Depending on the outcome of the sex-determining process, each individual will begin the formation of either ova (oogenesis) or sperm (spermatogenesis) in the gonadal tissues. Despite the wide variation in reproductive strategies and modalities, the process by which gametes are produced is quite similar in a wide array of fish species—in fact, in all vertebrates (10). In both oogenesis and spermatogenesis there is an initial period of genial proliferation in which oogonia and spermatogonia proliferate by mitosis (cell division). This is the initial determinant of the number of gametes that can be produced. Both types of sex cells then go through a defined sequence of genetic and cell structure modifications that ultimately lead to functional oocytes in females and spermatozoa in males. For details in fish, see Refs. 11 and 12; for invertebrates see Ref. 13.

Although the basic processes for the development of mature ova and sperm are very similar, there are two points of divergence that are important to be aware of with respect to reproduction in aquaculture species. First is the timing of meiosis (division in sex cells to reduce chromosome numbers). In the female primary oocytes (oogonia that have become enveloped by somatic cells) begin meiotic division, but arrest during the first meiotic prophase (11). Meiosis is not begun again until the oocytes are ready to be ovulated, or released from the surrounding somatic cells. With invertebrates, meiotic division is not reinitiated until after activation by penetration of sperm. On the other hand, spermatocytes go through meiosis during development without being arrested and then go through final maturation stages. This sequence of events makes artificial manipulation of chromosome numbers possible in aquaculture species (14).

The second difference is the energetic requirements for achieving the final maturation of ova and sperm (15). Since most of the currently cultured species are oviparous (i.e., fertilization and early development occur externally) and the resulting embryo is, essentially, free living, it must be endowed with all the nutrients required for the completion

of its development (16). This is accomplished by packaging in the egg all the nutrients (primarily protein and lipid) needed for metabolism and tissue formation (17). These materials are synthesized and placed in the egg during the process of vitellogenesis, which occurs prior to ovulation. On the other hand, sperm does not contain the quantity of materials that ova do, and, consequently, the energetic "cost" for production is lower.

The effect of these requirements is that the management of reproduction with aquaculture species should commence with the husbandry of the adult animals that will produce the gametes to create the next generation. Research with fish has shown that ration size, feeding rates, nutritional status, and stress have an impact on the size of eggs, number of eggs produced per female, and quality of eggs produced (18). For example, rainbow trout females fed a low ration (0.4% of body weight per day) for the first four months of the annual reproductive cycle had lower fecundities and a lower percentage of fish-producing mature gametes than those fed a high ration (1.0% of body weight per day) (19). Husbandry conditions that may affect sperm production and quality have received less attention, but research has shown that sperm quality can be altered by feeding regime, quality of feed, and the rearing temperatures experienced by males (20). Consequently, appropriate culture conditions and management

procedures for adult fish used to produce the next generation are essential to the reliable production of seed for growout.

Exogenous (environmental) factors also play a major role in the control of gamete maturation, and release. Most aquaculture animals are seasonal breeders and changes in environmental factors (e.g., water temperature, water flow, or day length) provide the cues for initiation and adjustment of reproduction. The pathway by which this control is exercised in vertebrates is diagrammed in Figure 1. Environmental information received by the sensory system is interpreted internally by the brain. Based on the signals that are received, the hypothalamic region of the brain will secrete substances that activate the pituitary, a small organ at the base of the brain. The pituitary then releases hormones (gonadotropins) that are relayed to the gonadal tissue via the blood stream. This activates the processes of gamete recrudescence, maturation, and release in the gonads, which also produce hormones (steroids) that affect reproductive development. At various points in the pathway, both positive and negative feedback mechanisms can accelerate or halt the development of gonadal tissue (21). Consequently, this pathway is not a unidirectional, temporal flow, but has multiple inputs throughout the entire cycle that are coordinated by the stimuli received by the central nervous system (CNS). While the overall system of gamete
Figure 1. Diagram of the neuroendocrine axis, the pathway by which reproductive development is controlled in many vertebrate aquaculture species. Dashed lines indicate where feedback mechanisms operate to enhance or moderate development of gametes.

production, maturation, and release in invertebrates is conceptually similar to that outlined in Figure 1, there is little known about the specific controlling mechanisms or their methods of action.

There have been a number of procedures developed to utilize these inputs to manage reproduction in aquaculture operations (22). The most extensively employed procedures are manipulation of photoperiod (change in day length) and manipulation of temperature. For example, with rainbow trout, photoperiod alteration can advance or delay reproduction, depending on when during the reproductive cycle it is used and whether length of the day is increased or decreased (23). In fact, photoperiod control can be used to induce the normally annually spawning rainbow trout to mature again after only 6 months (24). Increases in water temperature are routinely used to induce and synchronize reproduction in molluscan shellfish species (25). Pacific oysters, for example, that have been conditioned by intensive feeding at high temperatures (20 °C) for a period of time can be induced to spawn by raising the water temperature from 20 °C to 28–30 °C (26). The use of environmental manipulation to change spawning time is particularly attractive for those species with very high fecundities (i.e., number of eggs per female), since only small numbers of broodstock need to be maintained under these artificial conditions.

In many circumstances, the physical environment is simply not appropriate to elicit the final stages of gamete maturation, release, and deposition. In these situations, intervention with hormone therapy can be used to overcome a missing control element. Furthermore, hormone treatment can be used to alter the natural time sequence of the events leading to final maturation and to synchronize final maturation of gametes. For example, with shrimp, the practice of eyestalk ablation is routinely employed to induce final maturation and can be considered an induced endogenous hormone manipulation (27). Other aquaculture species require exogenous treatment with hormones that are derived from fish and other animals (most commonly mammals) or are produced synthetically.

Initial work on the use of hormones to induce spawning concentrated on the pituitary gland and its hormonal products. In the 1930s, studies in Brazil laid (28) the foundation for this approach to spawing fish, and its practical application has revolutionized fish culture (22). Subsequent investigations have shown that some mammalian gonadotropins, as well as some steroids obtained from gonadal tissue, can be effectively used in fish (29–31). Recently, the synthesis and successful use of superactive analogs of gonadotropic hormones with fish has expanded the potential for use of hormone treatment in aquaculture species (29).

Hormone delivery is accomplished by adding it to the food or by injecting the material into either the muscle (i.m.) or the peritoneal cavity (i.p.). The major goal in these treatments is to introduce adequate amounts of material to increase the circulating hormone levels to a high enough concentration for an ample period of time to precipitate gamete maturation and ovulation or spermiation. If fed as a part of the diet, the hormone will be exposed to the digestive enzymes and hence must be resistant to

degradation so that the levels that eventually get to the blood stream are high enough to be effective. Drawbacks to injection include the limited capacity of the muscle to accommodate introduced material and the possible damage to internal organs when using the i.p. route. Also, both of these methods may necessitate repeated handling for multiple injections, which increases stress and possibly affects endogenous endocrine functions associated with gamete maturation or ovulation/spermiation. Recently, techniques for administrating drugs or hormones via implants have been developed, which are as effective, but less stressful on the fish (32–34).

It should be noted that management of reproduction through the use of hormones is almost entirely limited to influencing the terminal stages of gametogenesis. Thus, for the procedures to be effective, the broodstock must have progressed to a point where they are responsive to the treatment. Consequently, the treatment schedule and dose administered to adult fish must be carefully controlled for the treatment to be successful; many of these procedures are detailed in Donaldson and Hunter (29).

In some aquaculture species, hormone treatment can lead to spontaneous spawning (35). However, in others the stage of readiness to release the gametes is not so apparent and, furthermore, the removal of gametes prior to complete maturity can adversely affect quality, especially that of ova (36). Thus, with some species, it is desirable to periodically check the status of gamete development to ensure collection at the optimum stage. For the most part, sperm maturation has not been as problematic as that of eggs, and thus, analyses have emphasized evaluation of the status of maturation of the ovum. In some species, such as trout and salmon, gentle abdominal pressure can be used to expel a few eggs for analysis (37). In others, collecting egg samples may involve catheterization (38) or surgical removal of a sample of eggs (39). There are a variety of indicators for determinating the status of maturation of fish ova (22), but the most definitive assessment is by evaluating the position of the germinal vesicle (GV), or nucleus. When maturation is complete, the GV migrates from the center of the ovum to the periphery and the nuclear membrane disintegrates, a process know as germinal vesicle breakdown (GVBD).

In many aquaculture operations, spawning and fertilization take place under seminatural conditions in the water column, and the fertilized eggs or young animals are collected subsequently (40–42). This minimizes handling and stress on the broodstock and ensures, as much as possible, that the culminating environmental cues before spawning (e.g., courtship and substrate conditions) lead to successful reproduction. However, the approach is not always suitable, and it may be desirable to have more control over the process of fertilization by manually removing the gametes.

Where seminatural spawning is not possible or desirable, the eggs and sperm can frequently be collected from the female and male animals, respectively, by manual stripping (37) or surgical removal (39), and fertilization is conducted outside of the water column in containers. Fish ova are usually stripped into a dry container, avoiding contamination with water until the milt (sperm + seminal

fluid) has been added and mixed with the eggs. The change in ionic concentration resulting from the addition of water initiates rapid changes in the gametes (36,43), including activation of the sperm to penetrate the egg and start the process of fertilization.

Fertilization with most aquaculture species involves, essentially, two steps: A sperm enters the egg, either through a small hole in the egg (termed a micropyle) or via enzymatic action at a specific site on the surface of the egg (44). Then, this step activates the egg and initiates the final stages of meiosis to reduce the chromosome number to a haploid (1N) number. Subsequent to the completion of meiosis, the egg and sperm pronuclei join to form a diploid nucleus in the embryo and the process of embryonic development commences (16).

There are numerous factors that can affect the success of artificial fertilization. Premature addition of water can cause rapid changes in the gametes, including closing of the micropyle due to water absorption by ova (45) and premature activation of very short-lived sperm (46). Fertilization with species that have adhesive eggs presents another set of problems with respect to fertilization. These have been addressed by the use of physical coatings with organic or inorganic materials (39,47), treatment with chemicals (48), or the use of enzymes (49) to eliminate adhesiveness prior to, or during, fertilization. The amount of sperm per egg used can also have an impact of fertilization. The concentration of sperm in fish milt can range from 2×10^6 to 5.3×10^{10} cells per ml (50). Under normal circumstances, the minimal sperm: egg ratios for successful fertilization are about $3-6 \times 10^5 : 1$ (49). Problems can obviously arise when there are too few active sperm in situations where males are either not fully matured or have been excessively used (52) or where cyropreserved sperm are employed (53). In fact it has been recommended that the ratio of sperm:egg be increased 5- to 10-fold to ensure adequate fertilization rates with cryopreserved sperm (53). On the other hand, polyspermy (entry of multiple sperm) can be a problem in some species and this can be minimized by diluting the sperm (46). Saline solutions have been developed for this purpose and for extending sperm activity (54,55).

Control of reproduction in aquacultured species has led to two major improvements in management of seed production. First, aquaculturists can obtain specific information about the production potential of their operation through measurement of gamete yield, rates of fertilization and hatching, and survival during early life-history stages. Egg production in aquaculture species is generally high compared with other vertebrates (16,56), but fecundity varies with reproductive strategy. Enumeration of egg numbers can be accomplished by a variety of methods (45). Fertilization rate can be most accurately evaluated after gastrulation, since developmental mortality associated with gamete quality is highest during cleavage stages (16). Subsequent survival can be managed and enumerated in a well-designed incubation system in which appropriate environmental conditions are maintained (45). Use of these data provide the information for allocation of incubation, rearing, and growout facilities, and for accurate prediction of production potential.

The second improvement in management is the opportunity to genetically improve or domesticate desirable stocks. Controlled breeding is central to genetic selection for the improvement of stock, and artificial fertilization allows specific crossing schemes to be defined that will meet the needs of selection. Controlling fertilization makes possible a broad repertoire of methods by which gametes can be combined to meet the preferences, desirable specifications, or particular demands of aquaculture.

Whether in nature or in captivity, selection of animals with desirable traits and their subsequent propagation are integral parts of the "creation" of an organism. In natural situations, selection acts through the influence of the environment on the survival and reproduction of particular sets of traits (phenotypes). Not all phenotypes are equally fit to compete in a particular environment, and those phenotypes defined by genotypes (genetic composition) with low survival potential will be eliminated from the population (57). This process of natural selection is how a population of organisms becomes adapted to the environment in which it must exist. Organisms grown for food production are also subjected to artificial selection, which refers to a set of rules designed by humans to govern the probability that an individual survives and reproduces (58). Judicious selection of breeding stock combined with mating practices that maximize the probability of combining the most beneficial traits in the offspring comprise the process of selective breeding.

The major difficulty with selective breeding as just outlined is that it is based on the phenotypes of organisms, which result from both the expression of the genes in the organisms and the environmental influences on the traits. This can be briefly expressed by

$$\text{Phenotype} = \text{Genotype} + \text{Environment}$$

or

$$P = G + E$$

By way of exemplifying this concept, we can use a trait such as size at harvest measured as either weight (e.g., grams/fish) or length (e.g., cm/fish). The magnitude of such a measurement can be affected by the genes the animals contain (i.e., the genotype) and many other factors such as water temperature, quantity and quality of food, incidence of diseases, stress, water quality, etc. (i.e., environmental factors). Without the appropriate analyses, it is not possible to determine how much of the phenotype expressed in breeding animals is based on genetic differences that will be transmitted to future generations, or on environmental factors that may be rather transient and are not transmissible to the offspring of the breeders. Thus, to ensure that selective breeding is based on the genetic variation in the population and not on transient environmental factors, the relative influence of the genotype on the phenotype must be estimated.

The field of quantitative genetics has developed to provide these types of analyses and to predict the outcome of various selection and breeding approaches. Information on the techniques and methodology required to obtain genetic estimates for traits can be found in a number of publications (57,59,60). One of the most useful values

that can be derived from these analyses is the heritability (designated h^2) for a trait. Heritability is broadly defined as the fraction of the total variability that is due to genetic differences; for example, $h^2 = 0.25$ means that 25% of the total observable variability in a particular trait is due to genetic differences.

Heritability can be used to develop a second concept important to selective breeding, estimation of the response of organisms to selection. The relationship between the selection of breeders and the response of their offspring is

$$R = h^2 S$$

where R = response, h^2 = heritability, and S = selection differential. Thus, by calculation of the selection differential (i.e., the difference between the mean value for a trait in the selected breeders and the mean value for the same trait in the source population) and the heritability of a trait, an animal breeder can estimate the gain/loss anticipated for that trait in the next generation. Expectations for the use of these values are diagrammatically shown in Figure 2.

While there are some crucial assumptions made in this diagram, several inferences can be derived about the components of this relationship and about the expectations from conducting a selection program. First, if a trait does not have some level of genetic determination, no response will be exhibited in the offspring. Next, the magnitude of change due to selection is a product of the
selection differential applied and the amount of genetic variability. Thus, to some degree, a low amount of genetic variability can be compensated for by an increased selection differential. Finally, this relationship points out one of the values of planned selective breeding, the ability to predict results in future generations.

The process of selective breeding for broodstock improvement for aquaculture is, basically, a two-step process. First, a prediction is made about the breeding value of the individuals that are to be used to reproduce the next generation. That is, the "worth" (i.e., breeding value) of an animal is estimated on the basis of a set of criteria that define the animal likely to produce offspring with desirable traits (e.g., rapid growth and good body conformation). Through the use of quantitative genetic analyses, statistical estimates can be utilized to provide more informed assessments of breeding values. After these estimates are obtained, the active, or second part of the process can begin; that is, breeding animals are chosen, crosses are made, and offspring are retained or discarded. There are many combinations of selection and breeding approaches that can be utilized (57), but the maximum response will be obtained only by giving strong consideration to the genetic information prior to making the selection and breeding decisions.

The next question that should be asked about selective breeding is "What is the suitability of aquacultural species with respect to such genetic manipulation?" One of the most important factors in the realization of genetic improvement is the amount of phenotypic variability in aquacultured species, and analyses have shown that these species have large quantities of variation relative to other species (61,62). While this may not directly equate to larger amounts of strictly genetic variability (62), research results indicate that "satisfactory" amounts are present to allow reasonable advancement in most traits. A summary of the h^2 estimates for a number of traits in aquaculture species can be found in Tave (63).

In addition to this, most aquaculture species exhibit two other biological characteristics that make their potential responsiveness to selective breeding programs more certain. First, a major proportion of the species used in aquaculture produce large numbers of offspring from a single cross (generally, in excess of 1,000). With such high rates of reproduction, a high selection intensity can be applied, which can, potentially, increase the magnitude of the response that can be achieved (57). Second, the oviparous reproductive nature of most aquaculture species allow the use of a wider range of breeding designs than can be utilized with many agricultural animals. Combining these characteristics with the large amount of variability exhibited by aquacultural species suggest that the potential for improvement via selective breeding is very good.

Although relatively few species have been subjected to a selective breeding program and the traits that have been investigated are relatively limited (64), the results of programs that have been conducted indicate that responses to selection can lead to major improvements in their performance (65–68). In most of these programs, the selection responses exceeded overall responses in similar

Figure 2. Schematic representation of the relationship between selection differential (S) and selection response (R) in a selection program for increasing a normally distributed trait.

traits reported for agricultural animals, although the programs with aquacultural species are still relatively short term.

Rather surprisingly, the promising results to date have not led to a major emphasis on selective breeding in the industry. There are several explanations for this (62), but increasing competitiveness in the future will require that adequate quantities of more efficient selectively bred stocks be available for production. This will undoubtedly be facilitated by modern molecular methods and genetic engineering (69,70). However, these approaches will not transcend the need for selective breeding in the production of improved stock for aquaculture. They will provide complementary techniques for changing the genome of aquaculture species in beneficial way, in much the same way that artificial fertilization provides a very necessary complement to selective breeding.

S

SALINITY

WADE O. WATANABE
The University of North Carolina at Wilmington
Wilmington, North Carolina

OUTLINE

Salinity has been traditionally defined as the number of grams of all solid material, including both the inorganic ions (e.g., sodium and chloride, organic phosphorus and nitrogen) and organic compounds (e.g., vitamins and plant pigments) dissolved in 1 kg (2.2 lb) of seawater with all the carbonate converted to oxide, bromine and iodine replaced by chlorine, and the organic matter completely oxidized (1). The symbol for salinity is S and is measured in parts per thousand (ppt). The salinity of freshwater is less than 0.5 ppt, while the open ocean averages about 35 ppt and ranges from 33 to 37 ppt. Salinity can vary widely in bays and estuaries, which are affected by tidal flow, freshwater runoff, and evaporation. Aquatic organisms are adapted to survive and to grow best under salinities that characterize their natural habitats. Depending on species, effective salinity ranges for reproduction and growth may be narrow or broad, can vary with life stage, and may be modified by other environmental factors, particularly temperature. Knowledge of the combined effects of salinity and temperature on survival, growth, and reproduction of an organism allows the aquaculturist to develop environmental management strategies for optimizing hatchery production of seedstock and for growout to marketable sizes.

MEASURING SALINITY

Since salinity is difficult to measure by direct chemical methods, it has been expressed in terms of chlorinity (Cl o/oo), which is defined as the total number of grams of chlorine, bromine, and iodine contained in 1 kg (2.2 lb) of seawater, assuming that bromine and iodine have been replaced by chlorine (2). The relationship between these variables is as follows: Salinity = 0.30 + 1.805 × chlorinity. To determine chlorinity, a sample of seawater is titrated with silver nitrate in the presence of an indicator (1). The halides precipitate out, and the amount of silver nitrate can be converted into equivalent amounts of chlorinity.

Chlorinity, however, is seldom measured by aquaculturists who prefer simpler, less time-consuming methods of determining salinity. These include measurements of density, conductivity, and refractive index, each of which can be converted into salinity. The least expensive method of measuring salinity involves use of a glass hydrometer to determine a water sample's density, which can be converted to salinity by using tables that correct for sample temperature. Glass hydrometers also provide a high level of accuracy (±0.1 ppt). Mechanical hydrometers are now available that permit direct reading in ppt and do not require temperature corrections. While less accurate (±1.5 ppt), they are inexpensive and useful for spot checking. Conductivity meters are relatively expensive and can be used to measure salinity with a high degree of accuracy (±0.1 ppt) and are therefore used mainly by researchers. They measure electrical conductivity through leads in a probe, which often break with repeated use. The simplest and most rapid means of measuring salinity is refractometry, which measures the refractive index of light passing through a sample solution. Handheld refractometers are moderately priced, compact, durable, require only a drop of sample, are temperature compensated, read directly in ppt, and provide a level of accuracy (±0.5 ppt) suitable for most aquaculture applications.

OSMOREGULATION

Osmoregulation is the maintenance of a relatively constant internal salt concentration against external salinities that are higher, lower, or fluctuating. Internal salt concentration is generally expressed as osmotic concentration, which depends on the number of undissociated molecules and ions per unit volume or weight of solvent. For example, one gram molecule (mole) per liter [0.25 g/L/(=2.2 lb)] (kg) of water of a substance (e.g., glucose) that does not dissociate has an osmolality of 1 osmole per kg (Osm/kg) or 1,000 mosmoles per kg (mOsm/kg) (3). On the other hand, one mole of sodium chloride per kg of water has an osmolality close to 2 Osm/kg, because this compound dissociates nearly completely in solution. Freshwater has a salinity of 0 g/L and an osmolality of 0 mOsm/kg. Seawater, with a salinity of 34 g/L, has an osmolality of 1,000 mOsm/kg.

Fish, in general, do not have an internal salt concentration that closely match the water in which they swim. In freshwater fish, internal salt concentration tends to be in the range of 8.5 to 10.4 ppt (248–305 mOsm/kg), which is hypertonic to (higher than) the surrounding

medium (0 ppt) (3). Fish living in marine waters maintain internal salt concentrations in the range of 12–15 ppt (352–440 mOsm/kg), which is hypotonic to (lower than) the external medium (33–37 ppt). Fish living under estuarine conditions are exposed to variable external salt concentrations, but tend to osmoregulate at around 9–15 ppt (263–440 mOsm/kg). Most marine invertebrates have internal salt concentrations nearly isotonic to (the same as) the surrounding water (4,5). Estuarine crustaceans, such as the juvenile stages of some penaeid shrimp species, are good osmoregulators and can maintain internal salt concentrations around 18–30 ppt (540–870 mOsm/kg) (6–8).

Through a process called osmosis, water moves through a semipermeable membrane, such as the gill epithelium of a fish, from the region of lower salt concentration to that of higher concentration until the salt concentration on both sides of the membrane is the same. Hence, freshwater fishes, which are hypertonic to their surrounding medium, continually gain water from the environment and lose salts in the urine and through diffusion at the gills. Freshwater fish must therefore eliminate excess water from their tissues and replace salts. This osmoregulatory problem is solved by having surface membranes of reduced permeability to inhibit water entry and kidneys that produce copious amounts of very dilute urine. Freshwater fish depend upon the salt intake in their food and active uptake through specialized "chloride cells" in the gills.

In contrast, marine fishes, which are hypotonic to the surrounding medium, continually lose water to the surrounding sea and gain salts by diffusion. To replace lost fluids, these fish must drink large quantities of seawater and then eliminate the excess salt. Kidneys of marine fish produce small volumes of urine containing relatively high concentrations of salt so that the urine is nearly isotonic (i.e., the same concentration) or slightly hypertonic to blood. The gills of marine fish also actively excrete ions that are absorbed.

SALINITY TOLERANCE

Fish are categorized according to their tolerance salinity. Those that tolerate a wide range of salinity at some phase in their life cycle are called euryhaline species. Anadromous euryhaline species commence life in freshwater, migrate to the sea as juveniles, but return to freshwater for breeding. Cultured anadromous species include Atlantic salmon *Salmo salar*, Pacific salmon, *Oncorhynchus* spp., striped bass, *Morone saxatilis*, and the white sturgeon, *Acipenser transmontanus*. Euryhaline marine fish species include red drum, *Sciaenops ocellatus* (9), which is grown in the United States and striped mullet, *Mugil cephalus*, (10) and milkfish, *Chanos chanos*, (11) which are grown in Asia and the Pacific. All are cultured in ponds over a broad range of salinity. The Asian sea bass, *Lates calcarifer*, is a highly euryhaline species that requires saline water (28–32 ppt) for spawning, but lives in brackishwater estuaries and in freshwaters (12). A remarkable euryhaline freshwater fish species is the mossambique tilapia, *Oreochromis mossambicus*, which grows faster in brackish

water and seawater than in freshwater (13–15) and is able to adapt to salinities as high as 120 ppt (16).

Euryhaline invertebrate species of aquaculture interest include the American oyster, *Crassostrea virginica*, which can adapt to a salinity range of 3 to 35 ppt (17), although growth and flavor are adversely affected at low salinities. The hardshell clam, *Mercenaria mercenaria*, has an optimal salinity range of 25 to 35 ppt, with salinities above 38 ppt or below 20 ppt producing reduced growth (18). Most cultured penaeid shrimp are euryhaline, although salinity tolerance varies from species to species. *Litopenaeus japonicus*, grown in Japan and Taiwan, has a broad salinity tolerance range of 10–55, but cannot tolerate low salinities and is recommended for culture within a range of 30 to 40 ppt (19,20). The tiger shrimp, *L. monodon*, grown in Asia, can tolerate 0.2 to 40 ppt, with optimal growth between 10 and 25 ppt (12). *L. vannamei*, which can withstand salinities ranging from 0 to 50 ppt, is the species of preference for pond farming in the western hemisphere, including Central and South America, where very low salinities are characteristic of the annual rainy season (12).

Fish that can tolerate only a narrow range of salinity are known as stenohaline species. Marine fish species such as gilthead sea bream, *Sparus aurata*, and sea bass, *Dicentrarchus labrax*, grown in Europe and the Middle East, and the red sea bream, *Chrysophrys major*, and yellowtail, *Seriola quinqueradiata*, grown in Japan, are considered stenohaline (2). Other stenohaline marine fish species of culture interest include the dolphinfish or mahimahi, *Coryphaena hippurus* (21), Atlantic halibut, *Hippoglossus hippoglossus*, and Pacific halibut, *H. stenolepis*, (22,23). While it is assumed that stenohaline marine species are unable to tolerate salinities much lower than full strength seawater, experimental data on lower lethal salinity tolerance limits and effective ranges of salinity for growth are lacking for most species.

Cultured stenohaline freshwater fish include common carp, *Cyprinus carpio*, grass carp, *Ctenopharyngodon idella*, silver carp, *Hypopthalmichthys molitrix*, and channel catfish, *Ictalurus punctatus*. These species have upper salinity tolerance limits of approximately 15 ppt (24), 14 ppt (25,26), 10 ppt (27,28), and 14 ppt (29–31), respectively.

THE EFFECT OF SALINITY ON REPRODUCTION

Aside from anadromous species, salinity exerts marked effects on the reproductive performance of many cultured species. For example, some euryhaline marine finfish, such as red drum, striped mullet, and milkfish, may be grown under brackishwater conditions, but require high salinities for reproduction. This is evidenced by annual migrations from estuarine to offshore waters for spawning. Hatchery installations for such species must be located near the sea or use synthetic seawater. For euryhaline freshwater species, choice of salinity for hatchery operation can have a significant effect on the economics of fry production when freshwater resources are in scarce supply. For example, in the euryhaline tilapia, *O. mossambicus*, fry production was three times higher at

salinities of 8.9–15.2 ppt than in freshwater (32). Hence, production of fry in brackishwater can reduce freshwater requirements for maintaining broodstock and for early rearing of fry (32–35).

In some cultured freshwater crustaceans, brackishwater is essential for reproduction. The freshwater shrimp, *Macrobrachium rosenbergii*, migrates from freshwater to estuarine areas to spawn and requires about 12 ppt salinity for proper larval development. The larvae move upstream into fresh water as they grow. Hence, hatchery protocols for this species must provide brackishwater rearing facilities for broodstock and for early rearing of larvae. In penaeid shrimp culture, the need for high salinity water for hatchery operation may also require that hatchery installations be located near the sea, rather than in the brackishwater areas where the growout ponds may be located (12).

ONTOGENETIC VARIATION IN SALINITY TOLERANCE

Smoltification is a physiological process by which anadromous salmonids adapt from fresh to saltwater (36). As transformation from dark fingerling to silvery smolt occurs, the fish become increasingly tolerant of salt water and will, in nature, begin their migration to sea. The ability to survive in seawater and hypoosmoregulatory ability, or the ability to regulate internal salt concentrations below those of the external medium, develop during the early freshwater phase of the life cycle, and preadapt them to subsequent seawater existence (36–38). These ontogenetic changes in salinity tolerance are known to be closely related to size, which is therefore an important criterion for determining the optimum time for release of hatchery-reared juveniles or for their transfer to seawater pens (39). Failure to attain a critical size before transfer results in mortality and stunting in seawater.

Ontogenetic alteration in salinity tolerance may be a general phenomenon among teleosts, including both steno- and euryhaline freshwater and marine species. Upper salinity tolerance in the stenohaline freshwater catfish, *I. punctatus*, increased from 8 ppt at hatching to 12.5 ppt at 6 months (40). Osmoregulatory capabilities in the euryhaline marine mullet, *M. cephalus*, improved with growth and reached a definitive state in juveniles at 7.5–8.5 months of age (41). In a number of freshwater euryhaline tilapias, *O. mossambicus*, *O. niloticus*, *O. aureus*, hybrid *O. mossambicus × O. niloticus*, and red hybrid tilapia, age (or size) at time of seawater transfer influences survival, with newly hatched fry being less tolerant than older individuals (42–45). Premature acclimation to seawater impairs survival in these fish and selection of proper transfer time, based on knowledge of ontogenetic variation in salinity tolerance, improves survival.

Improved salinity tolerance with age in fish is related to maturation events, such as a decreasing body-surface-to-volume relationship, with growth that reduces osmotic stress (46), ontogenetic changes from juvenile to adult hemoglobins, which are adaptive to more saline environments (47,48); and functional development of the hypoosmoregulatory system, including the salt-secreting

chloride cells of the gills (49,50) and the endocrine system (51).

ACCLIMATION TO SEAWATER: OPTIMUM RATE

While euryhaline species are generally unable to tolerate abrupt transfer from low to high salinity, gradual acclimation can assure very high survival. For example, whereas none of the commercially important tilapia species tolerate direct transfer from freshwater (0–2 ppt) to full-strength seawater (≥32 ppt) (42–44,52), a gradual, step-wise increase in salinity until full-strength seawater is reached has been successfully used to acclimate a number species. Required acclimation periods range from 4 days (2 days at 18 ppt, 2 days at 27 ppt) *O. aureus*, *O. mossambicus*, and *O. spilurus* to 8 days (4 days at 18 ppt, 4 days at 27 ppt) for *O. niloticus* and *O. niloticus × O. aureus* hybrids, depending on the degree of euryhalinity (57).

Salinity acclimation allows physiological changes to take place that enable the fish to regulate internal osmotic concentrations within permissible limits under changing external osmotic conditions. Following direct transfer of *O. mossambicus* from freshwater to 30 ppt seawater, a rapid elevation of plasma osmotic concentration to excessive levels occurs within 1 h (osmotic shock) leading to death within 6 h (53). On the other hand, transfer to a lower, sublethal salinity allows osmoregulatory mechanisms to adapt to, and gradually reduce, the rising plasma osmotic concentration to a new equilibrium level within 44–96 h (52,54). This seawater adaptation process (55) involves the functional activation of the salt-secreting chloride cells of the gills (56–58) and elevates Na-K ATPase (59), which enables subsequent transfer to higher salinities. For *O. mossambicus*, activation of chloride cells occurs within 12 to 24 h after acclimation to 20 ppt seawater (53,58). Seawater adaptation can be simplified through single-step acclimation, where pre-acclimation at one intermediate salinity (e.g., 12 ppt for 48 h or 20 ppt for 24 h) preceeds direct transfer to 36 ppt seawater (58,60). While not as effective as gradual salinity adaptation, pre-transfer feeding of a high salt diet (7–10% NaCl) in freshwater has been shown to stimulate the seawater adaptation process in *O. mossambicus*, *O. spilurus* and *O. aureus × O. niloticus* hybrids (61) and in chinook salmon, *Oncorhynchus tshawytscha* (62). Starvation reduces Na, K-ATPase activity and survival during seawater acclimation (14).

ACCLIMATION TO SEAWATER: THE INFLUENCE OF SALINITY EXPOSURE DURING EARLY DEVELOPMENT

Early salinity exposure through spawning and hatching under elevated salinities enhances salinity tolerance of young tilapia fry and may facilitate acclimation to seawater (63). In *O. niloticus*, 96-hour median lethal salinity increased from 19.2 ppt for broods spawned in freshwater to less than 32 ppt for broods spawned at 15 ppt (63). In red hybrid tilapia, fish spawned and reared through early ontogenetic development at 18 ppt had better growth and feed conversion at 18 ppt and

36 ppt than those spawned in 4 ppt (64). Formation of the perivitelline fluid after fertilization (65) modifies the environment in which the embryo develops and may induce adjustments that persist through later development, an irreversible "nongenetic adaptation" (66) to environmental salinity.

EFFECTS OF SALINITY ON GROWTH

Because osmoregulation is a metabolic process requiring active transport of ions to maintain internal salt concentration, the more salt the body of an aquatic animal must take in or excrete, the more energy is required and growth is restricted. Stenohaline freshwater and marine fish species have become physiologically adapted to salinities different from their internal salt concentrations. These species will generally show optimal growth in water with salinities similar to those in which the fish occur in nature. Euryhaline species may grow well over a broad range of salinity (2).

In euryhaline tilapia, growth response to salinity may be quite variable among species and related to degree of euryhalinity. Some species (e.g., *O. niloticus* and *O. aureus*) may be acclimated to full strength seawater, but growth is impaired under these conditions (35). In other species (*O. mossambicus* (13–15), *O. mossambicus* × *O. hornorum* hybrid (67), *O. spilurus* (68), and red hybrid tilapia (69)), growth is higher in brackish and seawater than in freshwater, indicating an advantage of farming these tilapias in brackish- or seawater (35,70). In red hybrid tilapia, this was attributed to increased food consumption (appetite) and declining feed conversion ratios with increasing salinity.

The effects of salinity on growth in fish are related not only to total concentration of dissolved solids (i.e., salinity per se), but are also influenced by the concentrations of divalent ions (Ca^{2+} and Mg^{2+}) due to their effects on membrane permeability and osmoregulation (71,72). High concentrations of environmental calcium help reduce salt loss through the gills and body surfaces in freshwater environments, so less demand is placed on the kidneys to maintain stable concentrations of blood salts, allowing survival of some marine species in freshwater. While red drum eggs and larvae appear to require salinities above 25 ppt, juveniles can be reared in freshwater if hardness is at least 100 mg/L (9,71,73).

Food can be an important source of salt for some euryhaline fish. In the euryhaline marine red drum, *S. ocellatus*, growth limitation related to salt deficiency in hypotonic media can be overcome by adding salt (e.g., NaCl) to the diet (74). In Atlantic salmon, *S. salar*, smolts, however, dietary salt supplementation had negligible effects on growth and feed efficiency of fish reared in freshwater (75).

Relative growth at different salinities may not necessarily reflect the cost of osmoregulation at these salinities, depending on the magnitude of nonosmoregulatory effects on metabolism. In *O. mossambicus* × *O. urolepis hornorum* hybrids, salinity-related differences in total metabolic rates could not be solely attributed to changes in osmoregulation costs, indicating that other nonosmoregulatory (e.g., behavioral) factors must also affect metabolic rate (76). Territorial aggression can modify growth response to salinity (77,78) in tilapias. The variability in reported salinity-growth responses in fish suggest that uniformity of physiological state is often lacking (79).

TEMPERATURE INTERACTION WITH SALINITY

Temperature tolerance and optima for growth in fish may be modified by salinity (66,80–84) due to their interactive effects on osmoregulation (81,85). In red hybrid tilapia, feed consumption and growth at 0 ppt reached a maximum at 27 °C (80 °F), while at 18 and 36 ppt, consumption and growth were highest at 32 °C (90 °F) (87). This suggested that in freshwater, heating water to temperatures above 27 °C (80 °F) would not be justifiable, whereas in brackish- and seawater, heating water to 32 °C (90 °F) can increase growth rates.

In *Marsupenaeus japonicus*, lower salinity tolerance was 5.4 ppt at 25 °C (77 °F), but only 19.3 ppt at 10 °C (50 °F). Under low temperatures, lowest mortalities occurred when the salinity of the water was isosmotic with the hemolymph of shrimp (88).

OVERWINTERING

Cold tolerance in some species is influenced by the salinity. For example, in red hybrid tilapia, maximum growth efficiency under rearing temperatures of 22, 28, and 32 °C (72, 82, and 90 °F) was higher at 18 ppt than at 0 or 36 ppt, although these differences were pronounced at 22 °C (72 °F) (87). This suggested an advantage of brackishwater rearing to improve growth efficiency of this red hybrid tilapia strain under suboptimum temperatures. Studies with a number of tilapia species, including *O. aureus*, *Sarotherodon melanotheron*, *O. mossambicus*, and red hybrid tilapias, show that fish have better cold tolerance when maintained in low-salinity brackishwater (5–12 ppt) than in freshwater or full-strength seawater (85,89–91), presumably because osmoregulatory stress is minimized at near isosmotic salinities. Hence, osmoregulatory failure is prevented at temperatures that would be lethal in hypo- or hyperosmotic media (91). In red drum, cold tolerance is also improved by rearing the fish in water of 5 to 10 ppt salinity (14).

SALINITY FOR DISEASE CONTROL

Salinity can often be used as a form of disease control when the salinity tolerance limits of the cultured fish exceed those of its parasite. For example, in the channel catfish, *I. punctatus*, the freshwater parasitic dinoflagellate *Ichthyophthirius multifiliis* can be controlled in water containing 2 ppt salt (92). Euryhaline freshwater tilapias cultured in full-strength seawater are susceptible to infection by the marine monogenetic trematode *Neobenedenia melleni*. While seawater-cultured tilapias tolerate a reduction in salinity to 15 ppt, the ectoparasite is unable to survive these hyposaline conditions for more

than 5 days, which makes this an effective therapeutic procedure (93,94).

CONTROL OF SALINITY IN AQUACULTURE SYSTEMS

Marine and brackishwater cage or net-pen aquaculture operations in embayments and estuaries encounter unstable salinities that may vary well below full-strength seawater due to freshwater runoff. The use of euryhaline species that can tolerate such changes may be important in some locations, since control of salinity is generally difficult under these conditions. While still in the early stages of research and commercial development, open-ocean mariculture, which reduces competition for space and water resources in the coastal zone, is becoming an increasingly attractive alternative. Stenohaline marine species would be grown in such systems were salinities are stable year round.

Land-based brackishwater and marine aquaculture systems, primarily for culture of fish and shrimp, have traditionally employed earthen ponds supplied by tidal flow. Alternatively, water may be pumped to ponds or tanks from a near shore location. A growing awareness of the need to conserve land and water resources, to preserve the environment, and to decrease reliance on natural water resources that may vary in quality, will require that aquaculture rely increasingly on recirculation systems or fish production systems that reuse water by removing wastes from the water and providing oxygen to the fish (95). Such systems utilize only a fraction of the water required by traditional fish production techniques and provide for the potential of a higher degree of control of the environment of the fish being grown, including salinity. In such systems, water of required salinities may be prepared from freshwater and artificial sea salts. Since there is little net loss of salt associated with the removal of wastes, required salinities are maintained by diluting with freshwater to replace water lost through evaporation. Net consumption of both water and salts are thereby minimized. Such systems can potentially allow marine fish farms to operate inland to avoid high-priced coastal land and may reduce the environmental impacts of waste disposal.

Salmon farming has grown from research/demonstration projects to a global industry over the past 25 years. In fact, farmed fish production now exceeds salmon production from capture fisheries (Fig. 1). In the marketplace, farmed salmon account for approximately 70% of all salmon and over 90% of fresh salmon served in restaurants or purchased for home consumption (Fig. 2). Salmon farming is a significant enterprise in Norway, Chile, Scotland, Canada, the Faroe Islands, Iceland, Tasmania, Ireland,
Figure 2. Percentage of salmon species produced from farming or from capture fisheries, 1998.

Table 1. Global Production and Value of Farmed Salmonids in 1998 (Preliminary Estimate, Scottish Salmon Board)

Salmonid Species	Annual Production (mt)
Atlantic salmon	639,200
Salmon trout[a]	87,900
Coho salmon	66,090
Chinook salmon	16,000

[a]Rainbow trout raised in sea cages.

and a number of other countries (Table 1). The total value of farmed salmon is over US$2.2 billion. Atlantic salmon (*Salmo salar*) is the most widely farmed salmon species with global production exceeding 640,000 mt in 1998. Chinook salmon (*Oncorhynchus tshawytscha*) and coho salmon (*O. kisutch*) are the other species of farmed salmon and are produced mainly in Chile (coho) and Canada (chinook).

The first commercial salmon farms were started in Scotland and Norway in the late 1960s and in Washington state (USA) in the early 1970s (1,2). In Washington state, early farms produced "pan-sized" coho salmon from marine net-pens, while in Scotland and Norway, larger (2–3 kg; 4.4–6.6 lb) Atlantic salmon were produced. Production levels were modest, and the combination of losses to disease, slow growth due to lack of appropriate feeds, poor site selection, and high costs of production limited expansion of salmon farming for a decade. Technical advances made in the areas of feed formulation and production, stock selection, vaccines, sex reversal in the case of chinook, and general husbandry practices resulted in rapid expansion of salmon farming and lower costs of production in the 1980s (3).

In Norway, individual farms were limited in size, in part to encourage individual rather than corporate ownership of farms; and this policy encouraged Norwegian farmers to

Figure 1. Salmon production from farming and capture fisheries, 1998.

Table 2. 1998 Production of Atlantic Salmon by Country (Preliminary Estimate From Scottish Salmon Board)

Country	1997 Production (mt)
Norway	327,600
UK	105,000
Chile	107,000
Canada	63,000
Faroes	30,000
Ireland	13,650
Tasmania	10,000
USA	4,600
Iceland	6,180
Spain	1,900
France	1,000
Sweden	600

expand production elsewhere, notably Canada and Chile. Backed by generous government support of research and guarantees on investment loans, Norwegians invested heavily in overseas salmon farming, bringing with them equipment and husbandry techniques that soon dominated the salmon farming industry.

The Chilean salmon farming industry was started by Chilean entrepreneurs in the latter half of the 1980s. Being in the southern hemisphere, Chileans were positioned to supply fresh Pacific salmon to North American markets during winter and early spring, six months out of phase with North American wild harvests.

In North America and Chile, Pacific salmon farming was soon supplemented with Atlantic salmon farming as Scottish and Norwegian investments were made and technology was introduced. At present, Atlantic salmon production leads that of Pacific salmon (Table 2). Atlantic salmon have the advantage of being somewhat less susceptible to early male maturation in a portion of a given year and class than Pacific salmon, increasing the proportion of high-quality fish that can be harvested. Unlike farmed coho salmon, which must be harvested before they mature as two-year-old fish, Atlantic salmon mature first as three-year-old fish, giving farmers an additional year of rearing. In addition, production of out-of-season smolts for stocking farms has made it possible to supply markets with Atlantic salmon more or less year-round.

CURRENT FARMING PRACTICES

Briefly, salmon farming is divided into two segments: the freshwater segment during which first-feeding fry (<0.5 g; 0.02-oz) are reared to the smolt stage and the sea cage-rearing segment, during which the fish are reared from the smolt stage (ca. 50–80 g; 1.7–2.7 oz) to harvest (3–6 kg; 6.6–13.2 lb). In nature, coho and Atlantic salmon typically migrate to the sea in their second year of freshwater life, while chinook salmon migrate in their first year (ocean type) or second year (stream type), depending upon the stock. Ten years ago only a small proportion of Atlantic salmon could be brought to smoltification in one year (the so-called S1 or one-summer smolts). Now, as a result of improved husbandry and feeds, and selection for S1 smolts

(S2s are normally culled), most farms produce a high proportion of S1 smolts. In addition, a proportion of the most rapidly growing fish are available for even earlier out-of-season transfer to seawater through photoperiod manipulation of smolting time. For reasons of economy, in areas where complete winter freezing of freshwater does not occur, fingerling salmon are placed in freshwater cages after the first-feeding stage. This is extremely cost effective in capital terms, but is coming under increasing pressure because of its eutrophication effect on the highly oligotrophic waters being used. As a result, tighter controls on phosphorus discharge from farms are being applied by environmental protection agencies. Thus, great pressures have developed for smolt cage farms to reduce stocking levels and thereby reduce discharges. This is forcing feed manufacturers to provide low-phosphorus feeds and will probably lead to almost all smolts ultimately being produced from flow-through or recirculation tank systems. The same improvements that have shortened the period of freshwater rearing for Atlantic salmon have had the same effect on Pacific salmon. Most smolts are stocked into sea cages in their first year of life.

Salmon growout to harvest is conducted in marine cages. A decade ago, the growout period in sea cages required at least two years; today fish often reach harvest size in 10–15 months after transfer to sea cages. Many factors have contributed to this improvement, including changes in feed formulation, feed pelleting technology, the introduction of effective vaccines, and the selection and domestication of farmed salmon stocks. The use of larger cages has also improved the growth rates of salmon, as has better site selection (higher water flow rates, deeper water).

NUTRITIONAL REQUIREMENTS

A great deal of research has been conducted on the nutritional requirements of Pacific salmon, but nearly all has focussed on studies with fry and juveniles in freshwater (4). In contrast to the situation with Pacific salmon, the scientific literature on the nutritional requirements of Atlantic salmon is far from complete, and what data do exist are often limited to fry or fingerlings, not growout fish (5). For both Pacific and Atlantic salmon, this is due to practical considerations. It is much easier and less expensive to conduct nutritional research on fry and fingerlings in freshwater research facilities than at sea. In sea cages, confounding factors such as variable water temperature, disease, natural prey (food), difficulties in quantifying feed intake, and so on, make it difficult to perform scientifically meaningful feeding trials. Nevertheless, limited research information on Atlantic salmon nutritional needs has been supplemented with information from Pacific salmon and rainbow trout studies and practical experience to permit the Atlantic salmon industry to reach its current level of production and efficiency. At present, feed costs account for 40–50% of the operating costs in a salmon farm (6).

Salmon require the same 10 essential amino acids as other vertebrates, but the quantitative dietary requirements for essential amino acids have only been

determined for Pacific salmon. The nearly exclusive use of fish meal as a protein source for Atlantic salmon feeds has made determining the essential amino acid requirements of Atlantic salmon a relatively low priority, since fish meals contain those amino acids at levels above presumed dietary requirements. Protein levels in salmon fry and fingerling diets are higher than in growout diets (>45% and 42–44%, respectively), and dietary energy levels increase with fish size.

Atlantic salmon also presumably have similar dietary vitamin and mineral requirements to Pacific salmon or rainbow trout (*Oncorhynchus mykiss*), but relatively few dietary requirements for Atlantic salmon have been determined (4,7). For the few micronutrients for which quantitative requirements have been determined for Atlantic salmon, they have been found to be nearly the same as those of Pacific salmon. For example, the required dietary level of vitamins B_6, C, and E are similar for Atlantic salmon and rainbow trout, as are published values for phosphorus, manganese, copper, and iron (Table 3). In practical salmon diets, vitamins and trace minerals are supplemented at levels above known requirements to give a margin of safety in the event that vitamin levels are reduced by pelleting and feed storage. The cost of this extra supplementation is not a significant proportion of feed costs, so at present there is little incentive to precisely estimate the requirements of growout salmon for micronutrients. This may become a higher priority in the future, especially if plant protein sources replace a portion of fish meal in salmon feeds, thereby lowering the levels of trace minerals.

Atlantic salmon have the distinction of being the first salmonid species for which the carotenoid pigment astaxanthin has been demonstrated to be essential, albeit as a vertically transmitted micronutrient. Christiansen et al. (8) demonstrated that fry from female Atlantic salmon deprived of astaxanthin require it in their feed, while fry from females fed diets containing astaxanthin do not.

Salmon require a dietary source of *n*-3 fatty acids, between 1 and 2% of the diet. These fatty acids are supplied by fish oil. The only plant oil containing significant amounts of an *n*-3 fatty acid is linseed (flaxseed) oil. Other fat sources can be used in salmon feeds, providing that the diet contains at least 1–2% *n*-3 fatty acids. Soybean oil and beef tallow have been used to replace fish oil in Atlantic and Pacific salmon feeds; and, as expected, the fatty acid profile of fish tissues reflects that of the dietary fat source (9,10). The *n*-3 fatty acid levels fillets made from farmed salmon are equivalent to levels found in wild Pacific salmon when the feeds of farmed fish contain fish oils rich in *n*-3 fatty acids.

FEED FORMULATION

Formulating feeds for salmon is relatively simple. Feeds are not formulated by establishing minimum levels of essential dietary nutrients, selecting from a range of feed ingredients, establishing minimum and maximum levels for various feed ingredients, or commanding a computer to find the least-cost formulation. Rather, formulations are generally limited to just a few feed ingredients, with limits placed solely on dietary protein and fat levels and total phosphorus levels. Formulations for salmon have thus been developed empirically, with limits on total phosphorus and feed conversion ratios being the principal factors determining formulations (Table 4). Vitamin and mineral premixes provide these essential nutrients at appropriate levels. Carotenoid pigmentation for coloration of the final product is supplied by Carophyll Pink™, astaxanthin produced by chemical synthesis, or, less commonly, from natural sources such as krill, yeast, or algae. Because it is chemically synthesized, Carophyll Pink™ contains equal amounts of R and S isomers,

Table 3. Dietary Micronutrient Requirements and Their Deficiency Signs for Atlantic Salmon

Micronutrient	Requirement[a]	Deficiency Sign
Vitamin E	35 mg/kg diet	Muscle degeneration, anemia, reduced carcass protein, increased carcass moisture and fat
Pyridoxine	15–20 mg/kg diet	Nervous disorders, anorexia, reduced alanine transferase activity
Vitamin C	50 mg/kg diet	Scoliosis, lordosis, anemia, mortality
Vitamin K	Required	Not determined
Riboflavin	Required	Not determined
Pantothenic acid	Required	Not determined
Phosphorus	0.7% of diet	Low bone ash, calcium, phosphorus and magnesium, bone abnormalities, poor growth
Manganese	20 mg/kg diet	Reduced hematocrit and vetebral manganese
Copper	6 mg/kg diet	Reduced serum copper and liver cytochrome C oxidase activity
Iron	73 mg/kg diet	Reduced hematocrit, red blood cell count and tissue iron level
Selenium	Required	Muscular dystrophylike signs
Iodine	Required	Not determined
Astaxanthin	5 mg/kg	Poor growth, mortality in fry from females deprived of dietary astaxanthin

[a]Dietary requirements determined in one or two studies only, and generally with fry or fingerlings. Adapted from Hellend, Storebakken, and Grisdale–Helland, in R.P. Wilson, ed., *Handbook of Nutrient Requirements of Finfish*, CRC Press, Boca Raton, 1991, pp. 13–22.

Table 4. Generalized Formulations Used for Grower and Fingerling Atlantic Salmon Feeds

Feed Ingredient	Grower Feed (g/kg)	Fingerling Feed (g/kg)
Fish meal	550	630
Soybean meal	50	0
Wheat by-products	0	230
Ground whole wheat	104	0
Vitamin premix	10	10
Trace mineral premix	1	1
Choline chloride (60%)	4	4
Ascorbic acid	1	1
Fish oil	280	124

whereas the S isomer of astaxanthin predominates in natural sources (e.g., krill). Forensic analysis of astaxanthin isomers in tissue samples can be used to determine whether fish are of wild or farmed origin. Protein sources constitute the largest proportion of the ingredient costs of a typical Atlantic salmon feed, followed by carotenoid pigmentation, fat, and vitamin and trace mineral premixes (Fig. 1).

