easily removed when higher volumes of water are needed to fill the raceways.

Flow regulators come in a variety of sizes. Flow regulators that will deliver less than 1 L/min (0.26 gal/min) can be used with small raceways [e.g., 20 L (5 gal) aquaria], while larger units may require flow regulators that deliver several liters per minute. The flow rate through such regulators is controlled by the size of the opening through which the water passes.

Water exiting the types of flow regulators previously described produces a thin stream under pressure. When that stream is allowed to run directly into the raceway, the incoming water is actually injected into the water within the culture chamber, causing turbulence and consequent aeration. A saturated level of dissolved oxygen (DO) can often be maintained in the presence of high fish biomass when such flow control devices are employed. In large tanks it may be necessary to have several water injection streams. If the culturist wishes to reduce the turbulence, as might be necessary when larvae or sensitive juveniles are being cultured, a length of pipe or plastic tubing can be placed downstream of the flow regulator to dampen the flow. While that may also reduce the oxygenation rate, in larval tanks, density of animals and low and maintenance of sufficient levels of DO are not usually a problem. Supplemental aeration can also be provided as necessary in all cases.

Each recirculating water system may employ one or more culture chambers in conjunction with each of the other main components of the system. The effluent from several raceways may be collected in a common drain system and flowed into the settling chambers and biofilter before reentering the tanks, or each culture chamber may have its own set of other components (which will add significantly to the expense of construction and operation). In systems wherein a number of culture chambers employ a single set of settling chambers and a commercial biofilter, the latter components need to be properly sized to accommodate the total volumes of water and waste that the system will be required to handle. Advantages to building large settling chambers and biofilters include economical use of space, especially indoors; limitation on the number of backup components required; and reduction in the need to duplicate plumbing. In general, the cost of constructing a few large units is less than that incurred in conjunction with building several smaller ones with the same combined capacity.

When the effluent from several culture chambers is pooled for treatment, an equipment malfunction can result in complete mortality of the animals in the system. Total power failures can lead to serious consequences in any closed water system; however, the failure of a single pump or aerator would be less crucial to the producer if each unit had its own mechanical devices than if several culture chambers shared the same pump and aerator. Duplicating primary and backup systems is expensive, but so is the loss of one or more tanks of animals.

A disease outbreak in a recirculating water system with more than one culture chamber can rapidly spread. Further, if the proper precautions are not taken, diseases can be spread by the culturist from one closed system to another. Disease treatment is often difficult in closed systems because exposing the biofilter to chemicals can kill the beneficial bacteria that reside therein. Isolating the culture chambers for treatment is not generally feasible, unless there is a sufficient volume of suitable quality water to put the culture chambers in a flow-through mode during treatment.

Settling Chambers

In most closed aquaculture systems, effluent water from the culture chambers passes through one settling chamber before entering the biofilter and another settling chamber after leaving the biofilter. In closed systems, mechanical filtration through sand or other types of filters has also been frequently used to remove particulate matter from culture tank and biofilter effluents. Removal of particulates using a hydrocyclone device prior to biofiltration has also been found effective (3).

A settling chamber is merely a tank in which the exchange rate is sufficiently slow that particulates will settle. In many such chambers, the water is made to flow in and out at the top so that the material that has already settled does not become resuspended. A valve should be located at the bottom of the settling chamber to provide a means by which settled material can be removed periodically. Sloping the bottom of the chamber to the drain will make removal of solids more complete and require less water usage during the sludge-draining process. In some designs, the primary settling chamber is ignored or is incorporated into the biofilter.

Solids removal with a primary settling chamber is important because it cuts down on the loading of the biofilter. The material that is removed from the settling chamber is nutrient-rich and can be used as fertilizer. The material is composed largely of feces (and pseudofeces when certain invertebrates are under culture), unconsumed feed, and bacterial floc.

Water leaving a biofilter will contain bacterial floc that sloughs off the biofilter medium. While bacteria will certainly grow on the walls of pipes and on the walls of culture chambers and settling basins, the bulk of the bacteria in the system is contained within the biofilter, and most of the sloughing occurs in that part of the system. Removal of sloughed material in a secondary settling chamber helps keep the water in the culture chambers from becoming turbid.

Proteins dissolved in the water from various sources will form masses of bubbles when the water is sprayed from one of the units in the system to another. Protein skimmers have been designed to remove the bubbles, thereby also reducing loading on the system. A skimmer may simply be a vertical arm that confines the bubbles and causes them to spill over the sides of the settling chamber, or it may be more elaborate, such as a moving belt with paddles on it that pass over the surface of the settling chamber and push the bubbles over the side or into a collection area leading to a drain. Some commercial biofilters also have foam removal components incorporated into them.

Biofilter Media and Function

Mechanical filters have been used on both experimental and commercial recirculating water systems in place of biofilters, but clogging and the resultant channeling and poor filtration efficiency have produced serious water-quality problems. Sand filters tend to clog rapidly when subjected to heavy loading. Gravel filters are less subject to clogging, but channeling is not uncommon if they are not frequently backwashed. When a mechanical filter becomes clogged, organic material, including bacteria and other organisms that have colonized the medium, will die and begin to decay. The filter can quickly become anaerobic. Not only does it lose the biological filtration activity that it may have once had; it will also begin to emit hydrogen sulfide, ammonia, and other toxic substances, as well as release water that is either very low in or devoid of oxygen. Thus, the filter will begin doing just the opposite of what it was designed to do.

Many functioning biofilters have been designed by using media that will not easily clog. Various types of plastics have been used, for example. For small-scale systems, pieces of plastic pipe cut into lengths of a few centimeters have worked well. Closed systems have employed Teflon rings, fiberglass, Styrofoam beads, and all sorts of plastics as media. Anything that bacteria will colonize can serve as a suitable medium for a biofilter. Commercial biofilter media are available as well. Those media are typically honeycombed sheets or cylinders of plastic with holes or slots cut in the sides and with protrusions of various kinds. In all cases, the void space is very large relative to the surface area of the material. Surface area for bacterial growth is enormous in sand or gravel filters compared with that of biofilters containing plastics, but the efficiency of the former tends to be very poor because of the clogging and channeling problem previously mentioned.

In recent years, advancements have been made in the utilization of more tightly packed media in biofilters. Ion exchange media (4,5) and the application of fluidized-bed technology with activated charcoal (6) have been successfully employed.

The major function of a biofilter is the nitrification of ammonia. Ammonia is excreted into the water by way of the gills of fishes and other organisms and tends to be one of the most important natural toxic chemicals produced in water systems of all types. The nitrification of ammonia occurs in two steps, each undertaken by a different genus of bacteria. *Nitrosomonas* converts ammonia (NH_3) to nitrite

(NO_2^-), and *Nitrobacter* converts nitrite to nitrate (NO_3^-). The two genera of bacteria are aerobic and will only live and perform their function when there is oxygen in the water. When deprived of oxygen, even for a brief period, the bacteria will succumb and the biofilter will begin producing high levels of ammonia and nitrite.

Aerobic conditions can be maintained by bubbling air, compressed oxygen, or liquid oxygen into the biofilter chamber. Splashing water into the biofilter or exposing the bacteria to oxygen periodically (See the section on "Rotating biodisc filters") are also effective at maintaining aerobic conditions.

When a new recirculating system is put into use or when a system is restarted after having been harvested, drained, and cleaned, time must be allowed for colonization of the biofilter with the appropriate types of bacteria. At startup of a commercial system, the biomass of aquatic animals carried in the system may be sufficiently small that water quality deterioration will not occur before the bacteria become active. However, in most instances, it is best to ensure that the system is operating effectively before the aquatic organisms are added. This can be done by seeding the system with ammonia (e.g., in the form of ammonium salts), putting in a source of organic material that will deteriorate and form ammonia (e.g., prepared feed), stocking fish or other animals at low biomass, or some combination of these approaches.

The desirable bacteria are cosmopolitan and will soon colonize the biofilter without being inoculated. Commercial solutions containing bacteria are available. Reviews as to the effectiveness of those commercial preparations have been mixed.

Typically, *Nitrosomonas* will become active from several hours to several days before *Nitrobacter*; thus, spikes in nitrite production can be expected before the biofilter becomes fully functional. The time required for colonization by biofilter bacteria will vary as a function not only of loading, but also temperature and salinity. More rapid colonization generally occurs in warm as compared with cold water. Marine culture systems require a much longer colonization period than freshwater systems. Typical colonization rates are from a few to several days in freshwater to in excess of a month in saltwater. More rapid colonization has occurred in saltwater, but the colonization rate is generally slower than in freshwater.

The sizing of biofilters relates to anticipated ammonia production and the efficiency of the system in converting the ammonia to nitrate (2). At neutral pH (7.0), the activity of the biofilter is a function of temperature and the available surface area (7,8). Speece (7) produced a series of graphs that can help aquaculturists determine the amount of biofilter volume needed over a temperature range of 5 to 16 °C (41 to 61 °F) when the food conversion ratio of the aquaculture animals and the surface area of the biofilter medium are known.

Biofilters can be installed either indoors or outdoors, but the internal portion should be protected from exposure to sunlight and bright artificial lights to prevent the growth of undesirable algae. Algal growth can lead to clogging of the biological filter, and if blue-green algae become established, there is the potential of off-flavors or even

direct toxicity from certain metabolites produced by those organisms. The biofilter should also be protected from large temperature fluctuations, so outdoor filters should be insulated.

Four basic biofilter designs have received the attention of aquaculturists. They are trickling, submerged, updraft, and rotating biodisc filters. In addition, fluidized beds can act as biofilters.

Trickling Biofilters. Water enters trickling filters from the top and is allowed to pass by gravity through the filter at a rate that does not allow the medium to become submerged, although all internal portions of the filter are continuously wetted. Municipal sewage treatment plants often employ trickling filters with rock as the medium. Those units are much larger than the ones used in most aquaculture operations because the volume of waste from even small cities is dramatically higher than from most aquaculture facilities.

Submerged Biofilters. The design of submerged biofilters is often similar to that of settling chambers, except that the submerged filter contains a medium on which bacteria become established. Water enters one end of the filter, flows through the medium, and exits from the opposite end in most designs.

Submerged biofilters can be operated by gravity flow or, with the incorporation of a watertight cover, water can be pushed through them under pressure. If pressure is used, inflow and outflow pipes can be at any desired height without danger of losing water because of overflow.

Since the filter medium is constantly underwater in a submerged filter, it is necessary to ensure that sufficient aeration is provided to keep the filter aerobic. If the filter becomes anaerobic, ammonia will begin to be produced instead of eliminated.

Updraft Biofilters. An updraft filter is essentially the same as a submerged biofilter in that the medium is continuously submerged. The difference is that instead of the water moving horizontally through the filter, it enters from the bottom and exits near the top. A sedimentation chamber (primary settling chamber) can be incorporated into an updraft filter, thereby allowing the settling of solids below the influent pipe elevation. A drain valve at the base of the settling chamber allows solids to be removed as necessary. As is the case with submerged filters, those of the updraft variety need to be well oxygenated to maintain aerobic conditions. Alternatively, as described by Paller and Lewis (9), an updraft biofilter can be "dewatered" periodically to place the bacteria in contact with atmospheric oxygen.

Rotating Biodisc Filters. A rotating biodisc filter or rotating biological contactor (RBC) utilizes a concept somewhat different from that of the filter types previously described. In this case, the medium is moved through the water, rather than the water being moved past the medium. Rotating biodisc media are composed of numerous circular plates placed on an axle and set in a trough with half of each disc submerged and half exposed to the atmosphere. Fiberglass is commonly used as disc material, though Styrofoam and various types of plastic sheets have also been employed. The discs are rotated slowly (only a few revolutions per minute), usually powered by an electric motor and appropriate reduction gears. Bacteria colonize the plates as in other types of biofilters. Alternating exposure to the metabolite-laden water in the trough and to the atmosphere provide the bacteria with a continuous supply of nutrients and oxygen. Various systems have been established (both for research and on a commercial scale) employing homemade and commercially available rotating biodisc filter units.

Fluidized Beds. As previously indicated, fluidized beds can act as biofilters. A fluidized bed is typically composed of material the size (and usually composition) of sand that is placed in suspension by flowing water through it. Both aerobic and anaerobic fluidized-bed biofilters have been used in aquaculture. Anaerobic fluidized beds can remove nitrate (10), which, while normally not a problem, can reach undesirable levels in some instances. When nitrate levels reach several hundred parts per million in closed systems (such as has happened in large marine aquarium systems), remedial action may be required.

Given sufficient energy input, many solids can be made to behave as liquids. Fluidized beds have commonly employed sand or ion exchange resins, but they may also employ activated plastic beads, charcoal, limestone, or crushed oyster shell. Depending on the type of medium used, fluidized beds may act as biofilters, mechanical filters, or as a means of adding chemicals to the water.

Biofilter Size. The size of the biofilter required for a particular culture system depends on many factors. Reliable formulas for calculating the relative size required as a function of the number, kind, and biomass of animals in the culture chambers, total water volume in the system, and flow rate remain to be thoroughly developed.

Early in the growing season, the size requirements for biofilters may be small, since the biomass in the system is low and the amount of waste to be treated is not great. As the culture animals increase in size, the efficiency of the biofilter may increase because proper loading has been reached and then decline as the quantity of waste exceeds the capacity of the biofilter. Additional biofiltration capacity is required when efficiency begins to drop off because of overloading. Routine water quality monitoring is required so that the aquaculturist can determine when and whether to alter the biofiltration capacity of the system. If a new biofilter is placed on line to augment an existing system, sufficient time for colonization of the medium in the new filter should be provided.

Maintenance of pH

The accumulation of dissolved chemicals in recirculating water systems leads to depression of the pH, unless the system is buffered. As the water becomes more acid, stress is placed on the culture organisms, and if the pH becomes too low, death will eventually occur. Microorganisms colonizing the biofilter may also be adversely affected

by low pH. Organic acids and carbon dioxide are the primary causes of increased acidity. Wetzel (11) noted that ammonia is strongly sorbed to particulate matter at high pH — another compelling reason for preventing the water from becoming acidic. Since bacteria are also associated with surfaces, the nitrification process may be enhanced when adsorbed ammonia and microorganisms are placed in close proximity on a waste particle or on the biofilter medium.

For most freshwater aquaculture systems, the pH should be in the vicinity of 7.0 (with an acceptable range of 6.5 to 8.5), while saltwater systems should be maintained at a pH in excess of 8.0 (reflecting the differences in normal pH between natural fresh and saline waters). To accomplish pH control, calcium carbonate is often used as a buffering agent. This material may be in the form of crushed limestone, or more commonly, whole or crushed oyster shell. As hydrogen ions are produced in the system, calcium carbonate slowly dissolves. The carbonate ions remove hydrogen ions from solution to form bicarbonate.

Limestone and oyster shell are relatively inexpensive and require little or no attention once incorporated into the water system. Bacterial mats and other types of particulate matter can build up on the surface of the buffering material and may interfere to some extent with dissolution of the calcium carbonate. Cleaning may be necessary at appropriate intervals to ensure that the buffering capacity of the system is maintained.

The amount of buffer material present in the biofilter is not particularly critical. Most culturists utilize a few kilograms per cubic meter (pounds per cubic yard) of filter capacity. The buffering agent can be located nearly anywhere, but is commonly placed either in conjunction with the biofilter influent or effluent.

Moving Water

As the number mechanical devices in a recirculating system is increased, so are the chances of a failure. One high-quality continuous-duty water pump is often all that is required to move the water within such a system. The pump can be placed between any two components, except when an updraft filter is used, in which case it is desirable to place the pump on the influent side of the biofilter. In all types of systems, units downstream from the pump can obtain water through gravity flow, assuming they are placed at appropriate elevations relative to one another. When more than one pump is utilized, the design should ensure that water flow is balanced among the components in the system and that there is no potential for a component to be pumped dry.

Pumps can be expected to run intermittently or continuously for up to several years if they are properly maintained. Submersible pumps that run while submerged in water are handy for some applications, and pumps with impellers that are not corroded by salt water are available for use in mariculture facilities. Pumps of various types were discussed by Wheaton (12). Metal impellers will function well in salt water if the pump is allowed to run continuously, but trace metals may be released into the water. When present, even at low concentrations, some such metals can be highly toxic, particularly to larvae and,

when used in closed systems where their concentration will continuously increase until the system is drained and refilled with new water.

The amount of water to be moved through a water system is related to the size of the system and the optimum flow rate for the culture organisms and the biofilter. Optimum flow rates for a given species may change, depending on the life stage of the organism. For some species, few data are available and flows may have to be determined by trial and error. Turnover times in culture chambers may exceed 24 hr for larvae and may be several times an hour for juveniles.

Water can be moved with airlifts, such as those used in conjunction with submerged filters in home aquaria. Simple airlifts can be constructed from PVC pipe mounted vertically in the water column. These devices can be used to move water within a culture chamber, as well as to move water between culture chambers. In addition to moving water, airlifts provide aeration. They can operate at relatively low pressures and are quite economical in certain situations.

Tertiary Treatment

There are three phases involved in complete water treatment. The first, which involves the settling of solids and their removal from the waste stream, is known as primary treatment. Secondary treatment involves transformation of toxic chemicals into less toxic forms and is accomplished by biofilters such as those described earlier. The removal of dissolved chemicals, such as nitrates and phosphates, from water is known as tertiary treatment. Tertiary treatment is rare in sewage treatment plants, which are typically designed for secondary treatment at best, though some tertiary treatment has been employed in aquaculture systems.