FEEDS AND FEEDING

When salmon farming began, fish were fed moist pellets originally developed for juvenile Pacific salmon raised in enhancement hatcheries. These moist feeds were composed of dry mixtures combined with fish hydrolysates (11). Dry pellets made by compression pelleting were soon available to farmers. Feed conversion ratios with these feeds were close to 2:1, partly because of the quality of ingredients and formulations used at that time and partly because compressed pellets are dense, which causes them to fall through cages before the fish could eat them all. In the 1980s, several events changed salmon feed formulations and pelleting methods. First, fish meal manufacturers began producing high-quality fish meal specifically for use in salmon feeds (12). These fish meals were produced from fresh raw material using low-temperature drying. Second, the introduction of cooking-extrusion pelleting for salmon feeds enabled feed manufacturers to produce less dense pellets that slowly sank in the marine cages, reducing the proportion of uneaten feed. Extruded pellets can be sprayed (top dressed) with fish oil to achieve much higher levels of fat than can be achieved with compressed pellets, making it possible to produce high-energy feeds. Third, limits were established in some countries on total phosphorus and feed conversion ratios to reduce the impact of fish farming on the aquatic environment. Limits on total phosphorus in the feed and on feed conversion ratios eliminated many feed ingredients from salmon feeds, especially those high in ash and indigestible fiber. High-ash fish meal contains large amounts of calcium and phosphorus from fish bone, which in addition to contributing to phosphorus pollution, was a cause of cataracts in young salmon because it reduced the bioavailability of dietary zinc (13–15); The overall result of these changes has been to lower feed conversion ratios to 1.0:1 or less, meaning that for every kg (or lb) of feed

that is fed, the fish gain one kg (or lb) of weight, and to increase fish growth rates.

HEALTH MANAGEMENT

Given the high densities at which Atlantic salmon are reared, it is to be expected that maintenance of health can be difficult, as is the case with any farmed species. The aquatic medium and the ectothermic physiology of fishes means that, with the treatment of compared higher animals, there are many differences in approach to health management and disease control. Also, the principal infectious agents of salmonid fishes often have no direct counterparts in higher animals, so unique therapies must be used.

The principal diseases of cultured Atlantic salmon vary depending on the geographical location. In Norway and Scotland, for example, the three most serious conditions are infectious pancreatic necrosis (IPN), furunculosis, and salmon louse infection; whereas in Chile, only IPN and rickettsial infection are significant problems. In Australia, a different pathogen is prominent in salmon farming, namely a paramecium that invades the gills of fish during periods of high water temperatures.

A major development in Atlantic salmon health management has been the introduction in 1992 of oil-adjuvant antibacterial vaccines. These vaccines, originally monovalent against *Aeromonas salmonicida* (the cause of furunculosis), can now incorporate antigens to provide protection against a number of *Vibrio* strains and even an element of protection against IPN. Prior to the arrival of successful vaccination, the only means of control for microbial infections was the use of antibiotics in the feed and resting (fallowing) of sites for prolonged periods to break the infection cycle (16).

New diseases are continually being identified and addressed in the context of control and husbandry adjustment. Viral diseases are still a major concern because there are no treatments to prevent disease and because viral diseases can be transferred to new locations via egg exports. Currently, viruses of particular concern to salmon farmers are IPNV and infectious salmon anemia virus (ISAV). Egg producers have extensive monitoring and certification procedures in place to assure customers (and regulatory agencies) that salmon eggs are free from specific pathogens.

GENETICS AND REPRODUCTION

The closing of the reproductive cycle for farmed Atlantic salmon in the 1960s allowed the true domestication of the species for the first time. Extensive mass selection programs, particularly in Norway (17), allowed significant improvement in a number of heritable factors, including adaptability to confinement, proportion of S1 smolt production, growth rate, and feed conversion ratio. The exact contribution attributable to genetic selection as opposed to improvement in fish husbandry and nutritional quality of feeds is unquantifiable, but it is nevertheless likely to be significant (18).

The development of molecular genetics, and in particular its application to the analysis of the Atlantic salmon genome, has allowed microsatellite DNA probes to be defined leading to pedigree analysis at the family level (19). Subsequent work has allowed genetic fingerprinting to be applied to commercial aquaculture as a routine production tool.

Thus, the genetic fingerprint of highest performing production fish under commercial rearing conditions can be determined, and siblings among broodstock populations can be identified and their performance assessed. Best crosses can then be identified from among the broodstock based upon performance under commercial conditions, allowing for very rapid pedigree enhancement.

This technology, using standard breeding procedures rather than the controversial genetic engineering technology, is expected to contribute even further when specific genetic markers for particular desirable traits are identified. Such developments are expensive and technologically sophisticated and are, therefore, likely to lead to lead to further subdivision of the salmon farming industry into egg and smolt producers, large scale rearers, and downstream processors, as has happened in the swine and poultry industries.

Broodstock developments have not been confined to the genetic sector. Requirements for higher quality eggs, free from specific diseases and available across a long spawning period, have led to a variety of manipulations of the broodstock cycle. Diets have also improved over this period, although there is still a great deal to be learned about the nutritional requirements of salmon in the critical maturation period before fish cease feeding prior to spawning.

More important has been the increased understanding of the environmental cues that trigger the various stages of maturation and spawning (20). This has led to commercial exploitation of modified photoperiod, earlier freshwater exposure, and temperature control to allow normal egg and milt availability over a much longer timescale. Eggs can thus be produced and fertilized over a four-month period instead of the two-month window for natural spawning. Similarly, commercial exploitation of cryotechnology for both short-term and long-term cryopreservation of milt (though not of ova) has allowed genetically superior males to be used across wider ranges of maturing females and even across spawning generations (21).

The ultimate aim of such programs is to concentrate on the production cycle such that two crops of smolts per year can be produced for on growing in the sea on a 12-month time frame to harvest. Progress to this end is already considerable, but the final goal may be some years away.

INDUSTRY TRENDS

Atlantic salmon feeds have been overly dependent on fish meal as a source of dietary protein, but this is likely to change in the next few years. Currently, efforts are underway to evaluate alternate protein sources for Atlantic salmon feeds. Protein sources of plant origin under study include wheat gluten, corn gluten, soy protein concentrates, and soybean meal blends. In Chile, rendered products (e.g., poultry by-product meal, feather meal, and blood meal) are being used in limited amounts to supply a portion of the protein in Atlantic salmon feeds. In Canada, rapeseed protein concentrate is a possible protein source under evaluation in addition to the ingredients just listed. Information is beginning to accumulate on apparent digestibility coefficients of protein in these and other feed ingredients for Atlantic salmon.

Another future possibility in Atlantic salmon feeds is the "square diet," so-called because it is formulated to contain 35% protein and 35% fat. This diet would be fed to fish in sea cages, not juveniles in freshwater. The point of feeding such a diet would be to increase the percentage of dietary protein used by the fish to synthesize fish protein, as opposed to the fish using dietary protein as a source of metabolic energy. Whatever the future holds with respect to dietary fat level, it is critical that information be developed concerning the availability of amino acids in various protein sources used in Atlantic salmon feeds and that the dietary requirements of Atlantic salmon for essential amino acids be determined, thus allowing feed formulators to explore various possible alternate protein sources without unintentionally formulating a diet that lowers the growth rate of the fish.

Great emphasis is currently being placed on year-round smolt supplies and reduction of time to market from sea cages. This is leading to year-round availability of standard product at prices that compete well with other fish and white-meat products in the market. The added value of processed specialty products is also being widely addressed. Such developments push the product inexorably toward the high-volume commodity sector, as opposed to the high-value niche market, to which it originally was aimed.

Pressure on rearing sites for both freshwater and marine stages will tend to limit production in Europe and North America, unless more exposed, offshore locations can be utilized. However, the capital cost of large, offshore structures is high; and there is still considerable capacity for expansion in South America at lower cost.

Recirculation or, at least, water rehabilitation by removal of organic material and phosphates is slowly increasing in usage in the freshwater stage of salmon farming. The technologies are still developing and capital costs are high. Freshwater availability is likely to be the limiting factor for all aquaculture development in the long term, so replacement of lake-based cage systems with recirculation (water recycling) systems or engineered flow-through systems for high value, genetically improved salmon smolt production seem likely to develop.

Atlantic salmon are only 10 generations from the wild and already the domestication traits that have been expressed are distinctive and have contributed greatly to the productivity of the industry. Newer technologies involving family as opposed to mass selection and the use of sophisticated techniques such as DNA pedigree analysis, are being adopted by leading producers of eggs and smolts. Genetic engineering has been demonstrated to have great potential; but given the concern of consumers about genetic engineering, it is unlikely that this approach will be utilized by the salmon industry to improve farming productivity.

Elat, Israel

OUTLINE

The European sea bass, a member of the recently revised family Moronidae, is found from the Black Sea westward across the Mediterranean Sea, out into the eastern Atlantic Ocean north to Ireland and the Baltic and North Seas, and south to Morocco and Senegal (1). The genus *Dicentrarchus* contains two species: *D. labrax* and *D. punctatus*, which are very similar in appearance except for the presence of black spots on the back and sides of the latter. Sea bass are highly prized throughout most of their range and, like the gilthead sea bream, are heavily fished and thus were early candidates for domestication. In 1996, the reported catch of sea bass reached close to 15,000 metric tons (mt) (2) (16,500 short tons) (st), while aquaculture production exceeded 26,500 mt (3) (29,150 st). Sea bass are farmed similarly to gilthead sea bream in seawater ponds and lagoons, with the bulk of production occurring in sea cages. Greece, Turkey, and Italy are the three biggest producers of sea bass, yielding over 70% of sea farm production. Sea bass culture has paralleled sea bream development, rising from 270 mt (297 st) in 1985 (4,5) to 26,500 mt in 1996 (3), with the 1998 production expected to reach 34,100 mt (6) (37,500 st).

LIFE HISTORY

Sea bass frequent coastal inshore waters, occurring in estuaries and brackish water lagoons, and sometimes venture upstream into fresh water (1). Their euryhaline nature allows them to grow in completely fresh water without reproducing. As a result sea bass have been used as natural predators to control the proliferation of unwanted fish in freshwater culture systems and water carriers (7). Spawning of sea bass takes place from November to March in the Mediterranean basin (8,9) with the spawning period being delayed in the northern parts of its distribution (1,8). Adults spawn in estuaries and

inshore areas where the salinity of the water is close to that of seawater (30 ppt) (3.0%) (8).

Sea bass are round fish with elongated bodies and wide mouths, which they use to catch small fish and a variety of invertebrates, including shrimp, crabs, and squid and other cephalopods (10). Their bodies are grey to greenish black along the back, with silvery sides and white bellies. Both *D. labrax* and *D. punctatus* have dark spots on their back and sides as young fish. These spots disappear in *D. labrax* as they mature (7). Sea bass can reach maximum lengths of 1 m (40 in.) and weights of 15 kg (33 lb), although fish of 0.5 m (16.5 in.) and 4–6 kg (8.8–13.2 lb) are more commonly caught (11).

REPRODUCTION AND LARVAL REARING

Sea bass have been the subject of many studies, which have helped in understanding reproduction in marine fish (9,13–18). Sea bass were historically cultured along with other euryhaline species—gilthead sea bream and grey mullet—in coastal lagoons and tidal reservoirs for many years before a race to develop mass production of juveniles started in the late 1960s (5). Fish culture was initially associated with the production of salt in coastal evaporation pans and marshes. The salt was harvested during the high evaporation seasons of summer and autumn, and fish were cultured during winter and spring. The supply for this culture came from trapping schools of fish that lived in these estuarine areas and fed on the rich fauna flourishing in the nutrient-rich waters.

During late 1960s, research groups in both France and Italy competed to develop reliable mass-production techniques for juvenile sea bass. The fish were considered a "safe bet" for developing these techniques due to their large larvae, which are three times the size of sea bream at the yolk sac stage. By 1976–77, mass-production techniques were well enough developed to provide hundreds of thousands of larvae in France and Italy (5). This production reached 4.5 million by 1985, with Yugoslavia leading France and Italy in numbers produced (4). Some 147 million juveniles were reportedly produced during 1997 (12), some of which may have been from capture fisheries.

Sea bass are a dioecious species. Fish develop as either males or females, which, unless artificially induced, do not change sex during their lifetime. Males can produce sperm at one year, but females do not reach sexual maturity until the age of three. Photo and thermal cues control reproduction in sea bass. The fish respond to the shortened length of the day and to a reduction in water temperature, the latter being critical for egg quality.

Optimal reproduction can be obtained if brood stock are kept throughout the year at densities no higher than 5 kg/m^3 (11 lb/264 gal), in tanks that allow them to swim freely. Maintaining the temperature below 16 °C (61 °F) outside of the spawning season helps in obtaining high-quality eggs, as does feeding the fish squid a few times each week, starting two months prior to spawning. Dietary lipids have been found to be important for sea bass reproduction, because long-term deficiencies in *n*-3 highly unsaturated fatty acids (*n*-3 HUFA) can induce

early gonadal atresia, lower fecundity, and subsequent reduction in egg survival (19). At the onset of the reproductive season, the fish can be transferred to smaller tanks (1 m^3 = 264 gal) at densities of up to 2.5 kg/m^3 (5.5 lb/264 gal). During this time, the maintenance of a low water temperature ($\leq$13 °C = 55.4 °F) is important for spontaneous spawning.

In the eastern Mediterranean, captive populations start spawning in November, about a month before the shortest day of the year, and will continue until March, provided that the water is maintained below 15 °C (59 °F). As the spawning season approaches, the female's oocytes undergo vitellogenesis. The process stops just before maturation, when the oocytes reach 600–750 μm (2.36–2.95 × 10^{-2} in.). The oocytes remain unchanged for over a month, at which point they undergo atresia if the female is not induced to spawn. Sea bass have an annual reproductive cycle with group synchronous ovarian development and are multiple spawners (20). In captivity, up to six induced spawnings per season have been observed, with the number of eggs produced by a female per spawn reaching 5–20% of her body weight, or a total exceeding 1 million eggs per season.

If spontaneous reproduction does not occur in sea bass, then hormonal treatment with luteinizing hormone releasing hormone (LHRH) analogs either by injection, controlled-release implants, or microcapsules can be used to trigger maturation, ovulation, and spawning in 54–68 hr. During the time from hormonal induction to actual spawning, germinal vesicle migration (GVM) and breakdown (GVBD), hydration, and ovulation can be observed in a proportion of the oocytes (>50%). After the fish have spawned these matured eggs, another batch of oocytes is recruited and respond to the hormonal treatment in the same way—undergoing GVM, ovulation, and spawning (20). This process is induced six times over a three-month period (National Center for Mariculture, unpublished data).

In addition, injections of gonadotropin-releasing hormone (GnRH) analogs have been consistently used to induce spawning in sea bass. Two injections, 24 hours apart, of 15 and 10 μg/kg (6 and 4 × 10^{-7} oz/2.2 lb) of fish, or a single injection of 10–15 μg/kg (4–6 × 10^{-7} oz/2.2 lb), have been effective in inducing spawning. The time of injection has an effect on the rate of GVBD and ovulation, both being faster if hormonal treatment is administered in the morning rather than at night (21). Males usually have good-quality sperm without any treatment, but when levels of milt appear low, a 5 μg/kg (2 × 10^{-7} oz/2.2 lb) injection of GnRH analog can be highly effective in increasing short-term spermiation. Sustained-release GnRH analog increases milt volume and prolongs spermiation while maintaining high-quality sperm (22).

The strong influence of photoperiod on sea bass reproduction makes this fish a candidate for extending its reproductive season throughout the year. Providing groups of parent stock sea bass with artificial lighting that mimics changes in the length of the day and that shifts the shortest day, coupled with reduced water temperatures, allows year-round spawning (23). Advancing the time of spawning can also be achieved, in this case, by maintaining

a constant short photoperiod of 9 hr of light and 15 hr of darkness (24).

Larval rearing of sea bass is based on years of extensive research into environmental and biotic factors affecting growth and survival (25,26). The results of this research have been the development of successful mass rearing techniques that are presently used in hatcheries around the Mediterranean region. Techniques vary among the hatcheries, depending upon local experience, but all are based on the extensive research efforts carried out in the region since the 1970s.

Sea bass eggs are hatched and the larvae reared for 43 days at the National Center for Mariculture in Israel using the following procedure: Fertilized eggs are stocked at 100/L (380/gal) in either 400–1,700-L (104–442-gal) cylindroconical fiberglass tanks or 5,000–10,000-L (1,300–2,600-gal) flat-bottom tanks. Hatching success is estimated from aliquot samples. Rearing starts at seawater temperatures of $16.5 \pm 0.5\,°C$ ($61.7 \pm 0.9\,°F$) with the temperature gradually rising to $24.5 \pm 0.5\,°C$ ($76.1 \pm 0.9\,°F$) by the last 9 days of the 43-day rearing period. Filtered seawater ($10\,\mu m = 3.9 \times 10^{-4}$ in.) is continuously supplied to these tanks at a rate of one to four exchanges each day, depending upon the age of the larvae. The larvae are continuously supplied with freshly enriched rotifers (*Brachionus plicatilis* at a concentration of 10/mL = 296/oz) as their first food followed by newly hatched or enriched Artemia nauplii (*Artemia salina* at a concentration of 1/mL = 29.6/oz) as the second. In addition, the tanks are continuously supplied with single-celled green algae (*Nannochloropsis* sp.) through a special delivery system designed to maintain the algal concentration at 5×10^5 cells/mL (148×10^5/oz) during the 15 hr of light the larvae are given. Larval survival under these rearing conditions will be 35% by day 43, when the sea bass reach an average weight of 80 mg (2.8×10^{-3} oz).

An easier rearing procedure, which eliminates the use of rotifers by going directly to Artemia nauplii at first feeding, is also in use (26). This technique was developed to reduce the dependence of hatcheries on mass culture of microalgae and rotifers. It exploits the internal energy reserves of newly hatched sea bass larvae and has been reported to provide a 60% survival rate. (26). Eggs and newly hatched larvae are reared in complete darkness up to the stage of eye pigmentation and opening of the mouth. This is believed to save energy by reducing the spontaneous activity of the larvae. In addition, the salinity is lowered to 25 ppt (2.5%) in their tanks, which reduces the energy necessary for osmoregulation by the fish larvae.

Rearing procedures for sea bass have been improved by developing enrichment techniques to modify the *n*-3 HUFA composition of the live rotifers and Artemia the larvae eat. Studies have shown that the growth and survival of sea bass, in contrast to larvae of gilthead sea bream, are independent of the dietary level of *n*-3 HUFA within the range of 7.4–41.6 mg/g of dry Artemia (2.6–14.6×10^{-4} oz/3.52×10^{-2} oz dry Artemia) (25). Although at present, sea bass larval nutrition is based mainly on the enrichment of live food, the development of microdiets to replace it has been the goal of many research groups in the region (27).

Once sea bass pass the critical first 43 days after hatching, special care is given to minimize mortalities due to cannibalism. This is done by mechanically grading the fish into 2–3 size groups which are then reared separately. The more equal the sea bass are in size, the more cannibalism is reduced and survival improved to the point where the fish are stocked into growout systems.

COMMERCIAL CULTURE

The European sea bass, like its main competitor in Mediterranean aquaculture, the gilthead sea bream, is grown mainly in sea cages, although more land-based systems are being developed as competition for cage sites increases. This competition is the result of increased urbanization, tourism, industry, and environmental regulation. The growout density of sea bass in these systems varies from approximately 2 kg/m^3 (1.7×10^{-2} lb/gal) in extensive ponds to 20–30 kg/m^3 (0.17–0.25 lb/gal) in intensive raceways with high water exchange to 20 kg/m^3 (0.17 lb/gal) in cages (11).

The sea bass is a slower growing fish than the sea bream, requiring up to two years to mature to a commercial size of 250–350 g (8.8–12.3 oz) in the Mediterranean region (11). Improvements in feeds, better management practices, and improved quality of juveniles have all contributed to a reduction in the time needed to reach commercial sizes. Today, sea bass reach market sizes in approximately 16 months in sea cages in the Mediterranean region. Commercial sizes for cultured sea bass vary from 300–1,000 g (10.6–35.2 oz), while much larger fish of 2–3 kg (4.4–6.6 lb) usually come from fishing.

NUTRITIONAL REQUIREMENTS

Since the start of R & D to develop sea bass for mariculture, over the past three decades there have been intensive efforts to identify the nutritional needs of the various life stages of the fish. The development of this information has not been completed, but enough information is available to allow the formulation of practical commercial feeds that are in use today wherever sea bass are being cultured. Table 1 summarizes the available information on the nutritional requirements of this fish at this time.

DISEASE PROBLEMS

The sea bass is a euryhaline and eurythermal fish that lives in marine, brackish and, occasionally, fresh water. Although a sturdy species, sea bass are subject to a wide range of diseases under culture conditions. These outbreaks have had devastating effects on commercial production and have prevented the expansion of the industry in some Mediterranean countries.

VIRAL DISEASES

Encephalitis Viruses

Bass viral encephalitis is characterized by whirling movements, a loss of balance, and hyperexcitability in

Table 1. Summary of Known Nutritional Needs of the European Sea Bass[a]

	Percent of Diet Unless Otherwise Indicated
Protein	
Total dietary level	
Larval/juvenile	50–60[28,29;cf]
Growout	45–50[29;cf]
Indispensable amino acids	
Arginine	3.9[30] (% of dietary protein)
Lysine	4.8[31] (% of dietary protein)
Methionine + cysteine	4.4[32] (% of dietary protein)
Tryptophan	0.5[33] (% of dietary protein)
Estimates of remaining (IAA)[34b]	
Histidine	1.6[34] (% of dietary protein)
Isoleucine	2.6[34] (% of dietary protein)
Leucine	4.3[34] (% of dietary protein)
Valine	2.9[34] (% of dietary protein)
Phenylalanine + tyrosine	2.6[34] (% of dietary protein)
Threonine	2.7[34] (% of dietary protein)
Lipid	
Total dietary level	15–20[29c]
n-3 HUFA = EPA + DHA	
Larvae (43–75 days)	1.0[35]
Growout to commercial size	1.5–2.7[cfd]
Broodstock	Essential[36e]
Energy	
Maintenance requirement[f]	40.6 kJ/kg fish$^{0.8}$ [g]
Growth requirement	20–23 MJ/kg feed[rv]
Vitamins	NRC recommendations for rainbow trout[h]
Minerals	Commercial premixes[rv]
P : E ratio	Only partial data available[37,38]

[a]Numerical superscripts on values listed in table indicate research data from published literature listed in references; "rv" = recommended values; "cf" = values found in commercial feeds for sea bass.

[b]Estimates of IAA based on whole-body IAA to total IAA ratios.

[c]High-energy diets may reach up to 26%.

[d]Levels in high-energy commercial diets.

[e]EPA + DHA known to be essential for good egg quality, but quantities and DHA − EPA ratios are unknown.

[f]Energy requirement at zero growth.

[h]NRC 1993 recommendations for rainbow trout have been shown to be sufficient for *D. labrax* when used in practical diets (39).

response to noise and light. In the brain and other nervous tissue, including spinal cord and retina, extensive vacuolization is typically observed. Mortality often occurs within one week from the onset of the first symptoms. The syndrome was described in European sea bass cultured in Martinique, in the French Caribbean Islands (40,41). Possibly, the picornalike virus described in the same host in France was responsible for the disease (42). Recently, these viruses were found to be more closely related to the Nodaviridae family (43). No effective therapy is known.

BACTERIAL DISEASES

Pasteurellosis

The bacterium responsible for this disease, *Pasteurella piscicida*, is a halophilic member of the Vibrionaceae family. A new name for the bacterium, *Photobacterium damsela* subsp. *piscicida*, has been proposed (44). The disease is widespread in the United States, in Japan, and all around the Mediterranean basin. The infection develops rapidly into an acute septicemic condition characterized by an enlarged spleen with typical foci of bacterial microcolonies. In advanced cases, these lesions appear on the surface of the spleen as whitish spots and patches. Typically, *P. damsela piscicida* is a rather unreactive, gram-negative, nonmotile, oval-shaped, 0.5×1.5-μm ($1.97 \times 10^{-5} \times 5.9 \times 10^{-5}$-in.) rod, seen through the microscope with pronounced bipolar staining.

Commercial vaccines against *P. damsela piscicida* are available, but so far their effectiveness has been limited, in particular because the vaccine is given during the most vulnerable stages of fish development (postlarval and juvenile), in which the fish have an underdeveloped immunological system. Early detection and the use of medicated feed, before the fish lose their appetite, offers the best chance of saving infected fish. A characteristic of this bacterium is the speed with which it develops resistance to a broad range of antibiotics. An antibiogram should be performed before any treatment, to evaluate the effectiveness of the drug to be used. *P. damsela piscicida* is highly contagious, and strict sanitary measures should be adopted to limit its spread.

Streptococcosis

The common symptoms of streptococcosis are exophthalmia, hemorrhages, and distension of the abdominal area. Serosanguinous fluid accumulates in the peritoneal cavity and intestine. Diagnosis of this disease can only be done by culturing the pathogen, which grows best when blood is added to the culture medium. Streptococci are nonmotile, spherical, or ovoid bacteria that stain gram positive and form long chains in liquid culture. In Israel, the strain isolated from *D. labrax* was identified as *Streptococcus iniae*.

Mycobacteriosis

The etiological agents of mycobacteriosis, *Mycobacterium* spp., are slender, acid-fast rods that cause systemic, chronic, and subacute infections in fish and, on occasion, skin ulcers in humans. These bacteria require special media (Löwenstein−Jensen or Middlebrook) for culturing, which is usually a slow process, taking two to three weeks for the first colonies to become visible. Fish mycobacteriosis is widespread throughout the world in both marine and freshwater environments. *M. marinum*, the bacterium causing this disease, has been isolated from sea bass in Italy, Belgium, Denmark, Greece, and Israel (45,46). Superficial ulcers and exophthalmia are the only external signs of the disease, which can remain asymptomatic for a long time. The spleen and kidney, however, are severely affected and appear enlarged and covered with whitish nodules. In advanced cases, these lesions spread to all other visceral organs. Antibiotic treatment is generally unsuccessful.

PROTISTAN PARASITES

Amyloodiniosis

Amyloodinium ocellatus is a dinoflagellate that is highly adapted to parasitism. This organism is not selective in its host choice and is responsible for one of the most devastating parasitic diseases in temperate (47,48) and tropical mariculture (49–52). Its life cycle involves three main phases: trophont (the parasitic, feeding stage), tomont (the encysted, reproductive stage), and dinospore (the free-swimming, infective stage). The trophonts feed on the fish's epithelia by means of rhizoids, then drop from the fish, encyst on the bottom, and start dividing. The reproductive process finishes in two to three days at $24 \pm 2\,°C$ $(75 \pm 3.6\,°F)$ with the release of 64–128 infective, highly motile dinospores from each tomont that begin the life cycle of the parasite again (52). Dinospores remain infective for several days.

Copper compounds are effective against *A. ocellatum*, but care must be taken when using them due to the toxic effects of copper on fish. The concentrations used to kill the pathogen are close to the levels at which copper acts as a poison to membranes and can harm the fish's gills, liver, kidney, and nervous system. In addition, its immunosuppressive nature is a major drawback to the use of copper in treating fish (53). Despite these drawbacks, the treatment of infected fish is carried out over a 12–14-day period by maintaining a concentration of 0.75 mg/L $(2.39 \times 10^{-3}$ oz/qt) of $CuSO_4$ in the water (51), using a slow drip of a concentrated solution and closely monitoring its concentration in the water.

Dipping infected fish in fresh water for a few minutes will dislodge most of the parasites, but will not kill them. This treatment causes the parasites to turn into tomonts, which start to divide as soon as the seawater flow is restored.

Cryptocaryonosis

Cryptocaryonosis is caused by the ciliate *Cryptocaryon irritans*, of the class Colpodea (54), which is known to have intraspecific variants (55–57). Although typical of tropical seas, this parasite has a worldwide distribution that extends well into temperate environments. *C. irritans* invades the skin, eyes, and gills of its host and impairs the functioning of these organs. External symptoms of the disease are the appearance of pinhead-sized whitish "blisters" on the skin and increased production of mucus. The diagnosis of cryptocaryonosis is made by microscopic examination of gill, fin, or skin tissue to determine the presence of the large, revolving ciliate. The ciliate's life cycle involves four phases, the first is parasitic (trophont) during which it feeds on the fish's epithelia. After three to seven days of growth, it leaves its host, loses its cilia (protomont), encysts, and starts dividing (tomont), eventually producing up to 200 free-swimming infective organisms (theronts). The number and size of theronts produced vary with geographic location, the species of the fish infected, and water temperature (58). Theronts have a life span of 24 hr, but their ability to infect a host decreases rapidly after 6–8 hr (59,60).

Myxosporean Infections

Myxosporeans are polynucleate, usually immobile parasites that can either reside in visceral cavities, such as the gallbladder, swim bladder, and urinary bladder (celozoic species), or settle as inter- or intracellular parasites in blood, muscle, or connective tissue (histozoic species). They produce spores that are subspherical in shape and several μm $(= 4 \times 10^{-5}$ in.) in size, with characteristic polar capsules and coiled filaments. *Sphaerospora testicularis* and *S. dicentrarchi* were detected in sea bass in Spain (61), and *S. dicentrarchi* was found in sea bass in Greece. Both species cause relatively inconspicuous infections in various organs of the fish.

METAZOAN PARASITES

Monogenean Flukes

Most monogenean flukes display a narrow host specificity and, consequently, a relatively benign relationship with the host they parasitize. Diplectanids are common on farmed Serranidae. These parasites infest gills and feed on mucus, but can cause severe hyperplasia and hemorrhages where the hooks of the parasite are inserted into the fish (62). The bodies of monogenean flukes are elongated and characterized by a large, flat attachment organ (opisthaptor) with squamodiscs at the posterior end. European sea bass cultured in the Mediterranean and Red Seas are infested with *Diplectanum aequans* and *D. laubieri* (63,64).

Sea Lice

Caged fish are particularly vulnerable to parasitic copepods and isopods, which can be a mild nuisance or cause debilitating infestations. Sea lice appear to be attracted by the fluid secretions from skin wounds, so that fish injured by handling are easy targets during the first few days after being stocked into cages. The life cycle of these crustaceans comprises several free-living and infective stages and is typically faster at higher temperatures.

Caligus minimus is a copepod known to parasitize only sea bass, selecting the roof of the fish's mouth and its gill rackers as preferred infestation sites (65). The copepods' second antennae and maxillipeds are claw shaped, so adhesion to the host is assured through pressure from the parasite's shield-like cephalothorax acting as a sucker. Active feeding may cause deep ulcers.

Pranizae (larval stages) of gnathiid isopods feed on blood. Most of them are highly specialized to specific hosts and stay continuously attached to them, while others such as *Gnathia piscivora* and *Elaphognathia* sp., are indiscriminate in their host selection and, once engorged with blood, abandon the fish. In the Red Sea, they feed and molt three times before maturation to nonparasitic adults (66).

SEA TURTLE CULTURE: GENERAL CONSIDERATIONS

ROBERT R. STICKNEY
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

General Biology

Mariculture

Bibliography

Green sea turtle (*Chelonia mydas*) steaks were once a readily available and highly popular human food in Florida. As the population of wild turtles became depleted, the notion that commercial mariculture might be lucrative led to development of a commercial farming operation in the Cayman Islands (1,2). However, the Endangered Species Act placed the green sea turtle and other turtles under protection in 1973 and made it illegal to catch, sell, import, or own any part of the listed species. Sea turtles also gained protection under the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), which went into force in 1975 and has 125 nations as signatory members.

Green sea turtles continue to be reared in the Cayman Islands, partly for local consumption, but also for stocking in order to assist in recovery efforts. Sea turtle culture has been undertaken over the past century, for various reasons and with various species, in Australia, Barbados, Bermuda, Burma, Cambodia, the Cook Islands, Cuba, Cyprus, Fiji, French Polynesia, Grenada, Indonesia, Japan, Kiribati, Malaysia, Mauritius, Mexico, Palau, the Philippines, the Seychelles, the Solomon Islands, Suriname, Thailand, Tonga, the United States, Vietnam, and Western Samoa (2).

Most culture activities have been associated with enhancement efforts. Included are head-starting activities conducted by government agencies (see the entry "Sea turtle culture: kemp's ridley and loggerhead turtles"). Efforts on behalf of sea turtle conservation have provided a large amount of valuable information on the biology of these unique marine reptiles.

Through the efforts of many scientists and countless numbers of volunteers, some progress has been made to reverse the decline in the populations of at least some species of sea turtles. Nesting sea turtles have actually returned to at least a few beaches where they had not been observed in many years. Enhancement efforts have been augmented by reductions in the number of turtles taken incidental to trawling shrimp, through imposition by the National Marine Fisheries Service in the United States of a requirement that shrimp nets must be fitted with turtle excluder devices (TEDs). The U.S. government also bans the import of wild-caught shrimp from foreign nations if the shrimp were caught in nets that were not equipped with TEDs.

GENERAL BIOLOGY

There are several species and possibly a few subspecies of sea turtles in the oceans of the world (3,4). The recognized species are the green genus and species shown in first paragraph of entry, hawksbill, (*Eretmochelys imbricata*), leatherback (*Dermochelys coriacea*), loggerhead (*Caretta caretta*), flatback (*Natator depressus*), olive ridley (*Lepidochelys olivacea*), and Kemp's ridley (*L. kempi*). The species can most easily be distinguished by the pattern of plates (scutes) on the dorsal shell (carapace). The maximum size ranges widely between species, with Kemp's ridley, for example, reaching a few tens of pounds and leatherbacks, among others, reaching more than 1000 lb (>454 kg).

Many of the specific details on the general biology of sea turtles provided in the remainder of this section are drawn from information on the green sea turtle (3), but the overall patterns described can be generally applied to other species as well, unless otherwise indicated.

Sea turtles attain sexual maturity at various ages. Maturity may not occur in wild green turtles less than 30 years of age, though in captivity they may mature in less than 10 years. Males spend their entire lives in the ocean after leaving the beach as hatchlings. Females leave the sea only to lay their eggs.

Adults may travel distances of thousands of miles (1 mile = 1.67 km) from their feeding grounds to the nesting beaches. Each mated female hauls herself from the water at night and moves up the beach to a location above the high-tide mark. She then scoops out a body pit and digs a nest hole in the sand with her rear flippers. She deposits one hundred or more eggs in the nest pit, after which she covers both the nest and the body pits with sand. The female then returns to the ocean. She may come back to the beach at intervals of about two weeks to deposit subsequent batches of eggs.

The egg development rate is dependent on temperature and may typically be from 50 to 60 days (Fig. 1). Researchers have learned that the incubation temperature controls the sex of the developing embryos: Warmer temperatures produce females, while cooler temperatures produce males. Thus, in hatcheries, where temperatures

Figure 1. Newly hatched sea turtle and an unhatched egg. Photo courtesy of Texas Sea Grant College Program.

can be carefully controlled, it is possible to manipulate the sex of the turtles produced.

Various predators will dig up turtle eggs. Known predators of green sea turtle eggs include crabs, insects, reptiles, mammals, and birds. At one time, it was common practice for people to dig up turtle nests and harass the females on the beaches, but with the development of a strong conservation ethic and, more recently, active attempts to protect sea turtles and their eggs on the nesting beaches, that practice is now rare. More common is a female sea turtle disrupting an existing nest by digging a new nest pit in the same location.

All of the eggs that hatch in a nest do so over a brief time span. Hatchlings climb to the surface in a synchronous fashion over a period of days, using one another as "stepping stones" to move upward, in a virtual ball of baby turtles. Once they reach the surface, they scamper down the beach to the ocean (Fig. 2). Predators can take a heavy toll when the hatchlings are on the beach, but the vulnerability of the turtles to predation certainly does not end when they enter the water. Unable to dive until they have grown significantly, the young turtles are vulnerable to attacks from both above and below. Hatchlings have reportedly been preyed upon by crabs, fish, reptiles, mammals, and birds. Juveniles and

Figure 2. Hatchling heading for the water. Photo courtesy of Texas Sea Grant College Program.

adults have fewer predators, but there have been reports of attacks by a few species of fish, including sharks; a species of crocodile; and at least one type of marine mammal.

Most sea turtles are carnivores, although the green sea turtle is an herbivore that consumes sea grasses and algae of many varieties. Being a vegetarian, the green turtle does not have a strong flavor and for that reason became the most desirable species for human consumption. When the Americas were being colonized and European explorers were charting the oceans of the world from sailing ships, it was common practice to capture green sea turtles and strap them, upside down, to the decks of the ships. The turtles would live for long periods and provide fresh meat to sailors, who would otherwise have to exist on salted meat and fish.

Turtles tend to be true to their nesting beaches. Females will faithfully nest on the same stretch of beach where they were hatched. However, many beaches that once were used by nesting turtles have been abandoned, because human activity has either prevented access or scared the turtles away. Overfishing and destruction of nests by humans and other predators have also contributed to the demise of some nesting beaches. Recovery efforts often require moving eggs from the beach on which they were laid to another beach, where final incubation occurs, often in a hatchery situation. The hatchlings will, through a process known as imprinting, have a "memory" of the beach implanted in their brains that will cause them to return to the beach where they entered the ocean as hatchlings, not where they were deposited as eggs. Thus, in theory, new nesting beaches can be established and abandoned ones put back into use.

MARICULTURE

Culture of turtles has been for the purpose of assisting in the recovery of threatened and endangered species and for food production. Early recovery efforts involved collection of eggs laid in nature, incubation of those eggs in hatcheries, and immediate release of hatchlings into the ocean. Because of high mortality rates, however, an additional step, called head-starting, is sometimes employed. This technique involves maintaining the young turtles in captivity for several months, until they are able to dive and have attained sufficient sizes and swimming speeds to allow them to avoid many of the common predators (see the entry "Sea turtle culture: kemp's ridley and loggerhead turtles" for more detail). In addition to head-starting Kemp's ridleys and loggerheads, similar activities have been undertaken with green and hawksbill turtles (1,2).

Mariculture, Ltd. was the first sea turtle farm. Established in 1968 on Grand Cayman Island in the British West Indies, it was acquired by Cayman Turtle Farm, Ltd., in 1975 and by the Government of the Cayman Islands in 1983 (1,2). It remains in business and is the largest and longest running sea turtle mariculture operation in the world. A great deal has been learned about green sea turtle biology and culture over the three decades that the farm has been operating. In addition, the farm has developed a captive breeding program with Kemp's ridley turtles.

Taking its initial stock of green turtle eggs and adults from the wild, the Cayman Island farm was able to develop a captive breeding program, though in the 1970s it continued to obtain eggs from nesting beaches to supplement its production. In the 1970s, annual production ranged from 12,000 to 15,000 turtles. Virtually every part of the turtles produced were marketed. Included were the meat, oil, fatty tissue (known as calipee), leather from the skin, and shell. Yet, the farm was not a profitable operation. The situation become worse when changes in CITES regulations and the listing of green sea turtles under the Endangered Species Act in the United States, banned the importation of turtle products and their transshipment through Miami.

Once the Government of the Cayman Islands took over the farm in 1983, it was developed into a tourist attraction as well as a production operation. The farm is located on 6.4 ha (16 acres) of land. It features, in addition to the tourist center, a breeding pond, a hatchery, rearing tanks, research laboratories, an administration building, and a processing plant.

By 1988, the farm was showing a profit, largely based on fees paid by tourists. It was also moving closer to being able to export some of its products under CITES criteria, which included a provision under which second-generation captively produced turtles were exempt from the distribution ban.

In 1973, five years after the farm was established, adult turtles that had been held in captivity since the farm was established finally produced viable eggs. The first generation of captively produced females (hatched in 1973 and 1974) reached maturity and laid eggs first in 1989. It is the offspring of the 1989 adults that are the second-generation turtles that meet the CITES criteria. By 1992, the captive breeding population on the farm had reached a total of 280 turtles, with a ratio of three females for each male being maintained.

The main emphasis of the farm in the past several years has been on research and head-starting, with only limited production for sale. Tourism and local meat sales are primary income sources. About 4,000 turtles are marketed annually at 3.5 years of age, when they weigh about 24 kg (48 lb). The farm's head-start program began in 1980. Tourists and residents become involved in the head-start program by paying a fee for the privilege of releasing the turtles. By 1992, more than 22,000 head started turtles had been released (5).

Sea turtles require clean water, or else they become susceptible to a variety of diseases, including skin lesions. At high densities, daily tank cleaning is required unless flow-through water is used in the culture system.

Unlike finfish and invertebrate culture species, each species of sea turtle seems to have its own personality. Green sea turtles are docile and do not mind being touched. Kemp's ridley and loggerhead turtles tend to be more aggressive than green turtles, but the public enjoys watching all sea turtle species when they are on display. While not as popular as marine mammals, sea turtles do have a large following among those who visit public aquaria and various tourist attractions that feature aquatic animals.

The major remaining Kemp's ridley sea turtle nesting beach in the world is at Rancho Nuevo, Mexico. A few green turtles and loggerheads also nest at Rancho Nuevo. Collaboration between U.S. and Mexican government agencies and scientists to protect Kemp's ridley turtles has been ongoing for several years. During the nesting season, people from both nations gather at Rancho Nuevo to count the number of ridley nests and in some cases gather eggs for incubation in corrals located elsewhere on the beach. Most of the turtles hatch naturally or are released at Rancho Nuevo, but some have been used to reestablish nesting beaches in the United States as well. As a result of these activities, aided in no small part by conservation efforts, the number of nesting females at Rancho Nuevo has increased considerably. Kemp's ridley head-starting efforts also seem to be paying off, as at least a few tagged individuals known to have been head-started have been observed on nesting beaches at Padre Island and Mustang Island in south Texas.

Many sea turtle populations continue to be threatened or endangered around the world, but their plight is not quite so perilous as it was only a few years ago.

SEA TURTLE CULTURE: KEMP'S RIDLEY AND LOGGERHEAD TURTLES

CHARLES W. CAILLOUET, JR.
National Marine Fisheries Service
Galveston, Texas

OUTLINE

Rationale

Life History Pattern

Aquaculture of Kemp's Ridley and Loggerhead Sea Turtles

    Egg Collection and Incubation

    Sex Determination

    Imprinting

On a worldwide basis, sea turtle aquaculture is conducted for commerce and conservation (1). The U.S. Departments of Commerce (DOC) and the Interior (DOI) are responsible for protecting sea turtles under the Endangered Species Act, thus limiting sea turtle aquaculture in the United States to research and conservation. In 1977, the National Marine Fisheries Service (NMFS) laboratory in Galveston, TX, initiated sea turtle aquaculture research related to conservation, first with loggerhead turtles (*Caretta caretta*), a threatened species, and then with endangered Kemp's ridley turtles (*Lepidochelys kempi*). This research requires scientific permits and threatened- and endangered-species permits from the Texas Parks and Wildlife Department (TPWD), the Florida Department of Environmental Protection (FDEP), the U.S. Fish and Wildlife Service (FWS), and Mexico. When eggs, hatchlings, or larger turtles are received from other countries, Convention on International Trade in Endangered Species of Wild Flora and Fauna (CITES) export and import permits also are required.

RATIONALE

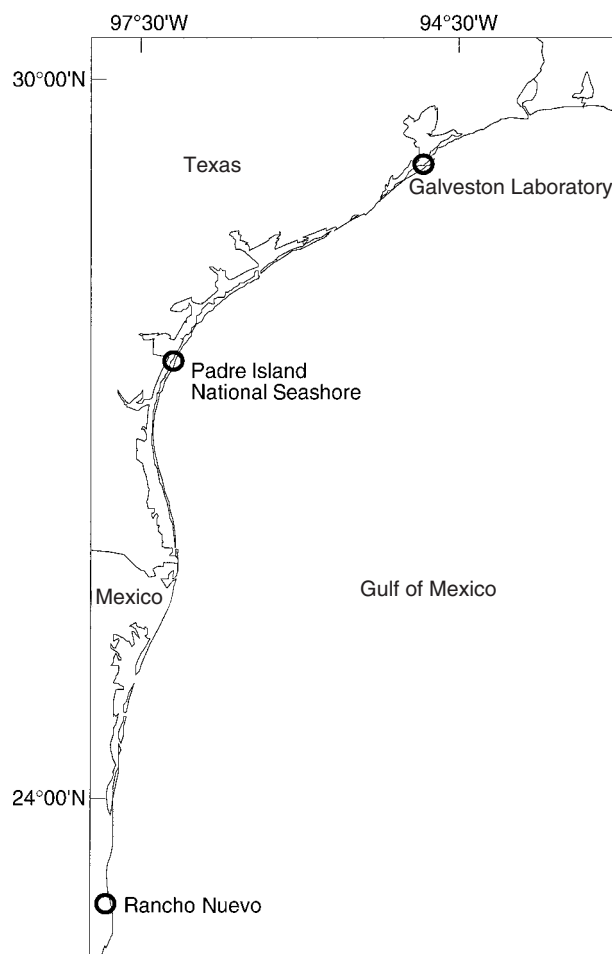
At a meeting in Austin, TX, in January 1977, representatives of Mexico's Departamento de Pesca, the U.S. Department of the Interior [specifically, the National Park Service (NPS) and FWS], the U.S. Department of Commerce (specifically, NMFS), and TPWD established a Kemp's ridley recovery program (2–5). At that time, the annual number of Kemp's ridley nesters was less than 800 and declining at the species' primary nesting site near Rancho Nuevo, Tamaulipas, Mexico (6) (see Fig. 1). Program objectives were to increase protection of nesters, eggs, and hatchlings at Rancho Nuevo; reduce incidental capture of sea turtles in shrimp trawls; and encourage research leading to improved management and population recovery. Prior to the interagency meeting, NPS and FWS regional representatives had been discussing a potential feasibility study (later called the "Kemp's ridley headstart experiment") aimed at establishing a nesting colony of Kemp's ridleys at Padre Island National Seashore (PINS), near Corpus Christi, TX (3–5). The experiment involved collecting and incubating eggs, imprinting hatchlings, and then captive rearing, tagging, and releasing the turtles into the Gulf of Mexico within their first year of life. It protected them from predators and other causes of mortality associated with those early life stages. Mexican agencies, FWS contractors (initially, the Florida Audubon Society, Maitland, FL; then Gladys Porter Zoo, Brownsville, TX) and volunteers carried out the Rancho Nuevo operations (6,7); NPS conducted incubation and imprinting at PINS (5,8); and the NMFS Galveston Laboratory captive


Figure 1. Locations of the Galveston Laboratory, Padre Island National Seashore, and Rancho Nuevo.

reared, tagged, and released the turtles into the Gulf of Mexico (9–11).

Regulations requiring turtle excluder devices (TEDs) in shrimp trawls were implemented during the late 1980s and early 1990s (12). The regulations led to the development of procedures to test TEDs before they were certified for use in shrimp fisheries. Certification required that a sample of sea turtles, passed one at a time through a TED installed in a shrimp trawl, rapidly escaped through the TED. The Galveston Laboratory was and continues to be the source of turtles used in TED certification procedures. Both Kemp's ridleys and loggerheads have been used in TED certification procedures, but two-year-old loggerheads have become the standard.

In addition to their use in the headstart experiment and TED certification procedures sea turtles at the Galveston laboratory have been the subjects of research on physiology (reproductive, respiratory, metabolic, fitness, anesthetic, and submergence), chemical imprinting, tagging, sex determination, temperature–sex relationship, and diseases. The laboratory also attempts to rehabilitate sick and injured sea turtles obtained from the wild and then releases those that do not have incurable illnesses or debilitating handicaps.

LIFE HISTORY PATTERN

Sea turtle species include leatherback (*Dermochelys coriacea*), green (*Chelonia mydas*), flatback (*Natator depressus*), loggerhead, olive ridley (*Lepidochelys olivacea*), Kemp's ridley, and hawksbill (*Eretmochelys imbricata*) (13). These species all have similar life history patterns (14), with the greatest part of the multidecade life span spent at sea, where capture, observation, and tracking are difficult and costly. In contrast, much has been learned through studies of sea turtles in captivity, at nesting sites, and by examining carcasses found stranded on barrier beaches. Specific life history characteristics of Kemp's ridley (15,16) and loggerhead (17,18) turtles have been described in detail.

Adult female sea turtles ascend beaches to nest during spring and summer, sometimes more than once during a nesting season, but not always each year (19,20). Females dig nests with their rear flippers, deposit clutches containing around 100 eggs each (ranging from tens to fewer than 250 eggs per clutch, and varying with species), and then cover the eggs with sand before returning to the water. The whole process takes about 0.8–2.5 hours, depending on the species. The eggs hatch after incubating 6–13 weeks, depending on the species and the temperature (20). Hatchlings emerge from the nest and crawl down the beach to the water. Recent studies suggest that a hatchling's biological compass is set during this crawl down the beach, providing a mechanism for possible magnetic navigation back to the nesting site after the turtle matures (21).

Eggs and young sea turtles are especially vulnerable to environmental factors, predation, and human activities (22–24). Eggs are eaten by crabs, small to medium-sized mammals, reptiles, birds, and humans, but they also sometimes succumb to inundation by high tides, heavy rain, or flood waters and invasions by insects, microbes, fungi, and plant roots. Hatchlings are exposed to avian, mammalian, and crustacean predators on their way to the water, where they are then faced with added threats from fish, molluscs, other marine animals, and sea birds. They swim out to sea, drifting with ocean currents and foraging for food near the surface for a year to more than a decade, depending on the species (24,25). Little is known about the whereabouts and habits of turtles at this young life stage, which precedes the larger immature and adult stages that are capable of benthic feeding. Turtles at the larger stages are vulnerable to both deliberate and incidental capture by various fishing gears and methods (12,23,24,26). Diet and feeding habits, from omnivory to carnivory, vary considerably among species (27).

Estimates of age at sexual maturity vary within species and range from one to five decades among species (24,28). Copulation takes place on migratory routes to nesting beaches, as well as near nesting beaches (20; David Owens, personal communication, February 1998). Males have large, curved claws on their foreflippers; their plastrons soften and depress during the mating season; and they have long, thick tails and large, curved penises. All of these factors aid the males in grasping females during copulation, which can last for hours (20,28). Females can store sperm to fertilize multiple clutches of eggs during a nesting season (20,29).

AQUACULTURE OF KEMP'S RIDLEY AND LOGGERHEAD SEA TURTLES

The Galveston Laboratory first reared loggerhead hatchlings, provided by the Florida Department of Natural Resources, in Jensen Beach, FL (30), to gain experience before shifting to headstarting Kemp's ridleys (4). After 1977, loggerhead hatchlings reared at the Galveston Laboratory were received from Clearwater Marine Science Center, Clearwater, FL, or Mote Marine Laboratory, Sarasota, FL (31). One clutch of loggerhead eggs was obtained from a nest on Bolivar Peninsula, near Bolivar, TX, and incubated at PINS, and its hatchlings were provided to the Galveston Laboratory.

Egg Collection and Incubation

Kemp's ridley eggs for the headstart experiment were collected annually from 1978 to 1992 by FWS contractors, Mexican turtle camp personnel, and volunteers. The eggs were exposed to the Rancho Nuevo beach sand or to PINS sand transferred to Rancho Nuevo in polystyrene foam incubation boxes (5,7,8,32), under the working hypothesis that chemical imprinting took place in the egg or hatchling stage (21,33). Eggs to be placed in PINS sand were caught in plastic bags as they were laid, so that they would not come in contact with Rancho Nuevo sand (2,7), and the people who handled the eggs wore sterile gloves. Eggs from a clutch were stacked in an incubation box containing a layer of PINS sand; next, additional sand was packed around and on top of the eggs to prevent them from coming in contact with the box. The eggs were then transported by aircraft, vehicle, or both to PINS for incubation (5,7,8,34). Hatchlings for headstarting also were transported by aircraft from Rancho Nuevo (32) and from the Kemp's ridley breeding experiment at Cayman Turtle Farm, Grand Cayman, British West Indies (10).

The mainstay of the Kemp's ridley recovery program—protection of eggs and hatchlings at the Rancho Nuevo and contiguous nesting sites (2,15,16,35)—is a form of artificial culture. Typically, most of the eggs laid are collected and transplanted into artificial nests within fenced corrals on those beaches, so that they can be monitored during incubation and protected from predators and human exploitation. Hatchlings from the corrals are then protected during their crawl to the water, but must fend for themselves thereafter.

Sex Determination

Sex in sea turtles is determined by the temperature to which eggs are exposed during incubation. More females are produced at temperatures above the pivotal temperature (i.e., the temperature that produces a ratio of one male to one female), and more males are produced at temperatures below the pivotal temperature (36). As Kemp's ridley eggs were stacked in an incubation box, a temperature sensing probe was placed in the center of the clutch, with a wire leading outside the box for

connection to a temperature recorder (5,7). The pivotal temperature for Kemp's ridleys was not known until 1985, and from that year through 1988, the NPS controlled incubation temperatures at PINS so as to produce mostly females (34,36,37). Prior to 1985, mostly males were produced (37,38). The Galveston Laboratory had no control over incubation of loggerhead eggs: All loggerheads reared at the Galveston Laboratory were obtained as hatchlings, with most coming from Florida and one clutch from PINS.

Imprinting

When the headstart experiment began, chemical imprinting was hypothesized to take place in the egg or hatchling stage (4,33). Kemp's ridley hatchlings that emerged from eggs incubated at PINS or Rancho Nuevo were allowed to crawl to the water before being netted and transferred to the Galveston Laboratory for captive rearing (5). If Kemp's ridleys return to their natal beach as adults, using magnetic navigation (5,21), then the procedures used in their crawl to the water as hatchlings should have sufficed to imprint them to their natal beach. The Padre Island incubation and imprinting phases of the headstart experiment were terminated in 1988, to focus on protecting, documenting, and monitoring Kemp's ridley nests at PINS (34).

Rearing Facilities and Seawater Management

The building housing the turtle rearing tanks is constructed of steel, and its concrete floor is slightly sloped toward drain troughs covered with fiberglass grates (see Figs. 2–4). Incoming seawater flows through PVC pipes laid in the same troughs that carry waste seawater from the turtle barn (see Figs. 2–4). Each fiberglass rearing tank is equipped with a seawater supply pipe and an elevated standpipe that maintains seawater level (see Fig. 4).

The sea turtles are reared in isolation from each other, to prevent incidents of biting, injury, and infections that arise when they are reared in groups (9,30) (see Figs. 4 and 5). Kemp's ridleys are especially aggressive, even as hatchlings, so isolation rearing increases their chance of survival. As hatchlings, the turtles are isolated in small plastic pots placed in groups of four within a plastic crate (see Fig. 5). After 60 days, the pots are removed, and hatchlings are redistributed, one per crate (see Fig. 5). The crates are bolted together with nylon fasteners into groups of 10 to facilitate handling (see Figs. 5 and 6). Each crate is lined on its four inside walls with high-impact styrene sheeting to prevent both dispersion of food and contact between turtles in adjacent crates. The bottom of each crate is fitted with vinyl-coated wire mesh to allow turtle excrement and uneaten food to sink to the bottom of the rearing tank. The crates are supported by a rack constructed of PVC pipe (see Figs. 3, 5, and 6). When the Kemp's ridleys are 9–11 months old, they are tagged and released into the Gulf of Mexico or adjacent bays (9–11,39,40).

Loggerheads approaching two years of age are required for TED certification. Since they are reared for a longer time than Kemp's ridleys in captivity, they outgrow the plastic crates and must be redistributed into larger vinyl-coated wire-mesh cages within the rearing tanks around one year of age (see Figs. 4–6). The walls of each cage are lined with high-impact styrene sheeting, and the bottom is made of vinyl-coated wire mesh (see Figs. 5 and 6). Cages, in groups of two, are supported by galvanized wire hangers or plastic cable ties attached to wooden poles laid across the rearing tank (see Figs. 4–6).

While isolation rearing is somewhat confining, the turtles exhibit high survival rates and good health. To accustom loggerheads to life in the wild prior to their use in TED certification and eventual release, the turtles are semiwild conditioned outside in seawater ponds or pens for about one month, while being closely monitored so that corrective measures can be initiated if aggressive biting occurs. They are fed squid (thawed after being purchased frozen) during that time and may also eat natural foods that they find within the ponds or pens. Except for Kemp's ridleys used in TED certification in the past, and turtles reared for more than one year in captivity (in some cases, to sexual maturity), captive-reared Kemp's ridleys have not been semiwild conditioned before release into the wild (4,9,10). However, an experimental exercise regimen was shown to improve swimming performance in captive-reared Kemp's ridleys (41).

Seawater is filtered through well points buried in the sand off the beach at Galveston as it is pumped from the Gulf of Mexico (9). It flows into a concrete-lined sump, where particulates are allowed to settle, and then is pumped into insulated fiberglass reservoirs (see Fig. 7). It receives no further filtration or chemical treatment, but is heated during winter with thermostat-controlled, electric immersion heaters placed in some of the reservoirs. Heated and unheated seawater are mixed to the appropriate temperature before being pumped into the rearing tanks, and the temperature is maintained thereafter by controlling the air temperature within the rearing building, using forced-air heaters during winter and exhaust fans during summer (see Fig. 2). The temperature of the seawater in the rearing tanks ranges annually from 23 to 31 °C (73 to 88 °F), with a mean near 27 °C (81 °F), and the salinity ranges 20–39 ppt, with a mean near 31 ppt. Three times per week, rearing tanks are drained to remove uneaten food and turtle wastes and are then refilled with clean seawater. Once per month, each tank is scrubbed with a high-pressure sprayer to remove algae and other materials adhering to the sides and bottom.

Keeping seawater clean and warm is of major importance to successful rearing and disease prevention in sea turtles. Various fungal infections, both external and internal, that eventually lead to death occur if the turtles are reared at temperatures below 20 °C (68 °F) (9,30). Whether this situation results from detrimental effects of cooler temperatures on the immune system, encouragement of growth of fungi by lower temperatures, or other factors is not known. Additional diseases and treatments have been described for Kemp's ridleys and loggerheads reared at the Galveston Laboratory (30,31). Sick or injured turtles are removed from the rearing building and treated in a separate "hospital," which is also used for quarantine, to avoid exposing healthy turtles to diseases.

Food, Feeding, Growth, and Survival

The turtles are fed floating feed pellets manufactured by Purina Mills, Inc. (9,42). Each turtle receives a daily ration based on a percentage of the average body weight of a sample of turtles of the same age. Feeding of newly hatched sea turtles is postponed for up to nine days, to allow time for yolk sac absorption (43). The daily ration for hatchlings is about 2% of the average body weight per turtle and is reduced gradually to about 1% by the time that the turtles are one year old. The percentage can be decreased or increased to control growth rate. Sea turtles fed *ad libitum* or oily fish quickly become obese, which eventually leads to fatty degeneration of the liver (44). Each turtle is individually fed a daily ration divided into two equal portions, one fed in the morning and the remainder in the afternoon.

Kemp's ridleys and loggerheads readily eat squid, blue crab, and shrimp, if given the opportunity. They quickly adapt to eating natural foods after long periods of eating pelletized diets (45). However, once they encounter natural foods, they resist eating pellets unless they are extremely hungry.

Under the controlled conditions of captive rearing described herein, Kemp's ridleys can grow to an average weight of 1.26 kg (2.78 lb) and an average straight-carapace length of 19.5 cm (7.7 in.) in a year (11). The first-year survival rate in captivity for the 1978–1992 year-classes combined was 87% (11), and in recent years it has exceeded 95%. Under similar conditions, loggerhead growth and survival during the first year in captivity are comparable to that of Kemp's ridleys (Clark Fontaine, personal communication, February 1998).

Captive Breeding

Responding to recommendations by prominent sea turtle scientists (46,47), the government of Mexico and the Galveston Laboratory distributed Kemp's ridleys to cooperating marine aquaria (see Table 1) in the late 1970s to mid-1980s, to be reared to maturity and held as a breeding stock in case other conservation efforts failed (2,3,15,28,48). The turtles were dispersed among numerous marine aquaria, in order to distribute the costs of their maintenance and to avoid catastrophic losses due to disease outbreak or other causes of mortality (47). Cayman Turtle Farm, which received most of the turtles, was the first to breed Kemp's ridleys successfully, producing viable hatchlings from seven-year-old captive reared animals in 1986 (49). Under an agreement with the government of Mexico, Cayman Turtle Farm still maintains about 400 Kemp's ridleys. Included are survivors from the original stock received from Mexico, as well as offspring produced by captive breeding survivors from the stocks received from both Mexico and the United States (Rene Márquez–Milan, personal communication, November 1997). The Kemp's ridleys at Cayman Turtle Farm provided opportunities for studying reproductive behavior and physiology (28,50–52). Other marine aquaria also gained valuable experience with captive rearing (see Table 1). The experimental captive breeding program in the United States was terminated in 1988, and most of the surviving turtles in the dispersed brood stock have since been released into the wild. For example,

survivors in the group of turtles originally obtained as yearlings by Cayman Turtle Farm from the United States were returned as adults by FWS to the Galveston Laboratory and released into Galveston Bay, TX, in 1992.

EPILOGUE

The Galveston Laboratory has reared, tagged, and released more than 23,000 Kemp's ridleys (40) and hundreds of loggerheads since 1978. Six nestings of headstarted Kemp's ridleys were documented from 1996 through 1998 at the Padre Island National Seashore, the beach to which they had been imprinted as hatchlings (53,54). Despite the Galveston Laboratory's successes in experimental captive rearing and reintroduction of Kemp's ridleys and loggerheads into the wild, the usefulness of such an approach in the conservation and management of sea turtle stocks remains in doubt (55). A listing of Galveston Laboratory reports and publications on sea turtle research (56) can be obtained by contacting the laboratory at 4700 Avenue U, Galveston, TX 77551 USA (Phone 409-766-3500, Fax 409-766-3508), or the National Technical Information Service (NTIS), 5285 Port Royal Road, Springfield, VA 22161 USA (Accession No. PB97-167415, Paper copy US$19.50 Microfiche US$10.00). A recent assessment of the status of Kemp's ridley and loggerhead stocks (57) can be obtained by contacting the NMFS Miami Laboratory, Sea Turtle Program, 75 Virginia Beach Drive, Miami, FL 33149 USA, or by contacting NTIS.

ACKNOWLEDGMENTS

Jackson, Maurice Renaud, Dickie Revera, Bradley Robertson, Wayne Witzell, and Roger Zimmerman reviewed the manuscript and provided many helpful suggestions.

INTRODUCTION

Shrimp aquaculture, the production of saltwater and freshwater shrimp in impoundments and ponds, traces its origins to Southeast Asia, where, for centuries, farmers raised incidental crops of wild shrimp in tidal fish ponds (Fig. 1). The shrimp were not considered of great value. Time has changed this perspective, and shrimp culture has
Figure 1. Shrimp aquaculture.

grown into one of the largest and most important aquaculture crops worldwide. Shrimp of all kinds (coldwater and warmwater) are highly desirable now in a world market. Most coastal countries have a harvest industry for shrimp, and about one hundred of those catch enough to export. Shrimp production has been increasing since 1975, when shrimp farming accounted for only 2% of the world market for shrimp. Of the shrimp-producing countries, over 50 practice shrimp aquaculture. Shrimp culture increased 300% from 1975 to 1985, 250% from 1985 to 1995, and if it increases 200% between 1995 and the year 2005, world shrimp culture production will be at 2.1 million metric tons (hereafter abbreviated as MT = 1.1 standard tons = 2,204.6 lb, or 1,000 kg). Present world shrimp culture production is 737 thousand MT annually, or 24.5% of the 3 million MT world market for shrimp (1). This entry discusses the major aspects of shrimp culture, its growth, and some of the problems encountered by the industry while producing shrimp for a world market. The major aspects (Fig. 2) of shrimp aquaculture are sourcing or obtaining brood for hatchery production, maturation and reproduction of broodstock, genetics, egg and nauplii production, larval rearing, postlarval holding and sales, growout in ponds and raceways, production of bait or edible shrimp, harvesting, processing, and sales to a world market.

HISTORICAL NOTES ON PENAEID SHRIMP AND SHRIMP CULTURE

The earliest record of Penaeidae is in Chinese history and traces back to the 8th century BC. Japanese literature referred to penaeids in 730 AD. The first scientific record of a penaeid was in 1759, when Seba of Amsterdam named and drew a North American penaeid. In 1815, Rafinesque recognized that penaeids were a distinct group within Decapoda and named them Penedia (corrected to Penaeidae by the International Commission on Zoological Nomenclature in 1955). Revision of these important decapods and the renaming continues today. Recently, Isabel Perez Farfante and Dr. Brian Kensley proposed some changes in the way scientists refer to the popular farmed shrimp species (2). Except for three species (*Penaeus monodon*, *P. esculentus*, and *P. semisulcatus*), the genus names were changed on other
Figure 2. Major aspects of shrimp aquaculture.

penaeids to *Litopenaeus*, *Fenneropenaeus*, *Marsupenaeus*, or *Farfantepenaeus*. Although these proposed changes and the addition of new genera have not been officially accepted by the International Commission on Zoological Nomenclature, the majority of the scientific community accepted the change, and this article will refer to the new names.

For hundreds of years, shrimp farming had only been considered a secondary crop in traditional fish-farming practices in many Asian countries. Modern shrimp culture actually began in the 1930s when the Japanese succeeded in closing the life cycle of the kuruma shrimp, *Marsupenaeus japonicus*. The Japanese cultured larvae in the laboratory and succeeded in mass producing them on a commercial scale. The work of M. Fujinaga in 1933 [also found in the literature as Hudinaga (1935)] (3) with *Penaeus japonicus* (*M. japonicus*) opened the way to modern shrimp farming. Fujinaga published (4) and spread the technology from 1935 to 1967 (5), and his work contributed largely to getting the industry started. In the early 1960s, the first commercial farms were built in the Seto Inland Sea of Japan. In 1935, J.C. Pearson described the eggs of some penaeid shrimp from the western hemisphere, and in 1939 he described the life histories of some American penaeids. A familiarity with the penaeid shrimp life cycle (Fig. 3) emerged and was an important

step in understanding what was required to obtain desired results in hatchery and growout procedures. Since adult shrimp migrate offshore to the more stable environment (better salinities and temperatures) of the ocean, where they mature and reproduce, commercial hatcheries found that they had to mimic natural conditions. Hatcheries worked better with higher salinities and cleaner water, whereas growout worked best in the back bays and estuaries with lower salinities.

Commercial shrimp growout attempts were made in Ecuador in the 1960s and in the U.S. starting in the late 1960s and early 1970s. The Ecuadorian industry was based upon *Litopenaeus vannamei* and *Litopenaeus stylirostris* and was started by accident when a broken dike on a banana farm allowed shrimp to enter. By the time the farmer repaired the dike, a crop of shrimp had been produced. Expansion of the Ecuadorian industry was made possible by an abundance of wild postlarval shrimp. Large groups of harvesters (Fig. 4) provide postlarvae (hereafter called PL) to the farm owners, by catching the seasonally appearing PL in scissor nets (Fig. 5). The PL prices generally fluctuated from US$2 for 1000 to US$20 for 1000, depending on their availability. After the industry matured and could not rely entirely upon the wild-caught PL for all of its needs, brood collection stations developed

Figure 7. Small, family-owned (called backyard) hatchery in Thailand.

along the coast and captured and spawned wild-mated females and provided an important nauplii source to meet the growing hatchery demand. The Ecuadorian industry has become more dependent on hatcheries as it has grown, and larvae from hatcheries have become stronger since new hatchery techniques and feeding combination diets have been developed. The initial U.S. industry attempts followed that lead, but were based upon native species of white, brown, and pink shrimp. When researchers grew exotic shrimp from the Pacific coast of Central and South America in the U.S., they proved to be easier to culture and more productive in the ponds. Gradually commercial producers in the U.S. concentrated on exotics, such as *L. vannamei*, now the most popular farm-raised shrimp in the western hemisphere (Fig. 6).

Once shrimp hatcheries (Figs. 7 and 8) began supplying large quantities of shrimp to farmers, the production of farm-raised shrimp expanded rapidly. The explosion of the industry continued into the early 1990s (Figs. 9–12), until problems began with disease outbreaks and water quality, which slowed worldwide production for a few years. In recent years, production has been on the increase again, as ways of controlling diseases have been found and water recirculation and reuse technologies are being more widely practiced (Fig. 13).

Figure 8. Large shrimp hatchery in India.

Many groups from different countries have continued to work on shrimp culture research and development. SEAFDEC (Philippines), TASPAC/MEPEDA (India), AQUACOP (France and Tahiti), NOAA/Sea Grant and USDA (USA), and United Nations/FAO (Rome, Italy) are just a few groups that have made progress through research.

WORLD SHRIMP CULTURE PRODUCTION

Rosenberry (1) is one of the best sources to keep track of current world shrimp production and affairs. The total world production of cultured shrimp grew from about 30,000 MT in 1975 (about 2.3% of the world supply) to over 600,000 MT in 1993 (about 28% of world supply). World shrimp production declined slightly in 1993 for the first time in 11 years, but production still remained at 609,000 MT and rebounded quickly in 1994 with record breaking numbers of 733,000 MT. Most of this impressive growth in production has occurred in Asia, where traditionally about 75–80% of cultured shrimp are produced. The remaining 20–25% is largely produced in Central and South America. From its peak in 1994, until 1997, world production of cultured shrimp declined slightly every year (1995 = 712,000 MT, 1996 = 693,000 MT, and 1997 = 660,000 MT). In 1998, the world shrimp production reached its highest point to date at 737,000 MT (Table 1). Thailand produced 210,000 MT, despite the white-spot syndrome virus (WSSV), the yellow-head virus (YHV), and other diseases. Thailand's ability to adjust and adapt procedures to limit the spread of diseases helped keep production up. Figure 13 shows how one farm (Aquastar) took three to four ponds out of production and circulated water through them to supply one production pond (in the lower right of the figure). Ecuador's production has remained relatively stable (around 130,000 MT/yr) and has adjusted to losses from the Taura syndrome virus (TSV).

The acceleration in shrimp culture activity in the early 1990s was influenced by a combination of factors. Economic conditions encouraged a rapid increase in demand

for shrimp, while at the same time simultaneous new innovative culture technologies were being developed. Among the most important factors influencing the demand for shrimp were (*1*) rapid income growth in areas where shrimp was a popular premium food (primarily Asia and some parts of Europe), (*2*) a shift in U.S. and European consumer preference away from traditional protein sources (e.g., red meat) to seafood, and (*3*) adjustments in currency relative to the U.S. dollar that encouraged shrimp consumption in Japan, China, and Europe. The most important technological breakthroughs for countries producing farm-raised shrimp were (*1*) the commercialization of shrimp-hatchery technology, (*2*) the development of high-performance feeds, and (*3*) improvements in overall pond-management practices. Through the present, the industry has continued to adjust and improve technologies, including disease control and water recirculation.

Although cultured shrimp production now contributes over 24.5% of the total world production of shrimp. (It represents a much larger portion of export volume.) This is largely because the developing source countries have an economic incentive to export. Cultured shrimp are generally superior in quality to their trawled counterparts because cultured shrimp get to the processor sooner, without the use of chemicals. The shrimp farmer can usually schedule production and minimize delays between harvesting and processing of crops. Because of these factors, it is generally believed that any further increases in demand for shrimp, especially shrimp of export quality, will most likely be met by increases in cultured shrimp production. Shrimp diseases and poor water quality were the chief reasons that world shrimp production declined slightly from 1995 through 1997, but there appears to be evidence that the industry is rebounding from these problems and is now producing more shrimp than ever

before (737,000 MT in 1998). However, the WSSV problem continues to plague the industry on a worldwide basis.

In India, Ecuador, Indonesia, and Thailand, industry revenues range from US$300 million per year to over US$1 billion per year. During the late 1980s Taiwan, Bangladesh, and the Philippines had developed large shrimp culture industries, but these markets have leveled off in recent years. China's shrimp-farming industry boomed until the early 1990s, but then crashed. India and Indonesia boomed until the mid-1990s and then leveled off or declined when problems related to overexpansion took place. More recently, Vietnam and Nicaragua have newly expanded shrimp culture industries. Honduras, Mexico, and Colombia all had substantial industries at one time, but production declined with diseases, water quality, and other problems. Smaller industries exist in Panama, Peru, Guatemala, Brazil, and Venezuela. Ecuador and Thailand have been leaders in the shrimp culture industry. These two countries have continued to adjust to problems in the rapidly changing industry and have continued to expand their industries despite troubles. Additionally, disease-resistant species and steps taken toward sustainable, environmentally friendly operations are assisting the industry recover. The most notable recovery took place in Mexico in the late 1990s, where the IHHN-resistant blue shrimp (*L. stylirostris*), also referred to as "Super Shrimp," is assisting the industry rebound. The disease-resistant strain was developed in Venezuela and is doing well there, as well as on the Pacific Coast of Mexico and a few other isolated areas, such as west Texas and the Dominican Republic.

Areas of the world that consume the majority of the shrimp produced are the United States, Japan, and western Europe. Also, more recently, China has begun to purchase shrimp from Thailand and other countries.

SHRIMP PRICES AND QUANTITIES CONSUMED IN THE UNITED STATES

The current prices for shrimp in the United States can be obtained on the internet free of charge at *http://www.st.nmfs.gov/st1/market_news/doc45.txt*, with quantities harvested by the shrimping industry. According to USDA's Aquaculture Outlook (6) (now available on the internet at the following web site address: *http://usda.mannlib.cornell.edu/emailinfo.html*), total shrimp imports in 1998 reached US$3.1 billion, an increase of 5% from 1997 and 27% from 1996. The increase was due to a 7% increase in volume, as the average price of all imported shrimp products declined 2% to US$9.86/kg (US$4.48/lb). The total trade deficit for the United States in 1999 averaged US$18.9 billion. Shrimp made up one-sixth of that deficit, and all seafood made up approximately one-third of it.

Imports of shrimp products totaled 313 million kg (695 million lb), with frozen products accounting for 86%, fresh shrimp for 1%, and prepared products (breaded, canned, precooked, etc.) for 13%. Shrimp imports are expected to continue to increase into the year 2000, as a strong domestic economy should increase both restaurant sales and home usage, and a strong U.S. dollar will encourage imports from major suppliers, such as Thailand, Ecuador, Mexico, and Indonesia. Although frozen products had dominated shrimp imports, a growing portion of imported shrimp is now being shipped as prepared products. In 1998, prepared-shrimp imports totaled 40 million kg (89 million lb), having a value of US$452 million, up 29% from 1997. Asian producers, notably Thailand, India, and Indonesia, were the major suppliers of prepared-shrimp products, accounting for 88% of total shipments in 1998. In 1999, shipments of prepared shrimp are again outpacing increases in fresh and frozen products. Higher away-from-home food consumption and the growth of prepared-meal sales at food stores drive the increases in prepared-shrimp imports. Imports from Thailand have been the fastest growing among the major shrimp suppliers. In 1998, imports from Thailand totaled 91 million kg (203 million lb) and were valued at US$1.1 billion (7). Thailand is estimated to be the largest shrimp-farming country, with total production in 1998 estimated at 210,000 MT on a head-on basis. Favorable exchange rates and a desire to gain foreign exchange earnings have bolstered Thai exports.

Imports of frozen-shrimp products reached 270 million kg (599 million lb) in 1998, up 5% from the previous year. Shipments of frozen unshelled shrimp are reported in nine different size categories and are grouped by count. The count sizes range from the largest shrimp, less than 33/kg (15/lb), to the smallest sized shrimp, with more than 155/kg (70/lb). Each country's role as a shrimp supplier to the United States varies with shrimp sizes. Mexico, India, and Bangladesh are major suppliers of large shrimp. Ecuador and Thailand dominate imports of middle-sized farmed shrimp. A number of Central American countries dominate imports of the smallest sized shrimp (6).

SALTWATER SHRIMP CULTURE IN OPEN POND SYSTEMS

Marine shrimp culture continues to generate a large amount of interest worldwide. Despite problems in an industry struggling to attain sustainability, average yields from most farms steadily increased in the early 1990s, partly due to improved techniques and these yields stimulated a higher level of interest among potential investors, entrepreneurs, and businesses wanting to diversify their holdings. In recent years, viruses such as TSV, WSSV, and YHV have taken their toll on production rates at shrimp farms. Even areas that practice High Health Genetically Improved (HHGI) technologies have been plagued with viruses, often resulting in 10–30% survivals in comparison to the normal 50–74% survivals during the four- to five-month culture period. Many have found that shrimp culture requires a large investment with hidden costs and that the returns can be low. But if planned and managed properly, it can also be a very profitable and rewarding business. A financial analysis spreadsheet is available for shrimp farming that assists in determining the economic feasibility of a proposed project over a 12-year horizon and calculates the internal rate of return (8). Another software program exists that assists shrimp farmers control parameters on the farm and forecast the production parameters, as well as look at the present financial status of a shrimp farm. This program is called AP/1 and is available in Ecuador.

Much progress has been made to fully domesticate shrimp, as the swine and poultry industries have done, but more technology development is needed in genetics, selection of disease-resistant strains, probiotics, and nutrition.

SALTWATER SHRIMP CULTURE IN SEMICLOSED OR RECIRCULATING SYSTEMS

With new environmental restrictions and regulations occurring in the shrimp culture industry, many businesses are further restrained and are finding it more difficult and expensive to conduct business under the new environmental constraints. Additionally, new viruses are discovered yearly. It is presently not as obvious in developing tropical countries, but in the United States, public sentiment falls on the side of sustainability and environmental soundness, and the laws reflect this. Agriculture and the seafood production industries (both wild harvest and aquaculture) are experiencing challenging and often difficult times. The wild harvest of seafood has reached its maximum sustainable yield and in some cases has declined. According to the Food and Agricultural Organization of the United Nations (FAO) (7), world commercial shrimp fishing production increased steadily from 1992 to 1995, but then dropped in 1996 and 1997. The number of live shrimp produced (in MT) in 1992 to 1997 were 2.22, 2.31, 2.38, 2.48, 2.40, and 2.35, respectively. Note that the 1997 figures dropped below the 1994 figures. According to this data, the world shrimp fishery began to decline in 1996 and has continued this trend. Data from 1998 and preliminary data from 1999 data are also indicative of this trend (7).

The recirculation technology is being used more now, because it is more cost-effective. In the late 1960s and in the 1970s, coastal property in Ecuador could be purchased for US$100 per ha (US$45 per ac) and a 250-ha (617.5-ac) farm cost approximately US$500 to US$1000 per ha (US$225 to US$450 per ac) to construct, including a pump station. Today, it costs approximately US$12,000 to US$15,000 per ha (US$5,400 to US$6,750 per ac) to develop new farms in Ecuador and in other areas of Central and South America. Additionally, most of the functional hatcheries have gone to recirculated operations, because they can control all phases of the hatchery cycle. This reduces losses by reducing the opportunities for opportunistic pathogens. During the past five years, the aquaculture industry has begun to modify average pond size by moving to smaller ponds. They have implemented and improved water treatment methods (both before and after use), have begun to implement biosecurity along with disease identification techniques, and treatment and prevention have now become top priorities. The degradation of the environment and more stringent regulations have encouraged the industry to move in this direction. At pond outlets, which are often someone else's intake, the industry has changed its attitude and is now doing what it can to discharge cleaner, higher quality water than it took in. A similar example from another industry is found in chicken production. That industry moved from barnyard production to 100% environmentally controlled growout units. Fifty years ago, it took approximately six months to produce a marketable chicken. Now, it generally takes six to seven weeks from hatchling to market. This is the direction where the aquaculture industry is headed. Traditional pond culture, like the barnyard, out of necessity, is being used less as time passes.

From 1990 through 1998, the Texas shrimp aquaculture industry produced 10.9 million kg (24 million lb) of shrimp with a farm-gate value of US$75 million, generating a US$225 million economic impact on the state's economy. This helps the United States offset some of its enormous seafood trade deficit. The shrimp farming industry generates more than 150 jobs in the state on a full-time basis, and the number increases during harvest season. The industry has positive affects on other areas, such as feed production (fishmeal, corn, rice bran, and other farm-raised products), processing, transportation, and sales. The same trend that has occurred worldwide has occurred in Texas. Production increased and expansion of the industry occurred until around 1995, when production took a serious dip because of diseases. The shrimp aquaculture production in Texas from 1987 to 1998 can be seen in Figure 14 and from 1990 to 1998 in more detail in Table 2.

Like the aquaculture industry, harvest fleets are being regulated more with limited entry, limited seasons, and limited gear. World markets are pressuring shrimp fleets and shrimp harvest countries to catch the product using certain standards, such as using fish-excluder devices to limit by-catch and avoid catching turtles.

Considering only natural products, next to oil, seafood is one of the greatest trade deficits in the United States. When all products are considered, seafood falls to fourth, after oil, automobiles, and electronics. Increased populations along the U.S. coasts have placed additional demands for seafood and have opened up new markets, but at the same time have placed additional burdens on the coastal environment. Seafood safety has become an issue, since environmental degradation continues. The United States officially implemented the Hazard Analysis Critical Control Point program (HACCP) in December, 1997, which placed additional controls upon the seafood industry. With limited entries, by-catch controversies, turtle- and dolphin-free industry requirements, the wild-caught seafood industry has no real area for expansion, and with new environmental regulations and restraints on our coasts, aquaculture is being restrained. The U.S. Food and Drug Administration (FDA), the U.S. Environmental Protection Agency (EPA), the National Marine Fisheries Service (NMFS), and others played roles in putting together the HACCP guidelines, which were designed to

Estimated farm-gate value of crop (in millions of U.S. dollars)[b]										$4 M	$4.7 M	$11 M	$11.2 M	$12.8 M	$3.5 M	$6 M	$11.49 M	$9.68 M

[a] M = million; lb = pounds; mt = metric tons; (1 mt = 2,205 lb); ac-acres; ha = hectares; (1 ha = 2.47 ac). Taura syndrome virus (TSV) did not appear in Texas Valley area in 1997–1998, but did occur on farms further north. Harlingen stocked 200 acres of *Litopenaeus setiferus* at low stocking densities as a precaution against TSV in 1996 & 1997. Bart Reid (Regal Farm) reported that at least 2 ponds produced 6,000 lb/ac with others producing from 4,000–5,000 lb/ac, using *L. stylirostris* (1996). Robert Smiley (Southern Star) reported figures for 1998. *L. stylirostris* can now be grown again in West Texas after being stopped by TPWD in 1997. Average state production from 1990–1998 was 2.66 million lb/year, and the average crop value over the same period was $8.2 M/year.

[b] Average farm gate, heads-on price in 1998 was down, ranging from 2.30–2.90/lb in Texas Valley. Total crop value estimated as follows: 595,000 lb at $2.30 = $1,368,500; 1.4 M lb at $2.90 av. = $4,066,832; 414,191 lb at $4.50 = $1,863,859; 172,000 lb at $4.00 = $688,000; 84,000 lb at $4.00 = $336,000; 144,000 lb at $3.00 = $432,000; and 320,000 lb at $2.90 = $928,000; totaled = $9,683,191.

check food safety within the fisheries and aquaculture industries. The HACCP guidelines, entitled *Fish and Fisheries Products Hazards and Controls Guide, January 1998*, contains 20 chapters in 267 pages. Chapters include the following: "Steps in Developing Your HACCP Plan," "Pathogens From the Harvest Area," "Parasites," "Natural Toxins," "Scombrotoxin (Histamine) Formation," "Other Decomposition-Related Hazards," "Environmental Chemical Contaminants and Pesticides," "Methyl Mercury," "Aquaculture Drugs," "Pathogen Growth and Toxin Formation (Other than *Clostridium botulinum*)," "*C. botulinum* Toxin Formation," "Pathogen Growth and Toxin Formation as a Result of Inadequate Drying," "*Staphylococcus aureus* Toxin Formation in Hydrated Batter Mixes," "Pathogen Survival through Cooking," "Pathogen Survival through Pasteurization," "Introduction of Pathogens After Pasteurization," "Food and Color Additives," "Metal Inclusion," as well as seven appendices, including FDA and EPA guidance levels.

Stricter environmental regulations and the desire to control the spread of shrimp diseases in the United States have forced some of the farms to recirculate water. Farms have learned to produce shrimp using far less water than ever thought possible.

SUSTAINABLE, ENVIRONMENTALLY FRIENDLY SHRIMP FARMING

In the mid-1990s Thailand led the way and started practicing the reuse, or recirculation, of water. In 1998, one Texas farm (Arroyo Aquaculture Association), produced over 637,435 kg (1.4 million lb) of shrimp on 139 ha (345 ac), or about 4,000 kg/ha (4,000 lb/ac) in a semiclosed system (Figs. 15 and 16). In 1999 the farm produced 816,000 kg (1.8 million lb) on 155 ha (385 ac). The management team is leading the way to sustainable, environmentally friendly shrimp farming by recirculating water (Fig. 17) and cutting its water use over time from 37,620 L/kg (4,500 gal/lb) of shrimp produced in 1994 to 2,508 L/kg (300 gal/lb) of shrimp produced in 1998 (Fig. 18). Most of the 2,508 L/kg (300 gal/lb) of water was used to fill the ponds and offset evaporation. The farm cut its stocking density from 50 shrimp/m^2 (50/10.7 ft^2) to 36 shrimp/m^2 (36/10.7 ft^2) and used more aeration, increasing from 8 to 10 hp/ac (Fig. 19). Additionally, the farm widened and deepened it discharge canal and placed aeration in it (Fig. 20). The results of these additions have dropped the total suspended solids (TSS) discharged per unit weight of shrimp produced. In 1994, the farm generated 1.6 kg (3.6 lb) of TSS/0.45 kg (1 lb) of shrimp, and in 1998 it only generated 0.45 kg (1 lb) of TSS for every 9 kg (20 lb) of shrimp produced. In 1994, it discharged almost 0.225 kg (0.05 lb) of ammonia (NH$_3$) for every pound of shrimp, and in 1998, it only discharged 0.45 kg (1 lb) of NH$_3$ for every 1,125 kg (2500 lb) of shrimp (Fig. 21). In 1994−1995, the farm discharged between 0.045 and 0.079 kg (0.1 and 0.17 lb) of carbonaceous biochemical oxygen demand (CBOD) for every 0.45 kg (1 lb) of shrimp, and by 1998 it only discharged 0.45 kg (1 lb) CBOD for every 45 kg (100 lb) of shrimp produced (Fig. 22). The amazing thing is that the farm surpassed

its 1994 weight per pond produced in 1997 and 1998 (Fig. 23), and it is now producing in excess of 4,000 kg/ha (4,000 lb/ac). This is leading the way to future, sustainable shrimp farming in the coastal areas. See (9) for more detail on the treatment of harvest discharge from intensive shrimp ponds by settling.

BACKGROUND ON U.S. SHRIMP CULTURE RESEARCH

Many early identifications of penaeid shrimp appeared in the literature before shrimp culture had been considered in the U.S. An example is when A.B. Williams published the "Identification of Juvenile Shrimp in North Carolina" (10). National Marine Fisheries Laboratory (NMFS)

Figure 21. Decrease in ammonia at Texas shrimp farm. (Data from Louis Hamper.)

Figure 23. Shrimp production per 5-acre pond at Texas farm. (Data from Louis Hamper.)

researchers in Galveston, Texas, made some of the more significant U.S. government contributions toward shrimp culture. Research on the culture of larval shrimp started there in 1959 as part of an investigation into the life history of native shrimp in the Gulf of Mexico. Even though it had nothing to do with shrimp aquaculture, it did lay the foundation for later work on shrimp culture. For example, Harry Cook published a generic key to the protozoea, mysis, and postlarval (PL) stages of the littoral Penaeidae of the NW Gulf of Mexico in 1965 (11). Sindermann (12) provided a more detailed list of publications from this period.

Other groups also worked on larval rearing of penaeids in the United States, mainly in the state of Texas. The

Texas Parks and Wildlife Department and some of the universities published works on the subject very early. One example is Ewald (13). A significant aquaculture research and development effort continues through the U.S. Department of Commerce/NOAA/Sea Grant and the U.S. Department of Agriculture.

The significant early contributions from private industry in the United States came from Ralston Purina in Crystal River, Florida, Marifarms in Florida, and Dow Chemical in Texas. Texas now produces more farm-raised shrimp than any other state in the nation, and has the second largest shrimp hatchery in the U.S. Florida has the largest hatchery in the United States, and possibly in the western hemisphere. The hatchery is capable of producing 180 million PL/mo, but sends them to the parent company's farm in Honduras for growout. Additional information on this hatchery is available at *http://www.seafarmsgroup.com/hatchery.htm*. Texas is followed in the amount of shrimp produced in the United States by Hawaii, South Carolina, and Florida. Florida had a shrimp culture industry in the late 1970s and early 1980s, but the last of the early companies, Marifarms, Inc., moved their operation to Ecuador when a hurricane destroyed their operation in Florida. They stocked hatchery-raised, native shrimp into a bay and were harvesting when the storm destroyed the net that held the shrimp in the bay. Florida now has nine permitted operations growing shrimp in high-chloride water at inland locations. Problems have been experienced at these farms with mortality after handling of the stock, but once the problems are solved, there is potential for growth in the industry.

LIFE CYCLE OF PENAEID SHRIMP

Juveniles and adults migrate offshore, and in the stable environment of the ocean, they mature, mate, and spawn eggs in nearshore or offshore waters (Fig. 3). All but one species within the family Penaeidae follow this life cycle sequence, although the sequences vary highly among species. Most tropical shrimp eggs are 220 micrometers = microns (0.00003937 in.) in diameter (Fig. 24) and sink, but hatch within 14 hours at 28 °C (82.4 °F). The nauplius is the first larval stage and is attracted to light. In a natural setting, the shrimp PL are carried by currents in the ocean to the protection of the estuary. PL that are carried to the ocean beach generally die in the surf or die from predation or lack of food. In the bays and estuaries, larval shrimp are provided with a diet rich in various sources of nutrition and remain there until the late juvenile or early adult stage. PL are primarily benthic in orientation.
The growout phase in bays and ponds generally takes 4–5 months (16–20 weeks). In bays and estuaries and in culture ponds this length of time depends upon the environmental conditions, and shrimp species. Also, the length of time in bays depends on when shrimp migrate in mass to offshore areas. They generally commence migration from the estuary to restart the life cycle in the ocean during the full moon at night with an outgoing tide.

REPRODUCTIVE CHARACTERISTICS OF PENAEID SHRIMP

Grooved shrimp (those having grooves on both sides of the last abdominal segment) mate differently than do nongrooved shrimp. Female grooved shrimp have a closed thelycum [i.e., *P. monodon* (Fig. 25) and *Farfantepenaeus aztecus*]. The female molts and then mates while her shell is soft. The eggs then develop within the ovaries and are spawned. Grooved shrimp can spawn several times on one mating or on one sperm packet, or until the female molts and loses the sperm packet. The sperm packet is held inside the body and part of it is deposited during spawning.

Nongrooved shrimp, (i.e., *L. vannamei*, *L. setiferus*, and *L. stylirostris*) first develop eggs and then mate and spawn. They generally spawn within a few hours after the spermatophore is placed externally during mating. Once the eggs are spawned, they may not all develop in the same manner. Some may develop abnormally, ending up nonfertile.

Sexual maturity in male and female shrimp occurs as early as 34 g (1.2 oz) for *L. vannamei* and 60 g (2.1 oz) for *P. monodon*. Females may spawn numerous times during their mature lifetime; however, some may not spawn at all. Smaller shrimp live approximately 1.5 years, and larger ones may live as long as 3 or more years.

Figure 24. Penaeid shrimp egg.

Figure 25. *P. monodon* broodstock.

DESCRIPTION OF CURRENT TECHNOLOGIES USED IN SHRIMP CULTURE

A female with ripe, egg-laden ovaries is said to be "gravid" (Fig. 26, top 3 shrimp; bottom is male). Once a gravid female is ready to spawn, she releases the eggs into the water, fertilizing the eggs by simultaneous rupturing of the spermatophore. The eggs exit the ovipositors, located at the base of the third pair of walking legs, and sink. In the nongrooved shrimp, the eggs brush back against the spermatophore (Fig. 27), as the female is continuously swimming. If the female stops swimming or if her swimming is interrupted, the eggs may fall straight down and are not likely to become fertilized.

Most cultured adult shrimp typically produce around 22,000 to 200,000 eggs per spawn, depending on the size of the female. The larger species, such as *P. monodon*, can produce 700,000 to over 1 million eggs during each spawn. For example, a 290-g (10.2-oz) female *P. monodon* might spawn 700,000 eggs, whereas a 454-g (1-lb) female might spawn 1.4 million eggs each spawn. The eggs hatch into the first larval stage, called the nauplius, which is only one of several larval stages. The microscopic larvae are planktonic and feed on their inner yolk sac for 48 hours. This is the best time to ship or transport young larvae. Starting at about 36 hours after hatching,
Figure 26. Egg development in the white shrimp.
Figure 27. Spermatophore attached to ventral side of white shrimp.

the hatchery introduces or feeds microscopic single-celled algae and later other minute forms of zooplanktonic microcrustaceans (usually freshly hatched brine shrimp, *Artemia* nauplii). Nine to 11 days after hatching (at 28 °C, or 82.4 °F, and fewer days if at 30–32 °C, or 86–89.6 °F), the larvae change into a form more closely resembling a typical shrimp. They are then called postlarvae. Some hatcheries shorten the larval time in the hatchery by raising the temperature, but care must be taken because some bacteria grow faster at the higher temperatures. The object is to stay ahead of bacteria and other diseases through preventive measures.

It is estimated that nature is capable of yielding shrimp survival levels of around 2% through the whole life cycle. The commercial shrimp hatchery and subsequent growout phase are capable of achieving much higher survival rates. Nursery ponds are smaller to ponds and can serve as an intermediate phase for the elimination of substandard juveniles used in stocking growout ponds. The growout ponds are used for the production of marketable shrimp. Not all farms use the nursery phase. Many farms stock PL, either from the wild or the hatchery, directly to the growout pond. The market-sized product is generally sold to the processing plant, and the plant, in turn, sells the product in its various forms to the world market.

The shrimp hatchery is very important to the industry. One of the most important aspects with respect to both location and functionality of the shrimp hatchery is water quality. Almost all hatcheries require that oceanic quality water be available on a 24-hour basis. Salinity is the most important water parameter impacting the production of shrimp in the hatchery, and salinity levels must be maintained in a narrow range, between 27 and 36 ppt for best results with most of the species of Penaeidae. Some species of shrimp have very restricted salinity and temperature requirements and preferences.

One such species is the Argentine red shrimp, *Pleoticus muelleri*. It prefers salinities between 33.27 ppt and 33.94 ppt. It is a cold-water shrimp, preferring waters between 9 and 23 °C (48 and 73 °F), and it is found in relatively deep water (25 to 100 m, or 82 to 325 ft). Aquaculture of this species has been overlooked, because it has rather restricted environmental requirements and does not grow as rapidly as some of the tropical species. It takes approximately six months to one year to grow to market size, depending on the source of information, whereas most tropical shrimp can be grown in four months. It costs more to grow them because of the time factor. *L. stylirostris*, can grow to 28 g (1 oz) in 120 days at 26 °C (78.8 °F). *P. muelleri* can grow to up to 7 in. (17.7 cm), but most are closer to 4 in. (10 cm) long. It has an excellent taste, but the flesh can be soft, and handling and processing must be done with great care. If the shrimp are not processed rapidly, they spoil quickly, as is typical of many cold-water species. Some research has been conducted on the aquaculture of *P. muelleri* and other marine species in Argentina and nearby countries since the 1970s. *P. muelleri* does indeed have future potential for commercial aquaculture development, but more research and development are required before it is commercially viable. The Argentine red shrimp is found in the southwest

Atlantic from southern Brazil south along most of the coast of Argentina. Its natural distribution ranges between 20 °S and 48 °S, or from approximately Coratina and Vitória, Brazil to Deseado and Bahia Laura in Argentina, with most being found in the narrow band between 41° and 44 °S, or offshore from Carmen de Patagones to Cabo Raso in Argentina. This narrow band is from the upper reaches of the Gulf of San Matias to Cabo Raso. A marine shrimp, it likes salinities a little less than full ocean salinity, it prefers colder temperatures, and it prefers deeper water. Although it is generally thought of as a deepwater shrimp, some are caught in water shallower than 25 m (82 ft). These parameters are those noted from its natural distribution, but known tolerances outside these ranges are not well understood, which has contributed to its slow evolution as an aquaculture candidate species.

An alternative species suggested by experienced researchers offers additional future potential for commercial aquaculture. Silvio Peixoto, in southern Brazil, states that the species of choice for aquaculture in that area is *Farfantepenaeus paulensis*. This temperate species ranges from Ilheus, Brazil, to Mar del Plata, Argentina, or 150 °S to 38 °S. *F. paulensis* represents a sizable fishery resource in southern Brazil. The species is cold tolerant, and the capture of wild broodstock in adjacent waters has allowed for closing the life cycle in captivity. This is an important feature of *F. paulensis*.

Numerous groups must successfully accomplish maturation, larval rearing, and PL production in order to support an aquaculture industry. Researchers conducting work on these species can be reached through E-mail at *lovrich@satlink.com*, *rivelli@compunort.com.ar*, and *jfenucci@mdp.edu.ar*. Additional literature on the species can be obtained from the Web at *http://tierradelfuego.ml.org/alca*. A beautiful Brazilian hatchery can be seen at *http://www.aqualider.com.br*.

In the shrimp hatchery, seawater is typically checked for pesticides, trace metals, and dissolved organic content on a routine basis. Furthermore, water used in hatcheries is typically filtered to a particle exclusion level of 0.5–1.0 microns (0.000019–0.000039 in.), ozonated, or UV sterilized prior to entering the facility. These treatments help to reduce introduction of bacterial and viral pathogens, as well as organic contamination. Some *Vibrio* spp. are resistant to UV sterilization.

Shrimp hatcheries (Figs. 7 and 8) require relatively small tracts of land and are operated in a labor-intensive manner. Here, broodstock or spawner shrimp from the ocean are brought either into a special facility for subsequent sexual maturation and reproduction or, as in the case of mated females, are allowed to spawn in a nauplii production facility. Some hatcheries prefer to control all production inputs and, thus, source both male and female broodstock shrimp from the ocean. The shrimp are first quarantined to determine extent of possible infection with shrimp pathogens and then placed at densities of five to seven shrimp/m^2 (five to seven shrimp 10.7 ft^2) in large maturation tanks 13 ft, or 4 m, in diameter.

The most important parameters for successful maturation of penaeid shrimp are a constant temperature, acceptable levels of salinity, pH, and light, and good

Table 3. Parameters for Tropical Shrimp Maturation and Allowable Ranges/24 hr

Salinity	Temperature	pH	Light	D.O.
27–36 ppt +/−0.5	27–29 °C +/−0.2 (80.5–84.2 °F)	7.8 +/−0.2	14 L, 10 D	5 ppm +

nutrition (Table 3). The object is to reproduce the near constant conditions found in the deeper oceans. Constancy is a must. Clear, pristine, oceanic quality seawater is the key to successful maturation. The following paragraphs describe the important parameters and give examples of how to maintain acceptable levels of these parameters.

1. Temperature for tropical shrimp: Optimum temperatures are 27–29 °C (80.5–84.2 °F) for most warmwater species. The author has found in a commercial setting that a minimum of 28 °C (82.4 °F) is required for *L. vannamei*, for best results, but 26 °C (78.8 °F) is sufficient for *L. stylirostris*. *P. monodon* will do best at 28 °C (82.4 °F). A 0.5° temperature fluctuation over a 24-hour period is acceptable. As much as ±2 °C has been experienced under commercial conditions by the author for *P. monodon* with no serious effects. The coldwater shrimp *M. japonicus*, has an optimum temperature range of 18–28 °C (64.4–82.4 °F) and a minimum spawning temperature of >20 °C (68 °F).

2. Salinity: Optimum salinity level is oceanic (32–35 ppt). Although maturation may occur at a lower or higher salinity (27–36 ppt), normal oceanic salinities are considered to be 35 ppt. Constancy is important. If the salinity is low in the hatchery, it is generally not a good idea to add salt and trace metals if the difference is more than 5 ppt. If artificial sea salts are used, consider using one of the best, which is made by Hawaiian Marine. One can save costs by using Morton's Salt (table salt quality) and buy trace metals separately. Rock salt is cheaper, but has many impurities and should not be used. Instant Ocean, Fritz "Supersalts" and others also sell trace metals. Salinities above 40 ppt should be avoided, because freshwater dilution may also interfere with trace-metal balances essential for maturation and high animal health. Carbon filters may also act to remove some trace metals from seawater.

3. pH: Optimum level is 8.0, but 7.8–8.2 is acceptable, compared with 6.5–10 for growout. Normal seawater, or average seawater, pH is considered to be 8.0. This can vary ±/−0.2 or more, depending on the location. If the pH is lower than 7.8 or higher than 8.2, the site should be avoided. Any addition of buffers or acids may interfere with the balance of trace metals and chemical reactions in seawater and should be avoided unless absolutely necessary. Some adjustments have been reported to maintain pH/alkalinity levels by using sodium hydroxide or calcium carbonate. Low pH affects blood affinity for oxygen. Growth is negatively impacted by pH levels below 5.0. Shrimp can tolerate high levels of pH for a short time. Phytoplankton often cause the pH in the pond to rise to 9 or 10, even sometimes higher, during the day, especially when there is a heavy algal bloom in

the pond. A high pH allows high levels of toxic, unionized ammonia to form.

4.   Light: Dim light, with approximately 14 hours of light and 10 hours of darkness is sufficient. The light cycle should be longer than the dark. Ablated animals reproduce in a wide variety of light regimes, but dim light helps keep them docile.

5.   Nutrition: One of the most important aspects in sustaining a maturation program is nutrition. A combination diet works best. There is strong evidence that bloodworms (*Glyceria dibrachiata*) are essential for commercial maturation of *L. vannamei*. There is no question that the animals prefer this food to others and become very excited when worms are placed in the tank. The source of the food needs to be carefully considered. Worms can be purchased in Panama or the United States. The United States, however, has strict entry requirements for worms from Panama, so check the rules before ordering. Worms can be purchased live or frozen.

Squid is most often used as the major food for penaeid maturation programs. Pathologists have found that Gulf of Mexico squid may carry Rickettsia (a microbe with similarity to both viruses and bacteria) and can infect the shrimp if used for feed. Therefore, it is recommended to purchase squid from a different area of the country and from a different climate to avoid contamination. Squid is relatively easy to obtain and inexpensive in comparison to bloodworms. Both food sources are high in protein, and squid is high in sterols, whereas bloodworms are high in long-chain, highly unsaturated fatty acids (HUFA).

Other parameters to consider in the maturation of penaeids are the following:

1.   Nitrogen levels (especially ammonia and nitrites) should be very low to nonexistent. Average seawater has

0.02−0.04 mg/L (ppm) NH_4-N = ammonium ion (total
ammonia nitrogen),

0.01−0.02 mg/L (ppm) NO_2-N (nitrite),

0.1−0.2 mg/L (ppm) NO_3-N (nitrate).