Nitrates, phosphates, and micronutrients accumulate in closed water systems even if a highly efficient biofilter is in operation. Although both nitrates and phosphates are required nutrients for plant growth and are not directly toxic to aquaculture animals when present at normal environmental levels, nitrate is known to be toxic at extremely high concentrations (13) and, for some life stages of certain species may be toxic at relatively low concentrations.

Nitrate can be removed from aquaculture systems through denitrification to elemental nitrogen. Effective removal of both nitrates and phosphates can be achieved by incorporating an additional culture chamber in the system for the production of plants. The plants, either terrestrial or aquatic, might best be located immediately following either the biofilter or secondary settling chamber.

Aquatic plant candidates for tertiary treatment include water hyacinths (*Eichhornia crassipes*) and Chinese water chestnuts (*Eleocharis dulcis*). Both grow rapidly, and each is efficient in removing dissolved nutrients from the water. Water chestnuts have economic value as human food. Water hyacinths, on the other hand, are generally considered a nuisance when they invade natural waters, but they do hold some potential as livestock feed, as do a large number of other aquatic plant species (14,15). Since

aquatic plants have very high water content, they can only be economically used as livestock feed when they do not have to be transported from the site of harvest. Drying the plants before shipment is not generally considered to be a practical or economical alternative.

An often more attractive type of tertiary treatment with plants involves hydroponics with terrestrial plants. The plants are grown either in water or in an inert medium that is continuously or intermittently wetted with nutrient-rich water. On an experimental level, various types of vegetables (including tomatoes, lettuce, and cucumbers) have been grown in association with the recirculated water of aquaculture systems in which several types of fish have been produced. Greenhouses have been used in conjunction with many such systems to provide the appropriate environmental conditions for the plants. In all cases where plants are utilized, sufficient natural or artificial light must be provided to maintain active photosynthesis.

Maintaining the proper nutrient concentration for plants raised in conjunction with a recirculating water system is not a simple matter. The amounts of nutrients being produced and taken out of the system are not in equilibrium, since both the aquaculture animals and the plants are continuously growing and will be harvested from time to time (but often not at the same time). In many instances it may actually be necessary to supplement the system with nutrients to help maintain plant growth. Macronutrients like phosphates and nitrates, and various micronutrients such as trace metals may require supplementation.

Backup Systems and Auxiliary Apparatus

In theory, a closed system can be operated with only the components outlined in the above sections. In reality, redundancy needs to be built in so that disaster can be avoided if, for example, there is a pump failure. In addition, various additional features can be added to help the aquaculturist avoid disease problems and increase the efficiency of the system.

Backup Systems. Each mechanical component associated with an intensive aquaculture system of whatever type should have a backup so that the integrity of the system can be maintained in the event of an equipment failure. Aeration is an auxiliary component featured in many water systems, but some aquaculturists depend on flow regulators to provide aeration. A backup pump should definitely be available, and most systems have a backup aeration system such as an air blower or air compressor. Backup systems need not be identical to the primary system. An air compressor might, for example, take over for a failed blower; bottled gas, liquid oxygen, or agitators could also serve in backup roles. Many backup systems require electricity, so both primary and secondary systems can be lost during a power failure. A gasoline or diesel generator should be available to provide power during electrical outages.

Modern technology has dramatically improved the effectiveness of backup systems. State-of-the-art generators remain continuously warmed up and may even start-up periodically for a few minutes to run self-diagnostics and ensure that they are operating properly. Autodialers can be used that will dial one or even several telephone numbers to alert aquaculturists of a power failure during nights, holidays, and weekends when the culture system may be unmanned. The more automated a backup system is, the more expensive it will be, but the cost will be more than offset if the backup components prevent a crop loss.

Auxiliary Apparatus. Backup devices are essential for the operation of intensive aquaculture facilities. In addition there are various types of auxiliary components that can be considered optional, though desirable. Auxiliary apparatus may be used in pretreatment, online operation, or posttreatment of the water used in a recirculating system.

Air compressors provide high-pressure air, which means that airlifts can be effectively operated when a considerable amount of head is present. Since air-compressor motors cycle frequently (depending on how rapidly the air is bled from the pressure tank), the starters and motors have been known to fail with unacceptable frequency. Air blowers, on the other hand, seem capable of operating continuously and reliably for extended periods of time. They produce large volumes of low pressure air at economical prices. Because the air is delivered under low pressure, such systems cannot operate against significant head pressures, although they are effective in tanks of standard depth.

Liquid oxygen has become popular with many aquaculturists. It is readily available in most areas, including those that one would generally consider to be quite remote. Large volumes of oxygen can be stored in a fairly small amount of space when liquefied. Until the 1980s, bottled oxygen and compressed air were often used as sources of emergency aeration. Liquid oxygen can serve that purpose and, in some operations, is used routinely as a means of maintaining oxygen at or near saturation in aquaculture systems.

Some means of pretreating incoming water may be required, particularly when the water is from either a municipal or surface source. Chlorine will have to be removed from municipal water, unless only small quantities are being used to replace splashout and evaporation. Filtration may be used in conjunction with surface water to eliminate unwanted organisms and turbidity.

Clinoptilolite, a natural zeolite with an affinity for ammonia, has been effectively used in aquaculture systems (2). As indicated by Slone et al. (1981), by removing ammonia, clinoptilolite indirectly controls nitrite levels as well (16). The material can be regenerated by backwashing with a sodium chloride solution when the absorption sites become filled (2). There are ion exchange resins that will remove ammonia from water efficiently, but they are much more expensive than clinoptilolite.

Air stripping, which involves agitation and aeration, can also be used to remove ammonia from water if the pH is greater than 10.0 (17,18). Removal of ammonia in either of these ways can reduce the volume of biofilter medium required, or eliminate the need for the biofilter altogether in small systems.

Ultraviolet Treatment. As previously mentioned, disease control is difficult in closed water systems. One of the methods that has been used to keep the level of circulating pathogens below detectable levels in such systems is continuous ultraviolet (UV) irradiation of the water. The effectiveness of UV light is dependent on the size and species of the pathogenic organism and water clarity. Levels of UV irradiation required to kill various pathogens have been determined (2,19).

Fluorescent bulbs are used in both commercial and homemade UV sterilization systems. The bulbs are kept from contact with the water by housing them in quartz tubes around which the water flows, or they may be placed around a transparent quartz or plastic pipe through which the treated water passes. The UV lights should be in as close proximity as possible to the water. In many cases the water is exposed to the light in a thin film or passes in front of the light in confined channels that are a few millimeters to a few centimeters thick. Some systems have been designed that allow thin films of water to pass under UV lights suspended from above.

The output of UV bulbs declines with time. According to Lucchetti and Gray (2), UV output decreases by 10% during the first 100 hr of operation and drops to 70% of the initial level during the first six months of use. The bulbs should be replaced every several months or sooner. Particulate matter tends to sediment out on the quartz and plastic tubes that separate the UV bulbs from the water, thereby further diminishing the efficiency of the sterilization system. Prefiltering the water through a sand filter before exposing it to the UV light will help reduce the problem considerably, but it may still be necessary to clean the system periodically and even to replace the protective quartz or plastic on occasion.

Ozonation. Ozone generators have been used in aquaculture systems to both oxidize organic matter and kill pathogenic organisms. (See the entry "Ozone.") Other beneficial effects of ozonation are reduction in biological oxygen demand, ammonia, and nitrite. Ozone (O_3) itself is extremely toxic. While little information is available on aquaculture species, the fathead minnow (*Pimephales promelas*) is killed at ozone concentrations of 0.2 to 0.3 mg/L ppm (20). Sublethal pathology has been observed in rainbow trout exposed to low levels of ozone, and oyster larvae can be killed by only trace amounts of ozone (21,22).

At relatively low concentrations, ozone will lead to improved water quality as was demonstrated with respect to Atlantic salmon (*Salmo salar*) (23). If used for pathogen control, higher concentrations may be required, and sufficient time must be allowed for the gas to convert back to molecular oxygen (O_2) before the water is exposed to either the culture chamber or the biofilter after being ozonated. Alternatively, active deozonation may be applied. The half-life of ozone is about 15 min (24), so it can take a considerable amount of time for safe levels to occur. Aeration assists greatly with the conversion of ozone to molecular oxygen and can reduce the time required for keeping ozonated water away from the culture animals and biofilter. Activated charcoal can also be used to strip ozone from water.

Ozone seems to be much more effective in controlling pathogens in seawater than in freshwater. While the chemistry is apparently not entirely understood, it is believed that ozone reacts with bromine in seawater to produce lethal bromides. The reaction apparently occurs very rapidly, and the efficacy relative to pathogen control is high.

Some systems have been designed in which a portion of the total water flow is ozonated during each pass. When the treated side stream is returned to the main flow, the ozone is diluted to a sublethal concentration. With continuous exposure of portions of the flow to ozone, both water-quality improvement and pathogen control can be achieved.

Careful monitoring of ozone is necessary and adjustments to the amount of ozone being added may be required at intervals. While sensors to monitor ozone in water have been developed, they have not been perfected and most monitoring involves sensing ozone in the atmosphere above the deozonating component of the system. Equipment for that purpose is quite effective. Automatic alarms can be set for a desired range of atmospheric ozone in conjunction with the deozonation chamber. If the level moves outside of the desired range, the system will alert the culturist by sounding an alarm. Such systems can also be connected to autodialers that will telephone the culturist to indicate that a problem exists during periods when the facility is not being physically monitored.

Adjusting Water Temperature. Temperature control in closed water systems can be achieved to a degree by placing such systems in a well-insulated building that can provide proper ventilation during hot weather and protection from the cold during winter. Supplemental heating or cooling of the water may be required depending on the species being cultured and on ambient water temperature. Adjusting the temperature of the water is very expensive. Chillers and various types of water-heating devices are available, but the energy costs associated with most of them are prohibitively high. Solar heating has been advocated by some, though when needed the most, the method may not be very efficient due to extensive periods of cloud cover. The initial investment for solar systems of the capacity required for an aquaculture system may also be too high to be practical.

Heat can be removed from water with heat pumps, as long as the water temperature is above the freezing point. Depending on the needs of the culturist, the water that is cooled may be used in the culture system or discarded. The heat removed from the water by a heat pump can be dissipated into the air or used to warm water that will be used in the culture system. Thus, by employing heat pumps, the culturist can produce quantities of both chilled and heated water and use one or both in conjunction with the aquaculture operation. The application of heat pumps to aquaculture has been described (25,26) earlier.

RECIRCULATION SYSTEMS: PROCESS ENGINEERING

MICHAEL B. RUST
Northwest Fisheries Science Center
Seattle, Washington

OUTLINE

Recirculation systems can be thought of as a series of unit processes. However, how those unit processes fit and work together can be the difference between an easy-to-manage well-functioning system and failure. Puting unit processes together is the subject of process engineering. Unit processes such as aeration, filtration, sedimentation, ozonation, chlorination, and disinfection are covered elsewhere in this encyclopedia. Fish performance engineering, which is related to this topic as well, is also discussed as its own topic. This entry is intended as a qualitative overview of unit processes and configurations that are used in intensive systems of aquaculture. More detailed information can be found on each unit process, water chemistry, and other aspects of intensive aquaculture elsewhere in this volume. For further information the reader is also referred to classic texts by Spotte (1,2) and Wheaton (3), and recent texts by Spotte (4), Timmons and Losordo (5), and Lawson (6).

FACTORS THAT AFFECT DESIGN

Objectives of Water Treatment

Objectives differ depending on the facility's needs for water treatment. These needs can be broken down into four areas: pretreatment, reuse treatment, recirculation treatment, and posttreatment.

Pretreatment encompasses all the unit processes needed to treat water that is being brought into a facility. It can include a wide range of unit processes and is dictated by the water source being tapped. For more information on pretreatments that might be appropriate for differing water sources, see the entry on "Water sources".

Reuse and recirculation are similar. Reuse treatment occurs between culture units in facilities where the total

water through the culture units is equal to the total new water introduced to the system and the total effluent. In other words, a reuse facility is similar to a flow-through facility, except that water is treated after the first culture unit(s) in a series, so it can be reused by different culture units downstream. In a reuse facility water is not returned to the point where new water is added. It is just treated between culture units. An example would be treatments between raceways arranged in series, where water is constantly supplied to the first raceway from a water source and the water from the last raceway in a series is discharged from the facility. Treatment in reuse systems occurs between rearing units and within rearing units.

Recirculation occurs when water discharging from the culture units is treated and then returned to the same culture units. In recirculating systems, water must be pumped. In fact, new water makes up only a certain percentage of the total flow to the culture units, as most of the water is used over and over. Treatment in recirculation systems can occur between rearing units, within rearing units, and at a centralized location.

Posttreatment relates to effluent discharges and is often dictated by law. Effluents may need to be screened to prevent fish from escaping into the environment or may require disinfection to keep pathogens from getting introduced into the receiving water. Guidelines on upper levels of temperature, salinity, dissolved nutrients, and solids may also dictate treatment to protect the receiving waters. For more information about this topic, see the entry on "Effluents: dissolved compounds".

Treatments needed for recirculation are often more comprehensive than for the other three operational objectives. The discussion from here on relates to all four objectives, but is focused specifically on recirculation systems. Typical water quality variables that are commonly monitored and controlled in aquaculture systems and the implications of some key processes are given in Table 1.

Choice of Organism(s)

Perhaps no other choice influences the function and selection of unit treatment processes more than the organism(s) to be cultured. The environmental requirements of the species under cultivation will determine how acceptable water quality is defined. Salinity may be very important to a stenohaline organism, but not for a euryhaline organism. Minimum acceptable oxygen levels for trout might be 6 mg/L (ppm), while for tilapia it might be 3 mg/L (ppm). Multispecies systems may require different water-quality criteria for each species. An example would be serial culture units, where striped bass are reared in the first culture unit, followed by sturgeon or catfish in the second serial culture unit, and then finally, tilapia are introduced in the third culture unit, with minimal or no water treatment between serial culture units. The environmental requirements for each species can be met as water goes from unit to unit. Acceptable water quality also changes from unit to unit, depending on species or unit process.

Since environmental criteria are usually determined by the culture organism, unit processes need to be chosen and sized to provide those environmental conditions. For example, a biofilter for a tilapia system will experience near optimal temperatures for the nitrifying bacteria, but could be low on dissolved oxygen, while the same biofilter used for salmon at sub optimal temperatures would have adequate dissolved oxygen. The specific surface area of media (area/volume of media used) that is needed to provide nitrification for the same biomass in each system would vary significantly because of the impact of temperature and oxygen on nitrification.

Feed

The feed used for different species will also influence the choice of unit processes. Ammonia comes primarily from the deamination of amino acids, the building blocks of proteins. The more a species uses protein for energy, the more ammonia will be produced. Carp and tilapia are typically fed low-protein feed that is made primarily of plant proteins. Salmon, on the other hand, are fed high-protein feed made from animal by-products. Animal proteins are typically more digestible and have a better amino acid balance than plant proteins. Well-balanced protein will be more efficiently used and will produce less ammonia than poorly balanced protein. Also, plant products often contain higher amounts of indigestible material than animal products, resulting in more solids. Feed choice will influence the design of nitrification and solids removal systems. For more information see the many feed-related topics in this encyclopedia.

Solids

In terms of the effect on other treatment unit processes, solids removal may be the most significant. Solids in the water increase biochemical oxygen demand (BOD), lower dissolved oxygen; clog biofilters; increase heterotrophic bacteria (which can limit nitrifying bacteria), decrease the effectiveness of ultraviolet radiation (UV) and aeration; and increase the demand for ozone or chlorine for oxidation or sterilization. Because of these wide ranging, mostly negative effects, early and efficient solids removal is very important.

Hardness, Alkalinity, and Salinity

Hardness and alkalinity affect pH, nitrification, foam fractionation, and fish stress tolerance. Salinity affects all of those and others. Species requirements and water ionic composition should be considered when sizing and choosing unit treatment processes. Materials such as stainless steel, which might be fine for a heat exchanger in a freshwater system, are not recommended for saltwater. In general, only glass, plastic, or titanium should contact saltwater in a recirculation system.