Any nitrogen levels above normal oceanic water levels should be taken seriously and dealt with, or maturation could be jeopardized. Chen and Chin (14) found that 0.1 mg/L (ppm) nitrite or above can affect reproduction.

2.   Water should be provided on a flow-through basis or in conjunction with a good recirculated system to keep metabolic wastes and food by-products from building up in the tanks. Most sustainable hatcheries now recirculate at least 80% of the water in order to maintain better control of the environment and diseases, but none, to the author's knowledge, are able to utilize 100% water recirculation, and still maintain a commercial production output.

3.   Total suspended solids, organics, brown or red tide, bacteria, and other debris in the incoming water should be filtered. Most suspended solids and organics should be removed during settling and slow sand filtration. All organics should be removed whether in flow-through systems or in closed or semiclosed systems. Food by-products, feces, and eggs provide substrata for bacteria, fungi, and protozoans. Brown tide or red tide can also become an occasional problem for the hatchery. If it is not economically practical to use carbon filters to remove these unwanted dinoflagulates, then chlorination may become necessary in a reservoir before water is brought into the hatchery. Depending on the organic load, normally 2−8 ppm chlorine treatment overnight is sufficient to kill dinoflagulates and bacteria in seawater. The treated seawater should be vigorously aerated to neutralize the chloramines. Extreme caution should be exercised if chlorine is used. Chlorine can form chloramines and other by-products in seawater as a result of chemical reactions with trace metals. Chloramines can cause stress to the animals and stop maturation. Chlorine can also be neutralized by sodium thiosulfate in a 1:3 to 1:6 ratio (one part thiosulfate for every three to six parts chlorine). Thiosulfate has been found to cause deformities in shrimp larvae, and it would be reasonable to assume that maturation and mating could be affected by a trace metal imbalance caused by the addition of yet another chemical, such as thiosulfate. Thiosulfate additions have caused deaths in broodstock of *P. monodon* in India at levels slightly above the suggested treatment ratio.

4.   Tank color should be black, because animals see it better and seem to be more comfortable and at rest in a darker environment.

5.   Noise levels should be kept low. All machinery, large air bubbles, or any human activity that would stress or disturb the shrimp should be avoided.

6.   Obstructions in the maturation tank should be kept to a minimum (e.g., stand pipes, hoses, tubes, water inlets, air lines, nets, etc.). These interfere with swimming and mating, as well as with capturing the mated shrimp with a net. Obstructions outside the tank (e.g., pipes on the floor) should also be avoided for the safety of the workers.

7.   Nets should be soft with small mesh, so as not to damage the animals during handling.

8.   A large swimming pool vacuum head should be used with 3.8 to 5 cm (1.5 to 2 in.), and a flexible hose should be used when vacuuming the tank. Most vacuum heads ride on rollers a set distance from the bottom and have a strong vacuum capability to clean the tank rapidly without injuring the animals. Large pieces of uneaten squid, molts, and other debris should be removed during the cleaning routine. Tank sides and bottoms should be brushed once a week to clean them of algae, fungi, and other fouling.

9.   Some hatcheries use bird bands or rubber tubing, placed over the shrimp eye, on the eye stalks, to mark the shrimp with eye tags. Nostril expanders can be used to stretch tubing like rubber bands. Other hatcheries simply cut a portion of the shrimp's uropod, or notch it, to mark the shrimp, when tagging is needed.

Females are induced to mature and spawn by a process known as unilateral eyestalk ablation, i.e., the removal, cauterizing, cutting, or ligation of the eyestalk (Fig. 28). See the entry on "Eyestalk ablation" for more detail. Within three to five days after ablation, and under the physical and nutritional conditions previously described,

Figure 28. One-pound (0.45 kg, or 450 gram) female *P. monodon* brood, with right eye ablated.

Figure 29. Typical algae room arrangement in shrimp hatchery to feed larval shrimp.

the females should begin to produce eggs. The first spawn usually occurs within one week after ablation, and the ablated animals should be in full production in three weeks. Most females will mature and spawn on a continuous basis, about once every five days to two weeks. The hatchery usually receives approximately three months of continuous production from one set of brood before it becomes necessary to bring in new animals.

Hybridization was attempted with *L. setiferus* and *L. stylirostris*, as well as other species, at Texas A&M University in the 1980s, but their offspring were sterile. Cryopreservation of eggs has been attempted with limited success, both at Texas A&M University and at the University of California at Davis. Reproduction of penaeid species is detailed in (17).

On a daily basis, hatchery technicians evaluate female shrimp in maturation tanks, showing advanced ovarian maturation. In the case of *Litopenaeus* spp. the female is also evaluated for placement of a spermataphore on the exterior and should show signs of being full of eggs (Fig. 26). Those females possessing a spermataphore (Fig. 27) are carefully removed and placed into spawning tanks, taking care not to dislodge the spermatophore. For hatchery operations that only source with trawlers for wild-caught, gravid females, this is the point where the shrimp enter the hatchery. Wild-caught shrimp are typically disinfected prior to stocking into the spawning tanks to prevent diseases and entry of unwanted parasites from feral populations. Female shrimp in hatcheries typically spawn between 1800 and 2300 hours and always spawn before daylight. Once hatched, the young larvae or nauplii are disinfected and evaluated for physical quality attributes. Those possessing suitable quality are transferred to larval rearing tanks and stocked at densities ranging from 100 to 150 nauplii/L (379–568 nauplii/gal) in an intensive culture hatchery.

During the larval cycle, shrimp are planktonic and are generally fed live microalgae and planktonic microcrustaceans. Often this diet is supplemented with artificial feeds, especially when larvae reach the PL stage. With the intensive hatchery method, the production of live feeds (e.g., microalgae; Fig. 29) is undertaken in separate facilities within the hatchery with staff dedicated to

this purpose (18–20). Once the young shrimp near the end of the larval stage, the amount of live feed they are offered is reduced, and the amount of artificial feed is increased. At the PL stage, shrimp are often transferred from the larval-rearing tank to a PL-rearing/holding tank. There they are stocked at densities of around 20,000–40,000 shrimp/m^2 (or the same number of shrimp per 10.7 ft^2).

Once PL have reached the PL8–18 stage (8- to 18-day-old postlarvae), they are typically sold to production farms. The species from the western hemisphere are generally sold at an earlier stage, such as PL8–10, whereas *P. monodon* is sold at PL18. Many hatcheries require transport by the farmer to the growout farm. This is an attempt on the part of the hatchery to reduce its liability with respect to shipment survival of PL. Often, the hatchery and the client farmer cooperate in harvesting and counting the PL in the hatchery, reducing the potential for disagreement. Most hatcheries provide customers with reports regarding the performance of the PL during their stay in the hatchery, as well as routine disease analysis reports. If requested by the client, some hatcheries will lower the salinity in the shipment boxes to assist with the acclimation process. Some farmers perform stress tests on the larvae and have them checked for diseases before purchasing them from the hatchery. However, for biosecurity reasons, most hatcheries have strict protocols for farmers visiting the hatchery.

PL are transported to production farms by a variety of means, largely dependent on their distance from the hatchery. In most cases, they are placed in 8–10 L (2–2.6 gal) of water, Styrofoam ice chests at densities between 625 and 2,000 shrimp/L (0.26 gal) (Fig. 30). The ice chests used in shipping contain two transparent plastic bags (one inside the other) that are filled with about 10 L (2.6 gal) of filtered hatchery water (Fig. 30). Once the shrimp have been placed in the water, the water temperature is slowly dropped to about 19 °C (66 °F). Small packets of granular-activated charcoal are added, and the bags are supersaturated with oxygen and sealed. The box is then closed, sealed, and all pertinent shipping information attached. Boxes are consolidated into one shipment and either placed on the transport truck for farm delivery or deposited with a freight expediter at the local

Figure 30. Placing shrimp larvae into styrofoam boxes and plastic bags for shipment.

airport (for long-distance shipping). Shipment of PL can be undertaken fairly efficiently if the total shipping time is less than 24 hours. Most competitive hatcheries allow 5% additional shrimp to reduce loss due to inevitable shipping mortality and have some form of transportation insurance.

PL can be transported in almost any container that holds water and that can be aerated. An example of PL transport in 1,000 L (263 gal) fiberglass tank via small truck can be seen in Figure 31. Upon arrival at the pond, a 12-volt submersible water pump brings water from the pond to the tank, where shrimp are gradually acclimated to pond conditions before being released.

SHRIMP GROWOUT CULTURE STRATEGIES (LEVELS OF INTENSITY)

Shrimp culture practices vary widely throughout the world, but have tended to evolve in line with each country's respective resource endowment. For example, in countries that have abundant supplies of wild PL in brackishwater tidal creeks of large river deltas (e.g., Ecuador and Bangladesh), extensive culture techniques evolved using wild stocking of mixed species of shrimp and other crustacean and fish species. Water enters the

Figure 31. Postlarval (PL) transport from hatchery to pond via truck and 1,000 L fiberglass conical tank.

simple tidal ponds via gravity tidal water flow through crude water control gates. An extensive culture farm in Indonesia can be seen in Figure 9.

Extensive culture requires little water exchange and little or no feeding. Instead, tidal exchange is adequate to maintain water quality, and there is sufficient natural food available in the ponds for densities less than 2 shrimp/m^2 (2 shrimp/10.7 ft^2) being cultured. The key characteristic of extensive culture is the reliance on the natural food available in the pond. Yields are low from extensive ponds, typically averaging less than 200 kg/ha/crop (approximately 200 lb/ac/crop) each of shrimp and fish. Because costs for inputs and labor are low and minimal capital investment is required for extensive culture, production costs are generally the lowest in the industry.

As extensive farmers gain more experience, they usually upgrade their ponds to accommodate higher stocking densities, called "semi-intensive" culture (see upper portion of Fig. 11). Peru is one example of a country that has, over time, intensified culture methods (Fig. 32). The ponds located near Tumbes, Peru, are right on the beach in very sandy soils. To prevent erosion from wind and waves, the ponds are long and narrow, with the short dimension perpendicular and the long side running parallel to the shore. Typical stocking for semiintensive culture is 30,000 to 150,000 PL/hectare (or per 2.47 ac). In extensive shrimp culture systems, the shrimp feed upon the food organisms that grow naturally in the pond, and with semi-intensive culture, the farmer must add supplemental feeds, since the higher standing stock of

Figure 32. Shrimp ponds on the beach near Tumbes, Peru.

shrimp exceeds the natural carrying capacity of the pond. At the lower end of the stocking density range, the shrimp continue to derive a significant portion of their nutrition from natural production, and the supplemental feed can be quite simple. As the farmer increases stocking densities, increasingly more complete rations in larger quantities must be applied. Even a well-fertilized and well-managed pond will only support up to 300 kg/ha (300 lb/ac) without supplemental feeding.

With higher feeding rates, the farmer must also apply more management effort to maintain water quality, including pumping to exchange water (Figs. 33 and 34). At the higher end of the semi-intensive range, aeration and water mixing are also necessary. Farmers must also improve their water control gates to exclude predator and competitor species and to allow for increased water exchange. Yields from semi-intensive culture systems range from 500 to 4,000 kg/ha/crop (approximately 500 to 4,000 lb/ac/crop), and production costs typically range from US$3.30–8.80/kg (US$1.50–4.00/lb) of shrimp produced. Peru has generally adopted semi-intensive culture, with the additional management technique of using feeding trays. This technique has improved the water quality, but has added to the labor costs. However, the food conversion

Figure 33. Large shrimp farm intake and reservoir in the Salinas, Ecuador.

Figure 34. One of 20 large intake pumps at farm in Salinas, Ecuador.

ratio (FCR) improved, and feed savings were realized, thus offsetting the increase in labor.

The most technologically advanced culture systems are intensive and were developed in such countries as Japan, Taiwan, and the United States, where wild PL are not readily available and where land and labor are expensive. To justify the high input costs and to maximize returns, high yields per unit area are required. Yields from intensive ponds can range from 3,000 kg/ha/crop to over 10,000 kg/ha/crop (approximately 3,000–10,000 lb/ac/crop). Some producers in Peru are bordering on intensive culture, but since they harvest shrimp at 12 g (0.4 oz), aeration is not needed, because very heavy biomasses or standing crops in the ponds are not reached, as they are during longer growing periods when larger animals are cultured.

At the high stocking densities typical in intensive culture systems, the nutritional contribution from natural food organisms in the pond is minimal. The farmer must provide the shrimp with a nutritionally complete ration. These feeds are very expensive compared with the supplemental feeds used in semi-intensive culture. Farmers routinely pay US$1.00 per kg (or per 2.2 lb) or more for intensive culture feeds, representing 60–70% of the cost of production. The feeding-tray method is becoming more popular in both semi-intensive and intensive farms, and as a result, much better FCR values are now being obtained (with a ratio often under 1 : 1, with the best at 0.6 : 1). The semi-intensive culture industry in Peru has proven that it is possible to produce up to 2,100 kg/ha (2,100 lb/ac) with each crop over a sustained number of years. Three crops per year are possible in a warm climate, although most farms average 2.6 crops on a year-round basis. Production levels during the cooler months will not be as high, and time is needed to treat pond bottoms between crops. Texas shrimp farms average 3,500–6,400 kg/ha/crop (3,500–6,400 lb/ac/crop) of heads-on shrimp, which generally fall into the 31–35 to 26–30 count tail sizes, with one crop per year. These are considered to be intensive farms and require aeration.

In addition to the added expense of extra feed, intensive farmers incur additional costs to control the degradation of water quality and the fouling of the pond bottom caused by the heavy organic load from the high feeding rates. These increased costs are related to the capital and operating expenses to build smaller, more manageable ponds (often with concrete walls), install pumps and wells to allow for high rates of water exchange or recirculation, and use mechanical devices to circulate and aerate the water (Figs. 11 and 19).

Taiwan, Japan, Thailand, and the United States are leaders in the development of intensive culture technology and have all averaged over 3,750 kg/ha (3,750 lb/ac) in the past, with some production exceeding 10,000 kg/ha (10,000 lb/ac). The cost to produce shrimp generally rises with increased culture intensity, due to increased stocking densities, feeding rates, and water-quality management efforts. The most cost-effective production strategy for any particular farmer depends on the size of the initial capital investment, the cost of available inputs (e.g., feed, PL, labor, fuel, and power), and the potential cost

savings realized from economies of scale relative to the total area under culture. A typical intensive farm layout can be seen in Figure 35, with pump station, primary distribution canal, secondary distribution canal, inflow gates, harvest gates, drainage canal, and sedimentation pond. The primary distribution canal and reservoir also act as a sedimentation pond, where most solids settle within 6 hours. Most of the farms that have been built in the last 10 years have been either semiintensive or intensive, but the majority of the production still comes from extensive culture farms. India, Vietnam, Bangladesh, the Philippines, and Indonesia are good examples of countries with large numbers of extensive farms.

Shrimp farms utilize a two- or three-phase production cycle. With the three-phase cycle, there is a hatchery, nursery ponds, and growout ponds. In the two-phase cycle, the nursery is skipped, and PL are stocked directly into growout ponds. Experience in Texas has shown little difference in survival and growth of shrimp farmed with just two phases. The nursery system allows the farm to stockpile larvae and confine them in a smaller space, saving overhead. Juveniles must be moved to growout, and there is usually mortality associated with any movement of shrimp.

Some countries practice superintensive culture (even more intensive culture than previously described). This method of culture is sometimes done in a greenhouse or in a building. Culture is often in raceways or small, lined ponds. Only a small percentage of the industry practices this level of intensity, and most superintensive operations have not been sustainable.

WORLD CONTRIBUTIONS TO THE ADVANCEMENT OF SHRIMP AQUACULTURE

One of the most detailed semiintensive marine shrimp-growout procedure publications was produced was by Villalon (21). Tseng (22) described the intensive method of growout in Asia, and Wyban and Sweeney (23) described the intensive culture method practiced in the United States. Other major contributions to the advancement of shrimp aquaculture came from around the world from countless groups (24−99). Methods of culture and optimum

Figure 35. Typical intensive culture farm layout. (Drawing by Joe M. Fox.)

parameters for cold-water shrimp culture can be found in Main and Fulks (100).

CULTURED SPECIES

The majority of the cultured shrimp in the past have fallen under the genus *Penaeus*. But recently taxonomists changed the genus names of the most commonly cultured shrimp, except *P. monodon*, *P. esculentus*, and *P. semisulcatus*. The shrimp *L. vannamei*, *L. stylirostris*, *P. schmitti*, *L. setiferus*, and *P. occidentalis* are now placed in the genus *Litopenaeus*. The pink and the brown shrimp previously referred to as *Farfantepenaeus duorarum* and *F. aztecus*, respectively, are now referred to as *F. duorarum* and *F. aztecus*, as is *F. brasiliensis*, *F. californiensis*, *F. notialis*, *F. subtilis*, and *F. paulensis*. *Fenneropenaeus chinensis*, is the new name for *P. orientalis*, as well as the new genus for *Fenneropenaeus penicillatus*, *Fenneropenaeus merguiensis*, and *Fenneropenaeus indicus*. *M. japonicus* replaces *P. japonicus*.

The giant tiger shrimp (*P. monodon*; Fig. 25) is named for its size and banded tail, and it dominates production everywhere in Asia, except Japan and China. Reaching a maximum length of 35 cm (13.7 in.) and 454 g (1 lb) in weight (Fig. 28), *P. monodon* is the largest and fastest growing of the farm-raised shrimp. Figure 36 presents growth curves of 11 penaeid shrimp under cultivation (33). It tolerates a wide range of salinities, as do other cultured species. There are often shortages of wild broodstock, and captive breeding can be difficult. Hatchery survivals are generally low (20−30%), and the shrimp tend to burrow into pond bottoms and require special harvesting techniques to retrieve them. The industry in Taiwan developed a specialized harvest technique with electrically charged 12-volt wires or chains that are used to "tickle" the shrimp out of the mud and then catch them in the net (Fig. 37).

The Pacific white shrimp, or the western white shrimp, (*L. vannamei*; Fig. 6) is the leading species produced in the western hemisphere. It can be stocked at small sizes and has a uniform growth rate, reaching a maximum length of 23 cm (9 in.). Its protein requirement (20−25%) is lower than that of *P. monodon*. Hatchery survival rates are high, ranging from 50−90%. During growout, *L. vannamei* has a reputation for being more forgiving or tougher than most penaeids. Harvesting is generally done with gravity draining into nets, but some of the intensive farms use an automated fish pump to remove the shrimp. The Magic Valley Heliarc pump, seen in Figure 38, is an example of the technology developed for the moving of fish and has been adapted for shrimp. Water is pumped into a large bin with a screen, and then shrimp and water are separated. The water is discharged, and the shrimp fall into a container of ice. Markets include the United States (70%), which takes raw, frozen, unshelled tails, called green-headless and value-added products, and Europe (30%), which takes whole frozen animals. Europeans like to see the animal with the head on, so that they can judge the freshness more easily. Japan is the newest market for western white shrimp, and there have been some efforts to grow the western white shrimp in the eastern hemisphere.
Figure 36. Growth curves of 11 penaeid prawns under cultivation (33) (with permission from CRC Press).

Other Important Species: *L. stylirostris* (the Pacific blue shrimp) (Fig. 1) occurs naturally from the Pacific coast of Mexico to Peru. The 'Super Shrimp,' is also a member of this species and was developed in Venezuela as an IHHN virus-resistant strain. *F. chinensis*, previously known as *P. orientalis*, (the Chinese white shrimp) is found in northern China and Korea. *M. japonicus* (the kuruma shrimp) lives in Australia, Japan, China,

and Taiwan; *F. penicillatus* (Taiwan and China) and *F. merguiensis* and *F. indicus* are grown on extensive farms throughout southeast Asia and more intensively in South Africa. *F. merguiensis* and *F. indicus* have become more popular with growers in South Africa. As a result of droughts, wild populations of *P. monodon* became hard to find in certain locations. The two more popular species tolerate low water quality better
Figure 37. Specialized technique for harvesting *P. monodon* in Taiwan. (Photo by Henry Branstetter.)

Figure 38. Automated harvester (Magic Valley Heliarc) at shrimp farm in Texas.

than does *P. monodon*, they can be grown at high densities, and because they tolerate higher salinities, they are readily available in the wild during periods of drought.

Researchers and farmers work with at least a dozen other species. Some common names of saltwater shrimp are banana shrimp, kuruma shrimp, yellow-leg shrimp, western white shrimp, greasy back shrimp, Chinese white shrimp, brown shrimp, pink shrimp, black tiger shrimp, Pacific white shrimp, Pacific blue shrimp, Mexican white shrimp, and the Argentine red shrimp. The freshwater prawn, *Macrobrachium rosenbergii*, is also farmed throughout Asia and in part of the Americas and is discussed next.

KNOWN WATER REQUIREMENTS FOR SALTWATER SHRIMP

Table 4 shows a compilation of water characteristics for shrimp culture from various sources in the literature, including lethal limits and optimum levels where known. All parameters in parts per million, unless noted otherwise.

U.S. SEAFOOD AND SHRIMP AQUACULTURE'S ECONOMIC IMPACT

The U.S. seafood industry both directly and indirectly contributes US\$49.5 billion/yr to the nation's economy;

Table 4. Known Water Requirements for Saltwater Shrimp (Lethal and Optimum)

Parameter	Lethal Limit	Optimum
Bicarbonate alkalinity ($CaCO_3$)	10	>20
Boron (B) normal at 35 ppt = 4.5		3.9
Cadmium (Cd)		0.1 (opt <3)
Calcium (Ca)[a]		
Carbon dioxide (CO_2)[b]		
Chloride (Cl)[c]		
Chromium (Cr)[d]	2–20	<0.05
Copper (Cu)	0.300–1.0	<0.1
Dissolved oxygen (DO):	Growth, 2–3 (min) wt specific	0.1–1.5 (species specific)
Fluoride (F)		<1.3
Free CO_2	>20	<2
Hardness as $CaCO_3$[a,e]		>20
Hydrogen sulfide	>0.1	<0.02
Iron (Fe)[g]		<1
Lead (Pb)	1.0–40	<0.03
Magnesium (Mg)[a]		
Manganese (Mn)[m]	5.0	0.08
Mercury (Hg)	0.01–0.04	<0.01
Total ammonia nitrogen (NH_4-N)[h,i]		0.40
Un-ionized form (NH_3)	>0.1	>0.1
Nitrite[h–j]		For growth <1.0
Nickel[k]		0
pH	(For growth: 7–7.5 min, 10–11 max)[h,l]	
Phosphate (PO_4)		ponds 0.15

Table 4. *Continued*

Parameter	Lethal Limit	Optimum
Salinity (ppt)	(unknown)	10–25 ppt (species specific)
Salinity	(for growth, 0–10 low, 30–40 high)[h]	
Sodium (Na)		Normal 10,000 ppm at 35 ppt
Sulfate (SO$_4$)[c]		
Suspended solids		<1
Temperature (°C) (tropical shrimp)	(12–15 low, 38 high)	26–29
Temperature	(for growth, 23–25 min and 33–34 max)	
Total dissolved solids (TDS)[f]		
Turbidity	(For growth Secchi disc of 8–10 in. or 20–25 cm)	
Zinc (Zn^{2+})[k]		1.0–10

[a]Hardness is the measurement of calcium and magnesium ions. Hardness should be above 20 ppm for water to be considered favorable for fish culture. Total hardness (calcium carbonate or CCO$_3$) should be 50–150 ppm for best results according to Boyd (101), between 20 and 200 ppm according to various other sources, and be above 20 ppm according to Johnson (102).

[b]Carbon dioxide (CO$_2$) is uncommon >60 ppm in well water. CO$_2$ is thought to be harmful to fish culture if levels are >20 ppm. The optimum for fish culture is thought to be <2.0 ppm.

[c]For best results in fish culture, chlorides and sulfates combined should be at levels of less than 50 ppm, but may be kept at levels ranging from 1 to 2,000+ ppm in wells considered to be freshwater. Common salt in water appears as ionized sodium and chloride (Na$^+$ and CL$^-$). In freshwater, the most common ionic constituents are calcium (Ca^{2+}), magnesium (Mg^{2+}), carbonate (CO$_3$=), and bicarbonate (HCO$_3$−). The chloride level in normal seawater should be 19,000 at 35 ppt salinity and 21,939 ppm at 41.6 ppt salinity.

Corrective actions should be taken when problems arise. Aeration of water at the well or other water source is usually adequate to correct for excess carbon dioxide, iron, sulfide, and DO deficiency. Low pH resulting from excess carbon dioxide may be corrected by aeration, but acidity caused by other dissolved constituents will be little affected by aeration. Adding chemicals can be helpful in some circumstances if the chemical, such as limestone, is inexpensive. When limestone dissolves, its hardness and alkalinity increase. Water already alkaline because of sodium carbonate content will be difficult to adjust for hardness because the solubility of the liming compound is lowered (102).

[d]Chromium concentrations of 0.1 ppm is U.S. coastal water quality criterion, and the detection limit is 0.08 ppm. Concentration of chromium may be higher in summer than in winter.

[e]Alkalinity is a measure of the water's ability to neutralize acid. Alkalinity is contributed by carbonate and bicarbonate ions. Normal seawater alkalinity is around 200 ppm at pH 8.3 and 35 ppt salinity. There is a linear relationship between the salinity level and alkalinity. For example, water with a salinity of 22 ppt should have an alkalinity level of 122 ppm, whereas seawater with a salinity of 12 ppt is expected to have an alkalinity of 67 ppm (assuming that the seawater has been diluted with distilled water). The actual alkalinity will be influenced by the alkalinity of the water with which the seawater is diluted. For example, the alkalinity of estuarine water can be lower if the seawater is diluted with runoff water high in tannic acid. It can be higher if the seawater is diluted with river water high in alkalinity. Both hardness and alkalinity should be above 20 ppm for water to be considered favorable for fish culture. Well water with a low hardness (<20 ppm) and high alkalinity (>200 ppm) is not desirable for fish culture.

[f]A total dissolved solids (TDS) reading of 1,000 ppm and above is considered saline, and a reading of less than 1000 ppm is considered freshwater. Drinking water usually has less than 500 ppm TDS. Livestock can drink water containing up to 2,000 ppm TDS, depending on their acclimation. Freshwater fish can endure 10,000 ppm TDS. Research concerning the effects of TDS on fish has been reported in salinity values. Salinity is a measure of total dissolved ions and closely approximates the numerical value of TDS for a water sample. Examples of maximum salinity readings are the following; Golden shiner fry and goldfish fry is 2,000 ppm; Channel catfish is 11,000 ppm, Grass carp is 12,000 ppm, common carp is 9,000 ppm, and tilapia is 20,000 to 30,000 ppm.

[g]The 96-hour median tolerance limit (TLm 96) to iron by aquatic insects, mayflies, stoneflies, and caddisflies is 0.32 ppm. Most iron appears as divalent (Fe^{2+}) in reducing conditions, but it is readily oxidized to the trivalent state (Fe^{3+}) as a colloid, which may also block the gills of shrimp.

[h]Many of these factors are directly or indirectly interrelated. For example, there is often a direct correlation between DO and Secchi disc readings/turbidity. The pH has a direct effect on the percentage of ionized and un-ionized ammonia in the water. The un-ionized form of ammonia is by far the most toxic, and the percentage of total ammonia that exists in the un-ionized state is a function of pH, temperature, and salinity. NH$_4$−N is safe in ionized form because the + charge prevents it from passing over gill cell membranes.

[i]NH$_4$−N = ammonium ion (total ammonia nitrogen): 96-hour LC$_{50}$ (see below) for PL6 is 11.51 mg/L (ppm). In the hatchery, NH$_4$−N levels reach 0.808 mg/L (ppm) routinely, and the NO$_2$−N (nitrite) levels can reach 0.118 mg/L (ppm) routinely. Un-ionized ammonia (NH$_3$−N) is the most dangerous and can be lethal, depending upon the temperature, salinity, pH, DO, and age of the animal. The allowed nitrogen levels increase with the age of the shrimp. The 96-hour LC$_{50}$ values for nitrite (NO$_2$−N) are as follows: nauplii = 5 ppm, zoea = 13.2 ppm, mysis = 20.6 ppm, and PL = 61.9 ppm (15).

Note: 96-hour LC$_{50}$ is the (lethal) concentration that will kill 50% of the animals exposed to it in 96 hours. The safe level estimates for nitrite are as follows: nauplii = 0.11 ppm and PL = 1.36 ppm (15). Chin and Chen (16) found with different parameters present, the 96-hour LC$_{50}$ for nitrite and PL6 *P. monodon* is 13.5 ppm. The authors also reported that a safe nitrite level for growout was 4.5 ppm.

Ten percent of the 96-hour LC$_{50}$ is usually considered a safe nitrite concentration. This often leads to a rather conservative figure that may be difficult or unreasonable to attain. Freshwater fish farmers have so many problems with nitrites because of low calcium and chloride levels in the water. In brackishwater shrimp culture, low chloride levels tend to be less of a problem, and the higher levels of chlorides serve as a buffer. There are so many factors that influence nitrite toxicity that it is virtually impossible to make recommendations on lethal concentrations or safe concentrations of nitrite in aquaculture. These include chloride concentration, pH, animal size, previous exposure, nutritional status, infection, and DO concentration.

[j]Normal seawater levels are as follows: Ammonium ion, or NH$_4$−N = 0.02–0.04 ppm; Nitrite, or NO$_4$−N = 0.01–0.02 ppm; Nitrate, or NO$_3$−N, is not as toxic and may be found at 1 ppm in normal seawater or as high as 200 ppm in some fish culture systems without causing problems.

[k]Japanese fisheries' criterion for zinc and nickel is <0.1 ppm. Zinc has been reported to accumulate in marine animals in levels ranging from 6 to 1500 ppm (U.S. National Technical Advisory Committee, 1968). It has also been found that shellfish concentrated zinc from shrimp feed when grown in shrimp farm effluent waters.

[l]pH and salinity are usually lower in coastal waters than in the ocean. Groundwater pH is usually in the ranges of 5.5 to 8.0. The most desirable range for the culture of fish is 6.5 to 9.0 and for shrimp is 7.0 to 11. Shrimp can grow at pH levels above 7.8 no matter what the alkalinity level is, but a rule to follow is, if pH reading in the pond is below 7.8 at midafternoon, then the alkalinity reading should be above 100 ppm (see also the note on alkalinity for more detail). Normal seawater pH is 8.0 ± 0.4. If the culture water is out of the 7.6 to 8.4 range (before being treated in any manner, such as through fertilization, liming etc.), care should be taken to watch all of the parameters thought to be important during the culture cycle to be sure that the normal ranges are not deviated from or that unanticipated chemical reactions are not occurring.

[m]One ppm and above manganese concentration is considered inappropriate for fisheries in Japan. Some underground seawater (seawater from wells) has been found to have 10–100 times the manganese concentrations of coastal seawaters. Concentrations of iron, zinc, nickel, cadmium, lead, chromium, tin, and cobalt are other important metals to observe. For example, high levels of tin in well water were found to be the limiting factor in raising shrimp nauplii in a Roswell, New Mexico facility.

this total is projected to reach US$62.9 billion by the turn of the century. Of the US$49.5 billion currently contributed, the food service and processing sector accounts for the largest percentage (77%). Harvesting injects 16%, with distribution and retail stores contributing only 7% (Fig. 39).

In addition, aquaculture products produced in the United States generate a US$4.15 billion economic impact. This industry employees 140,000 full-time workers for a value of US$1.7 billion annually. Shrimp aquaculture plays a role in impacting the economy, generating 2 million kg (4.6 million lb) in 1994. However, due to diseases, it generated under 1.35 million kg (3 million lb) in 1995, 1996, and 1997. In 1998, production again reached 2 million kg (4.6 million lb) of shrimp (Fig. 40).

Texas is the largest producer of farm-raised shrimp in the United States. It produced an average of 1.2 million kg/yr (2.66 million lb/yr) from 1990 through

1998, with an average crop value of US$8.2 million over the same period, having a US$24.6 million/year impact on the state's economy. As can be seen in Table 2 and Figure 14, diseases lowered the crop amount in 1995, but production has been increasing steadily since then.

PROBLEMS IN THE SHRIMP CULTURE INDUSTRY

Open Systems

Sustainability and environmental degradation, coupled with numerous viruses and other diseases, are probably the biggest problems facing open system aquaculture. The costs to producers generated by new environmental regulations are of great concern. In the United States, the economies of scale are nonexistent for the shrimp culture industry, as they are for the catfish industry, and shrimp producers say that less expensive feeds and other products would certainly make their industry more appealing and profitable.

Turbidity is generally an indication of the amount and type of phytoplankton bloom in the pond and is maintained with pumping and fertilizing procedures. Turbidity can also be affected by the amount of suspended clay and silt in the water. If there is an abundance of suspended particles in the incoming water, settling may be necessary before the water goes into the ponds. Usually a reservoir serves this purpose, and most solids settle within 6 hours (9). To keep track of the total volatile solids in the pond or solids that can be burned off in an oven (excluding clay and silt), the farmer generally takes a reading with a Secchi disc and then maintains a reading of 20−25 cm (8−10 in.). This means that the disc is lowered into the
Figure 39. U.S. seafood industry economic impact. (From National Fisheries Education and Research Foundation.)
Figure 40. U.S. shrimp aquaculture production.

water between 20–25 cm (8–10 in.) before disappearing from sight. By either flushing with new water or fertilizing, the optimum reading obtained from the Secchi disc can be maintained, and, subsequently, the proper algal bloom can be maintained in the pond. This same turbidity can become a problem when released as effluent. Regulatory agencies generally start by controlling turbidity levels at the discharge. Total suspended solids (TSS), total volatile solids (TVS), biological oxygen demand (BOD), and carbomase biological oxygen demand (CBOD) generally have upper limits placed on them, but dissolved oxygen (DO) has a minimum placed on it.

Excretory products can cause problems. The pond must be designed and managed so that excretory products or metabolic wastes do not build up. In ponds, most excretory products will break down rapidly, with the help of bacteria. In intensive systems, excretory products that do not break down must be removed. Soluble metabolic by-products, such as un-ionized ammonia, and by-products made up of organic materials breaking down to nitrites can be a problem. Tolerance levels in growout are not well known, but high levels have been recorded (0.75 ppm to 2 ppm and higher at pH 8.3) without mortality. Some gill damage may occur when the level of un-ionized ammonia goes above 0.5 ppm or when other stresses are present (e.g., low DO or handling). Growth is also reduced with high ammonia levels present. The by-products can also cause problems in discharge waters and are generally controlled by regulatory agencies.

SEMICLOSED AND CLOSED SYSTEMS

Interests in closed systems extend beyond culturists in higher latitudes, where climatic conditions limit the profitable growing season. Many tropical producers are either retrofitting farms or seriously evaluating closed-pond production techniques as plausible alternatives to traditional flow-through practices that increasingly are accused of being unsustainable.

Design and management of recirculating systems requires greater attention to water chemistry than design and management of flow-through systems. The latter system may export potential water quality problems to the local environment simply by flushing the pond, especially during harvest. When raising animals in closed systems, any such problems must be dealt with effectively within the culture environment itself. This often requires confronting water quality treatment issues at a more technical level. Most operations do not have that capability.

Since there are so few closed-system aquaculture companies, they receive a good deal of publicity, especially if they fail. Usually a company is started with private investment and later moves to public offering. If the company fails while under private ownership, often little is known about it. On the other hand, public offerings of stock further publicize the industry and the company offering the stock. A number of failures have been apparent in the industry, and the publicly owned companies are of higher profile. Developers out to make a quick profit often make projections that can not be reached. These problems occur in all industries, but shrimp culture in the United States is small, and these occurrences are usually of higher profile than the other closely related agricultural enterprises. These failures cause the risk factor to be very high with shrimp culture ventures, and most lending agencies will not loan money unless there is a proven track record.

Recirculation, or water reuse, is a rapidly growing segment of the aquaculture industry, but for the most part is still widely unused or unproven. Some people in the industry have found that they can reuse far more water than ever thought possible and still obtain respectable production.

The areas in the United States where expansion of the aquaculture industry is possible are offshore or inland (or within the coastal plain, but with recirculating or closed systems). The offshore industry will be severely limited by costs, weather factors, and the U.S. Department of Interior's Minerals Management Service laws. The most logical area for the aquaculture industry to grow is on the coast with closed, or partially recirculating, systems and inland, in environmentally friendly, closed, recirculating systems, close to the markets or in brackishwater aquifer areas, such as West Texas, Arizona, and New Mexico. Much interest is being generated in these new growth areas. There is an increased use of closed systems in the aquaculture industry. For example, the largest shrimp hatchery in the western hemisphere is located in the Florida Keys, and due to environmental requirements, regulations, and cost savings, it recirculates water numerous times before discharging into a settling pond. The second largest shrimp hatchery in the United States is located in Texas, and it also recirculates as much water as possible (up to 90%) to save on heating and water filtration costs. Other species, such as tilapia and hybrid striped bass, are being grown successfully on a commercial scale in closed systems, and this is stimulating increased interest in closed systems for shrimp. Unfortunately, there have been far more commercial venture attempts with shrimp culture in fully closed systems that have failed than have succeeded. There is still much to be learned about this method of culture before it is commercially sustainable.

SHRIMP VIRUSES ARE A MAJOR PROBLEM PLAGUING THE INDUSTRY

Shrimp viruses are natural occurrences and can to some extent be controlled. Like viruses in man, some shrimp viruses are more severe than others. One of the first shrimp viruses identified was the baculovirus (BP), found in the waters of the Gulf of Mexico, and described by John Couch more than 20 years ago. Rolland Laramore was one of the first researchers to make an electron micrograph of an occlusion body of the baculovirus. Once researchers developed the techniques to recognize the virus and began to look for it, it was found to be fairly common in the pink shrimp (*F. duorarum*), but was also found in other species from the Gulf of Mexico.

BP is widely distributed in cultured and wild penaeids in the Americas, ranging from the Northern Gulf of Mexico south through the Caribbean and reaching at least as far

as the state of Bahia in Central Brazil. On the Pacific coast, BP ranges from Peru to Mexico, and it has been observed in wild penaeid shrimp in Hawaii (96,103, and 104). BP affected shrimp aquaculture in the United States and other countries in the late 1970s and early 1980s, and, in some cases, shrimp larvae were pumped out on the ground and destroyed on Texas farms as a result of disease checks and directives from state regulatory agencies. The virus was controlled largely through the control measures implemented in shrimp hatcheries to recognize the virus in wild-caught brood animals. Thus, BP was no longer considered a major problem in either wild caught shrimp or hatchery animals once more was found out about its control.

The following is a compilation of the information known about baculovirus. Most of the information comes from Lightner (96,103, and 104) and other important sources cited. The known penaeid baculoviruses infect the epithelial cells of the hepatopancreas from protozoea through adult and the mid-gut epithelium of larvae and postlarvae. Baculovirus infections may result in disease in cultured penaeids that is accompanied by high mortality rates, but, for the most part, survival is usually above 30%. In hatcheries worldwide, the baculoviruses *Baculovirus penaei* (BP) in the western hemisphere, monodon baculovirus (MBV) (infecting *P. monodon*), and baculoviral mid-gut gland necrosis (BMN) (infecting *F. japonicus*) have been the cause of serious epizootic disease outbreaks in the larval and early PL stages of their principal host species. BP may cause disease and mortalities in juvenile and subadult animals, but BP has not been a major problem in recent years, because most hatcheries check their brood for it, and if they find it, the brood shrimp are destroyed. This is the most common way to control BP. The geographic distribution of these baculoviruses in cultured penaeid shrimp suggests that they are problems to shrimp culturists mainly in those areas where the virus is enzootic in local wild populations. This appears to be the case of BMN, which has thus far been observed in *F. japonicus* in hatcheries in Japan. However, MBV and BP have been documented as having been introduced into new geographic regions by the transfer of infected PL or broodstock to areas outside the normal range of the host species. According to Lightner (103), BP is widely distributed in cultured and wild penaeids in the Americas. In Brazil and Ecuador, BP infects larvae and PL of at least six penaeid species. It is significant that the imported Asian species *P. monodon* and *F. penicillatus* may also be infected. BP was found in Mexico in cultured larval and PL *L. stylirostris* at a facility near Guaymas, Sonora, in 1988 (104). BP and MBV infections may be readily diagnosed by identifying their characteristic occlusion bodies in either wet mounts or histological preparations of the hepatopancreas and midgut (104). BP occlusions are distinctive tetrahedral bodies easily detected by bright field or phase microscopy in unstained wet-mounts of tissue squashes (105), while MBV occlusions are spherical and difficult to distinguish from lipid droplets. The use of a stain-like 0.1 percentage aqueous malachite green in preparing wet mounts for MBV diagnosis aids in identifying the occlusions. The protein

makeup the occlusion absorbs the stain more rapidly than do most of the host's tissue components, making them distinctive within a few minutes (104).

Unlike BP and MBV, which are Type-A baculoviruses because they produce occlusion bodies, BMN is a Type-C baculovirus that does not produce an occlusion body. Hence, the diagnosis of BMN infections is dependent on the clinical signs of the disease, histopathology, and transmission electron microscopy (TEM) (104). Sano et al. (106) developed a rapid fluorescent antibody test for BMN that reportedly simplifies the diagnosis of BMN.

A baculovirus (*plebejus baculovirus*) was reported in *Penaeus plebejus* (107).

Today, BP is rarely found in larvae coming from a good hatchery source. The best prevention is to catch it at the hatchery. If the farm is diagnosed with BP, if it has kept good records about where the shrimp came from, and if it did not mix sources, it can narrow the BP-infected shrimp down to one larval source. BP is generally spread from mother shrimp to larvae and is passed on in the egg. It does not spread further after larvae are placed in the ponds like the more serious viruses do. Therefore, the source of BP on a farm is most likely the hatchery or the wild seed purchased.

Today, more than 20 known viruses infect shrimp, and 4 of these continue to pose a major threat to the industry (infectious hypodermal and hematopoietic necrosis virus (IHHN), Taura syndrome virus (TSV), yellow head virus (YHV), and white spot syndrome virus (WSSV)). In the western hemisphere, 9 of the 20 viruses have killed shrimp, and 5 are considered serious pathogens. In the eastern hemisphere, 12 viruses have been found with 5 causing mass mortality.

TSV was found to cause a problem in the Taura River basin in Ecuador in 1992. Through histological records, it was shown to be present in some samples taken in Colombia as early as 1990, and in 1999, Rolland Laramore found histological evidence that TSV existed in Panama in 1987. This evidence came as a result of looking at stained slides of sick animals that had been kept for future reference. However, the preserved animals had been destroyed after five years and were not available for further confirmation. It is now thought that the reasons Panamanian shrimp (*L. vannamei*) appear to be more resistant to TSV than shrimp from other areas is that they have been exposed longer and that wild stocks have had time to build up resistance.

TSV spread north into Central America and into Texas in 1995. It arrived on the farms in May, shortly after the first migrating birds appeared from the south, but the exact method of transmission was never determined. Shrimp-processing plants were also suspected sources of bringing in the virus with imported frozen shrimp. The shrimp hatchery in Texas was checked for diseases and found to be clear, but was contaminated by TSV from the farm at a later date and closed down for disinfection. In 1996, the Texas hatchery stocked only *L. setiferus* from their hatchery on the farm to protect against TSV infection, and the hatchery continued to produce *L. vannamei* and *L. setiferus* PL for the other farms to stock. They attempted to do the same in 1997, but *L. setiferus* PL production

levels were low. This approach apparently worked, because the hatchery remained disease-free, even through the 1999 season.

Ecuador's industries (both wild fishery and farmed shrimp) have continued even with the presence of TSV. There are some areas in Ecuador that have never been affected by TSV. The overall levels of farm-raised shrimp from Ecuador remained above 100,000 MT per year, mostly because of new and smaller farms starting up and taking the place of many of the larger farms. There are now 160,000 ha (395,000 ac) in production on 1,600 farms, supplied by 350 hatcheries in Ecuador (1). In 1997 and 1998, shrimp aquaculture production in Ecuador increased to 130,000 MT (1). The export value of the crop was worth US$871,723,000 in 1997 (7). Apparently resistant stocks from the wild and from selected stocks in the aquaculture industry have allowed both the aquaculture and the harvest industries to survive.

The threat of TSV appears to be subsiding in Ecuador, Panama, and other South American and Central American countries, but WSSV has now been recorded in all of the preceding countries and is causing serious mortality. TSV is also diminishing in Texas. In 1997 and 1998, the farms in south Texas did not have an epidemic of TSV and experienced a very good crop with 70% average survival, which was comparable to survival in 1994, before TSV hit. In 1997, Texas farms produced approximately 1,160,000 kg (2.56 million lb) of shrimp, and in 1998, they produced 1,440,000 kg (3.17 million lb) on 533 ha (1,316 ac). The Texas hatchery sent the same PL to the upper Texas coast farms in Palacios that had given the Texas Rio Grande Valley farms such a good crop in 1997–1999. The Palacios area has been hit with TSV every year since 1995 (including 1999), but survival in ponds increased to 31% in 1998, which was higher than in the previous two years (0–10% and 19%, respectively). In 1998, production in the Rio Grande Valley (without TSV) averaged 4,000 kg/ha (4,000 lb/ac), but in the Palacios area (with TSV), production averaged 1,200–1,500 kg/ha (1,200–1,500 lb/ac). In 1999 the Palacios area still had TSV, but production was up to 3,000–3,600 kg/ha (3,000–3,600 lb/ac). The virus was somewhat different in 1998 in that its presence was not obvious until the shrimp were tested at harvest time. There had been no obvious die-off or bird problems in relation to the disease as had been noticed in previous years. There is still much to be learned about shrimp diseases and their prevention.

Shrimp may become infected from many sources. A major potential exposure pathway to shrimp in the United States includes wastes from shrimp processing plants. Foreign shrimp boat harvesters may catch shrimp with diseases and ship them to the United States as a frozen product. Likewise, some foreign aquaculture operations harvest their ponds immediately upon finding disease and export the infected shrimp. Infected shrimp are now routinely found in U.S. retail markets. Shrimp viruses do not infect humans. The United States imported 118 million kg (262 million lb) of shrimp from the six largest exporting countries in Asia (China, India, Thailand, Vietnam, Indonesia, and the Philippines) in 1995 (7). Frozen shrimp, either unshelled or peeled,

make up 97% of all shrimp imported into the United States from Asia. Imports, in the United States and other countries, are typically repackaged at processing plants that are located along coastal waters, because the plants were initially constructed to process shrimp from nearby coastal fisheries. The solid waste and effluent from these plants were disposed of, often untreated, into the local waters and landfills. In addition, frozen imported shrimp from countries in which viral diseases are epizootic, were often used as bait shrimp by sport fishermen. This possible method of transmitting the viruses affects both wild and cultured shrimp and is a US$2 billion industry. The U.S. shrimp-processing industry employs over 11,000 people in 182 companies. Any new requirements that may be necessary to reduce disease risks will increase costs to producers and processors, and ultimately to consumers, but serious consideration of new regulations to control these virus pathways should be undertaken by the appropriate agencies that control this industry. Some voluntary measures have been taken by processors at the encouragement of U.S. regulatory agencies.

Estimated losses due to YHV and WSSV, according to Tim Flegel of Thailand, are sizable. Thailand's production dropped from 225,000 MT in 1994 to 220,000 MT in 1995, mostly due to YHV. At approximately US$8/kg, this represented a shortfall of about US$40 million. However, given that Thai production had been rising by 20,000 to 30,000 MT/year, the actual lost production may have been in the order of 30,000 MT, or over US$240 million.

WSSV was first reported in Japan in farmed *M. japonicus* and spread (96). In Asia, WSSV overshadowed the other diseases. In Thailand, production dropped from 220,000 MT in 1995 to 160,000 MT in 1996, a difference (lost production) of 60,000 MT, over US$500 million worth of shrimp. Using figures from some Thai sources, the yearly totals are different, but the difference (i.e., the estimated production lost) is about the same. The mid-1997 figures looked like there would be a further drop of 10,000 MT, giving a total lost production of around US$600 million. Those figures are for Thailand alone.

For China, the story is also similar. Their production dropped from 150,000 MT in 1992 to 35,000 MT in 1993, probably due to YHV and WSSV. They have since recovered somewhat, but are still well below the 1992 peak (1).

The total losses for all of Asia have been estimated between US$1 billion to US$3 billion per year. C.G. Lundin (World Bank), addressing the second Asia–Pacific Marine Biotechnology Conference, National Center for Genetic Engineering and Biotechnology, Bangkok, stated, "If we calculate an average price of shrimp at about US$5 per kg (or per 2.2 lb) for shrimp still with heads and total disease-related losses at 540,000 MT, the total annual loss based on 1994 data would be US$3 billion. This indicates a very significant problem that has implications for the well-being of millions of people in developing countries." His estimates of 1994 included the Americas.

In an attempt to combat viruses the USDA Shrimp Farming Consortium in Hawaii conducts a selective breeding program for shrimp in state of Hawaii. They

hold selected shrimp stocks in quarantine. Offspring from those stocks are challenged with various viruses in other locations away from the quarantine area. Results of the work are then transferred back to the central quarantine. This program is definitely making a difference in the United States, and is helping the industry control TSV and other diseases.

Until they were found in Texas in 1995, WSSV and YHV had mostly been found in the eastern hemisphere. There had been no reason to look for them to that point in the western hemisphere, and researchers had not fully developed dependable testing devices for detecting these viruses.

WSSV, or a "white spotlike virus," was diagnosed in native white shrimp *L. setiferus*, being pond cultured in south Texas in 1995, but did not appear anywhere else in Texas that year after the ponds were drained. In 1997, the same virus was found in a Texas research facility in wild-caught *L. setiferus*. In that facility, the virus did not infect other shrimp (*L. vannamei* and *L. stylirostris*), and all indications suggested that the virus had come in with the wild-caught animals. Apparently, three gene probes were then used in an attempt to identify the virus. The two probes developed in Asia did not show it to be the same as the WSSV that had been found on that continent. The probe developed by Don Lightner in Arizona did show it as WSSV. WSSV was found in Honduras, Nicaragua, and Ecuador in 1999. Histological records show that it existed in Ecuador back at least to 1995.

TSV hit South Carolina in 1996, but did not cause problems in 1997. Of the 20 farms in South Carolina, 7 were affected with an outbreak, and the state experienced a 62% reduction in production. Just as in Texas, some growers experienced losses as high as 90% of their crop. The outbreak started in May 1996, and drought conditions in South Carolina and higher than normal temperatures caused undo stress to farmed shrimp. This increased the susceptibility of the shrimp to disease, the transfer of the disease among the shrimp, and the mortality due to the disease. In 1995, before TSV, average shrimp survival was 60.4%, and average shrimp size was 18.72 g (0.04 lb), or 24 count. South Carolina did not have an epidemic of TSV in 1997.

WSSV was a problem in South Carolina in 1997 and 1998, and the white spotlike virus was detected in both cultured and wild stocks in South Carolina. Reports surfaced of WSSV having been found in crawfish that were being fed at an aquarium on the east coast of the United States. It is known that WSSV affects other crustaceans and has been found in crawfish, freshwater, and saltwater shrimp, as well as other crustaceans. WSSV was also found in shrimp from Texas bait stands in 1998. Paul Frelier, then a professor and researcher with Texas A&M University, College of Veterinary Medicine, and his graduate student, found the virus, but were not able to subsequently find it in four attempts. Lightner at the University of Arizona confirmed the virus diagnosis after 100 bait shrimp were held in quarantine for three weeks before the disease appeared.

We do not know for sure how long these viruses have been in Gulf of Mexico or how they arrived there. Thanks to technology developed by the shrimp aquaculture industry, techniques were developed to detect these viruses. The Texas Parks and Wildlife Department (TPWD) has only recently implemented a disease assessment of wild shrimp in Texas using the techniques developed by university and aquaculture industry researchers. This is not the first time that diseases have been looked for in wild populations in Texas waters, but the techniques for detecting WSSV and YHV were not used during earlier sampling. TPWD has found WSSV to be fairly widespread in the Gulf of Mexico, along the coast Texas, and it has been found in crustaceans, other than shrimp. The source of the virus is unknown, and the effects on wild populations appear minimal, because crustacean harvesting has been average or above in recent years.