Water Clarity

Water clarity can directly influence the effectiveness of UV sterilization. Indirectly, high-water turbidity or off-colored water can be indicative of high solids or dissolved organic chemicals. Dissolved organics can lead to slightly

Table 1. Typical Water-Quality Variables that are Commonly Monitored and Controlled in Recirculation Systems and the Effects of Some Common Processes Used in Aquaculture

Process	Dissolved Oxygen	Carbon Dioxide	TAN	Nitrite and Nitrate	pH	Alkalinity and Buffer	Salinity	Solids	BOD	Temperature
Water Transport:										
Mechanical Pumps								Can break up solids making, them harder to remove		Can add heat to water
Airlifts	Increases	Decreases			Can reduce CO_2, increasing pH		Can increase evaporation, raising salinity	Same as above, but to a lesser extent	Increased oxygen satisfies some demand	Can shift temperature toward air temperature
Sump/head Tanks							Same as above	May be used to settle solids		Heat gain/loss if not covered
Physical Treatments:										
Chilling/heating	Changes the saturation concentration of the water when temperature is changed	Changes the saturation concentration of the water when temperature is changed	Rate of biological and chemical process are affected by temperature	Rate of biological and chemical process are affected by temperature			Heating increases evaporation, raising salinity		Rate of biological process are affected by temperature	Controlled by heating and chilling
Gas transfer	Directly affected	Directly affected	Oxygen needed for nitrification	Anaerobic conditions needed for denitrification	Can reduce CO_2, increasing pH				Increased oxygen satisfies some demand	Can shift temperature toward air temperature
Mechanical Filtration								Removes solids	Reduces BOD	
Sedimentation								Removes solids	Reduces BOD	
Chemical Treatments:										
Carbon	Can remove oxygen from water when carbon is new				Can lower pH when carbon is new					
Clinoptilolite			Removes ammonia	Lowers by reducing ammonia			Salt may be used to recharge the resin. Will not work in saltwater			

(continued)

Table 1. *Continued*

Process	Dissolved Oxygen	Carbon Dioxide	TAN	Nitrite and Nitrate	pH	Alkalinity and Buffer	Salinity	Solids	BOD	Temperature
Chlorination/ dechlorination										
Ozone	Can increase DO especially if source gas is pure oxygen		Not very effective at oxidation of ammonia except at high pH	Very effective at removal			Can form hypobromous acid, bromate, and bromamines, which can be toxic. Especially a problem with algae and invertebrates	Reduces dissolved solids by improving sedimentation	Reduces BOD	
Ultraviolet light								Does not function well in water with high solids load		
Buffers and salts	Higher salinity can reduce gas saturation concentration	Higher salinity can reduce gas saturation concentration	Affects nitrification	Affects denitrification	Directly affects	Directly affects	Directly affects			
Biological Treatments:										
Nitrification	Consumes oxygen	Produces carbon dioxide	Oxidizes ammonia	Produces nitrite and nitrate	Produces acids, lowering pH	Reduces alkalinity	Efficiency changes with salinity	Is inhibited by high solids loads	Part of the BOD	Efficiency changes with temperature
Denitrification	Anaerobic process		Can increase ammonia	Reduces nitrite and nitrate			Efficiency changes with salinity			Efficiency changes with temperature
Hetrotrophic processes	Consumes oxygen	Produces carbon dioxide	Produces ammonia		Produces acids, lowering pH	Reduces alkalinity	Efficiency changes with salinity		Part of the BOD	Efficiency changes with temperature
Culture Units:										
Algae and Higher Plants	Adds oxygen when growing (with light)	Consumes carbon dioxide when growing (with light)	Consumes ammonia when growing (with light)	Consumes nitrite and nitrate when growing (with light)	Raises pH			Microalgae may be inhibited by suspended solids	Reduces BOD	
Animals	Consume oxygen	Produce carbon dioxide	Produces ammonia	Produces nitrite and nitrate via ammonia and urea	Lowers pH			Produce dissolved and suspended solids	Increases BOD	

increased BOD, increased heterotrophic bacteria, and increased demand for ozone. In some cases, it may be more cost-effective to operate the system with water the color of dark tea, rather than try to maintain crystal-clear water. Tilapia, for example, often grow quite well under these conditions, and as long as there is no off flavor associated with the dark-colored water, there may be no reason to attempt to make the water clear. In this case, UV would be a poor choice as a method of disinfection. In other cases, such as in aquaria, where fish are to be on display, water clarity is critically important.

Heating

Maintaining an acceptable environmental temperature for the culture organism cost-effectively is the primary advantage of recirculation systems. Water cost and availability is often the second most important factor. The system temperature, set by culture species and production schedule, will affect biological and chemical processes. Heating and cooling can have a significant effect on the partial pressure of dissolved gases. When water is heated in an enclosed vessel (such as a pipe), the effluent water may be supersaturated with dissolved gases. This can lead to fish stress and gas bubble disease. This is why it is a good idea to place aeration after enclosed heating processes. On the other hand, it might be advantageous to inject pure oxygen into the coldest water in the system and, under pressure, to maximize transfer efficiency.

Oxygen

Oxygen is needed to maintain the health of organisms and to facilitate chemical oxidative processes. Low oxygen levels can stress aquatic animals and reduce biofilter function. In general, aquaculturists seek to keep oxygen near or above saturation. For more information, see this topic and the topic on fish "Performance engineering" elsewhere in this encyclopedia.

Pumping

There are a great variety of pumps on the market that can deliver water at almost any flow and pressure. Most unit processes, including pumps, have a range of maximum efficiency. When designing a recirculation system, it is important to determine flow and pressure requirements for each culture and treatment unit. Once this is done, a pump that can supply the proper flow and pressure can be chosen. Head-pressure losses through each unit treatment should be added to head-pressure losses from the plumbing and elevation changes in the system to determine the total head pressure to be overcome by the pump. Due to the wide variety of options with pumps, it is relatively easy to find a pump that will supply the required flow and pressure at high efficiency.

THE ORDER OF THINGS

Parallel or Series

Several factors need to be considered in developing a treatment process train, including upstream treatments needed, pressure requirements, flow needed, down stream processes, and the need for a break in head. (Break in head refers to where water in an enclosed vessel under pressure is exposed to atmospheric pressure in an open vessel. At this point, water will flow downhill or must be pumped out. Examples include fish culture tanks, drum filters, packed columns, and head tanks.) The need for a break in head may require repumping or elevation of some components to allow gravity flow through the remaining treatment train. Once this information is determined, it will aid in selection and sizing of unit processes and the location of processes within the process train.

Unit processes can be arranged in either a parallel or series arrangement (Fig. 1). Often, treatment unit processes are arranged in series, while culture units are arranged in parallel. There are exceptions. For example, tanks or raceways can be put in series that use minor treatment (usually aeration) between culture units. In this scenario, water can undergo more treatment following the final culture unit before being returned to the first culture unit in the series (recirculation), or the old water can be discharged as new water is added to the first culture unit (reuse). In general, serial facilities allow for staged processing, while parallel facilities allow modular management, when servicing or responding to loading rates, and thus spread the risk of a unit process failure.

Treatment unit processes are often put together in series to take advantage of the positive effects of upstream processes on downstream processes. For example, early removal of solids improves the efficiency of biofiltration, disinfection, and aeration processes downstream. In highly loaded systems, aeration may be needed both prior to and after biofiltration to provide oxygen for nitrification and for the culture organism. Efficiencies can be gained by staging biological bacterial processes with carbonaceous oxidation by heterotropic bacteria occurring before nitrification.

Conversely, one unit process may negatively affect a downstream process and this should be avoided. For example, turbulent processes such as pumping can break solids into finer particles. This makes removal more difficult and increases rates of decay and associated oxygen consumption and ammonia production. One approach to the early removal of solids is the use of two drains in the culture units. One drain is to carry the majority of
Figure 1. Arrangement of treatments and culture units in series or parallel.

(a) Single treatment loop with serial culture units.

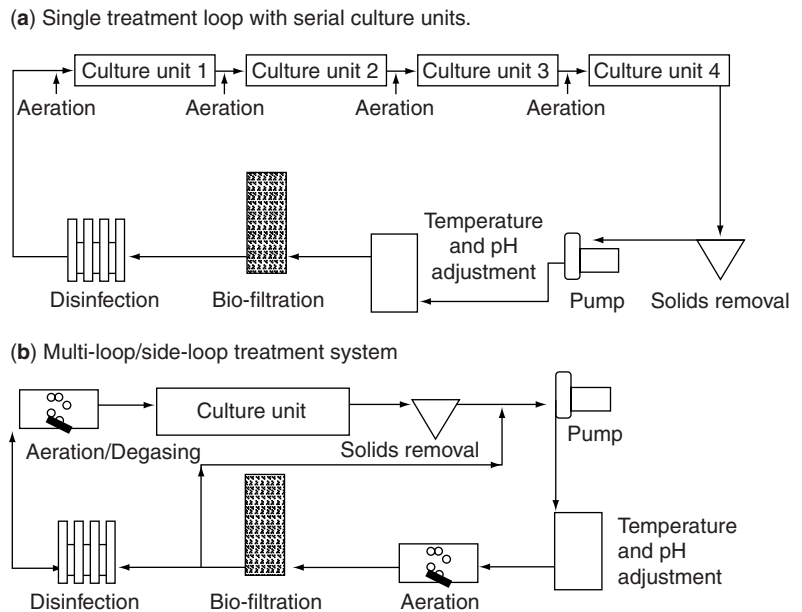
(b) Multi-loop/side-loop treatment system


Figure 2. Examples of two different treatment trains.

the flow, and is placed to take water from an area in the culture unit away from were solids settle. The second smaller drain is located where solids collect. The smaller stream of concentrated solids can then be treated more effectively. For more information, see the entry on "Tank and raceway culture".

The ordering of treatment processes into a treatment system (or train) will depend on the acceptable water-quality requirements needed and the set-point conditions desired. Examples of different treatment trains are given in Figure 2.

Complexity

The creation of systems with a high degree of complexity should be avoided if possible. The more unit processes in a system, the more chance there is that one or more of them will malfunction. In complex systems, some redundancy may be desirable for key unit processes. Competing unit processes should also be evaluated based upon complexity and the ability of staff to maintain and manage each process. It may be desirable to choose a less complex process over a more efficient one if the chance for malfunction or maintenance requirements are high. These types of considerations require an understanding of the needs and skills of the end users of a recirculation system and its intended use.

RED DRUM CULTURE

DELBERT M. GATLIN, III
Texas A&M University
College Station, Texas

OUTLINE

INTRODUCTION

The red drum (*Sciaenops ocellatus*), also known as redfish or channel bass, is a euryhaline sciaenid that has comprised important commercial and recreational fisheries in the Gulf of Mexico and the Atlantic Ocean for many decades. Overfishing in the Gulf of Mexico resulted in the state of Texas prohibiting the sale of native red

drum in September 1981 (1). Harvest restrictions imposed by various state and federal regulatory agencies in the early 1980s prompted heightened research efforts in the culture of this species for stock enhancement and food production.

NATURAL HISTORY

The natural range of the red drum has been reported to be from the Gulf of Mexico off the coast of Tuxpan, Mexico, to the Atlantic Ocean off the coast of Massachusetts (2,3). Red drum have a rather complex life cycle that begins when adult fish move from the open ocean to gulf–bay passes to spawn in the fall. Spawning typically occurs from August through January, with peak activity in September or October (1). During courtship before spawning, the male produces a drumming noise, from which the fish's common name is derived. Spawning fish generally produce several hundred thousand eggs that measure less than 1 mm (0.04 in.) in diameter. Surface currents carry the buoyant eggs and larvae from the spawning areas into brackish estuarine nurseries. The eggs hatch approximately 24 hours after being spawned, and the larvae derive nourishment from their yolk sac for at least another 48 to 72 hours. After they begin exogenous feeding, the larvae consume primarily zooplankton such as rotifers and copepods until reaching a size of approximately 50 mm (2 in.) (4). Red drum juveniles of 60 to 100 mm (2.4 to 4 in.) consume small bottom-dwelling invertebrates, for which their subterminal mouth is particularly well suited, as well as small fish. Juveniles, along with subadults, remain within the estuary for approximately three to four years, until they reach sexual maturity. Shrimp, crabs, and fish constitute the major food items for red drum larger than 100 mm (4 in.). As red drum grow, they consume more fish relative to crustaceans (5). Sexually mature adult red drum permanently emigrate from estuaries to areas that range from 16 to 113 km (10 to 70 mi) from shore (1).

CAPTIVE BREEDING

Techniques for controlled spawning of red drum in captivity were developed in the 1970s and have allowed for the production of large quantities of eggs and larvae, with limited effort on the part of the aquaculturist (6,7). A common feature of state hatcheries and commercial facilities consists of circular fiberglass tanks ranging in size from 4 to 6 m (12 to 20 ft) in diameter. The tanks typically contain natural seawater or freshwater amended with synthetic sea salts to achieve a salinity of approximately 32%. The water quality is maintained within acceptable levels by biological and mechanical filtration. The water also may be treated with ozone or ultraviolet light for sterilization.

Sexually mature broodstock for the hatchery are initially captured from the wild, most typically from gulf–bay passes during the fall. These fish may range in weight from 10 to 25 kg (22 to 55 lb). A variety of collection methods can be used, although hook-and-line capture seems to be the least stressful. State regulatory agencies should be contacted to determine regulations governing the collection of broodstock from public waters.

Once potential broodfish have been collected, they are typically stocked in tanks in groups of four to six fish, with equal numbers of males and females. Broodfish are typically fed combinations of shrimp, squid, and fish at the rate of approximately 2.5% of body weight per day, every other day. The fish are conditioned to spawn by subjecting them to seasonal variations in temperature and photoperiod that are commonly compressed into cycles of 120 or 150 days. The water temperature may be controlled directly, with the aid of heating and chilling units, or indirectly, by controlling the temperature of the ambient air. After passing through simulated winter, spring, and summer seasons, the fish typically spawn when the water temperature is about 23–25 °C (73.4–77 °F), with a photoperiod of 11 hours of light and 13 hours of dark. Once the fish begin spawning, the environmental conditions can be adjusted slightly so that spawning is continuous for several months. The fish typically produce over one million eggs per spawning session. The eggs, which are buoyant, are commonly removed from the brood tank with the aid of a skimming device at the water surface and are then concentrated in a bag constructed of 500-μm (0.02-in.) netting. The eggs are subsequently removed to another tank, where they hatch in approximately 24 hours.

REARING OF LARVAE

Red drum larvae obtain endogenous nutrients from their yolk sac for approximately three days after hatching. After that time, an exogenous source of nourishment is required and typically provided in the form of zooplankton. The type of zooplankton provided depends on the larval culture system employed. If larval red drum are to be reared under controlled conditions in tanks, the marine rotifer *Brachionus plicatilis* is a preferred first food (8,9). Stock monocultures of unicellular algae such as *Tetraselmis chuii* and *Isochrysis* sp. are usually used to support the growth of rotifers (10). Algae and rotifers have been successfully propagated separately in continuous culture, as well as together in batch culture. Rotifers also have been grown with yeast and fish oil emulsion, with or without algae (11). Typically, rotifers are provided to larval red drum cultured in tanks at a density of 3 to 5 rotifers/mL (89 to 148 rotifers/oz) to ensure that there is an adequate number of prey (12). This density of rotifers is generally maintained for 7 to 10 days, after which the larval red drum should be large enough to consume newly hatched *Artemia* nauplii, which are provided at a density of 0.2 to 2 organisms/mL (6 to 60 organisms/oz) (13). Procedures involved in hatching *Artemia* cysts and preparing the nauplii for feeding to larval fish are well established (14). Enriching rotifers and *Artemia* nauplii with highly unsaturated fatty acids by culturing them with fish oil emulsions has proven beneficial in the rearing of red drum larvae (15). During the time larvae are fed rotifers and *Artemia* nauplii, inert microparticulate diets also may be provided. However, the commercial larval diets that are currently available have not been able to replace live food organisms for larval red drum cultured intensively.

As the red drum larvae make the transition to juveniles, they may be gradually weaned to an artificial dry diet. After 10 to 14 days of being fed *Artemia*, a high-protein starter crumble for salmonids can be introduced to the fish. Fish will typically convert from the live food to the artificial diet in 3 to 4 days. The feeding of *Artemia* to the fish should continue until all fish are weaned onto the artificial diet. Cannibalism may be a problem in rearing red drum in intensive tank culture and can be minimized by maintaining uniformity in the size distribution of the fish.

An alternative way of providing zooplankton to larval red drum is to stock the red drum into fertilized, brackish-water ponds when the water temperature is approximately 22 °C (72 °F) or higher. This approach is generally less labor intensive and is commonly employed at commercial production facilities and state hatcheries. Various combinations of organic and inorganic fertilizers have been used to promote the growth of phytoplankton and zooplankton. Inorganic nutrients may include nitrogen in the form of urea and phosphorus as phosphoric acid. One of the most common organic fertilizers used in ponds for red drum larvae is cottonseed meal. A variety of fertilization regimes, which are initiated approximately 10 to 21 days before stocking of the red drum larvae, have been successfully used in growing the fish to juvenile size in ponds (16). The preferred zooplankton for larval red drum in brackish-water ponds include rotifers and copepods. Approximately two weeks after the larval red drum are stocked, a high-protein, finely groundfish starter diet may be distributed in the pond, so that the fish will gradually become accustomed to eating the prepared diet. Any uneaten feed also may serve as organic fertilizer.

Under normal conditions, red drum larvae stocked in fertilized ponds will grow to 37.5 mm (1.5 in.) in 30 days. It is desirable for each fingerling pond to be equipped with a concrete harvest basin into which the juvenile fish can be concentrated as the water is drained from the pond. Care must be taken to harvest the fish with soft nylon nets, in order to avoid injuring the fish.

ENVIRONMENTAL REQUIREMENTS

As previously mentioned, red drum are euryhaline fish that can tolerate substantial variation in salinity. Although red drum in nature normally spawn in full-strength seawater ranging from salinity levels of 32 to 40%, levels that allow their eggs to remain buoyant, larvae are generally exposed to much lower salinity levels in their estuarine nurseries (17). Some aquaculture facilities have reported successful rearing of larval red drum to juvenile size in ponds with salinities as low as 4 ppt. The most critical step in this process is the gradual acclimation of larvae to low salinity levels prior to introduction into the pond.

Once red drum reach juvenile size, they can tolerate rapid transitions in salinity. The fish can grow in water with less than 1 ppt salinity if the hardness of the water is greater than 100 mg/L (ppm) as $CaCO_3$ and chloride ions are at a concentration greater than 150 mg/L (ppm) (17). Chloride ions appear to be particularly important, as a level of 500 mg/L (ppm) resulted in better growth, feed conversion, and survival of juvenile red drum compared to when chloride ions were at a level of 150 mg/L (ppm) (18).

Another important water quality characteristic, especially in intensive fish production, is the level of dissolved oxygen. Red drum can tolerate levels of dissolved oxygen below 2 mg/L (ppm), but levels maintained that low for any length of time will serve as a stressor and reduce the growth of the fish (19). A dissolved-oxygen level above 5 mg/L (ppm) is generally recommended for red drum production.

Ammonia and its oxidation products are the major metabolites in aquaculture that may have adverse effects on red drum. Unionized ammonia concentrations as low as 0.3 mg/L (ppm) have been reported to adversely affect survival of three-week-old red drum; however, older fish are generally more tolerant (17). When the water has some salinity, red drum juveniles can tolerate rather high levels of nitrite without showing adverse health effects (20,21).

Another environmental factor that significantly influences aquaculture of red drum is temperature. This species is relatively tolerant of elevated temperatures, as it can survive in estuaries at 33 °C (91.4 °F). As with many other warmwater species, the temperature range for optimum growth of red drum is approximately 24 to 30 °C (75.2 to 86 °F) (17). However, this fish is relatively intolerant of cold temperature and has been reported to die between 8 and 10 °C (46.4 and 50 °F), which makes its overwintering in outdoor ponds, even in the southern portion of the Gulf coast states, a considerable risk. The absolute lower lethal temperature of red drum may be influenced by a number of factors, including the previous thermal history of the fish, as well as water salinity and hardness (22,23).

The red drum's relative intolerance to cold temperatures may constrain production of the species in earthen ponds in the southern United States. A variety of research efforts have addressed this constraint. For instance, advancements have been made in altering cold tolerance of red drum through dietary lipid manipulation. In a series of experiments, red drum fed diets containing saturated lipids had lethal temperatures up to 4.5 °C (8.1 °F) higher than fish fed diets containing menhaden oil, which contains highly unsaturated fatty acids of the n-3 series (24). The increased tolerance to lower water temperature appeared to be mediated by a progressive increase in unsaturation of tissue phospholipids.

In addition to dietary manipulation, advancements also have been made in overwintering red drum in ponds with the development of thermal refuges. These devices, which have included a variety of designs, have been evaluated as to their ability to retain heated water in a portion of the pond such that it attracts the fish when they sense that water in other parts of the pond has become unacceptably cold (25). Commercial facilities along the Texas coast have successfully overwintered red drum in outdoor ponds with the aid of thermal refugia. However, several factors, including the energy costs associated with heating water for the refuge, the efficiency of the refuge design in retaining heat, and the duration and severity of cold weather conditions all may influence the economics and ultimate success of overwintering red drum in outdoor ponds. Culturing these fish indoors in

areas where cold winter temperatures may threaten their survival is generally the safest approach but may increase production costs.

CULTURE SYSTEMS FOR FOODFISH PRODUCTION

A variety of culture systems have been used to grow juvenile red drum to a market size of 1–2 kg (2.2–4.4 lb). The systems include earthen ponds, recirculating raceways, cages, and net pens. Red drum can be grown from a weight of 1 g (0.002 lb) to approximately 1 kg (2.2 lb) in 8 to 12 months if environmental conditions, especially temperature, are favorable (26). At the time of this writing, earthen ponds appear to be the most cost-effective production system for red drum, although overwintering the fish in such ponds may be problematic in certain locations, as previously discussed.

Recirculating culture systems of several different designs have been used to produce red drum. The species appears to be relatively tolerant of the high densities and marginal water quality that are often encountered in the systems. However, the costs of operating such systems under intensive conditions may limit their profitability (27). Nonetheless, intensive production of fish in indoor, recirculating systems generally has been considered to offer such advantages over outdoor production systems as greater environmental control, flexibility in facility location, and reduced environmental and resource-use impacts.

The production of red drum in cages and net pens has been practiced commercially in some areas. In most cases, the bodies of water in which these units have been placed could not be drained and harvested by traditional means. In general, red drum are tolerant of such systems as long as critical water quality characteristics remain within acceptable ranges.

NUTRITION AND FEEDING

Nutrition is a critical factor in intensive aquaculture, because of its influence on fish growth and health, as well as on production costs. Development of nutritious and cost-effective diets is dependent upon knowing a species' nutritional requirements and meeting those requirements with balanced feed formulations and appropriate feeding practices. Studies to determine the red drum's requirements for specific nutrients were initiated in the early 1980s (28).

Satisfying the minimum dietary requirement for protein or a balanced mixture of amino acids is of primary concern because satisfying this requirement is necessary to ensure adequate growth and health of the fish. However, providing excessive levels is generally uneconomical, as protein is the most expensive dietary component. Several studies have been conducted with young, rapidly growing red drum to determine their minimum dietary protein requirement for maximum weight gain. The required values have generally ranged from 35 to 45% of the diet (29,30). Most recently, the metabolic protein requirements of red drum for maintenance and maximum

growth were established (31). In addition to supplying amino acids for protein synthesis, dietary protein also may be catabolized for energy. Carnivorous fish species, in particular, appear to be very proficient at using dietary protein for energy, due to the efficient way in which ammonia from deaminated protein is excreted via the gills with limited energy expenditure (32). An available energy level of approximately 15 kJ/g diet (1600 kcal/lb diet), or 35 to 45 kJ energy/g protein (3800 to 4800 kcal/lb protein), was determined to be adequate for maximum weight gain and desirable body composition of the red drum (29,30).

Dietary requirements of red drum for some of the indispensable (essential) amino acids have been determined (33–36). Requirements for total sulfur amino acids (methionine plus cystine) and lysine are typically the most critical to quantify because the levels of these amino acids in feedstuffs are usually most limiting relative to the amounts required by fish. The total sulfur amino acid requirement of red drum was determined to be 3.0% of dietary protein (34). This sulfur amino acid requirement appeared to be more limiting than the lysine requirement, which was quantified to be approximately 4.4% of dietary protein (33,35). The threonine requirement of red drum was quantified at 2.3% of dietary protein (36). Established relationships between patterns of indispensable amino acids in muscle tissue and levels required in the diet may allow all amino acid requirements of a species to be estimated after quantifying the requirement for only one or two of the most limiting amino acids (34,37).

Fish do not have a specific dietary requirement for carbohydrates, but the presence of these compounds in diets may provide an inexpensive source of energy. However, the ability of fish to use dietary carbohydrate for energy varies considerably, with most carnivorous species having more limited ability than omnivorous and herbivorous species (32). Although the red drum is a carnivorous fish in nature, it is not adversely affected by high levels of soluble carbohydrate in the diet, although it preferentially uses lipid more effectively than carbohydrate (30,38).

Fibrous carbohydrate, primarily in the form of cellulose, is essentially indigestible by fish and does not make a positive contribution to their nutrition. In fact, the level of crude fiber in fish feeds is typically restricted to less than 7% of the diet, in order to limit the amount of undigested material entering the culture system.

Lipids are important components of fish diets, because they provide a concentrated source of energy that is typically well used. In addition, dietary lipids supply essential fatty acids that cannot be synthesized by the fish.

The red drum, like most other carnivorous species, has been shown to efficiently use dietary lipid for energy (30,38,39). Between 7 and 11% menhaden oil in diets containing 40% crude protein have produced maximum weight gain in red drum. Marine oils containing highly unsaturated fatty acids (HUFAs) of the linolenic acid (n-3) family are needed to satisfy the essential fatty acid requirements of red drum (40). Juvenile red drum were determined to require eicosapentaenoic acid (20 : 5n-3) and docosahexaenoic acid (22 : 6n-3) at approximately 10% of the level of dietary lipid (40,41). The red drum also appears to have a very limited ability to elongate and desaturate shorter-chain fatty acids (40).

It has been established that fish generally require the same minerals as terrestrial animals for tissue formation and other metabolic functions, including osmoregulation (32). However, dissolved minerals in the aquatic environment may contribute to the satisfaction of the metabolic requirements of fish and may interact with dietary requirements.

Supplementation of phosphorus in fish diets is usually most critical, because the presence of phosphorus in the water and its use by fish are limited. The dietary phosphorus requirement of red drum has been determined to be 0.86% of their diet (42). The availability of phosphorus from feedstuffs also may vary considerably (43); thus, supplementing diets on the basis of available phosphorus is important. In addition to phosphorus supplementation, inclusion of 2% sodium chloride and/or 2% potassium chloride to practical diets has been shown to have positive effects on growth of red drum in freshwater and brackish (6 ppt salinity) water, but no positive effects were observed in full-strength artificial seawater (44). The beneficial effects of dietary salt supplementation for red drum in dilute waters appeared to be due to provision of ions that were scarce in these hypotonic environments.

Of the microminerals, selenium and zinc have been demonstrated in some fish species to be most important to supplement in diets, due to their low levels in practical feedstuffs and/or interactions with other dietary components that may reduce bioavailability (32). At this time, only the minimum dietary zinc requirement of red drum has been determined and is 20–25 mg Zn/kg diet (45), although higher levels are generally supplemented. Supplementation of practical diets with other microminerals has not been shown to be necessary in most instances. However, an inexpensive trace-mineral premix is typically added to most nutritionally complete diets for fish to ensure adequacy of the diets (32).

Fifteen vitamins have been established as essential for terrestrial animals as well as for the fish species that have been examined to date. Currently, there is specific information only on the quantitative requirement for choline by red drum (46). However, a typical vitamin premix for other warmwater species, such as channel catfish, is added to nutritionally complete diets to provide adequate levels of each vitamin, independent of levels in ingredients, and thus allow a margin of safety for vitamin losses associated with processing and storage.

Feed costs generally constitute the largest variable cost in intensive fish production; therefore, formulation of cost-effective feeds can significantly influence the profitability of fish production. The accuracy of diet formulation can be improved if information about the digestibility or availability of various nutrients from feed ingredients is known. This information has been obtained for red drum for most of the commonly used feedstuffs (43,47). Feedstuffs of marine origin, including various fish meals, have been most effective in diet formulations for carnivorous fish species, such as the red drum, because they are generally quite palatable and high in protein, lipid, and energy. However, these feedstuffs are usually quite expensive and substantially increase the cost of diet formulations. Other feedstuffs from animal by-products have been used to replace fish meal, with some success; however, their quality can be variable (48). Several protein feedstuffs of plant origin, such as soybean meal, cottonseed meal, and canola meal, are less expensive but have had more limited use in diet formulations because they may be deficient in at least one indispensable amino acid and are usually less palatable to many carnivorous species, including the red drum (49,50). A recent study indicated that relatively high dietary levels of soybean meal could be included without reducing growth or feed intake of red drum if a minimum of 10% of dietary protein was provided by fish meal (51).

A variety of grain by-products from corn, wheat, and rice have been used in fish diets to supply available carbohydrate for energy and to improve pellet stability. Relatively high levels of these feedstuffs are included in red drum diets that are manufactured by extrusion processing. Pellets produced by extrusion processing have high water stability and low density such that they float on the water or slowly sink. This characteristic may assist the aquaculturist in monitoring the feed intake of fish, especially in large culture systems. For this reason, diets prepared by extrusion processing are generally preferred for red drum production. However, use of floating pellets in ponds may increase the potential for interactions between birds and the fish feeding at the water's surface.

Appropriate feeding schedules and practices must be employed in aquaculture to ensure that maximum benefit can be derived from prepared diets. It is generally desirable for fish to consume as much of the diet as they desire on a regular basis. However, excessive feeding should normally be avoided because it not only wastes expensive diet, but also may deteriorate water quality.

Feeding schedules for red drum, like those for other species, are influenced by the size of the fish and water temperature. In general, smaller fish consume more feed, expressed as a percentage of body weight, than do larger fish. Smaller fish also should be fed more frequently than larger fish due to their higher metabolic rates. In addition, water temperature may significantly influence feed intake, with reduced consumption occurring above and below the optimal temperature. Specific feeding schedules for red drum have been empirically derived. The means by which diet is administered to red drum is largely dictated by the design and size of the culture systems.

PARASITES AND DISEASES

Red drum subjected to aquacultural production are susceptible to various disease-causing organisms, including some bacteria, viruses, and protozoan parasites. The most common of these pathogens is *Amyloodinium ocellatus*, a parasitic dinoflagellate (52). This organism attacks the gills, where it causes hyperplasia and fusion of the gill lamellae resulting in reduced oxygen uptake by the fish. Infestations of *Amyloodinium* are typically most serious in larval or juvenile red drum that are being cultured intensively and can result in high mortality rates in less than 24 hours if not properly diagnosed and treated. Chelated copper compounds, such as Cutrine®, have proved quite effective as a treatment at doses of 2 to 6 mg/L (ppm) (52).

Salinity appears to influence the occurrence of *Amyloodinium* infestations with fish generally being less susceptible at a salinity of 6 ppt or less.

One viral disease that has been reported to occur infrequently in red drum is lymphocystis (52). The virus associated with this disease invades the cells of the skin and causes an increase in cell size. This disease typically is not fatal, but may negatively affect the marketability of the fish. As with other viral diseases of fish, no treatment is known for lymphocystis.

Bacteria in the genera *Vibrio* and *Aeromonas* have been isolated from red drum. The red drum is generally resistant to many bacterial pathogens, except when predisposed by stressful conditions, such as crowding, handling, or deteriorated water quality. These diseases are most easily treated by administering an antibiotic to the fish through its feed. Currently in the United States, no antibiotics are registered for use with red drum, although extralabel use of certain antibiotics approved for other aquaculture species, such as Terramyacin® and Romet-30®, has occurred on occasion. Due to the extremely limited treatment options for bacterial diseases, it is much better to prevent the diseases by avoiding conditions that may predispose the fish.

HARVESTING AND PROCESSING

Harvesting methods employed in red drum aquaculture are generally dependent upon the design of the culture system and size of the fish. Larval and juvenile red drum are rather delicate and should be handled with extreme care. Use of soft knotless nylon netting is recommended for these fish. Red drum that are advanced in size are rather resistant to the stress associated with handling, although care should be taken whenever the fish are handled. Fish cultured in earthen ponds are generally harvested by seine once they attain a weight of 1–2 kg (2.2–4.4 lb). Red drum that are confined in more limited areas, such as raceways, have been removed from these systems with fish pumps that were originally designed for salmonids.

At the time of this writing, the market for red drum is limited primarily to states along the Gulf coast of the United States. Most cultured red drum are sold to wholesale seafood markets in the round. Some red drum also have been sold as processed filets in grocery stores. An increase in the demand for red drum and expansion of markets for this fish will likely determine whether commercial production of this fish will continue to expand.

RED SEA BREAM CULTURE

ROBERT R. STICKNEY
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

Reproduction and Larval Culture

Nutrition and Feeding

Production

Bibliography

The red sea bream (*Pagrus major*) is a member of the porgy family (*Sparidae*). It is a marine fish that is valued for its pink flesh, which can be enhanced in aquaculture by feeding the fish carotenoids, including astaxanthin derived from crayfish (1). It is known as the king of fishes in Japan where it is consumed at weddings, graduations, and other ceremonies (2,3). Red sea bream are widely distributed in the Far East and are actively cultured in Japan where production is second only to yellowtail, (*Seriola quinqueradiata*), Hong Kong, Taiwan, and Korea. Studies examining the potential of red sea bream as a culture candidate were being conducted in Japan as early as the late nineteenth century (3). Captive rearing is typically conducted in net pens. Major areas of production include the Nagasaki, Mie, and Kumamoto Prefectures (3). The fish has been the subject of enhancement stocking in Japan since 1962. Kagoshima Bay in southern Japan has been a major site for releases of cultured red sea bream into the environment (2).

During 1995, about 30 million juveniles were produced in Japan. Some 22 million were used in enhancement stocking programs, with the remainder being reared on commercial farms (4).

REPRODUCTION AND LARVAL CULTURE

Fingerlings used for stocking net pens or for release in enhancement efforts can be readily produced in hatcheries. Red sea bream are multiple spawners that reproduce during the fall and winter in Taiwan (5) and from late February until early June in southern Japan (4). One six-year-old captive female in Taiwan was observed to spawn 18 times over a one-month period (late February to late March). Average numbers of eggs spawned during each episode was 898,000. Fertilization rate ranged from over 98% to 100%, while hatching rate ranged from 66.5% to 96.0% (5). Hormones can be employed to induce gonadal development during the off-season, thereby making it possible to undertake year-round reproductive activities in the hatchery (6). Egg quality can be improved by feeding broodstock feed supplemented with cuttlefish meal or raw krill for about one month prior to the onset of spawning (7).

Natural spawning in southern Japan occurs when the water temperature is between 15° and 23 °C (59° and 73 °F) (4). At a temperature of 20 °C (68 °F), hatching requires from 60 to 64 hours (8). At first feeding (about three days of age), red sea bream will accept such small items as oyster larvae and rotifers (*Brachionus* spp.). They later consume brine shrimp (*Artemia* sp.) nauplii. Microbound prepared diets have been employed as a substitute for live feeds (9,10). The dietary value of brine shrimp nauplii to red sea bream can be improved through enrichment with certain types of lipids (11,12), as has been shown for various other marine fish larvae. Larvae transform to the juvenile stage at 26 to 33 days of age (13) and can be weaned to prepared feeds or minced fish. The fish are about 10 mm (0.4 in.) long when the transition from brine shrimp begins (2).