Clinical signs of infected shrimp may vary from hemisphere to hemisphere or from strain to strain of WSSV. WSSV from the eastern hemisphere causes juveniles and subadults to exhibit white spots or patches about 0.5–2.0 mm (0.019–0.078 in.) in diameter; these spots begin in the cuticle of the carapace and on the fifth and sixth abdominal segments and then spread to the whole body. The cuticle can also become loose. The white spots are abnormal deposits of calcium salts and are most apparent on the inside surface of the carapace. Infected animals are lethargic, stop feeding, swim slowly on the pond surface, and eventually sink to the bottom and die. Moribund animals display a pink to reddish-brown coloration due to an expansion of cuticular chromatophores. Populations of shrimp with these symptoms typically have high mortality rates that can reach 100% within 3–10 days after the onset of clinical signs. However, some shrimp with WSSV in the western hemisphere have not shown the signs of having white spot or do not show the presence of white spots on them (96). A number of diagnostic methods are available (see below).

Transmission of exotic pathogens can occur through a variety of means, including migration with humans, birds, and other animals, and through the shipment of infected frozen food products.

Possible methods for pathogen introduction of WSSV and YHV into Texas after the 1995 occurrence have been examined and Nunan et al. (108) concluded that the "introduction and spread of WSSV and YHV may be through the importation of frozen shrimp product." From frozen imported shrimp sampled in 12 grocery stores in Arizona, California, and Texas, it was found that 5 of the 12 samples of shrimp had either WSSV or YHV. Freezing does not damage the virus. In fact, this is the way that most pathologists preserve the viruses. Frozen imported shrimp were then fed to live shrimp and infection and mortality occurred. Polymerase Chain Reaction (PCR) tests, described in the next section, showed that the actual cause of the mortalities of the Pacific blue shrimp used was YHV.

NEW TECHNOLOGIES IN DIAGNOSING SHRIMP DISEASES

Diagnostic and detection methods for shrimp viruses include direct bright field, light microscopy, phase contrast, dark field light microscopy, histopathology,

enhanced histopathology, bioassay histopathology, transmission electron microscopy, fluorescent antibody, DNA probes, and PCR.

The majority of shrimp diseases in the past have been diagnosed using histology techniques and reviewing slides stained with H & E (stain used for most viruses), giemsa (stain for Rickettsia), or acid fast stain (for Mycobacteria) and require that the shrimp be iced, frozen, or preserved properly and sent to a certified diagnostic laboratory. Now, the rapid diagnostic techniques for shrimp viruses are based on genetic hybridization with probes. A series (for WSSV, TSV, IHHNV, NHP, HPV, MBV, BP, and YHV) of gene probe diagnostic kits are available (*http://www.diagxotics.com*). The shrimp specimens used for these kits are either hemolymph or unstained histology slides (in situ). The instructions are well written and straightforward and can be used by most shrimp-farming operations. This new advancement in technology allows the farmer to check for diseases on the farm, without sending the shrimp to a pathology laboratory. The DiagXotics "Spot-On, Rapid Field Test," for example, has four easy steps to follow and will give results in 15 min.

POLYMERASE CHAIN REACTION (PCR)

PCR is a widely used test to verify a shrimp virus and has been used by researchers to verify the results of other tests. The PCR test for WSSV and YHV was first developed in Asia. These tests seem to be dependable, but not all PCR tests are perfected enough to be considered dependable for commercial use. Some methods remain as research verification tests only. One such PCR test that was slow in development was the one for TSV. TSV accumulates in the lymphoid organ (small gland in front of the hepatopancreas or digestive gland of shrimp) and not in the blood, so it is much harder to detect without killing the animal. When a PCR test is given, the animal may not necessarily show the presence of TSV, because the virus is not in the blood. Paul Frelier (while at Texas A&M University, Veterinary Medical Center) said that the only effective way to look for TSV was through a bioassay, but Jeff Lotz (of Mississippi's Gulf Coast Research Laboratory) stated that, even then, the animals had to be destroyed to look at the lymphoid organ, and it was only a short-term test. After the 1995 epidemic hit, offspring from TSV survivors from Harlingen Shrimp Farm were held in Caldwell, Texas (an inland facility). The adults were sent to Lotz in Mississippi, where it was learned that the disease was not transmitted to the offspring, that the TSV survivors concentrated the TSV in the lymphoid organ, and that there was no sign of the TSV in the blood. Researchers now think that the animals that concentrate the TSV in the lymphoid organ may not pass on the TSV. More research is needed in this area. Other researchers have also stated that just because certain penaeid strains are resistant to a virus (IHHN, TSV, and WSSV), this does not mean that they do not carry the diseases. For example, even though *L. stylirostris*, or the Super Shrimp, is resistant to IHHN, it has been found to be a carrier of TSV.

A list of basic PCR equipment required for anyone wishing to do gene probing to detect WSSV or YHV can be obtained from Aquafauna Biomarine. It is best to seek the assistance and use of equipment from a government institution, hospital, or university, since most will have access to such equipment. PCR equipment is very expensive. Once you obtain the equipment or obtain access to its use, then you need to train a technician to run it. Then you need primers.

From the farmers' stand point, even if PCR tests are done at the hatchery and PL are shown to be clear, there is no assurance that WSSV won't come into the farm. A number of crustaceans and other arthropod species have been found to act as reservoirs for the virus. Detailed histological studies were required to confirm that suspected carriers had active viral infections. Three common crustacean residents of shrimp culture ponds (the sand crab *Portunus pelagicus*, the mud crab *Scylla serrata*, and krill *Acetes* sp.) have been known to become infected with WSSV. Normal histology, electron microscopy, and in situ DNA hybridization determined infection. Crab species and krill are considered viral reservoirs, since they are able to carry the infection and may persist for significant periods in the shrimp-farming environment (96). *M. rosenbergii* has been shown to exhibit WSSV. WSSV has also been found to exist in wild-caught shrimp (*P. monodon*, *M. japonicus*, *P. semisulcatus*, *F. penicillatus*, *L. setiferus*, *F. aztecus*) and crabs (*Charybdis feriatus*, *P. sanguinolentus*, and *Callinectes sapidus*) collected from the natural environment in coastal waters of Asia and the western hemisphere (Texas and South Carolina). Detection of WSSV in non-cultured arthropods collected from WSSV-affected shrimp farms revealed that copepods, the pest crab *Helice tridens*, small pest Palaemonidae (grass shrimp) and the larvae of an Ephydridae insect were also reservoir hosts of WSSV. Most hatcheries perform routine tests on their brood, and some perform PCR, but not on each batch of PL sent out as this would not be practical.

There are basic virus-avoidance procedures farms can take. Frelier wrote one such set of recommended procedures. The procedures are somewhat elaborate; therefore, the farmer has to decide which ones should be adopted. Chlorinating all incoming waters, for example, may not be economically practical or desirable, because it would kill even beneficial diatoms and zooplankton. Treating intake waters with an insecticide might be a better option, as discussed later in this article.

ADDITIONAL WAYS TO LOOK FOR SHRIMP VIRUSES

Virological recognition techniques include light microscopy, histological changes in host, electron microscopy with negative staining, and cell (tissue) culture.

Virological techniques for shrimp larvae are similar to those for larger shrimp. Routine examination of tissues for occlusion viruses, however, applies squash of a whole animal's mass. In larger larvae (PL), it is advantageous to remove a portion of the tail before making the wet-mount squash. This can be done by severing the tail at midpoint of the first tail segment with a scalpel while

viewing through a dissecting microscope. This procedure will cause the digestive gland and anterior intestine to wash free of other body portions. Certain stains (e.g., 0.1% aqueous malachite green) are used in tissue squashes.

SELECTED STEPS TAKEN BY SOME IN THE INDUSTRY TO AVOID SHRIMP VIRUSES

When used correctly, Dipterex^{TM} (or other insecticides) can eliminate crustacean carriers in farm water prior to stocking shrimp. In Thailand, 0.5–0.8 ppm (6.5 kg/ha or 5.8 lb/ac) Dipterex^{TM} has been used to treat intake waters. The water is used safely for the stocking of shrimp after a period of 7–10 days. Most importantly, insecticide-treated water *is not* discharged into the environment. This step only represents a portion of the overall biosecurity program that is being used by farmers to fight WSSV. The shrimp farmers are moving toward mimicking the traditional animal-husbandry systems where biosecurity and disease prevention are essential parts of the overall management scheme. The animal-husbandry business has many powerful tools, such as genetically improved stock with overall better hardiness, as well as vaccines, whereas, the shrimp aquaculture industry presently only has the basic biosecurity program and not much more. There is no doubt that other viruses (such as TSV), which are transmitted through similar vectors, can also be effectively fought. Besides controlling the vectors and reservoirs that harbor these viruses and implementing a strong biosecurity program, there is little that today's farmers can do against these very powerful diseases. The successful use of an insecticide in one area does not necessarily mean that it will be effective in another area. Dipterex^{TM}, which is an organophosphate, does not kill the crabs in Nicaragua; therefore, another insecticide may be more effective there. Other names for Dipterex^{TM} are 3-trichlorfon, Dylon, and Neguron trichlorfon dimethylphosphonate. Dipterex^{TM} is similar to other organophosphates, such as benthiocarb, diaoxathon, diazionon (Spectracide), ethyl-parathion, fenthion (Baytex, Entex, Tiguvon), malathion (cythion), methyl-parathion, and mevinphos (phosdrin). Most organophosphate insecticides, including Dipterex^{TM}, break down very rapidly, especially in waters with a high pH or high alkalinity. Sunlight also breaks them down rapidly, just as it causes chlorine to break down. Most households in the United States routinely use organophosphates around the outside of the house to control insects. In Thailand, the Dipterex^{TM}/trichlorfon used is a 95% active ingredient and is applied as supplied. In Thailand, it kills all the crustaceans in approximately 24 hours, and farmers stock shrimp after normal pond fertilization and bloom development. There do not appear to be any residual effects on the shrimp, as growth and survival rates are similar to those found in untreated ponds. As examples of research studies found in the literature on organophosphates, malathion took 14 ppb and 48 hours to cause mortality with penaeids, and diazionon took 28 ppb in 96 hours to cause 50% mortality in *F. aztecus* (brown shrimp). The sizes of the shrimp were not given.

A pyrethroid insecticide known as fenvalerato, or fenvalerate, has been effectively used in Central America as an aerial spray on one farm. When the farm was drained and dried, the spray was used to eliminate the possible vectors and pathways that spread TSV. The farm did not have further problems with TSV after using this, among other steps implemented to contain disease. Fenvalerato was sprayed initially; then, after subsequent sprays the following year, the farm was sprayed with the basic insecticide used on citrus fruits and for mosquito control.

Another pyrethroid used in Central America to accomplish vector control is cypermetrina 25C^{TM}. This cypermethrin is Alfa-ciano-3 Fenoxibencil (+) cistrans 3-(2.2 Diclorovinil) −2.2 Dimetil ciclopropano 25% and 75% inert ingredients.

The two pyrethroids have in common Alfa-ciano-3 Fenoxibencil. Apparently, the pyrethroids are completely different in chemical makeup from the organophosphates and also work differently to control insects. Cypermetrina is a pyrethroid that acts upon the insect's nervous system. It closes the nerve channel, and as the nerves fire and continue to fire, the insect becomes hyperactive and dies. If the chemical is applied on dry ground that remains dry, the pyrethroids will break down in 10 days, at the most, in full sunlight. In river water, pyrethroids have a half-life of 5 days, and will hydrolyze very rapidly. They will bind rapidly with organic matter and be absorbed by clay. According to Larry Keeley at Texas A&M University (personal communication, 1999), the pyrethroids hold up a little better than the organophosphates, but they all break down rapidly compared with the organochlorides. (The following are the insecticides that should be avoided. Aldrin, DDT, Dieldrin, Endrin, Heptachlor, Lindane and Methoxychlor.)

Cypermethrin was tested, and the results are shown in Table 5.

Fenvalerate was also tested, and the results are shown in Table 6.

One can obtain profiles on insecticides at *http://ace.orst.edu/info/extoxnet/pips/ghindex.html*.

Pesticides should be only a small portion of a farm's overall biosecurity and ecosystem management program. If a farm reuses old water that it knows to be free of viruses because of previous good harvests, there is no need for treatment. It is used as long as possible, because there is fear that new water will introduce new diseases. After 60 or more days of very low to zero water exchange (in aerated ponds), the water is pumped through a series of recirculating ponds and used again. Farmers developed this method because the only water that can be trusted is the water that holds live shrimp. When used in a closed, recirculating system, Dipterex^{TM} and other insecticides are environmentally benign. The fact that PL thrive in water that a week earlier killed older, tougher crustaceans implies that there is little residue.

Before these practices become widely adopted (and they will if they work, at least in countries without strong environmental controls), we need to know the following: (*1*) How persistent are pesticides in water, and what are the breakdown products? (*2*) Are there any residues in shrimp grown under these conditions?

The biosecurity programs generally consist of many distinct parts, with each part addressing a particular mode of transmission. Together, they help farmers eliminate or reduce the possibility of contamination. The theory holds true no matter the size of the farm or the size of the pond. Each farm needs to develop its program to fit local conditions.

The farm must start with clean animals and water and take steps to keep disease transmission down by cutting vector transmissions. The farm must eliminate the use of untreated water and use either no, low, or recirculating exchange systems to grow the shrimp. Additionally, the farm must keep the walking, swimming, and flying members of the animal kingdom (such as crabs, birds, and people) away from the shrimp and make sure that ponds on the same farm do not cross-contaminate. Swift and definitive action must be taken when the farm does identify diseased ponds. In the end, every little bit helps to better the odds, no matter what disease may come to the farm.

Health management on shrimp farms has become an important issue. At present, there are no cures or cost-effective treatments for emerging viruses. Management strategies have been developed to prevent the spread of viruses and improve the economics of disease-related problems.

One way of managing potential disease-related problems is to institute a health-management program to establish accurate, ongoing data collection and record keeping. Important parameters and information on shrimp health, diagnosis, and disease-control techniques must be decided and then routinely obtained, monitored, and stored. Farms have recently developed health-management programs incorporating (*1*) preventive strategies, (*2*) health monitoring, (*3*) diagnosis procedures, and (*4*) management techniques.

The following is a general protocol developed for limiting the introduction of diseases. If viral, bacterial, or fungal infections develop in production ponds, this disease-prevention practice can be set in place and modified to the particular needs of the farm.

- Implement a pond-bottom management procedure involving the removal of sediment, drying, and turning the soil when possible and applying a disinfectant.
- Disinfect the entire farm by spraying an insecticide that is not harmful to humans, birds, or large animals.
- Destroy all life in the reservoir supplying the growout farm. This is to inhibit any potential intermediate host from entering the water system and infecting the shrimp.
- Limit access to the facility, this includes disinfecting all PL containers, boxes, feed trucks, machinery, etc., before they are allowed on the premises, including the processing plant.
- Keep good records of all movement of shrimp, including information on shipping and transporting, so if a problem occurs, the specific source can be traced.
- At the time of stocking, put a subsample of PL in a survival cage to determine the survival rate 24 and 48 hours after stocking. Any moralities should be examined to determine the cause.

- Minimize the amount of water exchange as much as possible.
- Limit the escape of shrimp at harvest, and never release any shrimp into the wild for any reason.

Broodstock

Adult *L. vannamei* used for captive reproduction is either wild caught or grown out in pond areas a fair distance from the natural range. Generally speaking, wild broodstock collected from the ocean are preferred. They tend to produce larger quantities of nauplii that are stronger. However, experiments to improve *L. vannamei* captive production through pathogen control and selective breeding are showing potential, and disease resistance is being developed in a number of demonstration programs. In terms of pathogens, both wild-caught and pond-reared shrimp may have similar dispositions to associated microbial agents. Metazoan and some protozoan parasites are more likely to be present in wild-caught broodstock, whereas pond-raised shrimp may be more susceptible to emerging viruses.

Nauplii

The quality of nauplii is also an important concern. Historical data on nauplii used in hatcheries supplying stock to the farm should be collected and recorded. High-quality *L. vannamei* or *L. stylirostris* nauplii will be vigorous swimmers and have strong phototactic responses, be free of appendage deformities, and display high survival through the protozoa I stage. If particular females are producing inferior nauplii, reviewing the production records should reveal a pattern of reduced nauplii quality from the spawns of these females.

PL Stock

The need to stock virus-free PL on the farm from areas free of known viruses is imperative. Although hatcheries from infected areas may be free of viruses at the time of maturation and spawning. Viruses may be transmitted transovariantly (vertically) from an infected female into an egg or embryo. Here they may remain in eclipsed form until conditions are suitable for replication. There are limited ways to determine certain viruses, such as TSV, in the early PL stages as of yet with total accuracy. There is also the possibility of increasing the virulence of a virus when it is serially passed from one animal to another. There is some merit to holding the PL for a month to 6 weeks to check for the existence of TSV before releasing them into large growout ponds, but PL holding and rearing raceways would need to be designed into the farm for this procedure to become effective.

Stocking Densities

Certain management schemes have been developed to improve the economics of disease problems. Some people in the industry choose to stock at lower densities to limit the number of virus particles or bacterial infections being released into the environment, increasing the number of survivors. If the farm plans to utilize wild PL, it should stock at higher densities with quality animals, use feeding trays, and maintain high water quality to ensure the greatest possible survival rates. Many of the wild larvae may be other species that do not do well in pond culture, so overstocking will compensate for a mixture. Table 7 reflects some possible economic results of disease-infested populations and different stocking densities. The following assumptions were made in order to prepare the table: The average stocking rate is 15.5 PL/m^2 (10.76 ft^2), the average production is 1,961 kg/ha (1,961 lb/ac) [heads on] or 1,255 kg/ha (1,255 lb/ac) [tails] per crop, the survival rate is 67%, giving a harvest of 10.4 pieces/m^2 (42,088/0.45 ha or 42,088/ac), the average weight per tail is 0.01 kg (0.02982 lb), the price average is US$10/kg (US$4.55/lb) of tails, PL cost is US$8/1,000, growth of surviving shrimp will not always be the same each production cycle, and there are generally seasonal differences in temperature, water quality, and salinity that all interact to affect production.

From Table 7, if the survival rate is reduced to 40% by TSV, it is necessary to stock at a rate of 26 PL/m^2 (26 PL/10.76 ft^2) to get the same revenue per 0.45 ha (1 ac), as was obtained with a stocking rate of 15.5 PL/m^2 (15.5 PL/10.76 ft^2). The added cost of PL would be only US$340/0.45 ha (US$340/1 ac). *Note*: If TSV lowers survival rates to 30%, stocking at 26/m^2 (26 PL/10.76 ft^2) will not provide as much revenue per hectare or acre as was obtained earlier.

The table and stocking density scheme are subject to change from production cycle to production cycle, depending on the species being stocked and the degree of infestation on the farm.

Table 7. Possible Economic Results of Disease-Infected Populations and Different Stocking Densities

Stocking (PL/m^2)	Survival (%)	Pieces Harvested (per m^2)	Harvest Weight (lb tail/acre)	Revenue (per acre US$)	PL Cost (US$)
15.5	67	10.4	1,255	5,710	502
15.5	40	6.2	748	3,404	502
22	40	8.8	1,062	4,832	712
24	40	9.6	1,159	5,271	777
26	40	10.4	1,255	5,710	842
26	30	7.8	941	4,282	842

Hatchery Visit or Assessment of Wild-Caught Larvae

Hatchery and wild-caught PL examination protocol is designed to establish a knowledge of the farm's PL, encouraging the best quality PL purchased from the most reputable sources. The protocol is as follows:

- Historical background listing the location and source (wild vs captive) of broodstock and nauplii. It is good to know the progeny of captive broodstock to determine the genetic strain. Excessive inbreeding can produce genetically weak, or inferior offspring.
- Hatchery design, procedures, and operations are observed and documented to assure quality techniques.
- Clinical examinations of PL are conducted "on-site" in the hatchery prior to shipping.
- There are different criteria for judging PL quality; the most important is developmental stage along with size, age, stress tests, and physical condition.

Examination protocols for a subset of larval rearing tanks should be followed. A clinical index for each tank, or sample set, is established. Examine each PL and record the condition based on the following scale: 1 = poor, lowest, least; 2 = fair, mid-range, average; 3 = excellent, highest, most.

To remove crab larvae from wild-caught postlarval shrimp boxes and containers, place small pieces of white Styrofoam in the container for a short time. The crab larvae (stage dependent) are attracted to the Styrofoam and can be removed.

Use the following points to help identify healthy PL:

Tail

A PL tail should be noticeably open. The preferred age of PL at stocking for *L. vannamei* or *L. stylirostris* is 7−10 days old, and 18 days old for *P. monodon*.

Color

Good-quality PL have transparent bodies with star-like brown or dark brown pigmentation. Those with pink or red coloration indicate stress related to rearing or handling.

Activity

PL should be visibly strong and active, swimming from side to side. Active PL will swim against the current when the water is agitated, or whirled. While in a small container, PL may not be moving, but will react when the container is tapped, or if there is movement in the water.

Size

PL size should be uniform, and any significant variation is indicative of different age levels. Generally speaking, age variations are acceptable as long as size differences are minimal.

Appearance

PL are examined for signs of infestations (debris adhering to body, swimmerets, etc.) and deformities (broken rostrum, crooked body, undeveloped gills, etc.). Healthy PL appear clean and have no physical abnormalities.

Feeding

A dissecting microscope is needed to determine gut fullness. A healthy PL will have a full digestive tract, except after a long time in shipment. Empty guts in larval rearing tanks can be the result of underfeeding, disease, or stress.

Clean Shell

A clean shell represents frequent molts, indicating fast, consistent growth. Slow growth is indicated by the presence of protozoans, other dirt, and necrosis (black spots or brown lesions) on the shell.

Good Muscle Development

With the aid of a good microscope (better seen with three-dimensional phase microscopy) examine the sixth tail segment for good tail muscle development. The muscle should completely fill the shell from the gut down. When the PL is stressed the muscle has a grainy effect much like the grain in wood. The muscle will appear grayish or brown in color. Healthy PL have a clear, thick, smooth muscle.

Prestocking/Acclimation Examination of PL

Routine assessment of PL during acclimation consists of (*1*) microscopic examination of randomly select PL at the moment of arrival, or before being stocked into acclimation tanks and (*2*) routine assessment of PL throughout acclimation.

Microscopic Assessment

Microscopic assessment of PL should be done on PL upon arrival at the farm site to assess the effects of transportation on PL.

- Immediately upon arrival, collect twenty PL from one of the transport containers or bags while the acclimation supervisor examines the parameters of the water in the transport containers and bags.
- This evaluation should be done immediately to determine any stress resulting from transporting and not from being held in the acclimation container.
- Examine each PL sampled, and record the condition based on the clinical index mentioned earlier.
- Record all results on a PL State of Health Examination form.
- Collect 1 L (0.26 gal) of water from the acclimation tank (sampling from the bottom upwards), and carefully examine, with the aid of a dissecting microscope for more precise observation, PL for the following characteristics:

1. Index of gut fullness. Since water temperature should be maintained at around 22 °C (68 °F) during long transport, it is unlikely that the index of gut

fullness (formula given in next section, point 5) will be higher than two (average). However, a percentage estimate of gut fullness upon arrival can serve as a guideline for evaluating the intensity of feeding behavior during acclimation. Larvae collected from estuaries will probably contain higher gut fullness because the trip is shorter and the temperature is probably higher.

2. Mucus and debris on setae. Accumulation of mucus and debris on the setae, antennae, and appendages is a strong indicator of stress. Fine focus the microscope to get a three-dimensional effect, and examine the spaces between the setae and antenna hairs for any build-up of debris.

3. Opaqueness of swimmerets and tail muscle. An obvious sign of stress is change in opaqueness of the tail muscle. Normally, the tail muscle will be transparent with a few pigmentation spots. However, when stressed, the tail muscle and swimmerets may become opaque or, in extreme cases, completely white.

4. Morphological deformities. Although deformities are not directly related to stress, a large number of deformed PL within a population can be indicative of chronic diseases, such as IHHNV. Deformities can also be used as an indicator for future survival estimates in the growout pond. Morphological examination should be focused on the following:

- complete, well-developed, unbent rostrum
- no curvature or cramped tail
- well-formed eyes and eye stalks
- well-formed complete swimmerets
- overall physical appearance

Routine (Acclimation) Assessment

In addition to the microscopic examination, a routine assessment of PL should be done every hour during the acclimation period. Constant observations provide subjective assessments of the PL general condition during fluctuations of water quality inherent in acclimation. If indications of stress are observed, steps can be taken to slow down the acclimation process and decrease the stress. This routine assessment is performed by sampling a 1-L (0.3-gal) volume of water in the same manner as previously described and carefully examining the PL swimming in the container and the acclimation tank for the following:

1. Level of swimming activity. If PL accumulate on the surface, agitating aggressively, and if there DO level is low, inject pure oxygen into the water. If PL are lethargic and swimming activity is diminished, reduce the rate of water exchange, allowing PL more time to adjust physiologically.

2. Erratic swimming behavior. A periodic rhythm of cramping up and relaxing signifies an attempt to molt. A large percentage of the acclimation tank's population molting may indicate stress. If this occurs, reduce the rate of water exchange, increase

feed, and reduce the temperature to less than 23 °C (less than 73 °F) to suppress cannibalistic activity by the nonmolting PL.

3. Opaqueness of tail muscle. As already mentioned, this sign is an indicator of physiological stress. If noted at a high frequency, slow down the acclimation schedule to allow for physiological adjustments.

4. Presence of molts. Floating exoskeletons indicate molting. Take the steps just mentioned to discourage cannibalism. A slow acclimation water exchange is recommended to prevent molting. Do not mistake exoskeletons for dying or dead PL. If a major molt occurs, check gill movement and heart activity. If no organs appear to be active, mass mortality may be occurring.

5. Index of gut fullness. Active feeding and high index of fullness are positive signs, indicating that there is little stress. Generally, PL will not feed if they are under stress. A low index of gut fullness and excessive feed present may indicate stress. If this occurs, suspend feeding and reduce water exchange. The index of gut fullness should be represented as a percentage. The length of the intestinal track is classified as 100%, and an estimated length of the full gut is made. Use the following scale to grade gut fullness: 1 = poorest, least (<30%); 2 = fair, mid-range (30–60%); and 3 = excellent, high (60–100%).

6. Presence of mortalities. Under normal conditions, a mortality rate greater than 3% should put the acclimation supervisor on alert. Check water quality, reduce rate of water exchange, and if guts are full, reduce the temperature to slow the PL's metabolic rate. These procedures may provide sufficient time for a thorough investigation into the cause of the mortalities.

7. Frequency of cannibalism. Generally, cannibalistic behavior indicates that there are insufficient quantities of feed or a high level of mortality. An increase in feed quantity and frequency should minimize cannibalism.

Survival/Holding Cages

Survival cages and a holding tank with subsampled PL may be used to determine the survival rate and to monitor mortalities as follows:

- Before stocking, collect 200 PL from several different tanks and place them into different survival cages.
- Place the cages near the edge of a pond at a minimum depth of 50 cm (20 in.). The cages should be firmly anchored to the mud, with a minimum of 15 cm (6 in.) water depth in the cage.
- Do not feed PL in the cages, and leave them undisturbed for 48 hours.
- After 48 hours, remove all PL from the cages and count them individually. Live PL should be counted separately from dead ones.
- Divide the number of live PL by the number of PL originally placed in the cages to calculate survival

rate. Multiply that number by 100 to obtain the percentage of PL that survived.

- After counting the PL, examine seams and corners for trapped or squeezed PL and for holes where they may have escaped.
- The survival count is a useful indicator of the acclimation process. A survial rate of greater than 85% indicates a successful stocking, one of 65–85% may indicate poor-quality PL or excessive stress due to acclimation, and a rate of less than 65% strongly suggests problems.

Data Collection

Parameters recorded to monitor the health of shrimp in production ponds should be routinely collected, easily obtained, and accurate. The farm should monitor physical, chemical, physiological, and environmental parameters on a daily, weekly, monthly, seasonal, and historical basis. The parameters and time of collection are as follows:

Daily

Water Quality. Temperature DO, salinity, pH, and turbidity.

Weekly

Water Quality. Alkalinity, ammonia, nitrite, phosphorus, calcium, iron, and silicon.

Natural Productivity. Evaluation of algae communities and population numbers.

Bottom Sampling. Evaluation of benthic flora, fauna, and the presence of hydrogen sulfide.

Shrimp Sampling. Estimation of survival, growth rates, feeding rates. Clinical examination of shrimp for all or for a subset of the ponds on the farm for lethargy (inactivity), anorexia (empty intestinal tract), soft shell, fouled gills, or black areas on the shell, red tail, antennae, and appendages.

Monthly

Environmental. Phytoplankton communities, bacteria, and soil sediment.

Seasonal

Trends. In growth rates, feeding rates, nutrients, phytoplankton communities, survival rates.

Historical

Background Information On. Farm, individual pond construction, hatcheries, other farms in the area, and past production records.

Keeping good records of all parameters and physiological condition of the shrimp population can provide information for a retrospective study to determine the cause and onset of any problems that may occur.

Routine Health Monitoring

Sampling Populations. Shrimp should be randomly caught from various locations around the pond. The locations should be clearly marked on the sample sheet. For consistency, one individual should be designated to do the clinical examination.

- Sampling should be done weekly, or daily if a problem occurs, on 50–100 randomly caught shrimp.
- Percentage of shrimp demonstrating clinical signs of disease should be determined (e.g., shells, gills, tails, spots, deformities, bacterial necrosis).
- The percentage of sick animals can be followed to help determine when a specific problem first begins.

Clinical Examinations. If problems or deformities are noted during routine weekly sampling, clinical examinations should be done pond-side with live animals. The clinical exam determines the percentage of shrimp in the sample that are clinically ill.

- A clinical disease index for each pond during the production season should be established.
- A clinically ill animal in the sample may demonstrate the following signs: lethargy (inactivity), anorexia (empty intestinal tract), soft shell, fouled gills, or black areas on the shell, red tail, antennae, or appendages.
- Clinical examinations of shrimp are done from 100% of the ponds on a weekly or daily basis during heavy disease period. The samples ideally should consist of 50–100 shrimp per pond. However, during periods of outbreaks and low survival rates, it may not be possible to collect this many samples, and a smaller sample set will have to suffice.

Define Problem and Occurrence. When a problem or disease occurs, it must be defined and the onset determined.

- Using data from weekly clinical examinations, determine when a specific problem first began. Additional resources can then be used to define the problem, point of entry, and possible causes.
- Record a general statement of the overall health of the pond. Include a subjective evaluation by the pond manager regarding feed consumption as indicated by feed trays, bird activity, or the presence of dead or moribund shrimp.
- Define the problem in terms of survival, growth rate, feeding rate, extent of problem on the farm, historical data on the farm, and in the general area. A disease outbreak may be the result of certain management procedures that could be changed to inhibit the occurrence of the disease.

If survival rates are low, examine pond bottoms weekly to determine when and where animals are dying. Dive a predetermined section of the pond bottom along a path of 16–32 m (50–100 ft) in front of the harvest and outlet, while counting the number of dead shrimp. Mark the path with a rope or stake along the path and at each end to ensure that the same pond area is being examined during the entire growout season. If there is a prevailing

wind creating directional currents in the pond, check the opposite shores for debris and moribund shrimp.

Accurate Diagnosis

If a problem is disease related, it should be described clinically, bacteriologically, and, if applicable, morphologically, including a histological examination. An accurate diagnosis is required for a proper treatment. There are laboratories that will process shrimp samples bacteriologically, histologically, or using an in situ hybridization test. It may be necessary to preserve samples and send them to the lab for testing, depending on what the lab recommends. Eventually, it would be advantageous for the farm to develop these capabilities within their own laboratory and at least methods for preliminary testing. This would drastically reduce the cost of outside testing.

DNA probes-samples are first examined by conventional histopathology, and if a diagnosis is possible, then the more costly in situ hybridization test with gene probes is not necessary. To keep costs down and ensure higher probabilities of accurate diagnosis, collect nonrandom samples with apparent problems or disease.

Specimen Processing and Preservation Procedures. It is extremely important that proper sampling and preservative procedures be followed, so that histopathological analysis will not be jeopardized. The following procedures (96,103–105) should be followed explicitly to ensure proper preservation:

Collection

1. Collect shrimp by whatever means are available with a minimum of handling stress. For the study of presumably diseased shrimp, select those that are moribund, discolored, displaying abnormal behavior, or are otherwise abnormal (except in the case of intentional random sampling for estimation of disease prevalence). Shrimp sampled for normal histology should not be abnormal in appearance or behavior. Do not collect shrimp that are dead for any sample, unless it can be positively determined that they have died within the last few minutes. If recently dead shrimp must be sampled, be sure to make note of this condition and estimate the time since their death.

2. Transport the shrimp to the laboratory via a bucket with pond water. Supply adequate aeration to the bucket if the shrimp are to be left for a short period before actual fixation.

Fixation or Preservation

1. Have on hand an adequate supply of fixative. A rule of thumb is that a minimum of approximately 10 times the volume of fixative should be used for each specimen. [For example, a shrimp of 10 mL (0.3 fl. oz) volume would require 100 mL (3 fl. oz) of fixative.]

2. Davidson's fixative should be made as follows (1 mL = 0.03 fl. oz):

   a. 330 mL (9.9 fl. oz) 95% ethyl alcohol

   b. 220 mL (6.6 fl. oz) 100% formalin (saturated aqueous solution of formaldehyde gas, 37–39% solution

   c. 115 mL (3.45 fl. oz) glacial acetic acid

   d. 335 mL (10.05 fl. oz) distilled water

   e. store at room temperature

3. Inject the fixative 0.1 to 10 mL (0.0034 fl. oz to 0.3 fl. oz), depending on the size of shrimp), via needle and syringe (needle gauge also depends on the shrimp size) into the living shrimp. The site of injection should be laterally in the hepatopancreas proper, in the region anterior to the hepatopancreas, in the posterior abdominal region, and in the anterior abdominal region. Precautions should be taken to avoid skin and eye contact with the fixative (wear surgical gloves and eye protection). The fixative should be divided between the different regions, with the cephalothoracic region, specifically the hepatopancreas, receiving a larger share than the abdominal region. A good rule of thumb is to inject an equivalent of 5–10% of the shrimp's body weight; all signs of life should cease.

4. Immediately following injection, slit the cuticle with dissecting scissors from the sixth abdominal segment to the base of the rostrum, paying particular attention not to cut deeply into the underlying tissue. The incision in the cephalothoracic region should be just lateral of the dorsal midline, while that in the abdominal region should be approximately mid-lateral.

5. Shrimp larger than 12 g (1/2 oz) should then be transversely slit once at the junction of the abdomen and cephalothorax or again mid-abdominally.

6. Following injection, incisions, and bisection/trisection, immerse the specimen in the remainder of the fixative.

7. Allow the shrimp to remain in the fixative at room temperature for 24 to 72 hours, depending on the size of the shrimp.

8. Following proper fixation, the specimen should be transferred to 50% ethyl alcohol, where it can be stored for an indefinite period.

9. Record a complete history of the specimen at the time of collection: gross observations on the condition of the shrimp, species, age, weight, source (pond, tank or raceway identifying number), source of parent stock, and any other pertinent historical information that may at a later time provide clues to the source and cause of the problem. Use soft-lead pencil on paper, waterproof paper if possible.

Transportation or Shipment for Processing

1. Remove the specimens from the 50% ethyl alcohol.

2. Wrap with paper towels to completely cover the specimen.

3. Place towel-wrapped specimen in a sealable plastic bag and saturate with 50% ethyl alcohol.

4. Include the history, as previously explained with the shipment.

5. Place the bag within a second sealable bag.

6. Multiple small sealable bags can again be placed within a large sealable bag.

Interpretation of Histological Results. An analysis of the samples will include descriptions of the findings in terms of severity and morphology. When reading the results, refer to Table 8, which is a generalized scheme for assigning a numerical qualitative value to assess the severity of infections, surface infestations, and disease syndrome severity. The University of Arizona uses this assessment method.

MANAGEMENT SCHEMES

While several different pond-management and disease-treatment schemes are being implemented throughout the world, the most important is pond preparation and disinfecting prior to production. There are several different types of vaccines and immunostimulant products on the market used in the prevention of diseases. Most are still experimental and not economical. Presently, there are no policies or procedures for using organic or inorganic compounds for prevention or treatment. If the farm production ponds are affected by an epizootic infestation, such as TSV, or bacterial infections, such as *Vibrio* spp., it would be advisable to establish a prevention or treatment program utilizing some of the aforementioned products.

A typical farm scenario with a disease problem is as follows: The pond manager would notice that shrimp had a loss of appetite, observe cannibalism, would probably notice a change in the water color in the pond, and might see shrimp slowly turning a reddish color, followed by mortality. At first, there might be a few mortalities noticed each day. Then, after 3–4 days, the manager would notice 100 or more dead daily. Other nearby farms might be experiencing the same problems, so it is a good idea to communicate with neighbors. If the manager were to wait until harvest and not act to prevent further loss, survival could be very poor.

Without the benefit of a proper histopathological examination, the farm manager is operating on instinct, not certain knowledge. To properly manage a disease outbreak, the manager should collect a sample of moribund shrimp from one of the affected ponds, and split it into two subsamples. Collect hemolymph from one of the subsamples, and make plate cultures on TSA and TCBS media. If a high number of colonies (CFU) are detected, the manager should conduct an antibiogram of the isolate from one of the green colonies using the most common and effective antibiotics offered by the feed manufacturer. He should also check the plates at night for luminescence. The other sample should be preserved in Davidson's fixative (or less ideal, 10% buffered formalin), and the manager should submit all to the pathology lab. If the shrimp are *P. monodon*, *L. vannamei*, or *L. stylirostris*, the lab should check for WSSV, YHV, IHHN, LOC, BP, NHP, and signs of vibriosis. Corrective measures for the ponds should only be made based on the results of the health examination. By testing shrimp in a pathology lab, the manager can determine if the farm has a transmittable disease (and not a water quality problem). An easy and unsophisticated way to confirm a transmittable disease without sending samples off to a lab would be to collect moribund shrimp and feed macerated portions of them in an aquarium to healthy shrimp collected from another pond or tank. Look for development of identical disease signs in the experimental group. This will only tell the manager that there is a transmittable disease and will not identify the disease agent. One of the better references on shrimp diseases that emphasizes information that can be applied to understanding problems encountered in shrimp culture operations (especially *L. vannamei*) is Brock and Main (105).

PHILOSOPHIES OF DISEASES AVOIDANCE AND CONTROL

Ecuador, Mexico, Panama, the United States, and others have taken precautionary steps in preventing possible contamination from other areas of the globe by banning imports of nauplii, worms, crabs, etc., that could serve as possible vectors or pathways for diseases. The rationale of using lower densities to control stress is a factor being considered and tried in most countries. Asian shrimp farm production comes mainly from cooperative efforts, whereas

Table 8. Generalized Scheme for Assigning a Numerical Qualitative Value to Severity Grade of Infections

Severity Grade	Clinical Findings
0	No signs of infection by pathogen, parasite, or epicommensal present. No lesions characteristic of syndrome present.
1	Pathogen parasite, or epicommensal present, but in numbers or amounts just above diagnostic procedure minimum detection limits. Lesions characteristic of syndrome present, but disease not significant. Prognosis is for insignificant effect, except in developing infections by highly virulent pathogens.
2	Low to moderate numbers of pathogen, parasite, or epicommensal present. Light to moderate lesions characteristic of syndrome present. Prognosis is for possible production losses or slight increases in mortality if no treatment is applied.
3	Moderate numbers of pathogen, parasite, or epicommensal present. Moderate to severe lesions characteristic of syndrome present. Potentially lethal prognosis if no treatment is applied.
4	High numbers of pathogen, parasite, or epicommensal present. Severe lesions characteristic of syndrome present. Lethal prognosis.

834   SHRIMP CULTURE

Ecuador has multinational companies well structured with formidable power of investment that aggressively sought technologies and implementation of quarantines. Educational campaigns from the Chamber of Aquaculture in Ecuador were commonplace. The technical support and scientific community are strong in Eucador.

Multinational companies are generally willing to pay for solutions. The abundant stocks of larvae that were present during the 1998 season assisted the country in stocking most of its ponds. Environmentally speaking, Ecuador is a leader of organic shrimp production methods and bioremediation. Many natural and environmentally friendly policies have been implemented there because of the lack of working capital, and the cost of purchasing and importing chemical products is virtually impossible. Companies like GreenAqua, Inc. have established a set of operation standards or best management practices (BMPs) for ethical, social, and environmental issues governing the shrimp culture industry. The philosophy there is that most shrimp are healthy, but once the carrying capacity in ponds is exceeded, problems arise and become unmanageable. GreenAqua, Inc. produces Bioregulator®, which is a product that contains citric acid and garlic; Bioregulator® has been used successfully to treat TSV, NHP, BVP, IHHN and "colita roja" (red tail) outbreaks in Ecuador. Other ingredients in Bioregulator® that may assist in fighting diseases are Selenium and Germanium. The same company produces a 100% natural (nonnitrogen) fertilizer-like, pond additive made from Leonardita, a mineral/carbon less than 300 million years old. They market this product, called Biorganic®, as a rich mixture of humic and fulvic acids, which act to quick start primary and secondary productivity in ponds. The company has data and 15 years of experience to back their claims that these products promote rich soils, lower operating costs, promote higher survival rates, give better food conversion ratios, cleaner ponds, and good harvest yields. Apparently, WSSV was present in Ecuador as early as 1995, according to histological slide evidence, but techniques had not been developed to recognize it. It has also been suggested that the abuse of sodium metabisulfates in that country and others may have contributed to stress and eventually lead to infection and transmission of the viruses. The heavy use of Tilt as a fungicide by the banana industry to prevent black spots on bananas is also suspected of causing additional stresses in the estuarine waters of Ecuador.

The control of temperature or any sudden change in environment is important in the control of stress and WSSV.

OTHER MANAGEMENT PRACTICES

Saponin, or Tea Seed Cake, as it is commonly called, is made from a tea seed or from the lilly or camellia in the eastern hemisphere. It is used as an aquatic pesticide and is lethal to crabs, fish, and insects that would prey upon shrimp at relatively low levels (10−15 ppb); at higher levels it is lethal to shrimp. It is used to eliminate predator fish and crabs from ponds or in wild-caught shrimp transport containers. Saponin is used in terrestrial farming as an organic insecticide. It is effective against snails and slugs in rice fields and in vegetable and fruit farms.

Tea seed cake (or powder) is a residue remaining after the oil has been extracted from the seeds of certain plants in the camellia family. It is compressed into a cake shape (or powder form) and contains saponin (a toxin reacting in the blood that is suitable for many applications). Saponin in plants (as soapwort or soapbark) makes a characteristic soapy lather. Hydroscopic saponin mixtures are used as foaming and emulsifying agents and detergents. Saponin detoxifies quickly in water and is not injurious to cattle or people who may use the water, and it leaves no cumulative adverse residues.

According to C.P. Shrimp News, tea seed cake from the eastern hemisphere can be applied to ponds at 20−30 ppm for 6 hours, after which water is exchanged to take care of shrimp carapaces that are not smooth, fuzzy, and are dirty (caused by *Zoothamnium* fouling, algal fouling, or colloidal fouling). Saponin can be used to control *Zoothamnium*, and *Epistylis* on PL shrimp (20,103). A 10% saponin solution diluted and added at 5 ppm concentration can be used to treat larvae.

Saponin is also made in the western hemisphere, mainly in the United States. However, unlike saponin from the eastern hemisphere, U.S.-made saponin comes from the yucca plant and is not toxic to crustaceans and fish even at levels above 10−15 ppb. In fact, recent research by a private company (DPI) in the United States has shown that the yucca derivative saponin is actually beneficial to shrimp when placed in the diet. It changes the flora and fauna of the gut by attacking gram-negative bacteria. It has been shown that young shrimp actually grow faster with saponin added to the diet. Saponin does not effect the growth of plants, and compared with other chemicals, it is safe, inexpensive, and easy to use. The foaming agent in the soft drink root beer is from saponin; therefore, used in small amounts, it is not harmful to humans.

Saponin is generally not a pleasant substance to handle, and most chemical companies do not carry it or sell it within the United States. However, importers can obtain container loads relatively easy.

Some farms have used chlorine to disinfect their incoming waters before use in recirculating systems. Chlorine will eliminate all living things in the water. Treatment with chlorine is neither necessary nor desirable, because it leaves water with no algae and other beneficial organisms that are important for maintaining a healthy ecosystem. Insecticides and pesticides generally target certain organisms and have been found to be more effective and useful in controlling disease vectors.

ONE METHOD OF POND BOTTOM PREPARATION

Pond bottoms, especially in low areas, are tilled so that blocks of soil are broken and will oxidize by exposure to air. The UV light from the sun also helps bake or sterilize the soil. The internal canals should be kept free of sediment and dried. The depth of tilling in the central area should be restricted to 1−2 cm (2−3 in.), because this is the reactive depth between pond soil and water. Liming rates for soil

Table 9. Liming Rates for Soil pH[a]

pH	Dolomite (lb/acre) (kg/ha)	Burnt Lime (lb/acre) (kg/ha)
<5	2000	600
5–6	1000	400
6–7.5	500	200

[a] 1 lb = 0.45 kg and 1 ac = 0.4047 ha.

pH are shown in Table 9. Soils should be maintained at or near neutral (pH7).

After a pond is prepared for the next crop, it is ready to fill. One method of filling a pond starts by flushing or flooding approximately 60% of the pond bottom, ensuring that the interior canals are covered with water. The water is drained to flush unwanted hydrogen sulfide, organics, and possibly heavy metals that may have leached from the dikes or pond bottom. Harvest structures and effluent gates are re-sealed, and the pond is flooded again. No fertilizer is added until flushing is completed. Filling ponds for stocking is to be completed within 10 days after they are made ready for filling. The water level by stocking day will be 30 cm (12 in.) below the full mark. The water level from 8 to 15 days after stocking will be raised to 20 cm (8 in.) below full. The water level from 16 to 22 days after stocking will be raised to 10 cm (4 in.) below full. The water level from 23 to 30 days after stocking will be raised gradually to the full level. Microscreens (0.5 mm) are also removed from the inlets at this time. They are then cleaned, dried, labeled, and stored for the next crop. Once water exchange has begun, harvest and outlet screens should be thoroughly cleaned at the bottom to ensure that poor quality bottom water is flushed from the pond. Harvest and outlet screens should be checked regularly for damage. A microscreen bag at the discharge end of the pipe in the harvest catch basin should be set up to determine if any PL are escaping during water exchange. Mosquito screens (7 mm mesh) are removed from harvest basins and outlets once the shrimp population reaches an average weight of 5 g (0.01 lb).

FERTILIZATION LEVELS AND COSTS

One of the most important factors to keep in mind on fertilizers is the ratio of nitrogen to phosphorus (N : P) used. To promote beneficial diatoms and algae (and not blue greens, especially with higher salinities in the dry season) you need to keep this ratio at least a 5 : 1. A 10 : 1 ratio is better, and best is 20 : 1 or higher, according to most successful pond managers. This ratio is the quantity placed in the pond, not the %N versus %P. The following example is from Nicaragua: Nutrilake[TM] −10 kg: TSP−3.3 kg/ha (22 lb : 7.26 lb/2.47 ac). This is a 3 : 1 (in quantity) ratio and is not high enough. Urea−6 kg/ha: TSP−2 kg/ha (13.2 lb/2.47 ac : 4.4 lb/2.47 ac) also is a 3 : 1 ratio and too low. The source of nitrogen is important, but not as important as the quantity ratio with Phosphorus. If Nutrilake[TM] works better than urea, then use it. The cost of fertilizer is far below the cost of PL and feed. The manager should spend time trying to economize with feed and PL more than with fertilizers. Use what works best and shrimp growth rates should make up the difference in any added costs of nitrogen.

ONE METHOD OF INITIAL FERTILIZATION

Some of the best fertilizers to use are DI-ammonium phosphate 17-46-0 (DAP) in pellet form, triple superphosphate 0-46-0 (TSP), ammonium nitrate 33.5-0-0 (AM), urea 46-0-0, sodium nitrate 16-0-0, and molasses. The ratio of urea to DAP/TSP used in pond fertilization may vary from time to time from 5 : 1 to 10 : 1 (or higher), depending on pond nutrient level and the quality of the incoming reservoir water. The manager should decide which ratio is in effect at any given time. Either method (1) or (2) may be used for initial fertilization of ponds, depending on the requirements of the water.

1. Before filling ponds, apply 22.5 kg/0.4 ha (50 lb/ac) of diammonium phosphate (DAP) or triple superphosphate (TSP) and 22.5 kg/0.4 ha (50 lb/ac) of urea over dry pond bottoms. Spread fertilizer as uniformly as possible. To increase substrate area in some ponds, 225−450 kg/0.4 ha (500−1000 lb/ac) of rice processing water, or 113 kg/0.4 ha (250 lb/ac) bagasse may be applied to the pond bottom. The bagasse needs to be soaked for a few days in pond water while the pond is filling before being spread over the pond surface. While the pond is filling, add 15−19 L/0.4 ha (4−5 gal/ac) of molasses at the inlet. Fill the pond to 60−70% bottom cover, and hold this level for a couple days or until a bloom develops. Continue filling the pond to stocking level, 30 cm (12 in.) below full, applying routine fertilization daily or as required.

2. Initial fertilization begins the day after step 2 of pond filling begins. Fill the pond to cover at least 60% of the bottom. While the pond is being filled, fertilize with 9 kg (20 lb) urea and 0.9 kg or 1.8 kg (2 lb or 4 lb) DAP/TSP per hectare (2.4 ac) of total pond surface area at the inlets, so that water can gradually dissolve the fertilizer. When the water is deep enough, spread urea by hand directly from a boat. DAP/TSP is dissolved in a container and slowly poured into the water behind an outboard engine on the moving boat. This mixes the solution with pond water by the propeller action. After one day, begin bringing the level up to 50% pond volume. While filling, add 13.6 kg (30 lb) urea and 1.3 kg or 2.7 kg (3 lb or 6 lb) DAP/TSP per ha (2.47 ac), ensuring adequate distribution over the pond surface area. Skip another day. Continue to fill the pond to 5 cm (2 in.) below full mark (maximum operative level). While filling, add 22.6 kg (50 lb) urea and 2.2 kg or 4.5 kg (5 lb or 10 lb) DAP/TSP per ha. Additional fertilizer may be applied at the discretion of the manager if a bloom has not developed before the stocking date. The ammonia level must be checked daily preceding stocking to ensure that it is at an acceptable level for PL. If the ammonia level is unacceptably high, it can be reduced through pond

flushing. Fertilizer may be applied at reduced levels immediately before and after stocking to prevent excessive ammonia levels.

- Whenever the morning secchi disc reading is greater than 35 cm (14 in.), routine fertilization will be applied a minimum of two times per week.
- In the first few weeks of pond culture, it may be necessary to initially fertilize on consecutive days and after that every other day, and eventually biweekly routine fertilization should be enough to maintain turbidities of 35–40 cm (14–17 in.).
- When the turbidity reading is less than 30 cm (12 in.), suspend fertilization for that pond until transparency increases to 35 cm (14 in.) or greater.
- If turbidity readings are less than 20 cm (8 in.), suspend routine fertilization, as well as daily feed ration, and increase the water exchange rate by 20%, flushing until turbidity readings are greater than 35 cm (14 in.).
- If a phytoplankton crash causes low DO levels, emergency fertilization should be implemented by adding 6.8 kg (15 lb) urea and 0.67 kg or 1.36 kg (1.5 lb or 3 lb). DAP/TSP per hectare (2.47 ac) of pond surface area.
- TSP and DAP in solid form are never spread directly into the water. Always dissolve a container or secure the bags in the inlets. Villalon (21) gives a detailed account of Ecuadorian fertilization procedures. Table 10 comes from a farm in Belize that follows similar procedures to the ones described in Villalon (21).