Broodfish are maintained in spawning tanks at male:female ratios of 1:1 at the Kagoshima Prefecture

Mariculture Center (2), a production facility for red sea bream used to stock Kagoshima Bay. The adults are fed fresh fish, squid, and small shrimp. Spawning at the facility is from January to June with the peak coming between March 15 and April 15. The fish spawn naturally, and eggs are collected from the tanks with fine-meshed nets. The Center attempts to produce 3.5 million fingerlings annually — 2.5 million for enhancement stocking, and the remainder for net pen growout.

NUTRITION AND FEEDING

For commercial rearing, both dry and wet prepared feeds can be used (Fig. 1). Wet feeds are often prepared at the growout site by grinding trash fish and, sometimes, mixing in dry ingredients such as plant meals and vitamins. Extrusion can increase the nutritional quality of some ingredients by gelatinizing starch (14), but wet diets have been shown to be very effective. Adding various types of algae, including *Spirulina* spp. (15), *Ascophyllum* spp. (15–17), *Porphyra yezoensis* (17), and *Ulva* spp. (17–19) to prepared diets has resulted in improved fingerling performance.

A significant amount of research has been conducted on the nutritional requirements of red sea bream. For example, the requirements for various amino acids have been established (20–22). Diets containing 52% crude protein result in better growth and food conversion efficiency than diets containing 42% protein (23). The requirements of red sea bream for eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) have been evaluated (24,25). For juveniles, EPA and DHA levels should be 1% and 0.5% of the diet. Excessive levels of n-3 highly unsaturated fatty acids can lead to reduced growth (26).

Adding carnitine to the diet does not seem to promote growth, but it has been shown to both spare lysine (27) and promote the utilization of long-chain fatty acids (28). The dietary requirements of the vitamins choline, pantothenic acid, and vitamin C have all been established (29).

PRODUCTION

Between the time young red sea bream leave the hatchery and are stocked, they are maintained in land-based tanks (Fig. 2). Net pens used for the culture of red sea bream (Fig. 3) are the same as those used for yellowtail (*S. quinqueradiata*). Fish as small as 30 mm (1.2 in.) can be stocked in net pens (with the appropriate sized mesh). Fish of that size are approximately two-months old.

Red sea bream are susceptible to various diseases, though high incidences of mortality do not appear to be very common under normal culture conditions. One interesting phenomenon is the occurrence of black lines

Figure 2. Tanks used to rear young red sea bream to the size used for stocking net pens.

Figure 1. Freshly ground wet feed being loaded into boat for use in feeding fish in net pens in Japan.

Figure 3. Net pen used for rearing red sea bream, yellowtail, and other fishes in Japan.

that can occur in the muscle of both wild and cultured red sea bream. Providing shading from the sun for at least 17 days has been shown to be 90% effective in reducing the black line syndrome (30). Providing shade in net pens, produces a fish with high consumer appeal.

Enhancement stocking, also called red sea bream ranching in Japan, was developed as a result of declining catches that began in 1967 (2). Results of ranching nationally in Japan are not clear, though success has been documented in the Kagoshima area of southern Japan (Kyushu Island) where net pen culture of red sea bream is also occurring.

Prior to release, juvenile red sea bream, initially 30 mm (1.2 in.) long, are stocked in net pens where they are fed minced fish and prepared feeds for two months until they reach 70 mm (2.8 in.) in length. At that time they are released into Kagoshima Bay.

Released fish enter the capture fishery after about a year, though if they avoid capture they will survive for up to 11 years. Maximum growth occurs during the first three years (2), when the fish can reach some 37 cm (14.6 in.) and weigh 0.77 kg (1.7 lb). Maximum recaptures occur during the third year after release.

INTRODUCTION

Institutional, legal, and regulatory constraints have been identified as critical reasons for the slow growth of aquaculture in many regions (1–8). The National Research Council (9) concluded that consistent growth in new business starts in aquaculture tends to be primarily inhibited by issues political and administrative rather than scientific and technological. Indeed, the Marine Board of the National Academy of Sciences conducted a review in 1992 of the issues constraining aquaculture development in the United States and found that those constraints remain (10).

Aquaculture represents a fairly new use of coastal and inland resources and must compete with existing, established uses. It becomes a "chicken-and-egg" situation: the development of an institutional and legal system for aquaculture will evolve as significant strides in the industry are made. However, the industry may not be able to get off the ground until a favorable regulatory structure is in place. If governments are decidedly interested in promoting the development and economic success of aquaculture, they must consider the formulation of comprehensive and clear policies and regulatory programs as early as possible. Such regulatory programs can succeed in balancing the needs of the aquaculturist with those of other users of public resources and may actually enhance aquaculture development.

The development of comprehensive regulatory programs for aquaculture in many parts of the world has not occurred. Some nations have not felt the need to formulate such programs, which they may feel will actually limit growth of the aquaculture industry in their countries. In other countries, existing regulatory policies that do not incorporate the needs of aquaculture may be difficult to change, with the same result. However, countries without clear policies for aquaculture development may subject the industry to future risks and conflicts.

REQUIREMENTS OF THE AQUACULTURE INDUSTRY

The development and growth of the aquaculture industry is dependent upon the attainment of five basic requirements (11): (1) government commitment, (2) high water quality locations, (3) access to the aquaculture site, (4) assertion of exclusive fishing and culturing rights, and (5) financial investment.

Commitment of Government to the Development of the Industry

The development of aquaculture can be expected to accelerate only with governmental support. The nature of this support sets the tone for how the industry is regulated. Policies adopted by governments to promote aquaculture: (1) formally define what is meant by the term "aquaculture," (2) provide supporting policy statements (e.g., "aquaculture can help supplement existing capture fisheries in providing food fish to meet increasing demand"), (3) offer a number of incentives to underscore its commitment, and (4) define and streamline regulatory and legal requirements. Without endorsement of the government, foreign investors and local citizens alike find growth in the aquaculture industry difficult.

High Water Quality Locations

The availability and maintenance of high water quality environments are critical needs for aquaculture. The most favorable water locations are those that are free of pollution, possess suitable temperature (and salinity, if applicable) regimes, and are in areas environmentally suitable to the culture of aquatic organisms. A culturist must be assured that existing and future uses of the adjacent aquatic environment do not affect water quality conditions in areas where species are being cultured. The operator must also be assured of a dependable supply of high-quality water for direct use. Suitable areas for aquaculture, especially in public waters, are, as a result, limited.

Access to the Aquaculture Site

A critical issue for aquaculturists, concerned citizens, and local planning officials is the availability of adequate and accessible sites. The problem of locating suitable sites is compounded by the need to site an aquaculture project where it is permissible.

In choosing a site, a culturist considers an array of environmental, operational, and logistical factors. A reliable supply of electricity and access to transportation networks are two examples. More importantly, aquaculture usually requires both an aquatic environment and an adjacent on-land base of operation. A culturist may have to either obtain permission, rent, lease, or purchase the waters and/or upland sites to assure access.

Assertion of Exclusive Fishing and Culturing Rights

In many countries, common law provides their citizenry with rights to use public waters for navigation, recreation, fishing, and other activities. However, the nature of existing and emerging aquaculture technologies may require exclusive use of public water areas. Multiple use conflicts resulting from such allocations are possible.

The requirement of exclusive or semiexclusive use of submerged bottoms and/or superjacent waters is addressed in some aquaculture regulatory programs. Such use can be conveyed to culturists through implementation of a lease program, for example. Provisions of leases (and other property conveyance mechanisms) usually indicate the level of exclusivity provided.

The same must be said for the species being cultured; that is, ownership of organisms in the possession of the culturist remains exclusively with the culturist in some regulatory regimes.

Financial Investment

Many aquaculture ventures require significant financial investment. However, most investors see the aquaculture industry as a risky business for many reasons, including the ambiguity or absence of laws to protect culture operations from theft, vandalism, takeover, and other threats. Some governments have established a comprehensive regulatory program, accompanied by industry promotion through the provision of low-cost aquaculture loans and other forms of financial assistance, to address these issues. Such commitment from government enhances its ability to attract domestic and foreign investment.

REGULATORY CONSIDERATIONS FOR AQUACULTURE

Programs established to regulate the aquaculture industry reflect its complexity and multiple requirements. The diverse nature of the industry; conflicts with other, more traditional uses of inland, coastal and ocean waters; environmental concerns; and the existing legal and policy climate are key factors that shape the regulatory and permitting programs for aquaculture.

Nature of the Industry

A number of finfish, shellfish, and crustacean species are cultivated in the United States, including catfish, trout, salmon, striped and hybrid bass, tilapia, hard clams, oysters, mussels, crawfish, and penaeid shrimp. The industry is technologically diverse, with ponds, raceways, silos, circular pools, closed (water reuse) systems, cages and net pens, sea ranches, rafts, and long lines used according to the species cultured (12). Aquaculture remains a relatively young scientific discipline that is developing rapidly, with incorporation of a variety of modern technologies, most not yet fully adapted for widespread use (13). Indeed, there has been a trend toward intensification in both traditional and contemporary culture systems.

Aquaculture practices range from extensive, with few inputs and modest output, to intensive, with high inputs and output. On an annual yield per hectare of water basis, increased intensification requires greater resource use, ranging from simple pond culture to intensive tank and closed system aquaculture (14). These varying technologies are what make aquaculture the diverse industry it is, but they have wide-ranging resource needs, produce differing environmental impacts, and require a suite of technological and management responses.

Use Conflicts

While not yet a major problem for culturists with privately owned farm ponds, use conflicts represent one of the primary issues aquaculturists must face, and are likely to become more pronounced and frequent in the future (15). DeVoe et al. (16) found through a survey of the marine

aquaculture industry and state regulatory agencies that the competing use of the coastal zone by recreational users, commercial fishermen, and developers was frequently encountered. The escalating costs of acquiring access to coastal land and waters in the country exacerbated the problem.

In 1992, the National Research Council of the National Academy of Sciences predicted that, due to increasing pressures along the coastal zone, the best opportunities for future commercial aquaculture development are in recirculating (closed) systems on land and in confinement systems in the open ocean (10).

Aquaculture and the Environment

Much has been published since 1980 on the environmental impacts of aquaculture (e.g., 17–22; also see Estuaries, Vol 18:1A, 1995). However, ecological concerns had been raised by a number of authors in the 1970s (23,24). One of the major challenges to the aquaculture industry around the world will be how it responds to these environmental sustainability issues (15).

Aquaculture practices can generate environmental impacts as a function of (1) the applied technique, (2) site location, (3) size of the production, and (4) capacity of the receiving body of water (17). These can include impacts on water quality, the benthic layer, the native gene pool, and the ecosystem as a whole, and impacts from nonnative species, disease, and chemicals.

The state of knowledge regarding the environmental impacts of aquaculture is rapidly improving. Whereas two decades ago very few research data were available, there has been a surge in the number and scope of research and monitoring programs seeking to document these effects. Much work worldwide has focused on the effects of netpen culture on the environment, with the International Council for the Exploration of the Sea (ICES) leading the way. In the United States, early research efforts dealt with fish hatchery effluents and catfish ponds. As the domestic industry diversified, so did environmental research, with major federal studies examining the impacts of marine shrimp pond culture and salmon netpen culture, and the issues regarding species introductions, the use of chemicals in aquaculture, and effluent discharges.

Legal and Regulatory Structures

The current regulatory environment for aquaculture in the United States is a major constraint to its development (9,10,25). No formal federal framework exists to govern the leasing and development of private commercial aquaculture activities in public waters (10).

In a 1981 study commissioned by the Joint Subcommittee on Aquaculture, the Aspen Corporation examined the federal and state regulatory framework for aquaculture (26). As many as 11 federal agencies are directly involved in regulating aquaculture and another 10 are indirectly involved. However, only a limited number of permitting and licensing requirements are directly imposed by federal agencies. More characteristic are federal agency programs that indirectly regulate fish farmers (e.g., restrictions on drug use and federal laws administered by states).

Some 50 federal statutes (with accompanying regulations) were found to have a direct impact on the aquaculture industry, although the actual number of statutes that affect an individual operation vary depending on its size, location, the species being cultured, and other factors. In total, over 120 statutory programs of the federal government were found to significantly affect aquaculture development. Slightly over one-half require direct compliance from the fish farmer.

Seven federal agencies have regulatory programs that directly affect the marine aquaculture industry: the U.S. Army Corps of Engineers, the U.S. Environmental Protection Agency, the U.S. Fish and Wildlife Service, the U.S. Food and Drug Administration, the U.S. Department of Agriculture, the NOAA National Marine Fisheries Service, and the U.S. Coast Guard. Federal oversight of the marine aquaculture industry is fragmented; there is no overall federal framework to address aquaculture development in inland areas, the coastal zone, or in offshore waters. Further, while recent evaluations of marine aquaculture suggest that offshore locations may represent a viable alternative (10), no formal policies have been developed to manage aquaculture development in the U.S. Exclusive Economic Zone. As a result, existing federal policies vary from one agency to another (and may even differ among divisions within the same agency), and the permitting process can be time-consuming, complex, and costly.

The majority of laws and regulations that specifically authorize, permit, or control aquaculture are usually found at the state level. The Aspen Corp. study examined 32 state regulatory programs and discovered that over 1,200 state laws have some significant bearing on aquaculture operations. Policies and regulations were found to affect aquaculture in eight major areas: aquaculture species use, water quality, water use, land use, facility and hatchery management, processing, financial assistance, and occupational safety and health.

Major aquaculture problems that arise from state laws and regulations are caused by the lack of uniformity of laws among the states, the sheer number of permits, licenses, and certifications that must be obtained, and the difficulty in obtaining them (9,10). Each state has its own unique legal, political, and economic climate for aquaculture, and culturists must navigate the regulatory environment differently in each. Only a few states have developed the information management capability to present the applicant with a comprehensive list of all the legal requirements that must be met. State regulatory programs can be and are usually more restrictive than federal guidelines and regulations dictate. The result is that state agencies vary greatly as to what standards they apply to aquaculture (27), and some still apply laws designed for other applications such as those for public fisheries management (9,10).

Federal agencies that establish the ground rules that most state agencies must follow have adopted vague, confusing, and poorly conceived regulations, or none at all (27). This translates into inconsistencies in the development and application of laws and regulations at the state level (28). Few states have a comprehensive regulatory plan that satisfactorily balances economic development and environmental protection. As a result, regulations governing aquaculture are scattered throughout state statutes and do not necessarily fit aquaculture (29). Complicating matters is the fact that existing permit programs do not have provisions for determining the capacity of the coastal and estuarine system for aquaculture, land-based or in situ (28).

The complexity that results from the involvement of many federal, state, and local agencies responsible for all aspects (including advocacy, promotion, conduct, and regulation) of aquaculture leads to an array of planning acts, policies, and regulations (10). Federal laws are applied differently in various geographic regions of the country (9), and the industry remains concerned about the lack of coordination among agencies regulating aquaculture (25). Unfortunately, the federal government has yet to make any significant headway in reducing regulatory constraints (27).

Another limitation to the current regulatory regime for aquaculture in the United States is the lack of long-range and whole-systems planning (28). Aquaculture policy appears to be made by granting permits on a case-by-case basis (30), and the requirements are often determined using regulations and technical standards not originally developed or intended for aquaculture (31). Each permit is considered individually by the issuing agency, usually with no provision for examining cumulative impacts (28).

The problem is not just with the sheer volume of regulations to be complied with, or the difficulty in obtaining the required permits. It also includes the fact that only a few states have themselves developed the information management capability to present the applicant with a comprehensive list of all that will be required of the prospective culturist in starting up an operation. This is not an easy task, however, because each aquaculture operation is different.

THE AQUACULTURE REGULATORY ENVIRONMENT

Policies and regulations affect aquaculture in seven major areas: (*1*) siting an operation; (*2*) environmental quality controls; (*3*) aquaculture species; (*4*) facility/hatchery management; (*5*) processing and sale of aquaculture products; (*6*) commercial and financial assistance; and (*7*) occupational safety and health.

Siting of an Aquaculture Operation

Aquaculture requires the exclusive use of an aquatic environment, or portion thereof, and an adjacent on-land base of operation, which can take many forms. In the instance where water is brought in to fill a farm pond for the culture of trout, for example, the culturist must own the land or receive permission from the landowner to use it. On the other hand, a mariculturist growing mussels or oysters on strings or suspended from rafts must receive some form of right to use that saltwater area. In the former, land use rights are paramount; in the latter, water column use is the critical variable. Thus, before any investment in aquaculture is undertaken, issues of land

tenure and water rights must be resolved, especially in public areas where use conflicts may exist. If not, the aquaculturist faces an unstable and risky environment that could undermine the viability of the operation (32).

Three major land use issues face aquaculture:

1. Siting approvals are regulated at the city, county, regional and state levels. In many cases, strict application of the regulations or ordinances may constrain aquaculture development.

2. Aquaculture is a water-dependent industry. Locating culture facilities on property adjacent to growing areas is becoming very difficult due to escalating costs of waterfront property.

3. Very few local (municipal) land use planning and zoning ordinances acknowledge aquaculture as a legitimate land use. Those municipalities that do are not consistent with their classifications. Some classify it as industrial, others as commercial, still others as agricultural.

Land Use and Zoning. Unregulated aquaculture operations have the potential to be damaging to the environment (33). The need for a properly developed site and an operational plan is important in minimizing these impacts. If such a plan is developed and implemented, aquaculture can be compatible with many other uses.

Conte and Manus (33) suggested that a major issue facing the aquaculture industry is the location of adequate sites. Although many potentially attractive sites exist, the question of how culturists obtain access to those sites must be addressed. One important consideration is the "newcomer" status of aquaculture as a legitimate use of coastal and inland water areas. Most land use regulations do not acknowledge the existence of aquaculture; those jurisdictions with oversight usually do not have experience with aquaculture operations (33).

In countries where aquaculture has not been established, it is generally because (1) there is no tradition of eating fish and therefore demand is low, (2) fish harvested in coastal waters or rivers adequately supply the existing markets, and/or (3) there is a strong focus on agriculture and authorities have decided to use public lands (that might be suitable for fish farming) for further development of agriculture (32).

For instance, culturists who have (or plan to have) operations in the Caribbean have discovered that lands are not readily available to the culturist because of the perceived need to keep them productive for agriculture. Indeed, farmers continue to outnumber fishermen in the eastern Caribbean, and it is the farmers who hold the important political offices in the islands (34). Further, some say that "fish farming generally requires a higher level of management than conventional agriculture, in the sense that the technology as yet lies mainly in the realm of art rather than science" (35). This may, in part, be the reason that *Macrobrachium* sp. culture was unsuccessful in the 1970s in Jamaica; many problems were encountered with the leasing of suitable lands from the government (36).

The availability of appropriate land sites for use by culturists is another issue. For instance, land policies in Puerto Rico favor the use of good agricultural lands for agriculture. It has been suggested (34) that mariculture activities on prime agricultural fields may result in salt contamination of those lands, reducing their value for agriculture. However, in many cases, culturists must locate their operations near freshwater or brackish water areas in order to control salinity, areas that are found near river/ocean boundaries. Yet, because of regulations that prohibit building in areas subject to 100-year floods, the potential of these lands may never be realized. Furthermore, the construction of levees or dikes to reduce the likelihood of flooding is prohibited because farm and other lands upstream may be subject to flooding.

Another reason for the difficulty lies with the costs of obtaining land. Where does a small agrarian farmer get US$10,000 needed to purchase 0.4 ha (1 acre) of land in Jamaica? And in Ecuador, land acquisitions were only available in 10-year concessions and were not available for outright purchase. Ordinary businessmen may have to wait from one to three years to obtain permission, unless they expedite the process through "a series of unofficial payments given to members of the various government agencies," where a US$10,000 payment is not unusual for a 100-ha (250-acre) concession (37).

There are a number of programs that address concerns regarding land use for aquaculture. In the United States, for example, a number of state governments have developed policies that recognize aquaculture as a form of water "farming," or agriculture. This provides an expeditious route to get aquaculture recognized as an appropriate use of land and water resources, and has also provided aquaculture with a number of economic and incentive program benefits that agriculture already enjoys. It is instant legitimacy.

Detailed site surveys to determine the extent of available acreage for aquaculture (and other uses) are encouraged; the selection of sites through an early demarcation program has been suggested to preserve optimum sites for aquaculture (38). These efforts should be followed up with more detailed analyses which incorporate and integrate all users (actual and potential) in a land-use system. With a site plan in place, it is easier to identify and locate the types of aquaculture operations most suitable for particular areas.

Obtaining the necessary permissions to use identified lands for aquaculture operations must be achieved. In most cases, lands available are those for which no other primary uses are sought. Those areas are usually owned by the government or a community, and it is not uncommon for a culturist to gain access to them through long-term leases or permanent ownership (3).

Countries interested in promoting aquaculture might use land use planning (zoning) to identify areas available for siting such operations. In the United States, zoning is a state police power, usually delegated to local or municipal authorities (9), used to allocate lands for specified classifications of development. Localities develop "master plans" which provide guidelines for establishing zoning designations. But, because aquaculture represents a relatively new land use, most existing master plans do not recognize it. The adoption of new or the modification

of existing zoning regulations can be critical to the development of aquaculture as it competes with pre-existing and intended uses of valuable upland sites.

Use of Public Waters. The success of an aquaculture operation also depends on the ability of the culturist to exert control over the culture area through some means of property right. For operations that require the use of public waters, regulations that balance the needs of aquaculture with those of other uses must be followed. The major use conflicts associated with aquaculture are navigation, fishing, recreation (including tourism and aesthetics), and water quality.

Shipping and Navigation. Conflicts between aquaculture and navigation occur primarily in the territorial seas and major harbors and rivers of coastal states. Under United States law, the public has a right to use the navigable waters of a state for navigation, a right that is protected by the federal government (39); it is also a basic principle of international law. Although the right of navigation is subject to regulation and restriction, aquaculture activities are usually sited away from major navigation channels to avoid conflicts.

Fishing. Citizens of many countries have a common-law right to fish in public waters. Many countries have large recreational and commercial fisheries; the conflict between aquaculture and fishing can become a very exhausting battle for a number of reasons. Fishermen want to protect their prime fishing spots. They are also concerned with having to compete with cultured products at the marketplace. Aquaculture operations proposed for areas where major conflicts with fishing interests might occur are usually discouraged by government regulators. By designating prime aquaculture sites, states and countries alike could avoid conflicts of interest between these two sectors.

Recreation. Recreational fishing, bathing, and boating in navigable waters are traditional rights provided by many governments to their citizens. However, these rights are not absolute; states have the authority to regulate recreational activities. Because of increases in population and in leisure time of visitors and tourists, recreational activities are increasing and placing a greater demand on land and water resources. Inevitably, conflicts between recreation and aquaculture will occur. Governments have to decide which of the two activities will have higher priority, although some forms of recreation, such as swimming and diving, are highly compatible with aquaculture (1).

Water Quality. A viable aquaculture operation depends on the availability of clean water, whether the species being cultured are held under natural conditions or artificially in tanks or ponds. Low-quality waters can negatively impact the cultured species, affecting growth, survival, and quality of marketable product. The location of any aquaculture operation must include a high-quality environment.

Aquaculture Leases. The complexity of acquiring exclusive use of lands and waters depends on the type of waters to be used (i.e., fresh, brackish, or saltwater areas) and the geographic location of the proposed facilities. Agrarian aquaculture conducted in farm ponds on private lands is usually lightly regulated and therefore, requires few, if any, permits, while more intensive operations which involve the use of public lands and/or water resources may require a number of permits and approvals.

Unless aquaculturists have a property interest in the lands they intend to use for their operations, they cannot expect to be protected by the law. For instance, Jamaica lacks any laws that govern the use of seawater or the sea bottom (36). This was also the case in the United States in 1989, where only 12 of 23 coastal states had established regulatory programs for siting "contemporary" aquaculture operations (11).

Lease arrangements are one form of property interest frequently granted by states to confer certain use rights. Conditions of the lease arrangement determine the degree of protection afforded to an aquaculturist as well as the associated costs of such protection (40). Leases specify the types of areas that can be put into exclusive or semiexclusive use. Governments offering submerged bottoms and superjacent waters for lease will be able to accommodate a wide range of aquaculture technologies.

Existing land lease laws might provide governments with the authority to lease submerged lands for aquaculture. For example, submerged lands could be leased by the Department of Lands and Surveys of the Ministry of Agriculture, Fisheries, and Local Government under land lease laws established by the government of the Bahamas (41).

Ideally, an aquaculture lease program seeks to balance the needs of the aquaculturist with the rights of other resource users. In doing so, the leasing authority should recognize that the prospective lessee will want to know the following (42):

1. How large an area can be leased?
2. What type of area can be leased?
3. How are parcels or tracts allocated (e.g., through first application or competitive bid)?
4. How much total acreage may one individual hold and for how long?
5. Is the lease renewable and, if so, how often, and under what conditions can the lessee lose it?
6. What degree of exclusivity is granted (e.g., does the culturist acquire all fishery rights)?
7. What protection does the lessee have from competition from other marine uses (e.g., recreation, navigation, fishing)?
8. What agency or agencies grant and manage these leases?

Governments that have established an aquaculture lease program usually have designated a lead agency responsible for making submerged lands and superjacent waters available for aquaculture development. Leasing programs typically convey the necessary degree of exclusivity to the culturist to minimize risks caused by pollution, vandalism, theft, and other forms of encroachment while protecting the rights of the public. These protections are critical to the long-term economic

potential of aquaculture operations, without which financial investment will be difficult to obtain.

Leases usually set minimum and maximum limits on leased acreage: optimal conditions for the culture systems to be used and the overall amount of lands and waters available for lease are considered. Leases of five years or more, with renewal options, appear to offer the culturist enough time to become financially stable; leases of more than ten years may not provide the government, as steward of public lands and waters, with enough flexibility to manage its resources.

Aquaculture leasing programs may also include performance criteria that outline production, use, and resource protection within the lease. Sites not managed for optimum production by culturists may be more valuable to the government and its citizenry in their natural state or for other uses. To ensure adequate use, some leases include provisions, including the execution of bonds, to guarantee maximum productivity.

Finally, leasing programs may include other terms and conditions; for instance, user fees, royalty payments, assignability, and termination of lease agreements might be included in lease agreements.

The establishment of a program to provide land and water column leasing for aquaculture (or any other use) is usually within the context of overall land use planning. The creation of "zones" inland and along the coast where special protection could be offered to aquaculture is one approach some governments have taken. This amounts to a public (or private) decision to permanently protect those areas from incompatible uses and creeping water quality deterioration. For instance, the government of the Philippines forbids the sale of public lands that are suitable for aquaculture ponds and requires that they be leased for culture only (41). Hong Kong offers similar protections for its waters, where the Director of Aquaculture may designate such areas as "fish culture zones" (41). The Bahamas has also designated certain areas of the country to be used to attract aquaculture development.

Conversely, a government could prohibit or exclude aquaculture from particular areas, deciding instead to foster other uses at the expense of a location's potential for aquaculture.

Protection of Navigation and Water Resources. Leasing programs provide the aquaculturist with rights, guarantees, and certain responsibilities. On the other hand, the interests of the government, its citizens, and other users of public land and water resources must be protected as well. In many situations, a government may provide public protection for navigation and the use of water resources through the regulation of aquaculture operations.

The regulatory programs of the federal and state governments in the United States provide examples. At both levels, activities proposed in navigable waters must be conducted so as to prevent their unnecessary alteration or obstruction and to "protect and maintain the quality of... water resources" (40). Navigable waters can include rivers, creeks, lakes, and wetlands.

At the federal level, the Rivers and Harbors Act of 1899 regulates that those who wish to place structures or dredge in navigable waters must first obtain a permit. If the activity involves the discharge of dredge and fill materials into navigable waters, a permit is required under the amended Federal Water Pollution Control Act of 1972. These are described in more detail below.

Environmental Quality Controls

Little has yet been developed in the nature of environmental quality controls that suggests potential constraints upon aquaculture; nevertheless, protections afforded to and from aquaculture operations range from adequate to nil. The perception of the nature of aquaculture is that it is a "clean" industry, that it requires clean water for success. However, when water quality is considered, two points emerge: pollution affects aquaculture, and pollution is a by-product of aquaculture.

Aquaculture requires high-quality water locations and protection from external pollution discharges. It, thus, must rely on proper enforcement of existing pollution laws. Present-day concerns center primarily on non-point source (NPS) pollution. NPS pollution remains a serious problem because it creates a higher risk for investment. Pollution as a by-product of aquaculture has in recent years become a serious concern for the aquaculture industry. The two major pollutants emanating from culture facilities — organics and chemicals — are the subject of extensive research by federal and state entities. Relatively little information exists on the ecological impacts caused by these discharges; therefore, U.S. Environmental Protection Agency regulations, which provide for exemptions from NPDES requirements under certain conditions, are interpreted and enforced in varying degrees by the states.

Issues regarding water-quality impacts on aquaculture have already been covered. It bears repeating that aquaculture requires high water quality locations and protection from pollutant discharges. This is reflected, for example, in Puerto Rico's 1987 Aquaculture Task Force recommendations that call for the establishment of "protective measures for areas particularly promising for aquaculture to prevent environmental and water resource degradation which could hamper the development of aquaculture..." (43). Culturists must rely on proper enforcement of water quality laws. In Hong Kong, for example, any authorized person may arrest anyone polluting waters in the fish culture zone (41). However, these laws do not cover all sources of potential impact; pollution from non-point sources is an example. Adjacent uses, such as pesticide spraying on farmlands near culture sites, may not be compatible. Integrated land and water use policies and zoning is encouraged (38). Unless water-quality impacts can be anticipated and ameliorated, higher risks for investment and success will be created.

Water-Quality Impacts. Aquaculture practices can generate environmental impacts as well, as a function of (1) the applied technique, (2) site location, (3) size of the production, and (4) capacity of the receiving body of water (17). Water exchange has traditionally been required in all forms of aquaculture to prevent self-pollution from organic wastes and resulting oxygen depletion. Of most

concern are the high concentrations of nutrients, nitrogenous wastes, and biochemical oxygen demand (BOD) that can be produced (especially from high-density pond or tank culture systems) and discharged in effluent waters (10). However, information on the effect of marine fish farms on water quality in and around culture facilities has been insufficient to allow a detailed evaluation (19). Released phosphorus is responsible for the greatest effects in inland waters; nitrogen is usually of most importance in coastal areas. In addition, low-quality feeds can present a special problem, readily releasing their nutrients into the water and their fiber into the effluent.

Benthic Layer Impacts. All forms of aquaculture produce organic-rich particulate wastes. Oysters grown in rafts can produce tons of fecal and pseudofecal material (19). The impacts of uneaten food and feces falling on benthic communities beneath salmon cage operations is a worldwide issue (10). Finfish operations not only generate fecal waste, but also feeds not ingested by the culture species add to the particulate load in those operations where feed is provided. Rosenthal et al. (19) noted the following physical and chemical changes in the substrate: (*1*) increased organic carbon, (*2*) increased sediment oxygen consumption rates, (*3*) decreased sediment redox potentials, (*4*) generation of hydrogen sulfide and methane, (*5*) increased organic and inorganic nitrogen content, (*6*) increased phosphorus (*7*) increased silicon, and (*8*) increased sodium, copper, and zinc.

Water-Quality Protections. In the United States, the U.S. Environmental Protection Agency regulates discharges from aquaculture facilities ("concentrated aquatic animal production facilities") that are considered point sources. According to the regulations, a hatchery, fish farm, or other aquaculture facility is subject to a permit if it contains, grows, or holds aquatic animals in either of the following categories:

- Coldwater fish species and other coldwater animals in ponds, raceways, or other similar structures which discharge at least 30 days per year or produce more than 9,090 kg (20,000 lb) of aquatic animals per year, or are fed more than 2,272 kg (5,000 lb) of food during the calendar month of maximum feeding
- Warmwater fish species and other warmwater animals in pounds, raceways, or other similar structures which discharge at least 30 days per year or produce more than 45,000 kg (100,000 lb) of aquatic animals per year

This permit contains water-quality monitoring requirements for contaminants of concern. Conditions and stipulations are usually added to such permits requiring regular monitoring and site inspections. In addition, states may employ more stringent requirements than those set out in federal regulations.

Whether the regulation of discharges from culture facilities is necessary depends on the nature of the aquaculture operation and the condition and quality of the receiving water body. Extensive, low-technology operations with no supplemental feeding would probably not require such oversight. On the other hand, large, intensive operations using significant amounts of water and supplemental feeding may. Where the line is drawn is not yet that clear; thus, the collection of much more basic information on the types and quality of effluents discharged from culture facilities is necessary. Currently, most decisions are made on a case-by-case basis.

Aquaculture Species

The regulatory framework for each species used in aquaculture is widely divergent, with catfish the least restricted and marine species the most restricted. Regulatory requirements vary according to the choice of species being cultured, the degree to which the species cultured require the use of private versus public lands and waters, and the nature of containment and control measures. Historically, catfish culture has a long "track record" and was established before the environmental movement took hold in the early 1970s. There is also the perception that catfish culture is truly an agricultural activity.

Because aquaculture is a relatively new practice in North America, regulatory frameworks designed specifically for cultivated species have not been developed (38). Instead, many governments attempt to regulate culture species under traditional fishery laws. In many instances, regulations promulgated to manage natural (wildstock) fisheries are applied in aquaculture situations, due to the lack of formalized aquaculture policy frameworks and the need by the industry for agency response. Shellfish regulations offer an excellent example. Most coastal states administer size, season, and harvest regulations to manage natural shellfisheries; in many cases, these regulations have been applied to aquaculture operations.

Species regulations typically cover all aspects of "fish and fishing." Generally, governments place restrictions on methods of harvest, sizes, and seasons for freshwater and marine species, and may set limits through quotas and other restrictions on the amounts that can be taken. Permits, licenses, and certifications may be required for fishing, harvesting and equipment use, possession of, and packaging, selling, and transporting the animals. It is not surprising that fishery regulations are at times inappropriately applied to cultured organisms. However, more serious are the instances where protections and safeguards are not applied at all (40). This latter point is particularly true when exotic species importation and disease transmittal are considered.