IMPORTANCE OF NATURAL PRODUCTIVITY, SUCH AS PLANKTON, IN PONDS

One can produce good-quality shrimp without natural productivity, but it may cost more (in fertilizers and higher feed inputs), and the growout cycle duration might be longer than in a pond that has high natural productivity. Plankton is very important in extensive systems, relatively important in semi-intensive systems, and much less important in intensive systems. Plankton provide the essential micronutrients missing in many commercial shrimp feeds. In the absence of dietary input from natural productivity (e.g., indoor, clear water culture systems), the commercial shrimp feed used must be complete or growth will be poor. Newly stocked larvae will generally favor natural foods over crumbled feeds. If the newly stocked pond is deficient in plankton, the larval survival is at risk. Phytoplankton and meiofauna constitute the food sources for secondary productivity. If ponds are deficient in algae and bacteria, there will be very little zooplankton production, which may impact shrimp growth. Algae are natural biofilters and are very effective removers of soluble nitrogenous waste products, such as ammonia. Phytoplankton and suspended solids shade the water column, assist in hiding the shrimp from birds and other predators, and create a more favorable environment for the shrimp, which generally dislike high light intensities. The most economical way to aerate or oxygenate pond water is through algal photosynthesis. In ponds built in acid sulfate soil conditions, algae will assist in elevating water pH. Algae and bacteria will help in assimilating and neutralizing any residual antibiotic or pesticide that may be present. The type of plankton is also important. Diatoms are preferred for their superior nutritional content. Some algae possess natural antibacterial properties. Blue-greens and dinoflagellates are considered undesirable because they may cause unstable water chemistry and health problems (hemocytic enteritis, growth inhibition). One such algae is *Gleosystus major* and is suspected of causing problems in ponds in Texas. It has an envelope that carries bacteria and is thought to infect shrimp, but more research is needed to find the exact mechanism of infection.

Good pond managers try to identify and quantify the plankton in their ponds. There is some debate as to whether the resulting information justifies the cost and manpower requirement, but most farmers like to know what they have in their pond water.

ECONOMICS OF PRODUCING SHRIMP IN PONDS

Shrimp are produced in ponds, raceways, and tanks. Production costs vary from US$5.00/0.45 kg (US$2.50/lb) to US$10.00/0.45 kg (US$5.00/lb) because of the varied output costs associated with each form of production. Feed, processing, and larvae are the three highest costs. It generally takes 0.91 kg (2 lb) of feed to produce 0.45 kg (1 lb) of shrimp. The principal economic problems with culturing shrimp in the United States are availability of low-cost, high-quality feed; short growing season; one crop only in some areas because of temperatures; high cost of land, labor, high operating costs (e.g., power); foreign competition; and price fluctuations. Because of the cold climate, outdoor culture in the continental United States is limited to nine months in extreme southern regions. Roughly 40% of the body weight of shrimp is in the head. Shrimp producers generally contract a processing

Table 10. Routine Fertilization (1 lb = 0.45 kg; 1 gal = 3.79 L)[a]

Pond	Urea (lb)	DAP (lb)	Molasses (gal)	Pond	Urea (lb)	DAP (lb)

[a]Multiply urea lb by 1.5 if substituting with ammonium nitrate and by 3 if substituting with sodium nitrate.

plant to process the shrimp. An average of US$1.38/kg (US$0.63/lb) is charged for processing (icing, deheading, grading, packing, freezing in plate freezer, and one month in cold storage). Production in ponds often ranges from 2,000–8,000 kg/ha per crop (2,000–8,000 lb/ac per crop) in the United States with average U.S. pond production at 3,500 kg/ha per crop (3,500 lb/ac per crop). The relationship between total length and weight of shrimp is given in Table 11. A breakdown of the cost analysis of shrimp tails can be seen in Table 12.

A 20% profit margin is considered to be excellent in Ecuador. The real price of Ecuadorian shrimp has declined sharply since 1980. Profit margins have been

narrowing because of rising feed, labor, and fuel costs, and the exchange rates have hurt the farms. Government exchange rates have actually acted like high taxes to the farmers, and most people want to see a free exchange rate.

Present (1999) costs for a pilot shrimp farm in south Texas, consisting of four ponds, each 2 ha (5 ac), with a settling basin attached to each pond and one common 6 ha (14.8 ac) constructed wetland can be seen in Table 13. The facility is now in operation and was designed to treat water on site and to discharge water only during harvest. The farm takes in water only to fill ponds and offset evaporation and other water loss, and the facility is capable of producing 36 MT of shrimp per year (approximately 4,000 lb/ac). The average construction cost for the 14.1-ha (35-ac) facility is US$5,315/ha (US$13,130/ac).

The capital and operating costs of three different sized, flow-through system, hypothethical shrimp farms can be seen in Tables 14 and 15, respectively. The 20.2 ha, 40.4 ha, and 76.8 ha (50 ac, 100 ac, and 190 ac) facilities are itemized in detail. Not included are the extra costs of recirculation design, equipment, and wetland water treatment systems given in Table 13. As can be seen in Table 14, the average estimated construction cost is US$24,803/ha for a 20.2-ha farm, US$15,657/ha for a 40.4-ha farm, and US$15,882–17,126/ha for a 76.8-ha facility (US$10,042/ac for the 50-ac farm, US$6,339/ac for the 100-ac farm and US$6,430–6,934 for the 190-ac facility).

SHRIMP NUTRITION AND FEEDS

Feed prices vary, but current price for 35% protein feed in Texas, if purchased in bulk, ranges between US$.60/kg and US$0.68/kg (US$0.27 to US$0.31/lb). Standard quality feeds generally fall apart as soon has they hit water. Most of the feed companies offer a lower quality feed, but promote the higher grade feeds by saying that the FCR will be better, which is usually true. Many feed companies in the eastern hemisphere promise FCRs of around 1.8 kg feed: 1 kg shrimp (1.8 lb feed: 1 lb shrimp) produced, and an average growth of 3 g/10 days (0.09 oz/10 days) for *P. monodon*, with their top line feed and FCRs of 2.5 : 1 with their lower grade feed.

Table 13. List of 1999 Costs for a Pilot Shrimp Farm in Texas (Price in US$)

Contractual	
Construction Management, Equipment Operator, and Rental	20,045
Earth Moving	72,982
Electricity Establishment (Includes Electricity to Aerators)	25,000
Fencing 1,500 Meters or (5000 ft) Installed	10,815
Insurance, Repairs and Maintenance, Dues, Water Analysis, Miscellaneous	6,000
Legal Fees (Permitting, etc.)	50,000
Supplies	
Wetland Vegetation, Truck Fuel, Grass Seed, Tools, Miscellaneous	18,400
Pipe, Lumber, Hardware	20,073
Equipment	
Land 20 at $3,750/ha or (50 ac at US$1500/ac)	75,000
Pumps	5,000
Feed Equipment: Pond Feeder, Bulk Bin (8 ton)	10,770
Aerators, Controllers and Wire, 60 at 2 hp Each (US$476 ea)	28,565
Emergency Aerator	4,449
Tractor (Used, 140 hp), Truck (Used, 3/4 ton, 4wd)	25,000
Electrical Generator (Pto Driven, 50 kva)	5,000
Drains, Harvest Basins	7,953
Scraper Blade, Mower	4,000
Screens, Nets, Pl Acclimation Equipment	3,500
Trailer and Furniture (Office, Storage and Occasional Housing)	11,000
Water Quality Lab Equipment	8,500
Repairs, Contingencies, Miscellaneous	11,000
Personnel	
On-Farm Labor, Consultants	36,500
Total Costs	US$459,552

Source: Dr. Ronald Rosati, Texas A&M University in Kingsville, Texas.

Feed manufacturers have come a long way to improve the stability of shrimp feed. Formaldehyde-based binders were discarded, and vitamin-C stabilizers were added, to name a few improvements. Cruz (109) and SEAFDEC (110) covered shrimp feeding principles and practices. Some of the more useful feed and nutrition references are Piedad-Pascual (111), American Soybean Association (112), and New, Saram, and Singh (113). A good live-feed reference is Dhert and Sorgeloos (114).

Some of the protein requirements reported in the literature for various species of shrimp are the following: *F. aztecus* at 23−31%, *F. californiensis* at 35%, *F. duorarum* at 28−32%, *F. indicus* at 43%, *M. japonicus* at greater than 60%, *F. merguiensis* at 34−42%, *P. monodon* at 35−50%, *F. chinensis* at 40%, *F. penicillatus* at 22−27%, and *L. setiferus* at 25−28%. A nutritional review of *L. stylirostris* was done by Cuzon (115), and one for *L. vannamei* by Pedrazzoli et al. (116). The World Aquaculture Society published an excellent reference on crustacean nutrition in 1997 (117). A number of shrimp feed formulas can be seen in New (118).

SHRIMP GROWTH RATES

Growth of shrimp varies greatly with species, stocking density, and food supply (Fig. 36). Other conditions, such as water quality and temperature, are also major factors. Under ideal conditions, *L. vannamei* can reach 20 g (0.6 oz) in 120 days, whereas *P. monodon* can attain 35 g (1.05 oz) and *L. stylirostris* can attain 28 g (1 oz) in the same period. The normal weight in which *L. vannamei* are harvested is 16−18 g (0.48−0.54 oz). Generally, 62% of that weight is in the tail meat. Growth rate comparisons of other species can be seen in Figure 36. An example of a shrimp feeding regime can be seen in Table 16. The management of ponds stocked with blue shrimp (*L. stylirostris*) was described by Clifford (119). Optimum water parameters for shrimp farming can be seen in Table 17, and seawater analyses from around the world have been compiled in Tables 18a and 18b. Soil types that are conducive to shrimp culture in ponds are listed on Table 19 (120), and the optimum soil parameters, with normal, highs, lows, and ranges, are listed in Table 20 (120).

SPECIFIC ADVANTAGES OF WORKING WITH SALTWATER SHRIMP

Saltwater shrimp taste good to most people. The texture is firm, and it keeps well when frozen, because the shell protects the meat. It can be thawed and refrozen with minimal damage to the product. Market demand for such shrimp is generally high. Price is generally high in comparison with other seafood, and the product has nutritional benefits. Commercial feeds are available for shrimp growout. Processors, exporters, and importers often prefer cultured shrimp, because it is not as seasonal as wild-caught shrimp and is considered more reliable, more uniform in size, a higher quality, and a fresher product. Cultured shrimp availability can be predicted and planned for. This allows the industry to adapt to consumer demand regarding species and size. Shrimp can be provided live or near live to restaurants that serve seafood. Curricula are now available for teachers wishing to cover the foregoing aspects of shrimp culture in the classroom [see Treece (121).] Dall et al. (122) is a must-have text for the shrimp culture library.

TASTE DIFFERENCES IN SHRIMP

Shrimp reared at high salinity are more flavorful, while the shrimp grown in freshwater usually have a bland taste. Shrimp osmoregulate to adjust to osmotic pressure differences between fresh and saltwater. As salinity goes up, the shrimp increase free amino acids in the muscle, and some free amino acids are associated with taste.

FRESHWATER SHRIMP CULTURE

Introduction

The Malaysian prawn (*M. rosenbergii*, seen in Fig. 41) has been grown for centuries in Asia, but it has only been the subject of research and commercial enterprise

Table 14. Capital Costs for 50, 100, and 190 acre (20, 40, and 77 ha) Hypothetical Shrimp Farm Built in 3 Phases

Number of ponds	10	20	38
Water acres per pond	5	5	5

[a] Sverdrup et al., 1970.
[b] Förstner and Wittman, 1979.
[c] Riley and Chester, 1979.
[d] Miscellaneous sources.
[e] Hardness is the measurement of calcium (Ca) and magnesium (Mg) ions. Add these two and the total should be above 20 ppm for water to be considered favorable for fish culture. Total hardness (calcium carbonate or $CaCO_3$) should be between 50–150 ppm for best results according to Boyd, 1992; between 20–200 according to isc. sources and 20 ppm according to Johnson (SRAC pub. #A0901).
[f] Salinity dependent.
[g] Estuary with river inflow.
[h] BODS–1.5 ppm is normal for estuary and 8.5 is normal for intensive culture pond.
[i] Alkalinity (should be no lower than 20 ppm. Optimum range is 50–150 ppm in seawater at 35 ppt and pH 8.3).
*Indicates that the sample reading is out of the ordinary or not normal.

[a]Sulfur in soils above 0.75% indicates potential acid sulfate soil; Average of 346 ponds was 0.49%. Potential acid-sulfate soils often have 1–5% total sulfur.

Figure 41. *Macrobrachium rosenbergii* male (note long pinchers, claws, or chela).

in the United States during the past 40 years. The information in this section, except where noted, was taken directly from or summarized from D'Abramo and Brunson (123). Other species of *Macrobrachium* are indigenous to the United States, but none are as suitable for aquaculture as the Malaysian prawn. The other species (*M. acanthurus*, *M. carcinus*, *M. ohione*, and *M. olfersii*) do not reach sizes that are considered desirable for aquaculture (124). Basic production techniques were developed in the late 1950s in Malaysia and refined in Hawaii and Israel during the past 30 years. Mistakidis (124) published an excellent biological account of the freshwater shrimp, with line drawings of eggs and larval stages.

A major breakthrough occurred when Fujimura and Okamoto at the University of Hawaii made the mass production of PL possible in 1970 (125). Once this bottleneck was removed, freshwater shrimp culture began to spread to areas such as Mauritius, French Polynesia (126), Israel, and the state of Florida. Weyerhaeuser, in Florida, started an R&D program in 1974; soon after, other countries started similar programs (Puerto Rico in 1975, Martinique, French West Indies in 1977, Jamaica and the Dominican Republic in 1978, Central America in 1979 and Brazil in 1981). Bardach et al. wrote a classic paper on the species in 1972 (127).

At the same time, Weyerhaeuser, in Florida, and companies in other countries were developing R&D

programs. The states of South Carolina, Texas, and Louisiana conducted research into basic production techniques, as well as marketing, processing, and hatchery procedures. In 1974, Sun Oil Company established a pilot freshwater shrimp-farming company (Aquaprawns, Inc.) near Brownsville, Texas. The firm developed several new techniques to cultivate freshwater and saltwater shrimp, including the use of a harvest pump (128). In 1977, Hanson and Goodwin (129) reviewed the culture practices developed for *M. rosenbergii*, and S.K. Johnson described the diseases found in the species (130). In 1978, Sun Oil Co. closed its non-petroleum-related subsidiaries, and a new company (CSCI), was formed. In 1980, CSCI built a 27.2-ha (68-ac) freshwater shrimp farm near Los Fresnos, Texas. The operation was located several miles inland, but used saline groundwater to operate the hatchery.

Even though it is called a freshwater shrimp, a certain part of its life cycle is spent in saltwater. The natural life cycle involves the adult shrimp migrating down rivers toward estuaries to have their young, and juveniles return to the rivers to complete the cycle. Freshwater shrimp require brackish water (12–15 ppt) for larval development and can tolerate up to 5 ppt during growout. They are tropical in temperature requirements and do not do well in water temperature below 10 °C (50 °F). In 1981, population profile development and morphotypic differentiation in the species was described (131), and a fact sheet was published on the culture of the species (132).

In 1983, Aquaculture Enterprises, Inc. acquired an unsuccessful prawn farm in Puerto Rico (Shrimps Unltd., Inc.), and John Glude restarted the farm at Sabana Grande on the southwest coast. It experienced a large debt service and construction delays for five years before it became what was considered an economically viable size in 1988 (58 ha or 143.3 ac). The Weyerhaeuser technology was inappropriate for the environment in Puerto Rico, and production failed to achieve projected levels. A change in production strategy, termed the "Modified Batch System" was developed and tested in 1989 and 1990, and a production rate of 3,000 kg/ha (3,000 lb/ac) per year was achieved. A disease called the "white PL disease," caused by Rickettsia, hit the company hard, while a recession in the United States caused a drop in demand for the product, and the company was forced to put production on hold in 1992 (133). Additionally, by 1992, inexpensive Taiwanese frozen shrimp had appeared in the world market at US$10/kg (US$4.54/lb) and created fierce competition in the industry. Many producers' costs were higher than the shrimp were bringing on the market.

In Texas, CSCI produced large amounts of shrimp, but closed in 1985, unable to find a large, high-value market for the product. At least three companies in Texas produced and sold freshwater shrimp. In south Texas, Sweet Water Aqua-Farms, Inc. reopened the CSCI farm in 1989, raised freshwater shrimp, and distributed nationwide. Sweet Water had been marketing the Malaysian prawn for a number of years from Brooklyn, New York, and decided to move into production. They sold mainly to "white table cloth" restaurants, had a toll-free telephone number, and had an agreement with one of its investors (Federal Express) for overnight delivery of the product. In 1990,

Sweet Water Aqua-Farms, Inc. produced 544 kg (1,200 lb) of *Cherax* (Australian red claw) and 9,979 kg (22,000 lb) of freshwater shrimp. Although the numbers are not large when compared with the Texas marine shrimp production, the product was marketed as a specialty item for a niche market. The freshwater shrimp were shipped fresh (killed and heads-on at 1–3 °C or 35–38 °F). The farm suffered the loss of 9,979 kg (22,000 lb) of shrimp (valued at US$254,540) due to an Arctic cold front in November, 1991. The owner was able to save the broodstock and still made a little money, despite the freeze loss. The farm relocated to Puerto Rico, where year-round production was possible without the threat of cold weather.

Freshwater shrimp PL are quite expensive relative to saltwater shrimp. Even in the 1980s, freshwater shrimp PL cost between US$25–50/1000. Now they are generally selling for US$50–65/1000. By comparison, saltwater shrimp PL sell for US$8–10/1000 if purchased in the United States and US$6–7/1000 purchased from Central or South America or in large quantities. Part of the reason for the price difference is the larval cycle is longer for freshwater shrimp (25–45 days), whereas the saltwater shrimp hatchery cycle generally takes 18 days, or even less if the temperature is raised above 28 °C (82.4 °F).

Cannibalism has been a major problem in the freshwater shrimp industry. As is the case in most crustaceans, the larger shrimp prey upon the smaller ones. Producers of freshwater shrimp provide habitat or hiding places, vegetation in the pond, and harvest the larger animals routinely to minimize the problem. Another problem faced by the freshwater shrimp industry is that two-thirds of the animal is head and one-third tail muscle. Most producers are forced to sell the product fresh and with the head on. Digestive enzymes in the cephalothorax cause of the muscles to deteriorate if not properly handled after harvest, and producers say that the animal cannot be held on ice very long because the shells becomes soft.

During recent years, new management practices have dramatically increased the potential for economic success of freshwater shrimp culture in the southern United States. Research efforts have been complemented by demonstration projects designed to evaluate methods under large-scale commercial conditions. Freshwater prawns, like all crustaceans, have an exoskeleton or shell that must be shed regularly in order for growth to occur. As crustaceans grow, they shed the shell, or molt, and weight and size increase occur soon after each molt. When crustaceans molt, they have approximately 12% more water in their bodies, and they are soft, lethargic, and subject to attack by others. Because of these periodic molts, growth occurs in distinct increments, rather than on a continuous basis.

Females generally become reproductively mature before six months of age. Mating can occur only between hard-shelled males and freshly molted females. The male deposits sperm into a gelatinous mass that is held on the ventral side of the female, between the fourth pair of walking legs (123).

Eggs are laid within a few hours after mating and are fertilized by the sperm contained in the gelatinous mass. The female then transfers the fertilized eggs to the ventral

tail, into a brood chamber, where they are kept aerated and cleaned by movement of the abdominal swimming appendages (pleopods). The eggs remain attached to the abdomen until they hatch. As in saltwater shrimp, the number of eggs produced in each spawn is directly proportional to the size of the female. As long as water temperature exceeds 21 °C (70 °F), multiple spawns per female can occur annually, and eyestalk ablation (see the entry "Eyestalk ablation") is not necessary with the freshwater shrimp, as it is for commercial production of saltwater shrimp. Females carrying eggs, or berried females, are easily recognized by the bright yellow to orange color of newly spawned eggs, which gradually change to orange, then brown, and finally gray a few days before hatching. At 28 °C (82 °F), the eggs hatch approximately 20 days after spawning.

After hatching, larvae are released and swim upside down, tail first, like the mysis stage of saltwater shrimp. The larvae cannot survive in freshwater more than 48 hours and survive best in brackish water of salinity 9–19 ppt. As larvae grow, they become aggressive sight feeders and feed almost continuously, primarily on small zooplankton, worms, and larval stages of other aquatic invertebrates. Daniels et al. (134) found that larval feeding habits could be modified or improved with light manipulations and by keeping bacterial counts low. That work can be summarized as follows: In a 30-day larval cycle, 60 larvae/L (or per 0.26 gal) stock, 80% survival after 30 days; allow one week for wash down, dry out, and disinfecting; building 9.1 m × 27.4 m (29.8 ft × 89.9 ft); 6.3 million larvae for two runs, 3.15 million each run; large center drain for cleaning, disinfecting; 3.1 m × 3.1 m (10 ft × 10 ft) required to house blowers; six, 11,000 L (2,860 gal), conical tanks, not to exceed 1% slope; 6% volume of rearing tanks should be the biofilter's size 3,960/L (1,029 gal); five tanks used for conditioning water, saltwater storage, conditioning of filter media; broodstock held at 4 per m² (4 per 10.76 ft²) in intense light; from juveniles on, growout in freshwater or below 5 ppt salinity is best; ponds should be stocked at 39,520/ha (16,000/ac), a higher stocking, level will stunt growth; larvae salinity range 7–15 ppt, 12–15 ppt is acceptable, but 7–10 ppt is best; larvae stocked at 50 to 60/L (0.26 gal), up to 80–90/L (0.26 gal), should result in 90% survival.

Most larvae are fed *Artemia* nauplii throughout the hatchery phase, up to 45 days. Fuller et al. (135) looked at the economics of operating a closed, recirculating "clearwater" hatchery for the commercial production of PL.

During the hatchery period, larvae undergo 11 molts, each representing a different stage of metamorphosis. Following the last molt, larvae transform into PL. Transformation from newly hatched larvae to PL requires 15 to 40 days, depending upon food quantity and quality, temperature, and a variety of other water quality variables. Optimum temperatures for growth are 28–31 °C (82.4–87.8 °F).

After metamorphosis to PL, the shrimp resemble miniature adults, about 7 to 10 mm (0.3 to 0.4 in.) long and weigh 6 to 9 mg (50,000 to 76,000/lb). PL change from planktonic to benthic crawling individuals. When they do swim, they move like adults with the dorsal side up and swim or crawl in a forward direction. PL can tolerate a range of salinities and migrate to freshwater upon transformation. In addition to the types of food they consume as larvae, larger pieces of animal and plant materials are ingested. The diet includes larval and adult insects, algae, molluscs, worms, fish, and feces of fish and other animals. At high densities, or under conditions of limited food, freshwater shrimp become cannibalistic. PL are translucent and may have a light orange or pink head. As they change to the juvenile stage, they take on the bluish to brownish color of the adult stage. PL are juveniles, but through common usage, the term juvenile is reserved for the stage between PL and adult; however, no standard definition for the juvenile stage exists.

Older juveniles and adults usually have a distinctive blue-green color, although sometimes they may take on a brownish hue. Color is usually the result of the quality and type of diet. Adult males (Fig. 41) are larger than the females (Fig. 42), and the sexes are easily distinguishable. The claws (chela) and the head region of males are larger than those of the females. The base of the fifth or last pair of walking legs (periopods) of males is expanded inward to form a flap or clear bubble that covers the opening (gonopore) through which sperm are released. The walking legs of males are set close together in nearly parallel lines, with little open space between them, which helps distinguish immature males from females. A wide gap exists between the last pair of walking legs in females, and they have a genital opening at the base of the third pair of walking legs. Three types of males have been identified, based upon external characteristics. Blue claw males are easily distinguishable and are characterized by long, spiny blue claws (Fig. 41). Eventually, the male will either die or molt and return to a growth phase and later regain its blue claw status. Two other classes of non-blue claw males exist, orange-claw and strong orange claw males (123).

There are three phases of culture of freshwater shrimp: hatchery, nursery, and growout. For detailed information on the pond growout phase, refer to (136). Those contemplating starting a freshwater shrimp production enterprise should forego the hatchery phase at least initially and possibly the nursery phase by purchasing

Figure 42. *M. rosenbergii* female (note eggs on underside of tail).

juveniles from a supplier (137). As production increases through successful pond growout, plans can be made to develop a nursery and possibly a hatchery. There is a limited number of juvenile shrimp suppliers, but increased demands will lead to a need for more enterprises that deal exclusively in the production and sale of PL.

Ponds should have a minimum depth of 0.6 to 0.9 m (2 to 3 ft) at the shallow end and a maximum depth of 1 to 1.5 m (3.5 to 5 ft) at the deep end. The slope of the bottom should allow for rapid draining. Publications that provide additional information on pond design and construction are available on the Internet at http://www.msstate.edu/dept/srac/fslist.htm.

A soil sample should be collected from the pond bottom to determine whether lime is needed. Take soil samples from about six different places in the pond, and mix them together to make a composite sample that is then air dried. Send the soil sample to a soil testing laboratory and request a lime requirement test. There may be a small charge for this service. If the pH of the soil is less than 6.5, you must add agricultural limestone to increase the pH to a minimum of 6.5, and preferably 6.8.

The final phase of freshwater shrimp production is growout of juveniles to adults for market as a food product. Research in Mississippi, Kentucky, and other southern states in the United States has demonstrated that this can be a profitable enterprise (136–138). Unless you have a hatchery/nursery, you must purchase juveniles for the pond growout phase.

Shipping costs can be minimized if the hatcheries are located within a one-day driving distance of the growout facility. Otherwise, it is best to have the shrimp shipped via air or express courier, but this significantly increases the cost.

Ponds used for raising freshwater shrimp should have many of the same basic features of ponds used for the culture of channel catfish (136). A good supply of freshwater is important, and the soil must have excellent water retention qualities. Well water of acceptable quality is the preferred water source for raising freshwater shrimp. Surface runoff water from rivers, streams, and reservoirs can be used, but quality and quantity can be highly variable and subject to uncontrollable change. The quality of the water source should be evaluated before any site is selected (see the entry "Site selection").

The surface area of growout ponds ideally should range from 0.4 to 2 ha (1 to 5 ac), but larger ponds have been successfully used. The pond should be rectangular to facilitate distribution of feed. The bottom of the pond should be smooth and free of obstructions to seining (136). After filling the pond, fertilize it to provide an abundance of natural food organisms for the shrimp and to shade unwanted aquatic weeds (see the entry "Fertilization of fish ponds"). If a water source other than well water is used, it is critically important to prevent fish, particularly members of the sunfish family (e.g., bass, bluegills, and green sunfish) from getting into the pond when it is filled. Screening or filtering the incoming water is advised if it is not from a well. The effects of predation by these kinds of fish can be devastating. Birds, especially cormorants and hingas can also be a problem. (See the entry "Predators

and pests.") If there are fish in the pond, remove them before stocking shrimp, using 0.95/L (0.25 gal or 1 qt) of 5% liquid emulsifiable rotenone per acre-foot or 1,233 cu m (325,900 gal) of water when water temperatures exceed 21 °C (70 °F). Rotenone is a restricted use pesticide, and either a commercial or private pesticide applicator license is required to purchase and apply this material in the United States.

Juvenile freshwater shrimp must be gradually acclimated to conditions in the growout pond to prevent temperature shock or other types of stress. The water in which they will be stocked should gradually replace water in which PL and juveniles are transported. This acclimation procedure should not be attempted until the temperature difference between the transport and culture water is less than 2 to 4 degrees. The temperature of the pond water at stocking should be consistently at least 20 °C (68 °F) to avoid stress because of low temperatures. Juvenile freshwater shrimp are more susceptible than are adults to low water temperature exposure. Juveniles, preferably derived from populations that have been size graded, ranging in weight from 0.1–0.3 g (0.0002–0.0006 lb), should be stocked at densities of 29,640–39,520 shrimp/ha (12,000–16,000 shrimp/ac). The size grading results in more uniform growth and helps to reduce the percentage of smaller, nonmarketable individuals at harvest. Lower stocking densities will yield larger shrimp, but lower total harvested weight. If the market demands whole, live or fresh ice-packed shrimp, stocking at lower densities will result in larger, more marketable individuals. The duration of growout depends on the water temperature, and the time generally is 120 to 180 days in the southern United States. Freshwater shrimp could be grown year-round if a water source is found that provides a sufficiently warm temperature for growth (136).

Juveniles stocked into growout ponds are able to initially obtain sufficient nutrition from natural pond organisms. At the stocking densities recommended by D'Abramo and Brunson (123), begin feeding when the average weight is 5.0 g (0.01 lb) or greater. See Table 21 for feeding rates for semi-intensive pond growout. Commercially available, sinking channel catfish feed (28–32% crude protein) is an effective and economical feed at the recommended stocking densities. The feeding rate is based on the mean weight of the population. A feeding schedule can be developed based on three factors: (1) a feed-conversion ratio of 2.5, (2) 1% mortality

Table 21. Weight-Dependent Feeding Rates for Semi-intensive Pond Growout of the Freshwater Shrimp (*M. rosenbergii*) (123)

Mean Wet Weight (g)	Daily Feeding Rate (% of body weight)[a]
<5	0
5 to 15	7
15 to 25	5
>25	3

[a]As-fed weight of diet/wet biomass of freshwater shrimp × 100.

in the population per week, and (*3*) mean individual weight determined from samples obtained every 3 weeks. At the end of the growout season, survival may range from 60 to 85%, if you have practiced good water quality maintenance. Yields typically range from 600 to 1,200 kg/ha (600–1,200 lb/ac). Weights of shrimp range from 35 to 45 g (10–13 shrimp/lb or 22–28 shrimp/kg). These yields and average sizes will be significantly influenced by initial stocking density.

Water quality is important in raising freshwater shrimp, as it is in raising saltwater shrimp, catfish, or any other aquatic species. Dissolved oxygen is particularly important and must be monitored several times daily, especially in the early morning hours.

Selective harvest of large shrimp during a period of 4–6 weeks before final harvest is recommended to increase total production in the pond. Selective harvesting usually is performed with a 2.54-cm to 5-cm (1 in. to 2 in.) bar-mesh seine, allowing animals that pass through the seine to remain in the pond and to continue to grow, while the larger shrimp are removed. Selective harvest may also be accomplished with properly designed traps. Shrimp can be trapped using an array of traditionally designed crawfish traps. Selective harvest can help extend the duration of the availability of the fresh or live product to the market. However, there is a lack of research to show whether selective harvesting or complete bulk harvesting is the most economical approach. Regardless of the harvest method employed, some shrimp will remain in the pond and will have to be manually picked up. Rapid draining or careful seining can minimize this residual crop. Harvested shrimp should be quickly chilled to preserve the integrity of the muscle tissue, thus maintaining a firm, high quality texture. The product may be marketed fresh on ice, processed and frozen, or frozen whole for storage and shipment (123).

Culture of freshwater shrimp in combination with fingerling catfish has been successfully demonstrated under small-scale experimental conditions and appears possible under commercial conditions. Before introducing catfish fry, D'Abramo and Brunson (136) recommends stocking juvenile shrimp at a rate of 7,410–12,350 per ha (3,000–5,000 per ac) and recommends stocking catfish fry at a density to insure that they will pass through a 2.54-cm (1-in.) mesh seine used to harvest the shrimp at the end of the growing season. Soft water (<7 ppm total hardness) can be expected to cause a softening of the shell. Hard water (>300 ppm) has been implicated in reduced growth and lime encrustations on freshwater shrimp.

Polyculture of channel catfish and freshwater shrimp may be best achieved through cage culture of the fish. A scheme for intercropping of freshwater shrimp and red swamp crawfish was developed and evaluated in the United States. Intercropping is the culture of two species that are stocked at different times of the year with little, if any, overlap of their growth and harvest seasons. Intercropping provides for a number of benefits that include: (*1*) minimizing competition for resources, (*2*) avoiding potential problems of species separation during or after harvest, and (*3*) spreading fixed costs of a production unit (pond) throughout the calendar year.

Adult mature crawfish are stocked at a rate of 8,892 per ha (3,600 per ac) in summer (late June or early July). Juvenile shrimp are stocked at a density of 39,520 per ha (16,000 per ac) in late May and harvested from August through early October. In late February, seine harvest of the crawfish begins and continues through late June before stocking of new adult crawfish. Freshwater shrimp are small enough to pass through the mesh of the seine used to harvest crawfish during the May–June overlap period. Other intercropping scenarios involving such species as bait minnows, tilapia, and other fish species may be possible, but to date no research has been conducted in the United States (123).

Nitrites at concentrations of 1.8 ppm have caused problems in hatcheries, but there is no definitive information as to the toxicity of nitrite to shrimp in ponds. High nitrite concentrations in ponds would not be expected given the anticipated biomass of shrimp at harvest. Levels of un-ionized ammonia above 0.1 ppm in fish ponds can be detrimental. Concentrations of un-ionized ammonia as low as 0.26 ppm at a pH of 6.83 have been reported to kill 50% of the shrimp in a population in 144 hours. Therefore, every effort should be made to prevent concentrations of 0.1 ppm or higher un-ionized ammonia.

High pH can cause mortality directly through pH toxicity and indirectly because a higher percentage of the total ammonia in the water exists in the toxic, un-ionized form. Although freshwater shrimp have been raised in ponds with a pH range of 6.0 to 10.5 with no apparent short-term adverse effects, it is best to avoid a pH below 6.5 or above 9.5, if possible. Constant high pH stresses the shrimp and reduces growth rates. High pH values usually occur in waters with total alkalinity of 50 ppm or higher and when a dense algae bloom is present. Liming ponds that are built in acid soils can help minimize severe pH fluctuations. Another way to avoid problems with high pH is to reduce the quantity of algae in the pond by periodic flushing the top 30 cm (12 in.) of water. Alternatively, organic matter, such as corn, grain or rice bran, can be distributed over the surface area of the pond. This procedure must be accompanied by careful monitoring of oxygen levels, which may dramatically decrease due to the decay processes.

Other than the "white PL disease," caused by Rickettsia, discussed earlier, diseases do not appear to be a significant problem in the production of freshwater shrimp, but as densities are increased to improve production, disease problems are certain to become more prevalent. We know that white spot syndrome virus (WSSV) is spreading worldwide and affects many crustaceans.

Production levels and harvesting practices should match marketing strategies. Without this approach, financial loss due to lack of adequate storage (holding) facilities or price change is inevitable. Marketing studies strongly suggest that a "heads off" product should be avoided and that a specific market niche for whole freshwater shrimp needs to be identified and carefully developed. To establish year-round distribution of this seasonal product, freezing, preferably individually quick frozen (IQF), is an attractive form of processing. Block

frozen is an alternative method of processing. Adult freshwater shrimp can be successfully live-hauled for at least 24 hours at a density of 0.22 kg/3.8 L (0.5 lb/gal) with little mortality and no observed effect on exterior quality of the product. Transport under these conditions requires good aeration. Distributing shrimp on shelves stacked vertically within the water column assists in avoiding mortality due to crowding and localized poor water quality. Using holding water with a comparatively cool temperature 20–22 °C or (68–72 °F) minimizes the incidence of water quality problems and injury by reducing the activity level of the freshwater shrimp (136).

ECONOMICS OF RAISING FRESHWATER SHRIMP

Based on an average feed cost of US$250 to US$300/907 kg (or per 2,000 lb), a cost of US$65/1,000 juveniles, a 2.5 : 1 FCR, expected mean yields of 1,000 kg/ha (1,000 lb/ac), and a pond-bank selling price of US$9.35/kg (US$4.25/lb), the expected return can be as high as US$4,940 to US$6,175/ha (US$2,000 to US$2,500 per ac). Revenue and ultimate profitability depend on the type of market that is used. This estimated return does not include labor costs or other variable costs that differ greatly from operation to operation. Some thorough economic evaluations that incorporate annual ownership and operating costs under different scenarios for a synthesized firm of 17.4 ha (43 ac), having 4 ha (10.25 ac) of water surface in production, are provided in (137).

NUTRITION

The nutritional requirements of *M. rosenbergii* were summarized and compared with species of penaeid shrimp by D'Abramo (139). Other important contributions toward our knowledge of the nutrition requirements and other aspects of these animals have been published (140–149). According to D'Abramo (139), the quantitative amino acid requirements for *M. rosenbergii* remain undefined, a situation generally attributed to the common lack of success in using crystalline sources of amino acids in shrimp diets to supplement protein sources deficient in one or more essential amino acids. In contrast, crystalline amino acids have been successfully used in investigations of amino acid requirements of fish. Farmanfarmaian and Lauterio (150) showed evidence of growth enhancement achieved with a 1% supplementation of either arginine, phenylalanine, leucine, or isoleucine to a commercial diet. Analysis of the free amino acid content of whole body and tail muscle tissue of juvenile shrimp revealed that arginine is the predominant amino acid (151). The quantitative dietary protein requirement for juveniles has generally fallen within the range of 30–40% (dry weight), but lower values have been reported (152). With use of soybean meal, fishmeal, and shrimp meal, the optimum dietary protein levels are between 35 and 40% (153 and 154). All other dietary requirements were detailed by D'Abramo (139). Distinct dietary differences exist between *M. rosenbergii* and other species of *Macrobrachium*.

SILVER PERCH CULTURE

ROBERT R. STICKNEY
Texas Sea Grant College Program
Bryan, Texas

GEOFF ALLAN
Port Stephens Research Centre
Taylors Beach, Australia

OUTLINE

Culture Requirements

Bibliography

The silver perch (*Bidyanus bidyanus*) belongs to the family Teraparidae, (Fig. 1) which includes freshwater grunters, or perches (1). They are endemic to Australia, occurring through most of the Murray–Darling drainage system from southern Queensland in the north to Victoria in the south (1). They are now uncommon in the wild. Silver perch are omnivorous, and key features, such as rapid growth rates and high survival rates when cultured at high stocking densities in earthen ponds, tolerance to relatively poor water quality, and excellent eating attributes, have made silver perch a popular fish for culture. Research conducted by New South Wales Fisheries in Australia has shown that this species has the potential to form a large industry (greater than 10,000 tons/yr) based on high-value

Figure 1. Silver perch.

and low-cost production (2). Official production was about 135 tons in 1996–1997 (3).

The authors thank S.J. Rowland for providing some of the information used in this entry.

CULTURE REQUIREMENTS

Silver perch are temperate species that can tolerate water temperatures from 2 to 38 °C (36 to 100 °F) (2), but with optimal temperatures between about 23 and 28 °C (73 to 82 °F). In the wild, silver perch spawn after migrating to upstream areas behind the peaks of floods (1). In ponds, silver perch mature at about two years of age for males and three for females, but will not usually spawn. Females are fecund (approximately 150,000 eggs/kg) and in hatcheries are induced to spawn using hormones such as HCG (200 iu/kg HCG; Rowland, 1984).

The hatchery phase [broodstock to 30 mm (1.2 in.) fry] usually takes about six to eight weeks, commonly over the spring or summer months. Fry are then usually reared in fertilized earthen nursery ponds at stocking densities up to about 100,000 fish/ha (40,000/acre) for 3 to 4 months over summer and autumn (2). The growout phase usually occurs in drainable, aerated earthen ponds. Stocking densities of up to 21,000 fish/ha (8,400/acre) have been shown not to reduce fish performance (4), and fish can grow from 50-g (1.7-oz) fingerlings to 500-g (16.7-oz) adults over 5 to 7 months if summer growth is included as a part of the rearing period. If fingerlings are stocked in autumn, after the nursery phase, the growout phase will take up to 12 months (2).

In common with many species reared in freshwater, silver perch can acquire off-flavors associated with blue-green algae and some types of pond bacteria. Farmers ameliorate off-flavors by purging live fish for one to three weeks in tanks supplied with water that does not contain the offensive material. Fish are not fed during this process. Purged silver perch have qualities excellent for eating; they are firm, white-fleshed fish with an excellent fillet yield of about 40%. Silver perch are an excellent source of n-3 fatty acids, which are thought to provide health benefits for humans.

Silver perch have been bred for many years for stocking into farm ponds. Their diseases are well known (5,6).

Major ectoparasites include white spot, chilodonelliasis, ichthyobodiasis, and trichodiniasis. Fungal diseases include epizootic ulcerative disease and fungus or cotton wool disease. Bacterial diseases include tail rot, columnaris, and goldfish ulcer disease (2,5,6).

Silver perch are omnivores with relatively low protein requirements. Recent research has established that silver perch can be farmed on diets without fishmeal that are based on agricultural ingredients, such as meat meal, poultry offal meal, grain legumes, such as lupins and peas, and wheat (7). Diets that contain 30 to 35% protein can yield growth rates of around 3 g/day (0.1 oz/day) and apparent food conversion ratios of 1.5–2.0 : 1 (8). Current research on further ingredient evaluation, nutritional requirements, and feeding strategies should result in a further decrease in the cost of feeding silver perch.

SITE SELECTION

GRANVIL D. TREECE
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

Initial Considerations Prior to Site Visit

Other Important Aspects to Consider in the Site Selection Process

Sources of Information on Sites

Site Assessment

General Information on the Site

Detailed Information on the Site and Details About the Land

Soil Details for Construction Purposes

The selection of a suitable site is one of the first and most important steps toward making an aquaculture project a success. The selection of the site could determine the success or failure of the project and should not be taken lightly. The site selected depends upon a number of important criteria, which are discussed in this entry. Site selection is crucial, because it can determine the tank, raceway, or pond design; farm layout; supportive infrastructure; production methodology; management strategy; and hatchery location.

INITIAL CONSIDERATIONS PRIOR TO SITE VISIT

Before the potential aquaculture site is selected and visited, the overall objectives of the company should be determined. The market for the product to be grown at the site should be assessed and tested, if possible. Conducting a market survey and analysis is recommended. Unless the project is totally integrated and the company will have its own processing operation, the processing plant in the area is usually the market. Most large farms are integrated and sell to a world market, where competition is fierce. Know your market channels and realize what it takes to get the product there in good shape.

Once the market is researched and tested, determine how much of the product your company wants to produce or what production level is desired. Determine the level of technology that is best for your company and the site; the desired and feasible number of crops per year; and the required land area, which is a function of the desired production level, the number of crops per year, and the production strategy. The species to be cultured should be chosen, and the overall productivity of the farm should be predicted as accurately as possible. A farmer can select a site to suit the species or a species that will be best suited for a particular site.

The financial returns of the project should be assessed and the preset return thresholds met. Because of many failures in the industry, most investors and lending agencies consider aquaculture to be a high-risk operation. Most lending institutions will not consider funding a project unless it has already been proven to work on a small scale at the particular site and the management team has proven experience and plans to work full time at the site. In addition, lending institutions will not be interested in a project unless it meets a given internal-rate-of-return threshold. Generally, the projected financial returns are much higher than the actual returns, because there are many unexpected costs; therefore, the financial assessment should be done very conservatively. In my opinion, if the internal rate of return is projected to be above 20%, and preferably in the 30–50% range over a 12-year horizon, then the site selection procedure should be continued. Depending on the company's goals, if the projected returns fall below 20% per annum, then the project should be dropped before any further money is spent. Generally speaking, to be competitive, entrepreneurs entering the business for the first time must have added benefits (such as already owning the land), to assist the overall financial return.

OTHER IMPORTANT ASPECTS TO CONSIDER IN THE SITE SELECTION PROCESS

The political stability in the area should be reviewed; areas with political instability should be avoided. It is also important that aquaculture sites be located away from any significant sources of pollutants, including agricultural runoff (e.g., from crop spraying), sewage outfalls (both municipal and industrial), storm runoff canals, harbors, and refineries. Water samples should be collected and tested on a routine basis, and the results should be placed in a database, to monitor future pollution, help enforce existing regulations, assist in designing cleanup operations (if needed) in severely impacted areas, and help identify suitable sites for aquaculture development in the future. It is also important that the site be located away from wetlands, mangrove areas, or any other environmentally sensitive location. Most countries now have laws governing the use of these areas, although it may still be possible to negotiate the use of these areas through mitigation.

SOURCES OF INFORMATION ON SITES

If the financial return of the aquaculture operation looks good, then all possible sources of information concerning the site should be looked into before it is visited. These sources include, but are not limited to, the Internet; fisheries reports; regional development plans; zoning regulations; local, state, and national government aquaculture

regulations; economic development plans; remote satellite sensing; aerial photographic surveys; oceanographic surveys; hydrological surveys; land-use surveys; soil-type surveys; and engineering and topographical surveys in the area.

SITE ASSESSMENT

The next step is to visit the site and gather as much information as possible, through personal reconnaissance and by reviewing topographical, hydrological, meteorological, and biological data. A site and zone description or general description of the entire area should be obtained, as well as more specific information about the site, such as specific location; types of vegetation, water, roads; and drainage potential. Obtain the following information while on the site-assessment trip:

General Information on the Site

This includes a map, details on how to get access, to the site, and information on the location; wave action; water salinity at high and low tide; water pH; elevation above seawater source; land topography; benthic topography or description; distance of seawater inlets from the site; type of inlet prescribed; water depth at the inlet site; pollution potential; organics in water; turbidity; nearest river; source, price, and conditions of broodstock; electrical power in the area; source of freshwater; aquaculture distributors in area; source of trained workers, and potential for a well.

Detailed Information on the Site and Details About the Land

This includes information on the total amount of land available, expansion potential, current or previous use of the land, owner of the land, cost of the land, available lease terms (if any), and topography.

Soil Details for Construction Purposes

This category includes soil samples taken by location, a map of the area from which the samples were drawn, the depth at which the samples were taken, and the site stability determined by soil type.

Details on Seawater Quality at the Site

This category includes information on the potential source of seawater, distance of the seawater from the site, color of the seawater, potential for storms, appearance of the beach, erosion, accretion, freshwater plume, proximity of rivers to the site, tidal flux, type of tide (diurnal or semidiurnal), navigation traffic, industrial activity on or near the source of seawater, and a description of the nearest port.

Details on the Freshwater at the Site

This includes information on the nearest river; size of the river; other sources of freshwater; rainy- and dry-season river depth and width; estimated hydraulic flow during seasons; potential for flooding; last major flood damage; distance of the source of freshwater from the site; potential for building well, a pipeline, or canal; potential sources of effluent; and agricultural pollution.

Meterological Data at the Site

This includes data on the duration of dry and rainy seasons and temperature variance in seasons.

Flora and Fauna at the Site

This includes a description of the marine and freshwater fisheries, including all relevant details, and information on the distance to broodstock and fishing grounds, typical fishing vessels, and the nearest fishing port.

Utilities and Resources at the Site

This category includes information on the electrical supply, nearest transformer, type of current, capacity, cost of electricity, potential for power shortages, availability of petroleum and other lubricants, building materials, laboratory equipment, heavy construction equipment, and available computers.

Socioeconomic Data at the Site

This includes data on the nearest city, industries, labor force, construction contractors, engineers, aquaculturists, university and research backup, business schools in the area, nearest village or town, local industries, local government, degree of political peace and tranquility or unrest, other aquaculture projects (such as hatcheries and farms) in the area, and extent of government assistance.

OTHER INFORMATION NEEDED AT MARICULTURE SITES

A description of the climate in the region should be obtained, including air and water temperature, wind, rainfall, solar radiation, and evaporation. It is pertinent to know the air temperature, because it can change the temperature of the water. Wind and solar radiation also influence water temperature. Data on air temperature (in °C or °F) should be recorded if local data are unavailable.

Knowing the water temperature is important, because it determines which species will grow best at the site or which species should be grown during a particular season. Table 1 serves as an example of preexisting water-temperature data found during a site assessment for a tropical shrimp farm.

Table 1. Water Temperatures at a Site

Month	AM Temperature °C (°F)	PM Temperature °C (°F)
December	22–23 (71.6–73.4)	26–28 (78.8–82.4)
January	22 (71.6)	24 (75.2)
February	19–20 (66.2–68)	21–23 (69.8–73.4)
March	25 (77)	28 (82.4)
April	21–25 (69.8–77)	29–32 (84.2–89.6)
May	26–27 (78.8–80.6)	31 (87.8)
June	27–30 (80.6–86)	31–33 (87.8–91.4)
July	No data	No data
August	29 (84.2)	33–35 (91.4–95)
September	No data	No data
October	22–24 (71.5–75.2)	25–32 (77–89.6)
November	19–27 (66.2–80.6)	28–30 (82.4–86)

From these preexisting records, it appears that the cool months are November through February (four months out of the year) and that the hotter afternoon temperatures of concern fall in the month of August. These data can be useful in assisting management decisions on species to culture during the different seasons.

The prevailing or dominant wind direction should also be obtained. This information can assist in pond design and layout. Wind has three major effects on water in culture ponds. First, it circulates the water, thus mixing the layers of differing density that tend to form in ponds (a phenomenon called "stratification"). The circulation helps oxygen- and phytoplankton-rich surface waters to reach the organism being grown. It also moves water containing less oxygen, with higher concentrations of waste (metabolites), to the surface, thus encouraging reoxygenation and stimulating the biodegradation of metabolites. Second, wind tends to lower the water temperature, by increasing evaporative cooling. Third, it generates waves in a pond, causing erosion of pond banks.

Hurricanes, typhoons, and large storms may be a threat to a site. Storm winds can rip out pond liners if water is not in the pond and can destroy tanks and raceways if they are not weighted with water. A storm surge can cause flooding and loss of a crop in tanks, raceways, and ponds and may cause erosion and dike collapse in ponds. For example, Hurricane Mitch caused much damage to the aquaculture industry in Central America in 1998.

Information on the average yearly precipitation for the site should be obtained. Rainfall influences aquaculture in several ways: (1) It dilutes saltwater, thus lowering salinity in brackish areas; (2) it erodes the pond banks, roads, etc.; (3) it promotes the growth of erosion-preventative grasses on the pond dikes; (4) it lowers the water temperature.

In the tropics, rains are intense and seasonal. The result is that the heavy rains may cause damage to dikes and roads, while the long period of dry weather discourages the growth of protective vegetation. On the other hand, monsoon rains usually tend to lower the water temperatures of ponds during the hottest time of the year, when they need to be somewhat lower. Data on rainfall are generally available from government sources, such as a national weather service.

The main concern regarding rainfall is potential for flooding. One should try to obtain the 20-, 100-, or even 200-year flood-plain data for the area, if available. One should also try to obtain data on the maximum intensity of rainfall recorded, the duration and frequency of rainfall, yearly precipitation, and the watershed characteristics. Data on rainfall, soil properties, types of vegetative cover, topography, and the extent of the watershed that drains into the area determine the potential for flooding. The outer-dike or perimeter-dike elevation is generally based on the highest known flood and its height.

There is usually a definite season of low water temperatures at any given site, even in the tropics. Solar radiation influences water temperature and growth of phytoplankton in ponds. Phytoplankton rely on sunlight to convert carbon dioxide into carbon and oxygen. Carbon is essential for growth, and oxygen is released into the environment. Phytoplankton are fundamental to pond growout technology. Not only do they provide the primary production in the natural food chain, but they are also the major source of dissolved oxygen in ponds. In addition, phytoplankton bind or convert certain toxins, such as metabolites, thus purifying the water. However, in the absence of sunlight, phytoplankton become a net consumer of oxygen. Thus, during prolonged periods of overcast weather, water may be stripped of oxygen, which may stress aquatic animals, inhibiting their growth, and, in severe cases, lead to mortality. Solar radiation may also cause evaporation, which causes a rise in salinity in brackish environments. Evaporation during the dry season may also contribute to evaporative cooling at night, such that water temperatures in the pond drop considerably and may even slow growth or stress the animals being cultured.