The selection by a culturist of a candidate species will depend on a number of factors. Bardach et al. (35) stated that there are five desirable characteristics in a cultured animal:

1. Be responsive to techniques to induce reproduction in a captive environment
2. Produce eggs and larvae that can withstand the methods used by culturists in the hatchery
3. Have feeding requirements that are easy to satisfy
4. Can be grown in highly concentrated densities and maintain good rates of growth
5. Be resistant to pollution and disease

However, there are not many species worldwide that can meet all five criteria. Those species that are highly desirable by culturists must usually be brought in from other countries or jurisdictions. The potential for the introduction of disease, infestation by pests, and competition with indigenous species is thus great. Most countries are aware of these concerns and are looking to maintain strict control over the introduction of exotics.

Importation of Exotic Species. In the United States, much of the production from agriculture is based on introduced species (20). Many times in aquaculture, exotic species exhibit more highly desirable characteristics (e.g., growth rates, hardiness, disease resistance) than native populations. However, introductions require careful thought and screening and must consider the political, environmental, and cultural implications, as well as production values (10). Nonnative species can be introduced via (*1*) translocation beyond their natural range by water traffic, (*2*) deliberate transplantation of organisms into new areas, (*3*) accidental introductions in connection with the transfer of other species, and (*4*) escape of organisms transferred for purposes other than deliberate introduction (13). Concerns with nonnative species introductions include the potential for "genetic pollution," ecosystem disturbances (e.g., competition with native populations), and introduction of disease. See Mann (44) and DeVoe (20) for a discussion of these issues in greater detail.

Disease Impacts. Disease remains a major concern for the culturist and can also become a problem in the surrounding environment. Many states have some form of disease testing or certification program for animals being imported across state lines; however, the established programs are limited primarily to freshwater species (10). Salmon egg and smolt importations are highly regulated and, in some states, a quarantine period exists prior to introduction. For marine species, the necessary expertise to conduct effective inspections is lacking (10). Also, routine shipments of live oysters, clams, and crabs, intended for direct sale to consumers, are seldom ever checked for diseases, parasites, and competitors, nor are most shipments of bait organisms. Diseases within an aquaculture operation also represent a potential problem. Outbreaks can occur with little or no warning and spread rapidly throughout the often highly dense culture population. Water-borne diseases can be transferred out of the production unit via the normal water exchange protocol used by many culturists. Internal pathogens can be transferred with accidental (or intentional) release of organisms into the natural environment.

Genetic Impacts. The contamination of wild stocks through the escape or release of mariculture organisms can be problematic. Potential impacts are believed to be severe (10,45); however, very little documentation exists. These impacts can be grouped into two categories. First, the potential exists for overwhelming the "wild" gene pool with the more restricted gene pool of a hatchery stock through repeated and massive intentional stock enhancement efforts (e.g., salmon and striped bass) (10). Second, there exists the possibility for weakening the "wild" gene pool as a result of interbreeding among native wild stocks and accidentally released nonnative culture species (45).

Aquaculture Species Management. Some government regulations established to manage and control exotic species introductions for aquaculture use the following criteria (46, modified by Sandifer, in 34):

1. The degree of need for the importation of exotics
2. Possible species competition with valuable native stocks
3. Their ability to live and grow, but not reproduce, in the natural environment
4. That "enemies, parasites, and diseases" which could attack native stocks not be brought in along with the animals
5. Their susceptibility to pathogens or parasites in the introduced environment
6. Their ability to "live and reproduce in equilibrium with its culture environment"

Many authors (including Sandifer, in Refs. 34 and 36) strongly suggest that governments should encourage the development of culturable indigenous species first and, if exotics are to be imported, ensure that adequate safeguards are put into place.

Ownership of Cultured Organisms. As Pillay (3) pointed out, the practice of aquaculture requires holding and ownership of the stocks being cultivated. Problems with ownership of the cultured animals exist in private farm pond operations as well as with aquaculture in public waters. Fisheries have become part of the commons; resources that are available to all. Without policies that clearly provide vested rights to the organisms being cultured, the culturist or the government may have difficulty exercising "ownership rights for aquaculture stocks" (3).

Wildsmith (4) provided a detailed review of the property rights culturists have in the cultured animals. It appears from his review that possession of animals has much to do with capture. Further, there is little in common law that protects rights to cultured organisms once they are released from the culturist's possession. With respect to cultured plants, it appears that ownership in the lands (fee simple, lease) gives rise to property rights in the plants. It should be noted that Wildsmith's analysis deals primarily with the legalities of cultured organism ownership, as decided by the courts of the United States and Canada.

The practical question that requires attention is what protections are or will be afforded to the culturist against theft or removal of his stock? In Jamaica, for example, only about 10% of oyster production is suitable for market, in part, because of poaching (47). The development of several types of aquaculture is constrained in the Bahamas because of the difficulty of preventing theft of cultured species (41). Government regulations in some cases include clearly stated provisions over property

rights to the organism, alone or incorporated into leasing agreements with the government. Regulatory programs that lack such protections increase the risks in the industry to a point where few will attempt to enter.

Aquaculture Facility and Hatchery Management

There are several cases where the regulation of aquaculture facilities and hatchery management may be necessary to ensure the production of high-quality, disease-free product and maintain healthy environmental quality conditions. A government may require permits or licenses to operate a fish or shellfish hatchery. Some jurisdictions require fish-breeding licenses and permits for acquiring wildstock for spawning, depending on its availability. And the importation of eggs, larvae, or fish may require certification of freedom from disease or parasites, which is sometimes difficult to acquire due to a lack of agency facilities and diagnosticians.

Drugs, Chemicals, Vaccines, and Pesticides. In the United States, any drugs or chemicals used on food fish must be registered and cleared. It is a costly and time-consuming process; however, these safeguards are necessary to protect the health of seafood consumers. Any drugs or chemicals used on food fish must be registered and cleared with the U.S. Food and Drug Administration. The problem is that only a few drugs or chemicals have been approved for use. Since the prospective market is small, few drug manufacturers have pursued registration.

Vaccines are regulated and must be certified separately for each species cultured. The use of vaccines is regulated by the U.S. Department of Agriculture. Few are registered (again, due to time, cost, and the lack of markets). Each vaccine must be separately certified for each species grown in culture.

Pesticides, herbicides, and other chemicals used for predator control are regulated by the U.S. Environmental Protection Agency. Permits may be required in the United States before any chemicals are applied.

Whether the regulation of drugs and chemicals is necessary will depend on the nature of the culture industry in any particular locale. Many low-technology aquaculture operations will not require the use of these substances and therefore, these considerations may not be necessary. However, in large-scale, intensive systems, the use of drugs and/or chemicals may be necessary and will require approvals.

Water Use. Aquaculture may require significant amounts of water for the operation of hatchery, nursery, and growout facilities. Generally, species exhibit improved health, growth, and survival with adequate water exchange. The use of fresh surface water, brackish and marine surface waters, or groundwater might be necessary, depending on the type and location of the operation. If water resources are limited, a government may have to consider allocating water use rights among users.

This could take several forms. All operations might be asked to report water use on a regular basis if single-day or seasonal maximums established by the government are exceeded. In South Carolina, "capacity use areas" are designated for locations where significant groundwater use threatens the underlying aquifer. Activities needing groundwater and proposed in a capacity use area require a permit. Alternatively, a government may establish maximum water use levels and allocate water use in a specified area among existing and proposed users.

Regardless of the approach, significant water use by aquaculture operations may require government monitoring to ensure that all public and private needs remain satisfied.

Water issues that culturists may face include groundwater availability and allocation and interbasin transfers. However, a number of secondary, but significant, issues emerge, including: (a) water rights and riparian ownership law; (b) proscriptions on the use of public waters; (c) competition from other water uses (multiple use conflicts), and (d) federal, state, and local water management programs. Direct contact with state permitting officials should be made to clarify regulatory requirements.

Processing and Sale of Aquaculture Products

One of the advantages of aquaculture is that with control over the organism, the culturist can plan to harvest and sell product at almost any time of the year. The market may also demand seafood products that do not meet minimum sizes or weights as established for the capture fisheries. Some governments have adopted policies that exempt the aquaculture industry from minimum size and weight requirements and closed season laws, which provide marketing advantages to the aquaculture industry.

Other regulations that aquaculturists may face include licensing, operational, and labeling requirements meant to inform and protect the consuming public. These requirements are administered by the U.S. Food and Drug Administration at the federal level and by food, drug or health agencies at the state level. Health officials may require processing facilities to be licensed and certified as clean and safe. Problems regarding fish contamination and depuration of fish products may exist. Procedures for processing seafood products may be established, and site inspections frequently made. Minimum standards may also be set for package labeling. While many of these regulations are not unique to aquaculture, they may actually be useful in product marketing in that product differentiation between domestic and imported, or harvested versus cultured, products may be desired.

Sanitation and human health concerns regarding aquaculture products are usually addressed through regulatory programs. In some jurisdictions (e.g., Jamaica) no laws exist that cover these concerns (36).

It is important that aquaculture products be of high and consistent quality regardless of the species. Uniform standards throughout the industry are desirable. In some cases, industry and government have joined together to set, advertise, and maintain quality standards for cultured products. A federal seafood inspection program using the Hazard Analysis Critical Control Point (HACCP) methodology has been implemented for seafood and aquaculture operations in the United States.

Commercial and Financial Programs

Rules and regulations must also be followed by culturists when obtaining loans and financing. Those of the Internal Revenue Service (IRS) and the Securities and Exchange Commission (SEC), in particular, can have a detrimental effect on small business investment in the United States. There are regulations also in place for investment, financing, taxation, marketing, and insurance.

Labor and Occupational Safety

Labor and safety concerns in the United States are covered under Occupational Safety and Health Administration (OSHA) regulations, primarily. The unique aspects of aquaculture are not acknowledged.

FEDERAL PERMITTING PROCEDURES AND REQUIREMENTS IN THE UNITED STATES

Introduction

Although most of the permits required to operate an aquaculture facility are issued on the state level, several federal agencies are also involved in the permitting process. The major permits issued by federal agencies include the Section 10 and Section 404 permits issued jointly by the U.S. Army Corps of Engineers (ACOE) and the U.S. Environmental Protection Agency (EPA). These permits regulate the placement of structures and the discharge of dredge and fill material in the nation's waterways, respectively. The EPA also issues National Pollution Discharge Elimination System (NPDES) Permits that control the amount of waste and effluents released from aquaculture and other industrial facilities. This permit can be issued by states as long as the relevant state program has been designated with the authority by the EPA.

Several other federal agencies are also involved in regulating the aquaculture industry, including the U.S. Fish and Wildlife Service (FWS) and the U.S. Food and Drug Administration (FDA). These agencies regulate species selection and drug, feed, and pesticide use by aquaculture operations, respectively. The EPA and the ACOE are also required to solicit and consider comments from these and other agencies before issuing the Section 10, Section 404, and NPDES permits. Comments are also solicited from the U.S. Coast Guard and the NOAA National Marine Fisheries Service during the permitting process.

Many of the permits presented below require similar information for consideration by the agencies. Culturists should always begin the permitting process by contacting the permitting officials of each of these agencies to determine beforehand the information required for the permit application. In some instances, the information needed is quite technical in nature which may require the culturist to solicit the aid of a consultant to assemble the information necessary to begin the permitting procedure. Some states have set up aquaculture permitting assistance offices to help culturists identify the permits that would be required to begin an operation. Although these offices do not operate as permit processing centers, they can be extremely helpful in identifying the state and federal laws and regulations that may apply to a particular operation and the permits that may need to be obtained.

Section 10 and Section 404 Permits

Introduction. The U.S. Army Corps of Engineers (ACOE) has been regulating activities in the nation's waterways since 1890. However, the focus of their regulatory activities has shifted from protecting navigation to the consideration of the full public interest for the protection and utilization of water resources. The ACOE has regulatory jurisdiction over the obstruction or alteration of navigable waters under Section 10 of the Rivers and Harbors Act. The ACOE has also been given administrative responsibility for Section 404 of the Clean Water Act by the U.S. Environmental Protection Agency (EPA). Section 404 regulates the discharge of dredge and fill material into the waters of the United States. These permits can be obtained through a joint application issued by the ACOE.

Section 10 of the Rivers and Harbors Act of 1899. The ACOE is the lead federal agency for permits that involve protection and utilization of the water resources of the United States. These activities are covered under Section 10 of the Rivers and Harbors Act of 1899 (33 U.S.C. 403). Activities regulated under this authority include the placement of structures within navigable waters and the obstruction or alteration of navigable waters of the United States. The purpose of this permit is to ensure the free passage of ships and water-based traffic in public waters.

Section 10 of the Rivers and Harbors Act prohibits "the creation of any obstruction... to the navigable capacity of any of the waters of the United States." This law also makes it unlawful "to build or commence the building of any... structures in any... water of the United States... except on plans recommended by the Chief of Engineers and authorized by the Secretary of War." Section 10 also makes it unlawful to "excavate or fill, or in any manner to alter or modify the course, location, condition, or capacity of... any navigable water of the United States, unless the work has been recommended by the Chief of Engineers and authorized by the Secretary of War prior to beginning the same." This Act created the Section 10 regulatory program.

The Section 10 permit issued by the ACOE is required for all prospective culturists whose operations involve locating a structure in navigable waters. All water-based aquaculture operations will require a Section 10 permit. Examples of structures that would require a Section 10 permit include piers, intake and discharge pipes, floating docks, netpens, and any open water growout or depuration facilities (48).

Section 404 of the Clean Water Act. The EPA has statutory authority on all permits that fall under Section 404 of the Clean Water Act (33 U.S.C. 1344); however, administrative responsibility has been given to the ACOE on behalf of the EPA. Any activity that involves the discharge of dredge or fill materials into navigable waters requires a Section 404 permit. Some

examples of aquaculture activities that would require a Section 404 permit include the construction or alteration of impoundments, bulkheads, road fills, and the dredging of canals or channels.

Section 404 of the Clean Water Act authorizes the Secretary of the Army, acting through the Chief of Engineers, to "issue permits, after notice and opportunity for public hearings, for the discharge of dredged or fill material into the navigable waters at specified disposal sites." All public notices must be made within 15 days of the date that all application materials are received. The Administrator of the EPA is allowed to prohibit the specification of an area as a disposal site. The administrator is also allowed to deny or restrict the use of an area for specification as a disposal site as long as an explanation for the decision is made public.

Section 404 also allows the ACOE to issue general permits on a state, regional, or nationwide basis for the discharge of dredge or fill material. The activities covered under a general permit must be "similar in nature, will cause only minimal adverse environmental effects when performed separately, and will have only minimal cumulative adverse effects on the environment." General Permits can only be issued for a period of up to five years. If, after opportunity for public hearings, the ACOE finds that a general permit has significant environmental impacts, it may revoke or modify the permit.

Section 404 requires permits for the following activities: (*1*) the discharge of dredged or fill material into navigable waters that brings the waters into a use that it was not previously subject, (*2*) the discharge of dredged or fill material that impairs the flow water in navigable waters, or (*3*) the discharge of dredged or fill material that reduces the reach of navigable water. However, normal farming activities, the maintenance or emergency repair of structures such as dikes, dams, and bridges, the construction of farm or stock ponds and temporary basins, and the construction of farming and logging roads that use best management practices and that require the discharge of dredged or fill material are exempt from the regulations.

The EPA retains two major functions under Section 404. The first is to develop and provide environmental standards to the ACOE for its use when evaluating a permit that involves the discharge of dredge or fill material into waters and wetlands of the United States. The EPA is also authorized to veto or restrict an ACOE permit that allows the discharge of dredge or fill material in a wetland. The EPA reviews all applications to determine if a proposed discharge will have a significant impact on municipal water supplies, shellfish beds, recreational areas, and wildlife and fishing areas (49).

Permitting Process. Obtaining a permit usually takes two to three months; therefore, culturists are encouraged to begin the application process as early as possible. It is important that culturists begin the permitting process with a preapplication interview. During this initial meeting, the ACOE can advise the applicants on what types of permits the project will require. Applicants must be flexible to meet the requests of the ACOE and other federal agencies that must be consulted during the public

comment period. Generally, most permits are issued if the permittee is willing to make the necessary design changes.

The Engineer Form 4345, *Application for a Department of Army Permit*, is used to apply for both Section 10 and Section 404 permits. These applications are available from ACOE district regulatory offices. Some states may use a slightly modified form to facilitate joint processing with a state agency, such as a coastal management agency. The information required by these joint applications is similar to the standard ACOE application. Some projects may be previously authorized under nation-wide or region-wide general permits. The permitting process may also be abbreviated for other projects and only require a letter of permission from the ACOE. Most projects, however, require the full permitting procedure, including public notice and consultation with other federal agencies. The ACOE must balance the need and expected benefits of the proposal against the probable impacts of the project when reviewing an application. The ACOE is also required to take into consideration all public comments and other relevant factors in a process known as the public interest review.

The ACOE uses the following general criteria in its evaluation of permit applications:

1. The relative extent of the public and private need for the proposed activity
2. The practicability of using reasonable alternative locations and methods to accomplish the objective of the proposed activity
3. The extent and permanence of the beneficial and/or detrimental effects which the proposed activity is likely to have on the public and private uses to which the area is suited

The ACOE also identifies the possible impacts that the proposed activity may have on several other items when deciding whether to grant or deny a permit during the public interest review. These items include the following: conservation, economics, aesthetics, general environmental concerns, wetlands, cultural values, fish and wildlife values, flood hazards, floodplain values, food and fiber production, navigation, shore erosion and accretion, recreation, water supply and conservation, water quality, energy needs, safety, needs and welfare of the people, and considerations of private ownership.

The ACOE must also evaluate a permit application using the criteria established under Section 404(b)(1) of the Clean Water Act if the proposed activity will involve the discharge of dredged or fill material. These guidelines restrict discharges into aquatic areas where less environmentally damaging alternatives exist. However, final veto authority for Section 404 permits belongs to the EPA. They may override any decision reached by the ACOE regarding the discharge of dredge and fill material.

The ACOE is also required by federal laws and executive orders to solicit comments on proposals from certain federal agencies during the public review period. The following agencies are required to review applications under both Section 10 and Section 404 permits (adapted from 48):

Agency	Law/Regulation
1. U.S. Environmental Protection Agency	Fish and Wildlife Coordination Act,
2. U.S. Fish and Wildlife Service	16 U.S.C. 661 et seq. and Executive
3. National Marine Fisheries Service	Order 11990 (for nos. 1–3)
4. Federal Emergency Management Agency	Executive Order 11988, Floodplain Management
5. U.S. Coast Guard	Rivers and Harbors Act of 1899, Section 10

Evaluation factors for Section 404 permits are based upon sequential criteria, including the following: (*1*) Can the proposed project be avoided or moved elsewhere? (*2*) Have environmental impacts been minimized? (*3*) Can wetland losses be minimized?

During review for a Section 404 permit, the first criterion must be satisfied before the second is considered, and the second satisfied before the third is considered. The landowner must also comply with all other local, state, and federal requirements before a final permit is issued. The permit application must also be distributed to the federal agencies already mentioned as well as any applicable state agencies, for review. It is possible that mitigation measures might be required if an aquaculture facility is constructed in a wetland (30).

Permitting decisions are usually made within 60 days of receipt of the application. However, complexities of a project, incomplete applications, changes to the project, and public hearings, if required, can all increase the amount of time it takes to reach a decision. Fees are only assessed when a permit is issued. The fee for noncommercial activities is $10, for commercial activities $100.

The ACOE has prepared a document that outlines all of the requirements for the permitting process. It is available at all regional and district offices.

National Pollution Discharge Elimination System Permit

Introduction. Aquaculture operations have the potential to discharge significant quantities of dissolved and particulate wastes in large volumes of effluents into surface waters. The effluent stream also represents the most direct route for accidental escape of nonnative species; chemical, drug, and pesticide residues; and disease organisms. As a result, the aquaculture industry has faced heavy scrutiny from federal, state, and local resource officials who are concerned about the impacts of aquaculture on the aquatic environment. Therefore, the industry is subject to the rules and regulations of the National Pollutant Discharge Elimination System (NPDES) program. The NPDES program is designed to (*1*) limit discharge according to federal "technology-based" discharge standards or state water quality standards, (*2*) provide schedules for compliance, and (*3*) require monitoring and reporting for effluents (30).

Federal Policies. Effluent discharges into waters of the United States are regulated by the EPA to maintain and improve potability, aesthetics, and recreational quality of the receiving waters, under provisions of the Clean Water Act (CWA), including the Federal Water Pollution Control Act as amended in 1972 (PL 92–500; U.S. Congress 1972), the Clean Water Act of 1977 (PL 95–217; U.S. Congress 1977), and the Water Quality Act of 1987 (PL 100-4; 50). The 1972 amendments created the NPDES program, which requires that anyone discharging wastewater from a point source to a "water of the United States" apply for a discharge permit. Under NPDES regulations (40 CFR Part 122), which are generally administered at the state level, a "concentrated aquatic animal production facility" is defined as "a hatchery, fish farm or other facility which meets the criteria in Appendix C" (outlined below), or "any such facility which the Director determines is a significant contributor of pollution to the waters of the U.S. based on a non-site inspection of the facility" (50).

Under Appendix C, a hatchery, fish farm, or other facility is a concentrated aquatic animal production facility if it contains, grows, or holds aquatic animals in the following categories:

1. Coldwater fish species or other coldwater aquatic animals (including the Salmonidae family of fish, e.g., trout and salmon) in ponds, raceways, or other similar structures which discharge at least 30 days per year, but does not include (a) facilities that produce less than 9,090 harvest weight kilograms (20,000 lb) of aquatic animals per year, and (b) facilities that feed less than 2,272 kilograms (5,000 lb) of food during the calendar month of maximum feeding.

2. Warmwater fish species or other warmwater aquatic animals (including the Ameiuride, Centrarchidae, and Cyprinidae families of fish, e.g., catfish, sunfish, and minnows, respectively) in ponds, raceways, or similar structures that discharge at least 30 days per year, but does not include (a) closed ponds that discharge only during periods of excess runoff, or (b) facilities that produce less than 45,454 harvest weight kilograms (100,000 lb) of aquatic animals per year.

The CWA defines a pollutant as "dredged spoil, solid waste, incinerator residue, sewage, garbage, sewage sludge, munitions, chemical wastes, biological materials, radioactive materials, heat, wrecked or discarded equipment, rock, sand, cellar dirt, and industrial, municipal, or agricultural wastes discharged into water." The wastes produced by most aquaculture facilities meet these criteria and, therefore, are subject to the conditions of the NPDES permitting program. Likewise, aquaculture facilities located within a "defined managed area" of U.S. waters determined by the EPA to be ineligible for an initial exemption, or a continued exemption and discharge into that area for maintenance of production of harvestable fresh water, estuarine, or marine plants or animals, are also subject to the NPDES permit program.

Permitting Procedures. The process for obtaining the NPDES permit varies from state to state because

permitting authority can be delegated by the EPA to state agencies. Generally, prospective culturists are encouraged to contact the regional office of the EPA to determine what applicable state agency is charged with issuing NPDES permits. To determine if an NPDES permit is necessary, the applicant sends a letter of determination to the applicable agency that includes a description of the facility, operation plans, preliminary or conceptual designs, and information on anticipated wastewater discharges. The permitting agency reviews the information and informs the applicant of any required permits for the specific operation.

States given the authority by the EPA to handle NPDES permits oversee the entire permitting process, including the assurance that all federal standards are met. When a state is not delegated to administer the NPDES program, culturists are required to comply with both federal discharge standards and any state discharge water quality standards (51). Currently, all but the following states issue their own permits under the NPDES program: Arkansas, Idaho, Illinois, Maine, Massachusetts, New Hampshire, New Mexico, Oklahoma, and South Dakota (49).

When issuing a NPDES permit, the permitting agency must apply the following criteria: (1) federal (EPA) technology-based standards (industry-specific process or end-of-pipe discharge standards or effluent criteria required for any plant in that industry), and (2) more stringent state water quality-based standards if the discharge is likely to affect the water quality-based objectives for the receiving waters. Under the CWA, states designate uses for bodies of water (such as swimming, fishing, and drinking), and may establish stricter standards than those of the federal to maintain designated uses and prevent water quality degradation (30).

NPDES permit program regulations promulgated in 1973 revised the classification of fish hatcheries from "critical industry" status to that of an agricultural facility, effectively reducing the need for the EPA to develop maximum technology-based discharge standards for the aquaculture industry. Although proposed regulations were published in the Federal Register in 1974 (40 CFR Part 115), the EPA has not issued effluent guidelines and minimum levels of treatments for aquacultural discharges. However, in 1998, the EPA published a Notice of Proposed Effluent Guidelines Plan (Fed. Reg. 1998) that sought public comments on its intent to develop new and revised effluent guidelines; fish hatcheries and farms are included as possible candidates for such attention. Currently, permit requirements for aquaculture are established on a case-by-case basis, taking into consideration related guidance that has been issued and any specific water-quality standards applicable to the receiving waters (50). Additionally, states are authorized to place additional requirements on these discharges, and, in some cases, effluent monitoring in aquaculture facilities is required even if the production capacity is less than the limits defined in the NPDES protocol (10).

The lack of a properly prepared EPA guidance document for effluent discharges from aquaculture operations has resulted in inconsistencies in regulating such activities. This is not a recent phenomenon; EPA's regional offices and the states administering the NPDES permit program were using different criteria for aquaculture discharge permits during the 1970s. For example, it became extremely difficult in Hawaii to discharge aquaculture effluents due to a lack of knowledge and communication in the following areas: (1) characteristics of aquaculture species and technology, (2) economic feasibility of conventional wastewater treatment alternatives before discharge, (3) environmental impacts, both positive and negative, of nutrient-rich effluent on the nearshore clean environment, (4) time and cost involved in completing the permit applications (e.g., consultant costs for reports and environmental assessments), and (5) inexperience and uncertainty in granting and administering the permit (52).

Other Regulations

Introduction. Although the Section 10, Section 404, and NPDES permits previously described represent the bulk of federal permits required before a culturist can begin operation, several other agencies are also involved with regulating the aquaculture industry. Federal regulations that affect aquaculture focus on the coastal zone, species selection, pesticide approval, and drug and vaccine limitations. The agencies that are involved in these regulations include the NOAA Office of Ocean and Coastal Resource Management, U.S. Fish and Wildlife Service, U.S. Food and Drug Administration, and the U.S. Environmental Protection Agency.

NOAA Office of Ocean and Coastal Resources Management. If an aquaculture operation is located within the "coastal zone" of the United States, it is subject to the federal Coastal Zone Management Act of 1972 (CZMA; PL104–150). The CZMA is administered by the Office of Ocean and Coastal Resources Management within the National Ocean Service of the National Oceanic and Atmospheric Administration in the U.S. Department of Commerce. Through the CZMA, funds are provided to states and territories to develop and implement coastal management programs (CMPs). A CMP is a comprehensive state plan designed to identify and protect coastal resources and minimize any environmental impacts associated with activities proposed within the coastal zone of the state (51). Many CMPs rely on a variety of regulatory and permitting programs conducted by the state under its statutory authority. An individual or entity proposing a significant activity or development within the coastal zone must obtain the requisite coastal management approvals.

In 1996, the CZMA was amended. Included in the revisions was new authorization for states to use a portion of their CZMA funding for the adoption of procedures and policies to evaluate and facilitate the siting of public and private aquaculture facilities in the coastal zone. This revision enables states to develop, administer, and implement strategic plans for marine aquaculture. However, only a handful of states have taken advantage of this opportunity.

In some states, such as South Carolina, the coastal permitting process has only a minimal impact on the freshwater aquaculture industry. However, for any aquaculture activity that is proposed within the state's

eight coastal counties, the culturist will be required to obtain a "Critical Area" permit.

All coastal management regulatory programs are administered at the state or local level. Prospective aquaculturists are encouraged to contact the coastal management program office in the state or territory of interest before proceeding with their plans.

U.S. Fish and Wildlife Service. The U.S. Fish and Wildlife Service (FWS) is primarily responsible for the protection and management of fish, migratory birds, and wildlife and is the lead agency for several laws and permits that affect the aquaculture industry. Several programs that are administered by the FWS applicable to the aquaculture industry include review and comment responsibilities on proposed construction projects and the regulation of fish and wildlife imports and exports (48).

The Lacey Act and the Lacey Act amendments of 1981 (16 U.S.C. 3371) were enacted to protect indigenous species and prevent the trade of endangered or threatened wildlife (30). Its purpose is to restrict the importation of a species that might be injurious to human beings, agriculture, horticulture, forestry, or wildlife resources (51).

Aquaculture operations are also prohibited from raising endangered or threatened species because these species cannot be sold, offered for sale, imported, exported, taken, received, or shipped in interstate commerce. The federal government protects these species through the Endangered Species Act of 1973 (ESA) (16 U.S.C. 703−712). The regulation of imports and exports of fish and wildlife across both international and state boundaries is presented in Title 50 CFR, Parts 10−24. This jurisdiction of the FWS is based upon the above and the following laws: the Marine Mammals Protection Act (16 U.S.C. 1531−1543), the Migratory Bird Treaty Act (16 U.S.C. 3371), and the Injurious Wildlife Act (16 U.S.C. 152).

The FWS is also the lead agency in issuing the Fish and Wildlife Import/Export License. The license is required for any person who imports or exports animals or fish with a value exceeding $25,000 per year for purposes of propagation or sale. The FWS is allowed 60 days to process applications (90 days if endangered species are involved). The license fee is $125 per year and a fee of $25 is assessed for each import or export shipment. A completed "Declaration for Importation or Exportation of Fish and Wildlife" clearance form must also be completed and submitted to the FWS inspector at the port-of-entry for approval. This approval is required to obtain a shipment release from the U.S. Customs Service (48).

U.S. Food and Drug Administration. The U.S. Food and Drug Administration (FDA) is responsible for approval and regulation of drugs that can be used in aquaculture operations, based upon the Federal Food, Drug, and Cosmetic Act (FDCA; 21 U.S.C. 301). Drug regulation can include the use of drugs as additives in feeds as well as drugs for the treatment of diseases and parasitic infestations in aquatic animals sold for human consumption (48). The primary goal of the FDCA is to protect the health and safety of the public by preventing deleterious, adulterated, or misbranded articles from entering interstate commerce (51).

The FDA is charged with approving the use of drugs that culturists can use to fight the threat of disease. However, there are currently very few approved drugs available for culturists to use to fight diseases caused by bacteria, viruses, parasites, and fungi. The FDA uses a two-step process to approve drugs for use in aquaculture operations. First, the drug itself must be approved by the FDA based on the research conducted by the manufacturer of the drug. Next, the use and dosage of the drug must be approved for aquaculture applications. Culturists should be careful to follow FDA guidelines when using any type of drugs in their operations. Mishandling of these drugs can result in serious fines for the culturist, their products being declared unfit for human consumption, or their product being confiscated from the market (48).

Occasionally, the FDA grants Investigational New Animal Drug (INAD) exemptions to ease the approval process for "minor use" compounds in major agricultural industries. However, the FDA has recently tightened the requirements for INADs due to a concern over the effects on public health and lack of a drug residue monitoring program for the aquaculture industry (30). Additionally, the FDA has started working closely with state and federal agencies and the aquaculture industry to address drug and chemical use issues in aquaculture.

U.S. Environmental Protection Agency. The U.S. Environmental Protection Agency (EPA) regulates the use of pesticides under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) (7 U.S.C. 136). This legislation requires that all chemicals intended to kill pests must be registered with the EPA. The EPA requires the manufacturer of the chemical to show that the product performs as claimed, that the labeling is appropriate, that there is no unreasonable adverse effect on the environment, and that its use is safe. Although no formal permitting procedures are required by the EPA, culturists must be sure to adhere to the regulations set forth by the EPA when using these chemicals to avoid severe fines and penalties. The use of unregistered chemicals by a culturist could also result in penalties. In fact, some chemicals require application only by a professional who must be registered with the EPA (51).

REPRODUCTION, FERTILIZATION, AND SELECTION

WILLIAM K. HERSHBERGER
National Center for Cool and Cold Water Aquaculture
Lectown, West Virginia

OUTLINE

Text
Bibliography

Reproduction in aquatic species, as in other animals, serves two important basic biological functions: (*1*) perpetuation of the species and (*2*) transmission and recombination of genetic material. From a more utilitarian perspective, the production of aquatic species (i.e., aquaculture) can only be successful as long as there is an adequate supply of 'seed' in the form of fertilized eggs or juvenile animals; this can only be assured through careful management and control of reproduction.

Many cultured aquatic species were initially propagated by collecting seed from the natural environment (1,2), and this is still practiced with some aquacultured species (e.g., mussel culture) (3). However, relying on the natural production of seed has the three major drawbacks. First, natural production of seed does not yield consistent supplies over time. Year to year variation in weather conditions and other environmental parameters can have major effects on the success of natural reproduction and on the survival of juvenile animals. Second, this practice does not allow for the genetic manipulation of stocks to increase production efficiency. As will be discussed later in this section, genetic selection is based on the ability to cross-breed specific animals with desirable traits; there is no assurance that those with the traits needed for improved aquaculture efficiency will mate in the natural environment. Finally, the natural productivity of a species can be negatively impacted when the demands for seed reach high levels. Thus, the ability to manage reproduction is not only a major factor that contributes to the success of aquaculture, it is also crucial to its sustainability.

Aquatic species exhibit one of the most diverse collection of reproductive modalities and strategies in the animal kingdom. However, the species currently raised in aquaculture (about 150) exhibit a fairly limited array of the reproductive strategies found in the natural environment.

Most aquaculture species are dioecious; that is, they have separate and distinct sexes. The genes necessary to define maleness or femaleness are transmitted to each individual at fertilization. In most higher vertebrates these genes are concentrated on morphologically distinctive chromosomes (e.g., "X" or female chromosome and "Y" or male chromosome in mammals), and some species of fish have been shown to contain similar types of sex-determining systems (4). However, few aquatic species exhibit physically discernible chromosomes (5), and the genetic determination of sex has been found to vary from a few genes to more complex combinations of genetic elements (6). The absence of chromosomes that are easily identified in one sex makes cytological determination of sex in these species practically impossible. Furthermore, the apparently diffuse nature of sex-determining genes may contribute to the relative ease with which phenotypic sex can be altered in some species (7) and also may play a role in the hermaphroditism (i.e., both sexes develop in a single animal) exhibited by some aquaculture species (8,9). Although most aquaculture species show inheritance of sex in a straight-forward and predictable manner, the mechanisms by which the genes are expressed as a sexual phenotype are not completely understood.