GENERAL TIDAL CHARACTERISTICS AT MARICULTURE SITES

Tidal amplitude is important at the site, because it can determine pond-bottom elevation, dike elevations, pumping costs, and the drainage pattern. Tidal frequency determines the pumping schedule, fresh- and saltwater mixing, and the drainage schedule. The tidal fluctuation, or flux, at the site may either be small or be large and dynamic. A large tide allows for good flushing action, whereas special arrangements may be necessary to discharge water without a tide. Sites wherein tides are dynamic should have minimal problems with regard to the removal of discharge water at low tide, but might experience problems at high tide. Another problem might occur at low tide, when there is no intake water. Accordingly, farms in many areas oversize the pump station to compensate for pumping at high tide only and have very large reservoirs to supply water during low tide.

SALTWATER AND FRESHWATER RESOURCES

Large quantities of good-quality water with the proper chemical composition are generally required for aquatic farming. In a brackish environment, the salinity at the site is an important consideration: During the production phase, the species selected for culture needs to achieve maximum growth rates, and salinity levels influence growth rates. For example, most tropical shrimp grow best in salinities ranging from 5 to 25 ppt. Although they can survive at salinities outside of that range (to 0.5 ppt or less and 50 ppt or higher), growth rates would be depressed and, at the extremes, cease altogether. If shrimp culture is planned at the site, it is essential to source brackish water in the range of 5 to 25 ppt or to dilute full-strength seawater (30–35 ppt) with freshwater or brackish water. Catfish and other freshwater species may not tolerate or grow well at salinities above 5–10 ppt. See Table 2 for an example of analysis of selected water samples from Costa Rica.

Salinity is not the only factor that needs to be considered in evaluating potential saltwater sources. Other water quality parameters that need to be assessed include pH,

Table 2. Analysis of Selected Water Samples from Costa Rica[a]

Location	Temperature °C (°F)	Salinity (ppt)	pH	DO (ppm)	NO^3 (ppm)	NH$_3$ (ppm)	PO$_4$ (ppm)
Guanacaste	28 (82.4)	32	7.9	>6.0	0.45	0.67	13
North Punta	29 (84.2)	28	7.7				
South Punta	28 (82.4)	30	7.7				
Isla Negritos	28 (82.4)	30	8.1				
Rio Viscaya	26 (78.8)	10	7.6	6.0	0.50	0.31	0.25
Rio Estrella	24 (75.2)	0	7.2				
Estero Negro	24 (75.2)	21	7.7				

[a]Data from FAO.

alkalinity, hardness, sulfate, iron, nitrate, phosphate, biochemical oxygen demand, bacteria, and pollutants (such as pesticides).

The hydrogen-ion concentration (pH) is a measure of acidity. A pH of 7 is neutral (i.e., neither acid nor alkaline). Extremes in pH have detrimental effects on organisms and can also facilitate adverse chemical reactions in the water and soil of ponds. The pH of seawater at a chosen site should be expected to be in the neutral range throughout most of the year, ranging between 7 and 8.3. During the rainy season, water pH readings can be expected to be slightly lower. Low pH values usually correlate with lower salinities during and after rains and are attributable to dilution by rainwater runoff. Normal ocean water is generally in the pH range of 7.6–8.2. The pH of freshwater ranges widely, but is generally between 6.0 and 9.0. Alkalinity, on the other hand, as the term is used in natural water chemistry, measures the degree to which a solution is able to resist pH change. Note that this definition of "alkalinity" is different than the more familiar definition used in chemistry, where "alkaline" is synonymous with "basic." Speaking in terms of chemistry, solutions with a pH greater than neutral are thus "alkaline," and "alkalinity" refers to the concentration of hydroxide ions (OH$^-$).

In pond culture, the pH is usually lowest at or near dawn and highest at midafternoon. In most finfish culture, the desired pH range is 6.5–9.0. The point at which acidity becomes deadly occurs at a pH of approximately 4, and the alkalinity becomes deadly at approximately pH 11. When the pH is outside the desirable range, fish growth is slowed, reproduction reduced, and susceptibility to disease increased.

Most references state that normal ocean alkalinity is in the 100–200 ppm range. Sometimes, alkalinity is measured in meq/L; a normal reading at pH 8.3 would be an alkalinity of 2.3 meq/L. I have measured bicarbonate alkalinity ($CaCO_3$) at different sites and found it to be between 19 ppm and 200 ppm. Alkalinities 20 ppm are considered to be detrimental to aquaculture. If the alkalinity at a site is this low, many chemical reactions occur, and it is no doubt difficult to maintain phytoplankton in ponds at the site. Alkalinity has a straight-line relationship with salinity. If the alkalinity in a body of water is low compared with the salinity, the alkalinity in the water may be being consumed by acid entering the water from the soil (e.g., through seepage or rain runoff from land). To combat this problem,

white lime [calcium carbonate ($CaCO_3$)] can be added to the water after each heavy rain. Generally, ponds with acidic soil conditions and soft water are not good finfish production units.

Normally, the water source for the site should be within 1 km (0.6 mi) of the site, to keep construction and pumping costs reasonable. It should be free of pollution and from possible future sources of pollution. The physical parameters of the water source should be relatively stable on a year-round basis, to keep from stressing the cultured animals.

The water source should be matched with the requirements of the species to be cultured. Sometimes, a seawater source is mixed with freshwater in mixing ponds to bring the salinity to the desired level.

Hybrid striped bass can be grown in freshwater or seawater up to 45 ppt salinity, but grow best in freshwater. Usually, inland site permitting is less stringent than at coastal sites; therefore, an inland freshwater site should be considered for hybrid striped bass. A penaeid shrimp hatchery is most suitable at full-strength seawater (32–35 ppt salinity), whereas penaeid shrimp growout is best at 10–25 ppt in brackish water. Check the salinity of the water source by sending water samples to a qualified and reputable laboratory. It is best to check the water source over a one-year period, through rainy and dry seasons, to assess any seasonal changes. Some experts prefer to take their testing programs even further and test the water daily for one lunar cycle. If the site is in a tidal area, take water samples at high and low tides. Samples should be taken from both the top and the bottom of the water column, because salinities and other parameters vary with depth. A refractometer can be used to check salinity. If many samples are to be taken, one may want to use a portable water test kit and then verify the result with a few laboratory tests.

IMPORTANT COMPOUNDS, METALS, AND WATER PARAMETERS

In well water, the amount of dissolved gases and chemicals are important. Iron (Fe), oxygen (O_2), carbon dioxide (CO_2), hydrogen sulfide (H_2S), and ammonia (NH_3) may or may not be present. Most fish need at least 5 ppm of oxygen to remain healthy. Carbon-dioxide levels greater than 20 ppm are potentially dangerous to fish; some wells produce water at more than 60 ppm CO_2. H_2S is common

in well water and can be toxic to fish at 0.1 ppm. Aeration is generally used as a practical correction for O_2, CO_2, and H_2S problems. The hardness and alkalinity of well water should be at least 20 ppm. The total amount of dissolved solids should be less than 500 mg/L (ppm).

The phosphate (PO_4-P) level in the water source is of importance, since algae production in ponds will most likely require the adding of triple phosphate to culture water. Normally, phytoplankton removes phosphorous in ponds, but if acid sulfate is present at the site, most of the phosphate removal will be due to iron and aluminum binding with phosphate and silicate in the water source and in the sediments. The normal solution to this problem is to eliminate the acid in the soils by liming and to fertilize the algae blooms with an amount of fertilizer that will promote the growth of diatoms or beneficial phytoplankton. Ten parts or greater nitrogen (urea) to one part triple phosphate (10:1), up to a 46:1 ratio, is recommended. The ratio of the fertilizer components is important to promote the correct type of bloom. As a general rule, the criterion for dosage application is to ensure a water-source nutrient concentration of 1.3 ppm nitrogen and 0.15 ppm phosphorous in production ponds.

The sulfate (SO_4) level in the water is another important parameter to consider. Normal seawater at 35 ppt salinity has 2,648–2,712 ppm SO_4. The amount of SO_4 in average brackish water is 995 ppm, and the average level of SO_4 in freshwater is 16 ppm.

The total hardness of seawater (the calcium-ion level plus the magnesium-ion level) is another important parameter to consider in the water source. The typical magnesium-ion level in full-strength seawater is 1,350 ppm and in brackish water is 125 ppm. The amount of calcium (Ca) in normal brackish water is 308 ppm. The normal Ca-ion level in freshwater is 42 ppm. Ca hardness levels found in the literature range from 340 to 11,560 ppm. The optimum total hardness for most brackish water aquaculture is 850 to 2,550 ppm, with 340 ppm as a minimum. Freshwater hardness is addressed in more detail later.

Fecal coliform bacteria is another parameter that should be looked at in the water source. The total coliform bacteria level in water is normally around 1,330 MPN (most probable number)/100 mL (3.38 fl. oz or 13/mL), and the normal fecal coliform bacteria count is around 950 MPN/100 mL (3.38 fl. oz or 9.5/mL). As a comparison, the median fecal coliform bacterial concentration in swimming water should not exceed 20,000/100 mL, and for shellfish, harvesting should not exceed 14 MPN/100 mL. Waters used in processing (e.g., for washing, freezing) should meet standards for drinking water.

Biochemical oxygen demand (BOD) is a standard test for organic material. It is defined as the oxygen used in meeting the metabolic needs of aerobic microorganisms in water rich in organic matter (such as water polluted with sewage). It is sometimes referred to as biological oxygen demand as well. The BOD of the water source should be determined. BOD is usually reported in ppm, pph, or parts per total test time and is usually measured over a five-day period. On a per-hour basis, 0.5 ppm is considered rich and 0.05 ppm light. A per-total-test-time BOD of 1.5 ppm is considered to be average for an estuary, and 8.5 ppm is considered to be average for an intensive-culture shrimp pond. Often, watershed and river runoff bring organic debris with them, which can add to the BOD. A settling canal can be added to take care of most of the suspended solids if they become a problem at the site. This action should eliminate high BOD levels. Fish communities on pond bottoms and organic buildup on pond bottoms from metabolic wastes and uneaten food can add to the BOD as well. Careful pond management (e.g., feeding, water exchange, etc.) is the key to controlling BOD levels.

Water tests for heavy metals should be conducted. A variety of heavy metals are found in almost any water source. These metals may exist in several oxidation states with different reaction potentials, depending on their specific chemistries. Some metals are considered essential for growth, but may be toxic at high levels. Some heavy metals are generated at high levels by industry and become significant pollutants. Estuarine microbes may produce alkyl-metallic compounds that can be accumulated by estuarine species and may become potent toxicants.

Although heavy metals occur naturally in the aquatic environment as a result of weathering and land drainage, in recent years, the use of various metals in pesticides and fungicides has added large quantities of heavy metals to the aquatic environment. Excessive additions of heavy metals to the aquatic environment can have an adverse effect both on animals and on people who eat the animals as food. There are a number of reports on the toxicity of heavy metals to aquatic animals (see the entry "Pollution"). Additional results of water analyses for aquaculture sites can be found in (see the entry "Shrimp culture").

Trace metals in water are mainly associated with chlorides and other inorganic complexes. If one is ever faced with the problem of heavy-metal contamination, there are a number of ways to address it. For example, if elevated iron levels begin to influence algae blooms in ponds, aeration of the water will assist in neutralizing the effects, by oxidizing iron and forming a precipitate of $Fe(OH)_3$ that will settle out of solution.

GENERAL COMMENTS ON FRESHWATER SOURCES

Freshwater is mixed with seawater to achieve proper salinity, is the key medium for freshwater aquaculture, and, among other uses, serves as drinking water. Freshwater is generally required during construction and by workers during and after construction. The freshwater source at the chosen aquaculture site can become especially important during the dry season. It may be necessary to water grasses on pond dikes to prevent erosion. Any farm site will need a reliable source of freshwater, whether it is a freshwater aquaculture facility or a mariculture facility. The freshwater source is evaluated by calculating the required rate of flow (i.e., required pond depth, prescribed filling time, total losses due to evaporation, and percolation); the available rate of flow must be equal to or greater than the required rate of flow. Freshwater wells, especially shallow wells, can be unpredictable, of low capacity, and can deplete local

drinking water supplies. Deep wells require exploratory drilling and water analysis and can be expensive. Most sites require that a hydrological survey or study be conducted, to accurately assess the ground water.

Some of the most common measurements taken in testing freshwater determine the amount or level of the following factors: pH, salinity, specific conductance (or conductivity), total dissolved solids, suspended solids (or turbidity), trace elements, dissolved gases, organic material, total organic carbon, chemical oxygen demand (COD), biochemical oxygen demand (BOD), chlorophyll a, alkalinity, hardness, oil and grease, phenol, cyanide, total ammonia nitrogen (TAN), nitrite, and pesticides. COD is a speedy and reliable estimate of organic load; it is reported in ppm. A normal measurement is less than 10 ppm, and a high measurement is 60 ppm. Chlorophyll a gives an estimate of the amount of plant life in the water; unfertilized water might return a value up to 20 parts per billion (ppb), whereas fertilized water might range from 20 to 150 ppb. Phenol causes flavor problems in fish from polluted waters. Phenol levels in normal water are less than 1 ppm. Cyanide will kill fish at less than 1 ppm, and the total organic carbon level in normal surface water is expected to contain 10 ppm.

SITE VEGETATION

The types of vegetation at the site usually vary according to elevation and soil type. A high density of vegetation yields increased site development costs and should be avoided if possible. Mangrove or other swamps should be avoided. Table 3 describes some factors linked to the presence of certain species of vegetation at sites with brackish water.

Avoid sites that have nypa palm or other palms, because the palms are generally found in very sandy soils. Palms that stand straight up usually indicate that there is some clay in the soil, while palms that lean indicate that there is more sand in the soil.

SOIL CRITERIA RELEVANT TO SITE SELECTION

The physical factors of soils at the site should be considered. Will the soil type hold water? If not, seepage might be a major problem. Water that seeps through soil can carry heavy metals, which can then influence the algae blooms in ponds and cause health problems in the cultured

Table 3. Examples of Vegetation Indicators in Brackish-Water Areas

Physical/Chemical	Species Indicator
Elevated areas	*Avicennia* (mangrove)
Low-lying areas	*Rhizophora, Melaneura, Phoenix*
Clay soils	*Avicennia*
Sandy soils	Nypa palm, grasses
Peaty soils	Nypa palm, *Melaneura*
High organic content	*Rhizophora*
Potentially acidic	Nypa, *Rhizophora, Melaneura*
Less acidic	*Avicennia*

animals. The load-bearing capacity of soils should also be considered, as well as permeability.

The production methodology to be used depends on the soil criteria at the site. Use of lower levels of technology (such as in extensive culture) requires higher percentages of clay in the soils. Higher levels of technology allow for the use of artificial substrates or liners, due to the capability of high levels of technology to produce more than lower levels. Certain soil types provide for economical dike construction, and the larger the pond, the less soil that must be moved to build the pond. Smaller ponds require more soil to be moved, because of more and generally higher dikes or deeper ponds. Good soils help support primary productivity in a pond, while poor soils can work against primary productivity.

Soil texture at the site is also an important consideration. Soils may be classified by their texture, which is determined by the size of the particles that make up the soil. Sand, clay, and silt are the most common soil texture classifications, and a combination of the three types is found most often in the field. See (1) for ratings of soil types and water limitations in pond aquaculture.

According to engineers, a clay content of 30−50% is not always optimum for dike construction and pond bottoms, it was once thought to be, and Boyd (2) has stated that the old myth that good soil must be 30−50% clay is not true. Even soil that is 5−10% clay is fine, provided that the particle-size distribution is suitable. For example, heavy clay soils have many problems when used in aquaculture that are not associated with lighter, loamy soils. One should avoid soils with very high percentages of sand or clay, if possible. Although beach sites with high percentages of sand are used successfully for aquaculture in Peru, the construction costs are increased, because more land is required, and thicker, larger dikes with less of a slope are needed to avoid seepage and erosion. It is possible to import clay to use as the top layer of ponds and dikes, but construction costs are increased and are generally considered cost prohibitive for this method.

The best agricultural soils are loamy soils, made up of a mixture of sand and clay of different particle sizes (3). A sandy soil will not retain much water and has only a small capacity for adsorbing and holding nutrients. On the other hand, a soil with a majority of clay-sized particles binds water and nutrients tightly and is often sticky and difficult to till. A loamy soil is intermediate between the two extremes. A general rule is that soils that are considered desirable for terrestrial agriculture, that occur in suitable locations for pond sites, and that contain enough clay to provide a barrier to seepage can be used for aquaculture ponds (3).

SOIL SAMPLING HINTS AND SOIL CHEMISTRY ANALYSIS

Observe the entire site. Develop a sample matrix in which all areas are observed. Sample anomalies or abnormal areas as well as normal areas. Sample from different depths. Take at least one soil sample for every 16 ha (40 ac) (40). Check with the laboratory doing the soil analyses to see how much soil they require for each test. A reputable laboratory should look at the following soil parameters:

wet and air-dried pH, total potential acidity, total sulfide, exchangeable aluminum, total ferric hydroxide (iron), total organic carbon, and soil texture.

ACID SULFATE SOIL

Many factors may contribute to low productivity and low profitability of an aquaculture site, such as poor engineering, poor site selection, poor production methodology, poor management, and acid sulfate soil conditions. Acid sulfate soil can be identified in the field and confirmed by laboratory analysis. It has a bulk density of $1.0-1.4$ g/cm^3 $(0.036-0.050$ lb/in.$^3)$, is typically clay in texture, and has a pH range of 3 to 6.5, an organic carbon range of 1.5 to 18%, a total potential acidity level of 10 meq/100 g, and a total sulfur content range of 0.1 to 0.75%. Acid sulfate soils usually occur in low-lying areas or swamps. This type of soil is responsible for poor pond productivity, due to iron and aluminum binding with phosphate and silicate. Development of acid sulfate conditions occurs when sufficient amounts of sulfate and iron are present, along with a high content of organic matter. Inability of the tidal exchange to buffer carbonates, as well as limited aeration, will assist in the formation of acid sulfate soil. Pond productivity is generally low under acid sulfate conditions, because of a poor fertilization response. For example, benthic diatoms need silicate for the formation of their tests or shells. If the silicate is all bound up, then it is not available to the diatoms (which provide a primary food source in the pond).

To recognize acid sulfate soil in the field, look for the presence of pale yellow mottles, called jarosite, or reddish, brown ferric hydroxide. Ponds with acid sulfate soil may exhibit low water pH, and there is generally poor growth of vegetation on the dikes.

Potential acid sulfate soil is more difficult to identify. It is generally associated with sulfate-reducing root systems (*Rhizophora*) and a high organic content. Potential acid sulfate soil has gray to black specks and mottles. More information on acid sulfate soils can be obtained from (4).

Characteristics of optimum soil for shrimp culture are addressed in the entry "Shrimp culture", where examples of soil analyses can also be found.

HATCHERY SITE SELECTION

The most important parameters of hatchery site selection are water supply, water quality, proximity to broodstock, fishing industry in the area, physical access, pollution, pesticides, flood and storm potential, prevalence of disease in the area, proximity to growout ponds, culture methodology, degree of integration, competition, amount of training required for local workforce, technical support in the area, availability of building materials, availability and cost of utilities, freshwater source, and personnel comfort.

A hatchery site should be located near a disease-free broodstock supply. It should have a continuous supply of good-quality water. Shrimp hatcheries and stenohaline marine fish hatcheries should have year-round constant salinity. A hatchery site should be integrated with growout or the farms that it will be supplying. The hatchery should be located within the temperature range at which the species of choice grows best. The turbidity should be less than 100 ppm, so that expensive water treatment is avoided. The hatchery should be located in an area with low levels of dissolved organics (less than 10 ppm). There should be no hydrocarbon pollution in the area, and there should be no agricultural pesticides used in the immediate area.

BIOLOGICAL FACTORS

For hatcheries growing shrimp, the availability of healthy, wild postlarvae in the region for stocking ponds is a luxury. Milkfish are also produced primarily from wild fry. Studies to detect concentrations of shrimp postlarvae or fish fry in the region should be made. Note that their availability is not always predictable in numbers and in season; in other words, the postlarvae or fish fry are generally seasonal and are not always available when needed. As a result, the site may, at times, depend on hatchery-produced shrimp postlarvae or finfish fry for stocking. Other hatcheries in the area should be assessed. When rearing finfish, determine whether brood are available in the area, or if fingerlings can or must be purchased from a hatchery instead.

Other biological observations should also be made. For example, is the ground covered with a well-established growth of plants? If the site is in a coastal area, are the plants salt resistant? Does the terrestrial animal community include a large variety of birds and insects? If not, there may be a source of toxicity in the area. If the site is to be developed to grow fish or shrimp, are there healthy fish or shrimp already growing in the area?

Estuaries contain minerals and organic matter that have been leached from the soils of their extensive watershed and carried by runoff to the coastal area. Estuaries are where the freshwater mixes with seawater to form brackish water. Benthic algae should be found in the resulting nutrient-rich brackish water, which should provide the base for an extensive aquatic animal community. This faunal community should include a variety of fish and crustaceans that can be captured by local fishermen. Turbidity may be high in an estuary during the rainy season and may limit some of the aquatic growth. Oysters should be found naturally in the area, but may not be present if there are toxins or if the oysters have been overharvested.

The appearance of plant and animal life in an estuary has several relevant implications. First, carnivorous fish will be a direct threat to the production of small fish or shrimp larvae if the fish are allowed to enter the ponds. Second, noncarnivorous fish can also influence yields, by competing for available food and by increasing the metabolic load and BOD in the ponds. However, the presence of a variety of potential predators and competitors in the area should not be viewed in a negative manner. Their variety and appearance are a result of a high level of natural productivity at the site. This is a very favorable indication for the potential productivity, and the natural carrying capacity (i.e., food organisms that the cultured crop can eat) of the ponds can be expected to be relatively high. Indeed, this is why

the semiintensive culture system, rather than a more intensive one, is usually suggested, to take advantage of natural productivity. A less natural condition (e.g., intensive culture) requires considerably greater addition of fertilizer and higher quality feed. The appearance of aquatic life, particularly postlarvae, juvenile shrimp and finfish, is an obvious indication that the physical and chemical characteristics of the water at the site are well suited to the survival and growth of aquatic organisms.

INFRASTRUCTURE

Road and water access to the site should be assessed. Materials and heavy equipment will need to be transported to the site for construction purposes and deliveries. If adequate roads and water access to the site to support such efforts do not exist, then they may have to be constructed. Boats and barges should also be considered as viable methods of transportation to and from the site.

The power supply to the area should be assessed. If a utility supply does not exist, then generators can supply electric power until utilities can be brought in from the nearest supplier. All pumps can be powered by diesel engines, though the cost of pumping will be greater than with electric motors, or else electric motors can be used to run the pumps, powered by generators. Generators can also be used for lighting, laboratory use, and domestic needs. Most utility suppliers charge the user for the expense of bringing in power (e.g., poles, wires), but in some cases, the materials are provided as part of the service connection, while everything on the inside of the site boundary is the responsibility of the owner. In some countries, such as India and Nicaragua, the government generates and supplies the power at reduced rates. Arrangements must be made with proper authorities to ensure that an ample supply of power can be provided once the expense of providing the infrastructure is completed. It may be more desirable to use the low-cost government utilities and use generators as backup. In some areas, however, such as the U.S. Virgin Islands, electrical prices from the Water and Power Authority are in excess of US$0.22/kwh, and thus it may be cheaper for the company to produce its own power. Determine whether 440-volt, three-phase electrical power is available. Although it can be more dangerous, this power supply is generally cost efficient, with less energy loss in line transmittal.

Find out if aquaculture feed mills are available. Can they provide a constant supply of feed in the needed quantities? If not, make sure to add the extra costs of importing feed.

Communications at the site should also be assessed. A telephone system will be used to link the site with the world and is a necessity at any aquaculture site. A two-way radio will provide additional communication. With the cellular telephone systems available today, communications should not be a problem to obtain, even at the most remote site.

Other goods and services near the site should be assessed as well. The site should be relatively close to sources of building materials, equipment, and contractors. To minimize construction costs, the site should be within close proximity to heavy equipment. If the goods or services are not available in the area, they will have to be obtained from elsewhere, and some may require importation. The process of procuring supplies and equipment may need to be initiated well in advance, especially if they are to be imported and if customs must be cleared, duties must be paid, and other paperwork must be processed. This procedure calls for standardized systems and rigorous management. The development of nearby hatcheries and existing processing plants should greatly assist in providing stock and making marketing-channel connections.

SOCIAL AND CULTURAL CONSIDERATIONS

Social considerations at the site should be determined and will vary considerably from developed countries to developing countries. Neighbors are a very important factor, and the characteristics of the villages and communities near the site should be taken into account. The inhabitants can be employed at the site, but the potential effects of the site's development should be studied carefully before the decision to select the site is made. To counter any opposition by the inhabitants, the benefits that will result from the development should be pointed out to them, and any grievances should be addressed fairly and quickly. Local residents should be given priority in hiring at the site or for any other positions for which they might qualify. This will help to build good will in the community. A policy of promoting a good relationship with the community can often be the most effective means of maintaining security at the site. Wherever possible, trainees for technical positions should also be drawn from the surrounding villages. A security fence is usually a requirement to protect the crop from poaching, though fences may also disrupt the normal routine or travel routes of villagers. The Chilka Lake aquaculture project in India is one example for which a government declined a project development permit as a result of protests from fishermen; the potential displacement of the fishermen outweighed the project's benefits.

The labor profile in the area should be obtained. The labor profile is generally a compromise between skilled and unskilled workers, and most skilled labor is usually brought in. Also, the local customs and traditions of the employees should be considered. For example, in Panama and other Central American countries, a "13th month" is given from before Christmas to the first of the year as vacation to employees; this vacation must be budgeted into the project.

Although efforts should be made to employ as many local residents as possible, it is anticipated that a portion of the personnel for the operation of the site must be recruited from outside of the area. Graduates from technical colleges and universities are good candidates for on-the-job training for positions as technicians and technical supervisors. Technical aides should have had some secondary-school education. Mechanics, electricians, and personnel with office and management skills are often required to operate an aquaculture site. Security guards should be hired from outside the area, so that they are not familiar with or related to the locals. If you plan to raise finfish, ensure

that you have available a biologist or ichthyologist who is competent to make immediate diagnoses and proceed with proper chemical treatment of diseases, parasites, low levels of dissolved oxygen, and related problems.

The availability of potential housing for employees should also be assessed. To attract the highly skilled staff that is required for the site's development and management, it is important that pleasant living conditions exist or will be made available. Some of the technical staff must be available at all times at the production site and should be housed there. The majority, however, will live off site. Bailey et al. take a more detailed look into the social dimensions of aquaculture development (5).

OTHER IMPORTANT POINTS TO CONSIDER

When conducting the site survey, keep in mind that no site is perfect, that no two sites are the same, and that the survey should determine both technical and nontechnical parameters. It should include agricultural and economic data from the area. An expert who has selected sites for other aquaculture operations and has followed up on the results should conduct the site assessment or survey; a learner should not be in charge of site selection. The site assessor should use as much local assistance, extension services, and experience as possible, and the assessor should refer only to data that are documented and reputable.

SITE SURVEY EQUIPMENT

Site survey equipment might include a shovel, handheld auger, or backhoe for taking soil samples; soil and water pH meters; a handheld salinometer or refractometer; and a portable water test kit. Other equipment might include radios, a compass, plastic or glass water sample bottles, plastic soil sample bags, binoculars, a camera, maps, insect repellant, drinking water, and personal items. If soil samples are to be collected outside of the United States and shipped back to the United States for analysis, they must be mailed or sent via courier service; the United States Department of Agriculture (USDA) will not allow the personal transport of soils. A permit from the soil analysis laboratory is required and must be placed in the shipment. This permit ensures the USDA that the soil will be disposed of properly after it is analyzed. Some countries require the export of soil to be permitted by the Department of Mines.

AVAILABILITY OF CONSTRUCTION EQUIPMENT AND MATERIALS

Heavy equipment may not always be found or used in an area. Importation of equipment will add to the construction cost. The load-bearing capacity of the soil at the site must also be taken into consideration, as it will determine the type of equipment that can be used. If low-lying areas are to be developed, a drag line, Hymac, or other special equipment may be needed. A drag line can build a road or dike in front of itself by removing soil on either side.

Hymacs can knock brush or trees over and use them for a base while excavating. The availability of cheap raw materials will influence construction costs. The local price of sand, for example, can make a big difference in the cost of a hatchery.

OTHER LAND AND TOPOGRAPHICAL CRITERIA

The distance of the site from the water source can make a big difference with regard to costs and selection of pumps and piping. The slope towards the ocean or other drainage area should be considered. For best results, the area should have a minimum slope, or drop, of 2/1000 (i.e., for every 1000 units traveled horizontally, the elevation drops 2 units). Undulations will require fill or excavation and will add to the construction cost. The location of ground water is also important, as it will determine whether the site has sufficient elevation for proper pond drainage. A minimum of 30 cm (1 ft) is needed between the lowest part of the pond and the water table.

QUICK METHOD FOR EVALUATING A SITE

A quick method to objectively evaluate a site is to use a weighted ranking system. This system allows you to score the criterion from 1 to 5, where 5 is best and 1 is worst, and to assign a relative weight of importance to each criterion, on a scale of 1 to 3, where 3 is most important and 1 is least important. Multiply the score by the weight to obtain the weighted score. Add the weighted scores and compare them to the totaled ideal scores to obtain an objective evaluation. Tables 4 and 5 exemplify this process.

Table 4. Weighted Ranking System

Criterion	Your Score	×	Weight =	Weighted Score vs.	Ideal
Soil quality	3	×	3	9	15
Water quality	3	×	3	9	15
Social and economic factors	4	×	3	12	15
Topography	5	×	2	10	10
Elevation	5	×	2	10	10
Available area	5	×	2	10	10
Potential flooding	2	×	2	4	10
Ownership	5	×	2	10	10
Accessibility	5	×	1	5	5
Vegetation	4	×	1	4	5
Mechanization	3	×	1	3	5
Weighted score total (added from above)		=		86 vs.	110

Table 5. Site Evaluation and Scoring

Range of Scores (%)	Evaluation
100–80	Excellent site
79–60	Good to fair site
59–40	Marginal site
<40	Avoid site

In this site evaluation example, a score of 86 was obtained in Table 4, and thus the location was considered to be an excellent site (Table 5).

ENGINEERING SURVEY

Once the site is selected, to finalize the precise elevation and positioning of the ponds and water supply and drainage systems, it is necessary to have more detailed knowledge of the site's shape, topography, relationship to the surface-water source or estuary (if applicable), lateral profiles, natural drainage, and future locations of structures such as supply canals, dikes, drainage, and infrastructure. An engineering survey is generally required to be able to plan the project adequately. Physical references and benchmarks should be established that correspond to plotted positions on the site plans. The chosen site must be surveyed, because the engineers will require exact distances, directions and other detailed knowledge of the area.

See References 6–8 for additional information on aquaculture site selection.

SMOLTING

W. Craig Clarke
Pacific Biological Station
Nanaimo, Canada

OUTLINE

INTRODUCTION

Many salmonid fishes used in commercial aquaculture have an anadromous life cycle in which the adults migrate into rivers from the ocean to spawn. The juveniles reside in freshwater for a period of time and then migrate to the sea, where they grow into adults. Smolting is the process of development of juvenile salmonids from the parr stage, which lives in freshwater, to the smolt stage, which migrates out to sea and is capable of living in saltwater. This process is also known as the parr–smolt transformation, or smoltification.

There are two types of salmon aquaculture that involve the production of smolts. The first is salmon farming, an intensive form of aquaculture involving two distinct phases: a freshwater hatchery phase for the incubation of eggs and the rearing of juveniles to the smolt stage, followed by a seawater phase in which salmon are grown out to market size, usually in floating net pens. As a result of the expansion of salmon aquaculture around the world, many millions of smolts are produced for transfer to saltwater. In Norway alone, more than 100 million smolts are transferred into seawater net pens each year.

Salmon ranching is an alternative form of extensive aquaculture that involves the release of smolts from hatcheries and the harvest of the adults returning from the ocean. Several billion smolts are released annually in many countries, usually by public agencies or cooperatives in support of commercial or recreational fisheries. However, low rates of marine survival, concerns about the impacts of privately released salmon on wild stocks, and socioeconomic conflicts have constrained the development of commercial salmon ranching (1).

Currently, the value of salmon produced from intensive aquaculture exceeds that from the traditional capture fisheries. The main species used for salmon farming are Atlantic salmon (*Salmo salar*), chinook salmon (*Oncorhynchus tshawytscha*), coho salmon (*O. kisutch*), and rainbow trout (*O. mykiss*). The most important species raised in ocean ranching and enhancement programs are pink salmon (*O. gorbuscha*), chum salmon (*O. keta*), sockeye salmon (*O. nerka*), chinook salmon, coho salmon, Atlantic salmon, masu salmon (*O. masou*), and steelhead trout (*O. mykiss*).

The smolts produced must be of consistently high quality in order to achieve predictable growth and survival during the seawater phase of salmon aquaculture. The freshwater stage of the production system must be managed so that smolting is completed successfully. Hatchery managers must have a thorough understanding of the biology of the parr–smolt transformation and its control in order to produce high-quality smolts precisely at the times required by the production schedule. The transfer of smolts to saltwater before smolting is complete will cause osmotic stress, resulting in poor growth and excessive losses of stock due to death from osmotic shock or from outbreaks of disease.

The parr–smolt transformation is synchronized by environmental factors, mainly the annual cycle of changes in the length of the day (the photoperiod) and changes in temperature. Smolting involves a variety of morphological and physiological changes that prepare the juvenile salmon for life at sea. From the perspective of salmon farming, the most important characteristics are the development of the ability to adapt to saltwater and the change in growth pattern from the seasonally variable juvenile pattern to the more sustained growth observed in adults. Smolts produced for salmon ranching must be able to adapt to saltwater at a time when there is an adequate supply of prey available in order to allow them to grow and survive in the ocean.

BIOLOGY OF SMOLTING

Smolting involves a coordinated set of morphological, physiological, and behavioral changes that develop gradually under natural conditions over a period of several months in the spring. Salmon parr are dark, cryptically colored, and deeper bodied, while smolts are silvery, more slender, and have dark fin margins. The growth rate of parr in freshwater is highly seasonal, rapid during spring and summer and slow during the winter. Under natural conditions slow growth during winter is an adaptation to changes in food availability and is triggered by short-day photoperiod. In hatcheries, periods of slow growth can be minimized or avoided entirely by use of photoperiod manipulation to accelerate development.

A major change that occurs during smolting is the development of the capacity for regulation of salt and water balance in high salinity. Salmonids maintain the osmotic concentration of body fluids within a narrow range that is equivalent to one-third of seawater whether they are in freshwater or saltwater. In freshwater, the body fluids of the juvenile salmon are more concentrated than the fish's surroundings are, so water tends to diffuse inward and salts diffuse outward along the concentration gradient. Specialized cells termed chloride cells in the gills actively take up ions from the water, and excess water is excreted in the kidney. The urinary bladder reabsorbs sodium and chloride ions so that a dilute urine is produced. Once the fish is in seawater, the osmotic challenge is reversed: The external environment is more concentrated than the body fluids, so there is a tendency for salts to enter across body surfaces and for water to leave, causing dehydration. During smolting, the gill chloride cells develop the ability to actively excrete salts. Once smolting is complete, juvenile salmon can withstand direct transfer from freshwater to saltwater and can rapidly adjust their regulatory organs to maintain an appropriate salt and water balance. After entering salt water, smolts actively drink water, absorb the salts from the gut, and excrete them through the gill chloride cells. The kidney retains water, so urine volume is reduced and the urinary bladder no longer reabsorbs ions (2).

Life History and Anatomical Changes

On the one hand, the life cycle of most trout and charr species is completed in freshwater; on the other hand, juvenile Atlantic salmon, as well as Pacific salmon and steelhead trout, typically become smolts and enter the sea to grow for at least one year, until they reach adult size and migrate back to freshwater for spawning. The duration of the freshwater growth stage varies from a few weeks or months up to one or two years, depending on the species. As a result, the size at which smolting occurs also varies considerably among species (Table 1). Changes in body shape and color are more definite in species, such as the Atlantic salmon, coho salmon, and steelhead trout, that develop into smolts after one or more years of growth in freshwater. Of the many morphological changes taking place, the most noticeable is the increase in silvering of the body surfaces and darkening of the fin margins (3). Chinook salmon have two juvenile life histories, termed ocean type and stream type. Ocean-type chinook salmon enter the sea in their first year, whereas stream-type chinook smolts are at least one year old. Most stocks of chinook salmon used for commercial aquaculture have the ocean-type life history.

Domesticated rainbow trout are descended from wild freshwater trout and are sufficiently closely related to the migratory steelhead trout to be considered the same species. Although rainbow trout do not undergo a typical smolting, several strains are used for seawater aquaculture.

The condition factor, which is a measure of weight per unit length (calculated as weight $\times 100 \times$ length^{-3}, where weight is expressed in grams and length is measured in centimeters) declines in smolts relative to parr. This change in body shape of smolts results from a faster

Table 1. Approximate Age and Size of Smolts Under Natural Conditions

Species	Age	Weight
Atlantic salmon	2–3 yr	30–40 g (0.066–0.088 lb)
Coho salmon	1–2 yr	7–10 g (0.015–0.022 lb)
Chinook salmon (ocean type)	3 mo	4–6 g (0.0009–0.013 lb)
Chinook salmon (stream type)	1–2 yr	8–10 g (0.018–0.022 lb)
Masu salmon	1–2 yr	12–15 g (0.026–0.033 lb)
Sockeye salmon	4 mo–2 yr	2–5 g (0.004–0.011 lb)
Pink salmon	<1 mo	0.13–0.26 g (0.0003–0.001 lb)
Chum salmon	<1 mo	0.3–1 g (0.001–0.002 lb)
Steelhead trout	2–3 yr	40–50 g (0.088–0.11 lb)

growth in length than in weight. The amplitude of the change in condition factor is influenced by temperature and feeding rate. Condition factor is increased in response to a high feeding rate and in warm water. Therefore, under hatchery conditions, smolts that are growing very rapidly may exhibit only a slight decrease in condition factor.

Environmental Control

The photoperiod is the main environmental signal that synchronizes the seasonal cycles of growth, smolting, and reproduction in salmonids. Water temperature also has a significant role in the smolting process. Species differ with respect to their sensitivity to these two factors (Table 2). A rule of thumb is that species that live more than a year in freshwater before smolting are influenced strongly by the photoperiod, while those that enter the sea during their first year are not cued by the photoperiod. Growth of juveniles of ocean-type chinook, chum, and pink salmon, for example, is controlled mainly by water temperature and food supply; smolting is not cued by photoperiod. In contrast, Atlantic salmon fry emerge from the spawning gravel under conditions of a long spring photoperiod and then experience a sequence of long days during summer, followed by short winter days. The fry develop into smolts during the second or subsequent year as the photoperiod increases. Under intensive culture in a hatchery setting, care must be taken to provide a sequence of short photoperiods followed by long ones in order to synchronize the growth and smolting of species that are photoperiod controlled. If smolts are needed at the usual time in spring, it is sufficient to simulate the seasonal photoperiod cycle. However, if smolts are required for transfer to the sea at other times of the year, the hatchery manager must provide a coordinated regulation of both photoperiod and temperature conditions to allow growth and development to be completed successfully.

Water temperature has an important influence on smolting. First, it affects the rate of growth of fry and thus can control the attainment of the necessary body size for smolting. Temperature also affects the process whereby the fish adapts to seawater. Tolerance of salinity is greatest at moderate temperatures of 8–14 °C (46–57 °F), but is reduced considerably at temperatures above 17 °C (63 °F) or below 5 °C (41 °F). Daily and seasonal temperature cycles also influence smolting and initiation of seaward migration.

Table 2. Classification of Important Anadromous Salmonid Species According to Photoperiod Control of Smolting

Photoperiod Controlled Smolting	Photoperiod Independent Smolting
Atlantic salmon	Ocean-type chinook salmon
Coho salmon	Chum salmon
Stream-type chinook salmon	Pink salmon
Masu salmon	
Sockeye salmon	
Steelhead trout	

Hormonal Changes

Numerous changes in hormonal activity control physiological and morphological development during smolting. Although research is usually conducted only on one or a few hormones at a time, the various developmental changes that constitute smolting are controlled by a number of hormones acting in a coordinated manner. In smolts, an increase in thyroid hormone secretion is associated with silvering, increased growth, and olfactory imprinting. Administering the thyroid hormone triiodothyronine in the diet can induce the development of several characteristics of smolts, but tolerance of salinity is usually not affected (4,5). Cortisol secretion from the interrenal tissue is also increased at smolting. Cortisol promotes differentiation of the chloride cells in the gills and increases the concentration of the ion transport enzyme sodium, potassium-adenosine triphosphatase (Na^+, K^+-ATPase) in preparation for entry of the fish into saltwater. Other effects of cortisol include suppression of the immune system and a decrease in body lipid content. Growth hormone secreted by the pituitary gland promotes growth and facilitates adaptation to saltwater (6–8).

INTENSIVE SMOLT PRODUCTION SYSTEMS

Hatchery Tanks

Hatchery tanks traditionally fall into two categories: the flow-through or raceway type and the circulating tank. Raceways were commonly used in hatcheries that produced smolts for release to the sea. Circulating tanks are typically used in modern commercial facilities that produce smolts for stocking cages. Circular tanks provide better control over water velocity and fish distribution. Where feasible, hatcheries may use groundwater to avoid the introduction of infectious agents and maintain more moderate temperatures. Control of the photoperiod is also more readily achieved in these systems.

Net Pens

Often, net pens in freshwater lakes or ponds are used for rearing fish from the fry to the smolt stage. A major advantage of net pens is that costs for their construction and for operation are greatly reduced relative to costs of land-based hatcheries. Also, an ample water supply allows the production of greater biomass. However, a disadvantage is that control over environmental conditions is reduced, because water temperatures often vary widely and it is not feasible to exclude light to provide a short-day photoperiod stimulus. In addition, the stock may be exposed to pathogens from other fishes in the lake.

As an alternative to lakes, net pens may be suspended in brackish water in estuaries (9). The salinity should not exceed 20 ppt until the parr−smolt transformation is completed. The advantages of brackish water rearing are that the sea offers greater thermal stability than most lakes and the juveniles are able to acclimate to higher salinity more gradually. It is important that vaccination be completed before transfer of the presmolts into brackish water; the common marine bacterium *Vibrio anguillarum*

can cause severe mortality of juvenile salmonids that lack resistance to it.

Floating Enclosures

An improvement over netpens is the use of floating enclosures (10). Water is pumped through the enclosure in a manner analogous to the way a circulating tank works in a conventional land-based hatchery. In comparison with net pens, floating enclosures provide more control over water quality, because the intake for the pump can be placed at variable depths. The enclosures can be used in either fresh or saltwater. For use in the sea, the salinity of the incoming water can be controlled by a venturi device to mix fresh and saltwater (11). Thus, floating enclosures are intermediate between netpens and land-based hatchery systems, in that they have the portability of netpens together with the hydraulic characteristics of circulating tanks. Trials with a commercial version of the floating enclosure have demonstrated that it is possible to obtain more rapid growth and reduced mortality at considerably higher stocking densities than are possible in conventional netpens (12).

Stress

Extra care must be taken to minimize stress in smolt production facilities. The scales are more easily removed in smolts than in parr. Descaling makes the fish more susceptible to disease and impairs osmoregulation in saltwater. Smolts are also more susceptible to stress compared with parr (13), and their immune system is suppressed by hormonal changes, making them more sensitive to infection (14). Handling and transportation are two common sources of stress when smolts are transferred from hatchery facilities to growout facilities in seawater. The reduction of stress due to handling can greatly diminish mortality associated with entry of the fish to saltwater (15).

ANALYZING SMOLT READINESS AND QUALITY

Frequently, large and apparently healthy hatchery juveniles, though silvery in appearance, are not fully functional smolts (16). This is particularly true under intensive rearing conditions in which the synchrony of the various developmental events constituting smolting can break down. For that reason, it is necessary to have an objective method for assessing smolt quality and readiness for transfer to saltwater.

Seawater Challenge Test

The seawater challenge hypo-osmoregulatory test measures the ability of a fish to control plasma ion levels quickly after abrupt transfer to saltwater. The test was developed originally to measure the readiness of accelerated coho salmon smolts for transfer into seawater. The seawater challenge test exhibited a regular developmental pattern even at the increased temperatures used to accelerate the animal's growth (17). Its other advantages are that it is cheaper and simpler to conduct than are assays for gill Na^+, K^+-ATPase or plasma thyroid hormone.

To conduct the seawater challenge test, a sample of smolts is transferred to saltwater at the acclimation temperature. Salinity of the saltwater used for the test should be in the range of 28–32 ppt. If it is necessary to make artificial saltwater, a balanced salt mixture must be used because single ion solutions are toxic. After 24 hours, the smolts are anesthetized and a blood sample is collected. Plasma is separated from the blood cells by centrifugation and can be stored for up to 24 hours in a refrigerator or for longer periods in a freezer prior to analysis. Regulatory ability can be assessed by measuring either sodium, chloride, or osmolality of the plasma (18–20). Expected plasma sodium levels in smolts after 24 hours are in the range of 160–165 mmol/L. The corresponding level for osmolality is 330–340 mosmol/L, and for plasma chloride it is 140–150 mmol/L.

If mortality is observed during the test, the smolts have very poor hypo-osmoregulatory capacity, possibly due to gill damage or other health problems. Other factors that can influence the results obtained from the seawater challenge test include the temperature and density of the water during the test, descaling of the smolts, pollutants such as copper, and contamination of the blood samples with saltwater.

A single test is not sufficient to determine whether the fish's performance is increasing or decreasing. Therefore, it is advisable to perform the test regularly during the last two to three months before the planned date for transferring the fish to saltwater for growout.

Salinity Tolerance

The salinity tolerance test involves counting the number of dead fish 96 hours after they are transferred to hypersaline saltwater. Salinities of 35–40 ppt are necessary for the test because many large parr will tolerate 30 ppt indefinitely, despite the fact that they are unable to grow. Salinity must be measured precisely because mortality rises quickly with increasing salinity. The tolerance test is conducted in temperature-controlled containers so that the fish can be held at their acclimation temperature. The smolts are made to fast for 24 hours and are not fed during the test, to avoid fouling of the containers. Smolts that survive for 96 hours in high salinity are capable of direct transfer to typical salinities of 30–32 ppt for growout. More information can be obtained if a range of salinities is used simultaneously; this strategy allows probit analysis to compute the 96-hour median lethal salinity with confidence limits (21).

The main advantage of the tolerance test is its simplicity. However, its shortcomings relative to more complex tests are that a large number of fish are required for statistical comparisons and it causes more distress and mortality to the smolts.

Gill Na^+, K^+-ATPase

Biologists have shown that the level of Na^+, K^+-ATPase in gill tissue increases in smolts and have used it as an indicator of when smolting is complete, particularly in research. Na^+, K^+-ATPase is an enzyme that is concentrated in the chloride cells and is involved

in ion transport across the gills. Several methods are used for measuring gill Na$^+$, K$^+$-ATPase activity, including microassays, which can be used for nonlethal biopsies (22–24). Essentially, the assay involves the determination of enzyme activity (the breakdown of adenosine triphosphate) in a microsomal preparation from gill tissue. The amount of protein in the preparation is also measured, and the activity is expressed per unit wet weight of protein. The values obtained are dependent upon the conditions used for the assay. Therefore, it is important to maintain uniform conditions so that the results can be compared among assays.

Hormone Assays

As noted earlier, a number of hormonal changes occur at the time of the parr–smolt transformation. One of the best studied is that of the thyroid hormone thyroxine, which rises to a peak and then decreases (25). Folmar and Dickhoff (26) proposed using the proportion of the peak in plasma thyroxine levels that had been completed as an indicator of the time of transfer of smolts into saltwater.

OFF-SEASON TRANSFERS

Salmon respond to the length of the day in the same way that many plants and animals do: by measuring the length of the dark period. When they are exposed to light during a period of high sensitivity, a photoperiodic response is induced (27). The length of the period of light that must be exceeded in order to produce a photoperiodic response is termed the critical daylength and is usually between 10 and 14 hours (27). For juvenile coho salmon, the critical daylength is between 11.5 and 12 hours (28). The practical significance of this fact is that simple light-control systems can be used to provide the necessary stimuli, and changes in the photoperiod can be imposed abruptly. It is possible to produce short-day conditions by using lightproof covers that are placed on and removed from the rearing tanks according to a regular schedule each day.

Accidental exposure of juvenile salmon to artificial light during the night must be avoided in order to prevent disruption of the smolting process. This is particularly important during the short-day portion of the photoperiod cycle. Extensive research has shown that the parr–smolt transformation can be induced out of season by a sequence of a short-day photoperiod followed by a long-day photoperiod (29). However, there are species-related differences in the size at which the photoperiod treatment can be initiated. On the one hand, coho and stream-type chinook salmon fry can be given eight weeks of short-day exposure from the time of first feeding, followed by a long-day photoperiod, provided that water temperatures are sufficient to permit rapid growth to smolt size. The minimum growing temperature when one starts with the fry stage is 8 °C (46 °F), but larger and more uniform smolts are obtained at temperatures of 11–14 °C (52–57 °F) (30). On the other hand, Atlantic salmon must reach approximately 10 cm (4 in.) in length before they become competent to respond to the short-day treatment (31). It is customary to expose Atlantic salmon to a long-day photoperiod from the first feeding and then impose a short-day photoperiod about four months prior to the desired date for transferring the fish to saltwater. The smolts are ready for transfer to saltwater about 400 degree-days (°C) (720 degree-days, °F) after initiation of the long-day treatment, or approximately six to eight weeks, depending on the temperature (32).

INTRODUCTION

The snapper family contains a large number of species that are found throughout the world in tropical and subtropical areas (1). They are primarily bottom-oriented predators, occurring from shallow inshore areas to deep offshore waters. The snapper family represents an important fisheries resource in almost all areas in which they are found (2). As with many of our world fish stocks, most snapper fisheries are being harvested at or beyond their maximum sustainable yield. Because of their wide acceptance as an excellent food fish, high market price, and limited harvests from wild stocks, there is considerable interest in culturing a variety of snapper species. Despite the economic importance of this family, information pertaining to culture techniques is quite limited.

Although literature is scarce, techniques for spawning, larval rearing, and growout are available for several species of snapper such as mangrove red snapper (*Lutjanus argentimaculatus*) (3), John's snapper (*L. johni*) (4), mutton snapper (*L. analis*) (5), and yellowtail snapper (*Ocyurus chrysurus*) (6). Several other species, such as grey or mangrove snapper (*L. griseus*) and red snapper (*L. campechanus*), have been cultured in the laboratory through the larval stages (7,8). When considering raising species of this family, one must recognize that although eggs and larvae may be obtained using a variety of methods, in general the larvae are relatively small (1.5–2.7 mm total length) and difficult to raise. Considerable effort has been invested in the development of larval rearing techniques for snappers. Success has been limited and techniques are considerably behind those developed for other marine species. Because of their high market value and wide acceptance as an excellent food fish, small scale commercial growout of wild juveniles has developed in a variety of countries; however, if snapper are to become established species for aquaculture, techniques for controlled spawning and larval production must be developed to supply juveniles to the commercial industry.

BROODSTOCK MANAGEMENT

Fish, like many other animals, exhibit rhythmic physiological and behavioral patterns generally known as biorhythms. Fish reproduction (maturation, mating, and spawning) is often rhythmic and strongly correlated with the interrelated seasonal cycles of light, water temperature, and food supply. This naturally leads to a period of the year which can be defined as the spawning season. Based on natural history data for over 40 species, Grimes (9) reported that reproduction falls into two general patterns: (*1*) continental-shelf populations, which demonstrate restricted seasonal spawning, centered around summer, and (*2*) populations and species associated with small oceanic islands, which mostly reproduce year-round, with pulses in the spring and fall. Spawning frequently occurs at night, with distinctive courtship behavior culminating in an upward spiral accompanied by the release of gametes into the water column.

Under hatchery conditions, many species of snapper will spawn when suitable seasonal changes occur and food is not limiting. If natural spawning is to be encouraged, the fish must be maintained in a culture system that will ensure adequate water quality parameters and give sufficient room for mating behavior. Broodstock can either be obtained from the wild as adults or cultured from juveniles. If broodstock are to be collected from the wild, it is preferable to capture them by hook and line. This method offers the least amount of stress and a high rate of success. Abdominal distension, owing to overinflation of

the air bladder, is a common problem when obtaining fish from deep water. If this occurs, the air can be removed by puncturing the abdomen with a sterile hypodermic needle. Anesthetics, such as quinaldine sulfate or tricaine methanesulfonate, should be used when handling and transporting the fish.

Most snappers acclimatize quickly to captivity and begin to feed within a short period of time. Initially, fresh food items such as squid, shrimp, and fish should be offered on a regular basis, and the fish treated for any disease or parasite infections. Once the fish have been acclimated to captive conditions, they should be transferred to the hatchery or growout facilities. Juveniles may be grown under typical growout conditions by using commercially prepared feeds; however, once the fish approach sexual maturity they should be switched to a high-quality maturation diet.

The nutritional status of broodstock is one of the primary determinants of egg quality and consequently should be considered as a critical component of the production cycle. Although the overall nutritional quality of the diet is important, a variety of trace nutrients [e.g., polyunsaturated fatty acids (PUFA), particularly of the n-3 series, vitamins C and E, as well as carotenoids] are considered very important (10). The requirement for trace nutrients is generally satisfied by providing a mix of high-quality food items such as fresh squid, cuttlefish, shrimp, krill, and fish. If desired, both marine lipid and vitamin supplements may be included in the diet. Although semimoist and dry compounded diets are sometimes used as maturation diets, they are generally accompanied by a fresh component. Snapper have been spawned using both indoor [*L. campechanus* (11), *O. chrysurus* (12), *L. stellatus* (13)] and outdoor culture systems [*L. argentimaculatus* (14)]. In the laboratory, temperature and photoperiod can be adjusted to mimic seasonal changes (11). A typical indoor maturation and spawning system will consist of culture chamber, biological filter, particulate removal system, supplemental aeration, circulation pump, and temperature and photoperiod control. The annual cycle utilized to induce maturation and spawning can vary in length from a full year to a four-month condensed cycle. An example of a subtropical artificial cycle is presented in Table 1. As the fish pass though the artificial seasons, changing temperature and day lengths will result in the natural development of maturation and spawning. *Lutjanus campechanus*, and

O. chrysurus are examples of summer spawners which, under summer conditions, will spawn, releasing thousands of small floating eggs. Once spawning has initiated, it will continue as long as the fish are held under these conditions and nutritional reserves are adequate for ovulation. With the advent of controlled spawning techniques, a fish can be spawned any time of the year and held in spawning condition for an extended period of time. Additionally, the same fish can be utilized as broodstock year after year. It should be noted that under artificial conditions the spawning season can be extended for extremely long periods of time. For some species, extended spawning seasons and/or inadequate overwintering to allow gonadal reabsorption will often result in a decrease in egg and larval quality. Signs of overspawning vary between species, but often include reduced spawning frequency and egg production, changes in egg and oil globule diameter, and increases in larval sensitivity to stresses and/or difficulties in larval rearing.

If maturation and spawning does not occur using environmental manipulations or laboratory facilities for the manipulation of temperature and photoperiod are not available, spawning can be induced by using hormone treatments. Hormone treatments have been shown to be reliable methods of inducing spawning of various species of snapper, including *L. johni* (4), *L. argentimaculatus* (14), *L. campechanus* (15), *L. synagris* (8), *O. chrysurus* (8), and *L. analis* (5). The primary substances used for hormone-induced spawning are (1) pituitary extracts and purified gonadotropins (e.g., human chorionic gonadotropin, HCG), which are used to stimulate the ovaries and testes, or (2) luteinizing hormone-releasing hormone analogs (LHRHa) to stimulate the pituitary. Hormone treatments may be administered to fish with well-developed oocytes either by direct injection, utilization of an implant designed to slowly release the hormone, or oral administration (16). Monitoring of ovarian development is a critical component of hormone therapy, and only females with eggs at the yolk globule stage should be induced to spawn. Ovarian development can be determined from eggs sampled by catheterization, i.e., removal of intraovarian eggs by using a polyethylene cannule [e.g., 2.5 mm (0.1 in.) tubing attached to a suction device such as a syringe]. Single or multiple injections of HCG (500–1500 IU/kg body weight) as well as single injections of LHRHa (100 µg/kg body weight) have been successfully utilized to induce spawning in mature snapper. Induced spawning generally occurs within 24–38 hr after hormonal stimuli to prematured eggs. Both *L. johni* and *L. argentimaculatus* females (4–6 kg) are reported to release 1 to 2 million eggs per female, and they may spawn for four consecutive nights.

In general, spawning occurs at night and is highly synchronized. The fertilized planktonic eggs can be collected either automatically during the night or by hand in the morning. Most egg collection systems rely on a simple screening system, which includes (1) inflow of water containing eggs, (2) 500–750 µm screen or collection bag designed to retain the eggs, and (3) return of culture water to the tank or into an effluent drain. Once the eggs are collected, they should be counted by volumetric methods (e.g., 1,000 eggs/mL for *O. chrysurus*), treated to

Table 1. Manipulation of the Temperature (°C) and Photoperiod (hr) for Summer Spawning Broodstock Captured in the Summer and Acclimated to the Laboratory for 2–4 Months

Time (months)	Light : Dark	Temperature
Acclimation 2–4 months	15 : 9	27
2	12 : 12	22
2	9 : 15	18

1–4[a]	15 : 9	27

[a]Spawning should begin.

reduce the transfer of pathogens (e.g., 1 hr bath in 10 ppm formalin), and then transferred to hatching or rearing tanks. Care should be taken to make sure that the rearing tanks are at the same temperature and salinity as the spawning tanks. Although time to hatch is temperature dependent, tropical and subtropical species will generally hatch within 24 hr of fertilization.

LARVICULTURE

Snappers are members of the group of fishes known as pelagic spawners. The reproductive strategy employed by these fishes involves the production of large numbers of very small, buoyant eggs which, after being released into the water and fertilized, drift freely in surface currents with no further parental attention. Newly hatched larvae typically carry an elliptical yolk sac containing an oil globule. Energy stores in the yolks of these eggs tend to be minimal, resulting in small larvae that have both a small mouth gape at first feeding and little ability to survive on food of suboptimal nutritional value. Providing prey items of appropriate size and nutritional characteristics is a major concern in the culture of these larvae. Snappers produce particularly small eggs and larvae (1.5–2.7 mm total length), and defining efficient techniques for their rearing has been the primary constraint on the expansion of the commercial culture of snapper species.

Techniques that have been utilized for the rearing of larval snapper range from high-density, also called intensive, systems utilizing monocultures of phytoplankton and zooplankton to low-density, or extensive, systems that rely on wild plankton. One of the first reports of successful laboratory rearing of lutjanid larvae through metamorphosis to a juvenile was conducted by Richards and Saksena (7), who reared *L. griseus* larvae on a diet of size-sorted, wild zooplankton. Although only a few larvae reached metamorphosis, this marked the initiation of successful laboratory-scale larval rearing trials. Since this initial work, a variety of species have been raised in the laboratory and in pilot-scale operations.

Lutjanus analis, *L. synagris*, *O. chrysurus*, and a hybrid (female *L. synagris* × male *O. chrysurus*) larvae were cultured by Clarke et al. (8). They used cultured rotifers, algae, and size-sorted wild zooplankton for the first 13 days, followed by the feeding of *Artemia* nauplii through the end of the culture period. A similar technique was used by Riley et al. (12) in rearing *O. chrysurus*. Those initial successes have led to pilot-scale evaluations with *L. analis* and *O. chrysurus*.

Work by Watanabe et al. (5) described initial success of mass production of *L. analis* juveniles in a 30,000 L (7,926 gal) outdoor larval rearing tank. The culture tank was prepared by filling with unfiltered seawater, fertilizing with inorganic fertilizer and inoculating the culture water with *Nannochloropsis oculata* followed by ss-type rotifers, *Brachionus plicatilis*. Eggs were then stocked into the system at a density of 10.5 eggs/L (39.7 eggs/gal). Both rotifers and algae were supplemented to the culture tanks from batch cultures. Newly hatched *Artemia* nauplii, as well as lipid-enriched nauplii, were fed at 1/L (3.8/gal) from day 7 to 35 posthatch with artificial feeds introduced at day 24 posthatch. On day 38 posthatch, the fish averaged 0.3 g and had a survival from day two posthatch of 14.3%.

Similarly, ongoing research with *O. chrysurus* at the University of Texas at Austin, Marine Science Institute, Fisheries and Mariculture Laboratory, has resulted in closure of the life cycle for that species. Utilizing a modified version of the intensive larval rearing techniques developed for *Sciaenops ocellatus*, several thousand juvenile *O. chrysurus* have been reared from F1 generation broodstock. The procedure currently being evaluated includes the stocking of 9.4 eggs/L (35.4 eggs/gal) in 1,600 L (422 gal) culture tanks containing presterilized seawater. After hatching, the tanks are inoculated with algae (*N. oculata* or *Chlorella minutissima*) and rotifers from batch culture tanks. During the first four days of feeding, the rotifers are maintained at 10 to 20/mL after which, the rotifers are flushed from the tank each night and replaced with enriched rotifers on a daily basis. The feeding of microparticulate larval feeds is initiated at day 7 posthatch, and enriched *Artemia* nauplii are introduced at day 14 and maintained through day 30 posthatch. Initial trials have resulted in a survival rate of approximately 4% from egg to juvenile.

The commercial importance of the red snapper (*L. campechanus*) in the coastal fisheries of the southeastern United States has led to substantial interest in developing techniques for the culture of this species. Arnold et al. (11) first described the successful induction of spawning of captive broodstock using temperature and photoperiod manipulation. However, rearing of larvae to the juvenile stage was not successful (17). Repeated attempts at rearing red snapper larvae by this and other groups, [e.g., Minton et al. (18)], using the same controlled rearing techniques, were also unsuccessful and resulted in 100% mortality by day 21 at the latest. In this rearing approach, larvae are typically hatched and maintained in relatively sterile recirculating systems, and food organisms are collected and transferred from other environments (e.g., coastal waters, aquacultural growout ponds, and algae-based rotifer cultures).

A less-controlled mesocosm approach in which fertilized eggs were allowed to hatch in selectively managed wild zooplankton cultures in outdoor tanks resulted in modest survival of red snapper larvae (19). Pond-filtered zooplankton, collected during the day and consisting predominantly of rotifers, was supplemented to the culture water from day 4 through day 15 posthatch. Additions of night-collected copepods began at day 4 and continued through day 17 posthatch. The feeding of fatty acid-enriched second-instar *Artemia* nauplii began at day 16 posthatch, and juvenile snapper were offered chopped, dried krill starting at day 27. These cultures contained a variety of potential prey organisms, particularly copepod nauplii and various protozoan species. Both copepods and protozoans are significant components of marine zooplankton (20) and may be critical for proper nutrition of the larvae. Survival of larvae occurred in 4 of 11 culture tanks and averaged 3%.

The rearing attempts with red snapper (19) were based on outdoor techniques utilized in Asia for the culture

of the mangrove red snapper, *L. argentimaculatus* (14), and the John's snapper, *L. johni* (4). As noted by Duray et al. (21), rearing trials with *L. argentimaculatus* have been carried out for a number of years, using a variety of techniques, with limited success. Extensive larval rearing techniques were initially found to produce the best results. In this production system, eggs were hatched and larvae reared in 190 m³ (50,198 gal) outdoor tanks in which populations of various prey organisms had been established. Copepods, collected from earthen ponds, were cultured in separate tanks and transferred to the larval rearing tank from day 3 to day 8 posthatch. Rotifers cultured with baker's yeast and algae were offered from day 6 to 12 posthatch, and *Artemia* nauplii from 10 days to the end of the rearing period at 20 days. Copepod nauplii were the only organisms observed in the guts of larvae through day 11 posthatch. Rotifers were first observed at day 12. Up to 18,000 larvae, or nearly 100 larvae/m³ (380 larvae/1000 gal), at three weeks posthatch were produced.

The initial success of extensive larval rearing techniques for *L. argentimaculatus* has led to the development of a semi-intensive larval rearing technique using small rotifers (21). In this production protocol, newly hatched larvae were reared indoors in 3 m³ (792 gal) tanks at an initial stocking density of 30 larvae/L (113 larvae/gal) and water temperature of 25.5 to 28.7 °C (77.9 to 83.7 °F). *Chlorella* was added daily at $1-3 \times 10^5$ cells per mL as a food source for rotifers and as a water conditioner. The best results were obtained when harvested rotifers were screened to <90 μm during the first 14 days of feeding. Rotifers were maintained at 20/mL through day 20 and 10/mL from day 20 to day 30. Newly hatched *Artemia* nauplii were offered from day 21 to 25 and enriched instar II *Artemia* offered from day 26 to 50 at 1–3 *Artemia*/mL. Average survival at day 24 was 27%. During the second phase of rearing (day 25–55), increasing sizes of *Artemia* were fed, and starting at day 40 minced fish was provided. The mean survival during this phase of production was reported to be 10.6%.

Although results with several snapper species are promising, protocols for the reliable production of juveniles have not been established, and techniques are far behind those established for other species. There appears to be a consistent trend that snapper larvae perform best in large culture systems. This trend may be due to both muting of environmental changes (e.g., daily temperature shifts) as well as more stable food webs. Also, the larvae are very small and have limited endogenous nutritional reserves, so the first feeding and the nutritional quality of the feed is critical. Several authors have noted that snapper larvae are often sensitive to environmental changes and handling. This is most likely due to poor-quality spawns and/or inadequacies of the larval foods. With respect to larval feeds, there are several nutrient deficiencies that could explain the observed problems. Essential fatty acids (EFA) have been demonstrated to be critical for larval development, and deficiency symptoms include reductions in the resistance to stress (22). Although the EFA requirement for snapper larvae is unknown, a deficiency in EFAs and/or other nutrients would explain some of the problems encountered with larval survival. Consequently, it is recommended that the polyunsaturated fatty acid content of live food organisms should be optimized (23), and cofeeding of high-quality artificial feeds in conjunction with live prey items should be incorporated into production techniques whenever possible. As our understanding of snapper larvae nutrition expands and species-specific culture techniques are developed and/or adapted from other species, reliable techniques for larval rearing should be available in the near future.

GROWOUT

Many species of snapper may not exhibit growth rates and market prices that will justify commercial production, but several species are commercially cultured, and a number of species have characteristics that make them good candidates for culture. Unlike the larvae, which are generally difficult to raise, juveniles are quite hardy and adapt very quickly to culture conditions. Even juveniles captured from the wild will readily adapt to culture conditions and prepared feeds. Quite often they will initiate feeding on the same day that they are captured and transported into captivity.

Current literature indicates that only two species of snapper, *L. argentimaculatus* and *L. johni*, are considered economically important culture species (4,14). However, because of wide acceptance and marketability of snapper, a number of species are being evaluated for their culture potential. Despite the economic importance of snapper, data on the growth rates in the wild or under culture conditions are quite limited. Manooch (24) summarized the growth rates of a number of snapper species in the wild. Natural history data show that many species of snapper exhibit relatively slow growth rates, requiring several years to reach a marketable size. Four species that are currently being evaluated for their culture potential in the United States are *O. chrysurus*, *L. campechanus*, *L. griseus*, and *L. analis*. Based on predictive growth equations reported for *O. chrysurus* (25,26) and *L. griseus* (27) those species will only reach about 200 g after two years in the wild. By utilizing semiclosed recirculating systems, *O. chrysurus* has been raised to 489 g in 767 days posthatch (6). These growth rates are similar to the results obtained by Thouard et al. (28) using wild juveniles cultured in cages in Tahiti. Similarly, wild juvenile *L. griseus* (3 g initial weight) raised under controlled conditions reached about 500 g after two years of culture (6). Based on growth estimates of *L. analis* (29), this species will reach about 116 g after one year or 362 g after two years in the wild. Watanabe et al. (5) reported final weights of *L. analis* from a pilot-scale growout. In this growth trial, a mean body weight of 140 g was achieved at 265 days posthatch. These preliminary trials show that it is clear that growth rates can be achieved above those in the wild. Although it can be assumed that growth rates observed in these preliminary trials will improve as species-specific culture techniques and feeds are developed, a two- to three-year production period will most likely be required for these species.

The most extensive data on culture conditions for snapper are from Thailand and Singapore, where largely wild juvenile *L. argentimaculatus* and *L. johni* are used to supply small-scale net cage production. These species are primarily raised as an alternative to sea bass, *Lates calcarifer*, and groupers (e.g., *Epinephelus tauvina*, *E. salmoides*, *E. malabaricus*, and *E. bleekeri*) (4,30). In this production situation, wild juveniles are cultured in relatively small (e.g., 3 m × 2 m) cages and fed low-valued fish. Good growth rates and survival have been reported when juveniles are stocked at 60–90 fish/m^3. When acceptable culture conditions are maintained, growth rates, feed efficiency (wet weight gain/wet weight of feed × 100), and survival are very good, with both species reaching market size within 10 months. This type of culture is exemplified by the report of Chaitanawisuti and Piyatiratitivorakul (30). In those studies, juvenile *L. argentimaculatus* having a mean initial weight of 20 g were stocked at an initial density of 90 fish/m^2 in 3 m diameter floating cages and offered chopped carangids, *Selaroides* spp., to satiation twice daily. Mean environment conditions for water temperature, salinity, and dissolved oxygen were reported to be 28.9 °C, 31 ppt, 7.8 mg/L (ppm). At the conclusion of the 10-month growth trial, an average final weight of 806 g was achieved, with a feed efficiency of 15.6% and survival of 83%. Based on the results of this study, it was concluded that the results presented were in agreement with those reported by other authors and that the growth rates for *L. argentimaculatus* are similar to those obtained with sea bass and several groupers.

One of the primary restrictions for commercial culture of snapper is a reliance on wild stock, which is limited in supply and availability (4). Another problem, albeit one far less severe, is limited information on the nutritional requirements and the acceptance of prepared feeds by snapper species. However, it would appear that snappers readily accept commercially prepared feeds and that high-quality rations designed for other warmwater marine species, such as *S. ocellatus* or *L. calcarifer*, should be adequate.

SUMMARY

A number of snapper species have been spawned either by using hormone induction or by environmental manipulations. The literature indicates considerable variation in fertilization and hatch rates. This variable egg quality may be due to the use of hormone therapy and the presence of underdeveloped oocytes, inadequate broodstock nutrition, or natural variation in spawn quality. Despite some problems with egg quality, a number of species have been spawned in captivity and a good supply of eggs and newly hatched larvae can be routinely obtained. Currently, the development of mass-rearing techniques for lutjanid larvae fall far behind those which have been established for other marine species, such as *L. calcarifer* or *S. ocellatus*. Reports of larval rearing experiments indicate that larvae often have numerous prey items and prepared feeds in their digestive systems. Yet there is a general trend of high variability of larval survival and stage-specific larval mortalities. This may indicate a nutrient deficiency (e.g., essential fatty acids or vitamins). If a reliable supply of juveniles is to be developed, it is crucial that larval research be given high priority, particularly with respect to ontological development, nutritional requirements, feeding protocols, and larval rearing techniques. Once larval rearing techniques are developed and a steady supply of juveniles is available, commercial culture of a number of snappers will develop rapidly. Juveniles are quite hardy, readily accept commercial feeds, and adapt to intensive culture conditions. Given the high market price and consumer acceptability, commercial culture of snapper should be a viable business in a number of countries.

SOLE CULTURE

B.R. HOWELL
Centre for Environment, Fisheries and Aquaculture Research
Weymouth, United Kingdom

OUTLINE

Sole are not yet cultured commercially on a significant scale, but in Europe, two species (*Solea solea* and *S. senegalensis*) have long been considered to be prime candidates for farming, because of their widespread popularity and consistent high value. In the United Kingdom, for example, the Dover, or common, sole (*S. solea*) is among the most valuable fish landed, attracting a price comparable to that of halibut (*Hippoglossus hippoglossus*) and turbot (*Scophthalmus maximus*), both of which are now being farmed commercially.

Research on sole culture has a long history, dating back to the turn of the century, when the French biologists Fabre–Domerque and Biétrix (1) claimed limited success in feeding early sole larvae. Interest at that time was focused more on supplementing natural recruitment by releasing eggs and yolk sac stages into the sea than on developing rearing procedures for later stages, and hence little further progress was made. Significant progress towards the development of techniques for rearing the larvae to and beyond metamorphosis was not made until about 60 years later, when Shelbourne began his pioneering work in the United Kingdom on rearing marine flatfish larvae (2). Shelbourne's immense contribution to fish culture exploited the earlier observation by the Norwegian biologist Rollefsen (3) that plaice (*Pleuronectes platessa*) larvae could readily be fed on the naupliar stages of brine shrimp (*Artemia salina*). This live food organism remains the basis of hatchery production of commercial fish and shrimp farming.

Despite the demonstration that, by using brine shrimp as live food, sole juveniles could be produced readily in hatcheries, a concerted effort to develop farming techniques, primarily in the United Kingdom and France during the 1970s and 1980s, failed to achieve commercial viability, because of difficulties in feeding the subsequent juvenile stages. Problems initially centered on the attractiveness of formulated feeds, but even when this difficulty was alleviated, through the identification of chemical feeding stimulants (4), growth and survival remained unacceptably low. Recent advances in feed technology, combined with the desire of the now well-established marine fish farming industry in Europe to diversify its activities, have rekindled interest in the farming of sole.

THE SOLEIDAE

Soleidae is a family of flatfish that are typically found in relatively warm water, with most European species reaching the northern limit of their distribution around the British Isles (5). The family comprises a large number of species that generally inhabit sandy or muddy grounds in the relatively shallow waters of the continental shelf. However, the common sole, *S. solea*, and, to a somewhat lesser extent, the Senegal sole, *S. senegalensis*, are the two European species that have attracted the greatest attention in a farming context. *S. solea* has a more northern distribution and extends further into the Mediterranean Sea than the latter, but although differences between the two species are evident, particularly in relation to their response to temperature (reflecting their slightly contrasting geographic distribution), the two species have been found to present similar problems in culture. *S. solea*, however, has been the subject of more extensive study than its more southerly counterpart, and thus the information presented

in this contribution has largely been derived from work on that species.

General Biology

Sole are batch spawners, with each female ovulating and releasing batches of eggs every few days over a period of several weeks. The testes of the males are small, a feature that is indicative of the need for intimate courtship behavior to ensure that the gametes are simultaneously released in close proximity (6). Spawning is initiated when the water temperature reaches about 10 °C (50 °F) and thus occurs earlier in the year in the southern part of the fish's distribution than in its northern range (7).

The eggs, which range in diameter from 1.0 to 1.6 mm (0.04 to 0.06 in.), are buoyant and hatch after 5 days at a temperature of 12 °C (54 °F). The emergent larvae are without a functional mouth or pigmented eyes, features that develop about 3 days later, when the larvae begin to feed. The larvae metamorphose and settle to the bottom after 25–30 days at 14–16 °C (57–61 °F), when they are just over 1 cm (0.4 in.) long. Whereas the larvae are visual feeders, the demersal stages are nocturnal, becoming active at dusk and burying themselves in the substrate during the day (8).

The juveniles feed on benthic organisms, primarily polychaetes, molluscs, and small crustacea. Sole have a poorly developed stomach, in contrast to that of more predatory flatfish, such as turbot and halibut (9). An important consequence of this is that they need to feed relatively frequently, being unable to meet their dietary energy requirements with relatively large, infrequent meals.

CURRENT STATUS OF CULTURE METHODS

Broodstock Management

A reliable supply of eggs of consistently high quality is readily obtainable from sole, a species that spawns spontaneously in captivity, without the assistance of administered hormones. Spawning has been obtained under a wide range of environmental conditions (10), with fish held in tanks of 0.15–1 m (0.5–3.3 ft) depth and 0.15–25 m^3 (5.3–882.2 ft^3) volume, at densities of 1–6 fish/m^2 (0.1–0.6 fish/ft^2), and at sex ratios ranging from 0.5 to 3 males for each female. Illumination has been provided by natural light and artificial light with intensities of 25–1,500 lux. A variety of temperature regimes have been used, but there is evidence that a cyclic temperature appears to be essential for successful egg production, with relatively high winter temperatures appearing to reduce both the quantity and quality of the output. Out-of-phase spawning has been obtained by the synchronous manipulation of photoperiod and temperature, or even by manipulating temperature alone. The diet for spawning has consisted of a variety of polychaetes, molluscs, and, occasionally, crustacea, fed between three and six times a week. A diet consisting only of frozen molluscs does not appear to support good egg production. Mixed diets containing a live component invariably meet with greater success.

Reported values for egg production have ranged from 11 to 140 eggs/g (312 to 3,976 eggs/oz) of live weight of females (10). Since it is clear that many of the females within a stock — perhaps as many as 70–80%, — may not contribute to egg production in any one year, the relative fecundity of individual females may be much higher. Fertilization rates are also highly variable, with an average of around 60%. Assuming that an average relative fecundity of 100 eggs/g (2,840 eggs/oz) is achieved, a 10-m^3 (353-ft^3) tank stocked with 15 kg (33 lb) of females and about half that weight of males should, on average, yield about one million eggs during a single spawning season.

Egg Incubation and Larvae Rearing

Eggs are generally stocked at a density of about 300 eggs/l (1,350 eggs/gal) and hatch after five days at 12 °C (54 °F). Survival rates of fertilized eggs are usually in excess of 80%, probably reflecting, to a large extent, the high quality of eggs obtained from natural spawning. After two to three days of hatching, the yolk sac larvae are transferred to rearing tanks, about one day before the eyes have pigmented, the jaw has become functional, and the larvae are ready to begin feeding.

Sole is among the easiest of all marine fish to rear through the larval stages. Although some success has been obtained with formulated feeds (11), live food remains an essential requirement. The larvae can be reared on the rotifer *Brachionus plicatilis* (12). However, that organism is rarely used, because *Artemia* nauplii are more convenient and are acceptable from the outset of feeding as well. In laboratory-scale tanks stocked at an initial density of about 100 larvae/L, survival rates to metamorphosis have generally been in excess of 70% (12–14). Such survival rates have been achieved without prefeeding the nauplii on "booster" diets to enhance their content of highly unsaturated fatty acids (HUFAs), though recent unpublished work indicates that the hardiness of juveniles is improved if HUFA-rich diets, are provided. Although marine fish larvae are considered to have an essential dietary requirement for HUFAs (15), particularly eicosopentaenoic acid (EPA) and docosahexaenoic acid (DHA), the requirement of sole seems to be limited to the former (16). This almost certainly contributes appreciably to the relatively high survival rates obtained with cultured sole, since *Artemia* nauplii, depending on their origin, contain significant quantities of EPA, but negligible quantities of DHA.

As with other flatfish, reared sole may display various forms of pigment abnormalities. The cause of this phenomenon remains poorly understood, but the incidence of such fish among reared sole is generally less than 20%. Other defects, such as skeletal abnormalities, are rare as well.

Weaning

The transfer of metamorphosed sole to a formulated feed was the major obstacle confronting biologists in the 1970s. A marked reluctance to accept fish-based diets appeared to be related to the importance of olfaction

in the feeding behavior of this nocturnal, invertebrate-feeding species. The problem was partially overcome by inclusion in diets of either invertebrate tissue (17,18) or chemical attractants (4,19), but despite those measures, growth rates were generally low and survival rates highly variable. Studies focused on the attractiveness of diets, but an experiment in which survival was positively related to the level of hydrolyzed fish protein concentrate (20) suggested that the ability of the fish to use the diets may also be an important consideration. More recent trials were conducted with a larval feed produced by a process of agglomeration (SSF, Fyllingsdalen, Norway). That feed was based on high-quality protein with a relatively high soluble fraction and was supplemented with chemical taste attractants (21). Sole 2−3 cm (0.8−1.2 in.) in length accepted the feed, and mortality rates were negligible, while growth rates similar to those reported for live feeds were sustained. These advances now allow fully weaned sole to be produced on a routine basis with a high survival rate.

Growout

Growout is the most important phase with regard to economic viability and the least well-developed phase for sole. In intensive culture systems, profitability depends on the rate of production, which is a function of both the mean growth rate of the fish and the stocking density.

There is little documented information on the potential growth rate of sole to market size under optimum conditions and on the extent to which growout to market size may be achieved on commercially acceptable formulated feeds. Experimental evaluations of the dependence of growth rate on temperature in which the fish were fed live food were used by Howell (21) to provide an indication of potential for growth. Results of the study indicated that fish 5 cm (2 in.) in length would reach a minimum market size of 125 g (4.4 oz) in less than 300 days at temperatures close to the optimum of 20 °C (68 °F). Day et al. (20) grew fish to that size on a formulated feed in just under 600 days, but in that trial, temperatures were subject to seasonal variation and were consistently well below the optimum. Although this result is encouraging, there clearly is scope for considerable improvement.

With regard to the effects of stocking density, there is some indication that sole may be less suited to crowded conditions than other species. Their browsing mode of feeding may result in high levels of interaction between individuals, leading to reduced growth rates and high variation in size. Howell (21) reported that, over a 12-week period, the growth rate of 1.5-g (0.05-oz) fish stocked at 500 fish/m^2 (46 fish/ft^2) was about 15% less than that of those stocked at 17 fish/m^2 (1.6 fish/ft^2). The difference was attributable to social factors, as the experimental design eliminated the potentially suppressive effects of water quality variables. Ways in which these effects may be reduced need to be developed, which may involve regular grading to reduce size variation, and the adoption of feeding strategies that minimize or eliminate opportunities for individuals to dominate the food supply.

PROSPECTS FOR COMMERCIAL EXPLOITATION

For most marine fish, rearing through the early developmental stages presents the greatest obstacle to the realization of industrial-scale farming operations. In this regard, however, sole have a particular advantage, in that a regular supply of good-quality eggs can readily be obtained from captive broodstocks, and survival rates through the egg and larval stages are consistently high. The weaning of small juveniles to a formulated feed can also be readily accomplished with minimal losses. The current uncertainty is whether sufficiently high growth rates can be achieved on formulated feeds at commercially realistic stocking densities. In this regard, the inherent feeding behavior of sole puts them at a distinct disadvantage as compared with some other species. In contrast to turbot, for example, sole need to take their food from the bottom, rather than from the water column, and this spacial requirement may impose an unacceptably low limit on the stocking densities that can be achieved. It remains to be seen whether these difficulties can be overcome by imaginative system design and the adoption of appropriate husbandry practices.

An alternative opportunity may be to exploit the relative ease with which the early stages of sole can be reared to develop a more extensive form of cultivation. The relatively high growth rates achieved on live food suggest that the species may have potential for extensive or semiextensive cultivation in regions that have a suitable topography and climate.

Approaches for Reducing Effects of Stress

Bibliography

During the past decade aquaculturists have become increasingly interested in stress in fish and many now recognize that managing for stress is part of normal operations along with nutrition, disease, and genetics management. While a fish's response to stress is considered adaptive, stress is a concern in aquaculture because of its possible detrimental effects on important fish performance features such as metabolism and growth, disease resistance, and reproductive capacity. Despite this general acceptance of the importance of considering stress in aquaculture and fisheries management, the phenomenon of stress is still not completely understood.

Stress has been defined as the response of an organism to any demand placed on it such that it causes an extension of a physiological state beyond its normal resting state to the point that the chances of survival may be reduced (1,2). This is a useful working definition for aquaculture, as it incorporates both the notion of a physiological change occurring within the organism in response to a stimulus and the idea that, as a result, some aspect of fish performance may be compromised.

This is only one view and a precise definition of stress still eludes scientists despite the many years of research dedicated to this subject. The concept of stress from a physiological or medical perspective, which implies a threat to the maintenance of an organism's homeostasis (3,4) is somewhat different from the view of environmental stress that somehow impairs fitness in a Darwinian or evolutionary sense (5). Nevertheless, a common theme exists among widely ranging perceptions about stress; that is, there is a biological response to a stimulus at some level of organization.

Hans Selye, whose contribution to this branch of science was recognized recently by a major proceedings publication (6), developed the nucleus of the present underlying concept of stress more than a half-century ago. Stress in fish has been studied for about three decades and readers are encouraged to refer to a number of collected reviews in books (7–9), review papers in other publications (10–15), and other reviews cited herein for a more thorough background on this subject. The purpose of this entry is to describe what the scientific community currently knows about stress in fish and why an understanding of stress is important in aquaculture. Confusion still exists among scientists with respect to appropriate terminology used to describe stress. For purposes of this entry, the term "stressor" (or "stress factor") means the stimulus that inflicts stress on the fish. "Stress" (or "stressed state" or "stressful experience") refers to the altered state of the fish, whereas "stress response" is those physiological or behavioral manifestations that can be measured to indicate the degree of stress experienced.

CONCEPTS AND BACKGROUND

A misconception among biologists and practicing aquaculturists is that stress, in itself, is detrimental to the fish. The acute response to stress is an adaptive mechanism that provides the fish with a means to cope with the stressor in order to maintain its normal or homeostatic state. If the stressor is overly severe or long lasting, the continued response can become detrimental to the fish's health and well-being, or become maladaptive, a state often associated by many with the term "distress." This view is consistent with the original general adaptation syndrome (GAS) paradigm of Selye (16), which considered that an organism passes through three stages in response to stress: (a) an alarm phase consisting of the organism's perception of the stimulus and recognition of it as a threat to homeostasis, (b) a stage of resistance during which the organism mobilizes its resources to adjust to the disturbance and maintain homeostasis, and (c) a stage of exhaustion that follows if the organism is incapable of coping with the disturbance. The final stage is the maladaptive phase normally associated with the development of a pathological condition or mortality in fish culture.

Stressors in aquaculture are typically physical disturbances such as those caused by handling, grading, or transporting that invoke acute stress or those that are chronically stressful—for example, poor water quality and overcrowding. Responses to these types of stressors have

been grouped as (a) primary, which include the initial neuroendocrine responses, particularly both stimulation of the hypothalamic-pituitary-interrenal (HPI) axis, culminating in the release of corticosteroid hormones, and the direct release of catecholamines; (b) secondary, which include changes in blood glucose and lactate, electrolytes and osmolality, and hematological features that relate to physiological functions such as metabolism and hydromineral balance; and (c) tertiary, which refer to aspects of whole-animal performance such as changes in growth, overall resistance to disease, metabolic scope for activity, behavior, and ultimately survival (11) (Fig. 1). This grouping is convenient, but simplistic. However, stress affects fish at all levels of organization, from molecular and biochemical to population and community (8). Moreover, responses to stress at different levels of organization are not only interrelated functionally to each other, but often interregulated as well. Thus, to appreciate how fish can be affected by stress in aquacultural operations, it is useful to consider their responses in an integrated or holistic sense, rather than simply observe isolated physiological phenomena. The stressor may be a real threat to homeostasis (e.g., altered water quality, acute physical disturbance) or one simply perceived by the fish as a threat (e.g., predator presence, human presence near tank), but, in either case, the typical GAS-type of response appears to require some form of sensory input such as fright, pain, or discomfort (17). In that context, Mason (18) argued that an organism's response to stress is as much behavioral as physiological. How fish behave when stimulated by a stressor provides an outward whole-animal manifestation of the complex neurological and physiological changes that occur, thus allowing interpretation of the response at an ecological level (19).

Much of our present knowledge about stress in fish has been gained from studying the primary responses of the HPI axis and subsequent or secondary effects on metabolism, reproduction, and the immune system (2,12). The investigation of heat-shock proteins in fish as a general cellular response to various stressors is a recent

and rapidly emerging field (20). Although most research in this area is descriptive at this point, the elucidation of possible functional relationships between the cellular responses to stress and neuroendocrine, immune and other physiological systems may provide useful applications for aquaculture in the future.

When fish are exposed to a stressor, the stress response is initiated by the perception of a real or perceived threat by the central nervous system (CNS). The response of the HPI axis begins with the release of corticotropin-releasing hormone (CRH), or factor (CRF), chiefly from the hypothalamus in the brain, which stimulates the corticotrophic cells of the anterior pituitary, or adenohypophysis, to secrete adrenocorticotropin (ACTH). Circulating ACTH, in turn, stimulates the interrenal tissue (adrenal cortex homologue) located in the kidney to synthesize and release corticosteroids, mainly cortisol, into circulation for distribution to target tissues. Control of cortisol release is through negative feedback of the hormone to all levels of the HPI axis (21,22). Regulation of the HPI axis is far more complicated than this description implies, however. For additional details, Wendelaar Bonga (14) and Sumpter (23) recently provided more complete descriptions of the endocrine stress axis in fish, and Chouros (24) presented a thorough synthesis of the neuroendocrinology of stress in higher vertebrates, including a review of the multiple roles of CRH in the organism's response to stress.

Concurrent with the elevation of circulating corticosteroids during stress is the release of catecholamines, mainly epinephrine (adrenaline) and norepinephrine (noradrenaline), following sympathetic stimulation of the chromaffin tissue (adrenal medulla homologue) in the kidney (23). Other hormones, including thyroxine, somatolactin, gonadotropins, and reproductive steroids in circulation and serotonin and its derivatives in the brain can become either elevated or suppressed during stress (2).

The primary response, the release of corticosteroids and catecholamines, affects the secondary stress responses involved in metabolism (e.g., blood glucose and lactate, liver and muscle glycogen), hydromineral balance (e.g., blood ions and osmolality), and those related to hematology (e.g., circulating erythrocytes and leukocytes, differential leukocyte ratios, hemoglobin). Moreover, the corticosteroids and catecholamines can directly or indirectly affect aspects of fish performance of particular concern to aquaculturists, including disease resistance, scope for growth, feeding and avoidance behavior, and reproductive capacity.

One of the most rapidly appearing manifestations of acute stress is a change in behavior, which can occur within seconds after perception of the stressor (19). This is understandable as the natural response of the fish presumably would be to escape or avoid the noxious stimulus it perceives as an immediate threat to its well-being. However, fish already experiencing stress display a lowered ability for avoidance response behavior when threatened compared with unstressed fish (25). The initial perception of the disturbance and the concomitant behavior associated with it are followed by the neuroendocrine responses, which take seconds

Stressor: e.g., handling, chasing, grading, exercise, confinement, transport, poor water quality

Stress

Stress Response:

PRIMARY – e.g., corticosteroid and catecholamine hormones increase

SECONDARY – e.g., metabolic, hydromineral, and hematological features change

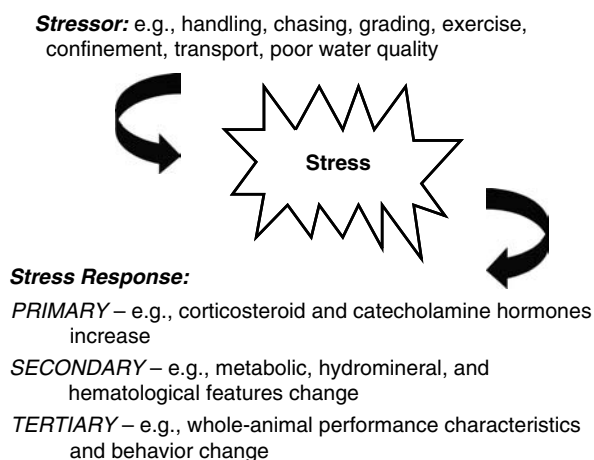
TERTIARY – e.g., whole-animal performance characteristics and behavior change


Figure 1. Typical stressors encountered in aquaculture evoke stress responses that can be classed as primary, secondary, and tertiary, which can be used as indicators to evaluate the degree of stress experienced by the fish.
Figure 2. Stress responses such as behavioral alterations can occur within seconds to minutes following perception of the stressor, whereas primary and secondary physiological responses can take from minutes to hours to manifest themselves as measurable changes. Changes in whole-animal performance characteristics may take much longer to occur and also recover from stress, but the timing of such changes is variable depending on the nature of the particular performance of interest.

(e.g., epinephrine) to minutes (e.g., cortisol) to become measurably elevated in circulation (Fig. 2). The secondary physiological changes that occur tend to take longer to manifest themselves in circulation, from minutes to hours (e.g., glucose, lactate, chloride), but often remain altered for more extended periods (Fig. 2). Timing of changes in whole-animal performance characteristics may be variable; for example, swimming stamina may be affected relatively quickly, whereas alterations in the immune system or reproductive function may not appear for hours or days or even weeks. Nevertheless, most research tends to support the notion that the magnitude and duration of the response reflect the severity and duration of the stressor. Thus, many of the primary and secondary stress responses documented in fish have become well established as useful monitoring tools to assess the degree of stress experienced by cultured fishes. Indeed, much of the following discussion is based on stress-related changes in plasma cortisol because of its proven utility as a sensitive acute-stress indicator (11,12).

FACTORS INFLUENCING STRESS RESPONSES

The normal responses of fish to stressful encounters are influenced by a suite of nonstress factors affecting both the magnitude of the response and recovery from it. These factors are genetic, developmental, or environmental. Fishes exhibit a wide variation in their responses to stress, particularly endocrine responses (12), ranging over as much as two orders of magnitude (Fig. 3). The cause for differences among major taxonomic groups is likely attributed to genetic factors. At our current level of understanding, however, it is unknown whether fishes that display relatively low stress responses are actually "less stressed" than others, or are as "stressed," but have a different capacity to respond to stress. Consistent
Figure 3. Fish species subjected to the same stressor may show considerable variation in their primary response to stress. Examples of peak poststress levels of plasma cortisol (+SE) in various fishes measured 1 hour after being subjected to the same 30-s aerial emersion stressor in a dip net. (Species without reference citation are from the author's unpublished data.)

response differences are not only evident among fish species, but also among strains or stocks within the same species (26,27) and even within the same population (28), a trend that appears to be at least partially heritable (29). The potential for selective breeding programs designed to produce fish with an attenuated stress response and, thus, show improved disease resistance is presently an attractive possibility for finfish aquaculture (30).

The developmental stage of the fish will affect its responsiveness to stress. A fish's ability to respond to a disturbance develops very early in life, for example, as early as two weeks after hatching in salmonids (31). Little evidence exists to suggest that fish show a consistent increase in stress responses as they develop, but they do appear to have heightened responses during periods of metamorphosis. For example, juvenile anadromous salmonids are particularly sensitive to stress during the period of parr-smolt transformation (32,33). As fish mature, primary stress responses may actually decrease in magnitude. Pottinger et al. (34) suggested that the threshold or "set point" for regulatory feedback may be lowered with the onset of maturity, thereby resulting in reduced responses of both cortisol and ACTH following stress.

Almost all environmental nonstress factors examined to date can influence the degree to which fish respond to stress. These include, but are not limited to, acclimation temperature, external salinity, nutritional state, water quality, time of day, overhead light, fish density, and even background color of the tank (2). An awareness of the extent to which these nonstress factors modify responses is important to both researchers and aquaculturists wishing to interpret experimental results and compare them with published values. For example, the fish's acclimation temperature or nutritional state is likely to have an appreciable effect on the magnitude of poststress elevations of cortisol and glucose, particularly the latter (35–38). In certain instances, stress-modifying factors that are themselves chronically stressful, such as

poor water quality, can actually attenuate the cortisol response to an acute second stressor (39,40).

Repeated acute stressors can have a cumulative response effect in fish (25,41,42). The implication of this phenomenon for aquaculture is that the fish's ability to recover from individual stressful events could be prevented if sufficient intervals are not allowed between separate acute disturbances such as tank transfer, grading, or hauling. Over a long term, however, fish can habituate or become accustomed to repeated disturbances such that responses to stress are lessened (43,44). Habituation to repeated stressful stimuli by using a positive conditioning protocol may have potential as an approach for improving the survivorship of hatchery fish following their transport and release (19,44).

MEASURING AND INTERPRETING STRESS RESPONSES

As judged by the prevalence in the literature and inferred earlier, the most popular approaches for evaluating stress in fish in aquaculture-related situations are measurements of plasma cortisol, glucose, lactate, chloride (and other ions), and osmolality and hematological features. Typical resting and stress-elevated values for those and other features are listed in Table 1. However, readers should note that these are approximate values to serve as a guideline only and have limited diagnostic value, as stress responses are highly variable, depending on genetic makeup, early life history, and the fish's environment. Extensive data indicating the point at which certain physiological features may actually indicate a life-threatening situation are not available, but plasma chloride and osmolality concentrations less than 90 meq/L and 200 mOsm/kg, respectively, have been suggested as indicative of compromised osmoregulatory ability in salmonids (45).

Methods of stress assessment in fish have been described (11,46) and include simple test kits (e.g., glucose, lactate) and easy-to-use meters (e.g., chloride, osmolality)

Table 1. Approximate Typical Resting and Stress-Elevated Values of Primary and Secondary Physiological Parameters Used as Indicators of Stress in Fish[a]

Physiological Parameter	Resting	Poststress
Plasma epinephrine (nmoles/L)	<3	20−70
Plasma cortisol (ng/mL)	<10−50	30−300+
Plasma glucose (mg/dL)	50−150	100−250+
Plasma lactate (mg/dL)	20−30	40−80
Plasma chloride (meq/L)	100−130	≈10% ↑ or ↓[b]
Plasma sodium (meq/L)	150−170	≈10% ↑ or ↓[b]
Plasma osmolality (mOsm/kg)	290−320	≈10% ↑ or ↓[b]
Plasma hemoglobin (g/dL)	5−9	<4
Hematocrit (% packed cell volume)	25−40	40−50+

[a]Compiled from references 11,12,48, and author's unpublished data. However, considerable variation among these values and exceptions outside of these ranges exist depending on genetic background, rearing history and environmental conditions. (See text.).
[b]Blood ions and other features related to hydromineral status will fluctuate upward or downward, depending on whether fish is marine or freshwater species, respectively.

for many of the physiological features of general interest. Measuring hormones like cortisol is more complicated, however, and usually involves a radioimmunoassay or enzyme-linked immunosorbant assay technique. Inexpensive, readily available, portable meters, such as those used clinically for glucose and other features, have been tested for their efficacy in fish stress monitoring (46) and show promise as a future useful tool for the aquaculture industry.

More problematic than actual measurement of stress in fish is the interpretation of results for three major reasons. First is the modifying effects alluded to earlier, that the various genetic, ontogenetic, and environmental factors have on the magnitude and duration of the response. Without knowing the extent to which other nonstress factors may have altered the response, it is difficult to interpret the biological significance of that response in a relative context. Second is the variation and apparent inconsistency among fishes in the responses of different blood-chemistry characteristics. For example, a species that shows the greatest endocrine response increase (e.g., plasma cortisol) compared with others may not be the same species that elicits the greatest increase in a secondary response, such as glucose or lactate, when subjected to the identical stressor (12). Thus, a species or group that appears "most stressed" by one feature may not necessarily be so if measured by another. Such discrepancies among different physiological indicators emphasize the importance of not relying on a single indicator and the need for appropriate controls in stress assessment. Third is the nature of the stress response itself. The response to stress is a dynamic process and physiological measurements taken during a time course are only representative instantaneous "snap-shots" of that process. A time lag, ranging from minutes to hours or more, exists that complicates the interpretation of results. A significant delay, depending on the level and type of response, occurs from the initial perception of the stressor by the CNS to the time when the physiological feature of interest reaches a peak level of response (Fig. 2). Thus, the measurement of a particular stress indicator may not necessarily reflect the degree of stress experienced by the fish at that instant of time, but more likely earlier.

IMPLICATIONS OF STRESS FOR FISH PERFORMANCE

Stress affects the performance of fish in four areas that have direct implications for aquaculture: metabolism, immunocompetence, reproduction, and behavior.

Metabolism

Among the most important factors for successful aquaculture are acceptable growth rates and food conversions of the target species. The speculated effect of stress on metabolism is based on the premise that coping with stress is a process that requires energy within the fish's overall scope for activity, which is then unavailable for other performances such as growth (12,17). Certainly when fish are stressed, energy reserves are mobilized, with characteristic increases in plasma glucose and lactate and decreases

in tissue glycogen occurring as a result (47,48). In the short term, the acute metabolic cost associated with stress is reflected by an increase in oxygen consumption, which is a direct measure of metabolic rate (49,50). However, the long-term effects of stress on metabolic functions, such as growth, and the involvement of the various endocrine axes are not yet clear (47). Moreover, it is difficult to attribute observed, apparently stress-mediated suppressions in growth rate to single isolated stressors because of possible confounding effects of individual factors encountered in fish husbandry, such as density, water quality, feeding regime, and social interaction (12), as well as the involvement of multiple endocrine axes (47).

Immunocompetence

Stress has a profound effect on the immune system of fish and increases their susceptibility to infectious diseases (51–53). Evidence is increasing that demonstrates that mediation of the immune system is through endocrine pathways, but precise mechanisms in fish are not yet well known, although the HPI axis is certainly involved (14,54,55). Peripheral hormones of the HPI axis affect a number of immunological features in fish, including a reduction in circulating lymphocytes, antibody production, and macrophage respiratory-burst activity (2,12,55).

Recent findings in higher vertebrates support the view that immune and endocrine systems are connected reciprocally and interact directly to affect health and disease outbreaks in stressed fish (14,24,55). In particular, the cytokine proteins involved in inflammation have directly stimulatory effects on the hypothalamic-pituitary-adrenal (HPA) axis, notably on stimulation of CRH and ACTH, whereas activation of the HPA axis has an appreciable inhibitory influence on the inflammatory immune response (24,56). However, the direct influence of the HPA axis on immune function is far more complicated than previously thought, as effects of corticosteroids can be both stimulatory and inhibitory, depending on timing, other immune factors, and host status (56). Detailed studies are still needed to clarify the existence of such stimulatory factors and their immune-endocrine interactions in fish (54,55), although many similarities exist between fish and mammals (14). Nevertheless, most experts agree that managing fish culture to reduce or minimize stress should decrease the likelihood of costly fish losses due to poor health and presence of disease, even if exact mechanisms of action are not understood.

Reproduction

Stress can have a significant inhibitory effect on the reproductive capacity of fish, particularly by suppression of the gonadal steroids. Substantial evidence indicates that this effect is mediated in large part by the HPI axis, particularly by cortisol (2,12,14,47). For example, a number of studies have documented a general suppressive effect of both stress and cortisol on plasma levels of testosterone, 11-ketotestosterone and estradiol (2,12,14). However, all evidence collectively is equivocal and investigations showing neutral or even stimulatory effects complicate interpretation of existing literature (47).

Stress may also affect reproduction negatively by acting directly or indirectly on other hormonal pathways and on vitellogenesis (23,47). Regardless of mechanisms, important concerns for aquaculture are whether stress affects gametogenesis, gamete quality, and survivorship. Although limited evidence suggests that gamete quality and progeny survival are reduced by culture-related stressors (57,58), this is an area of aquaculture research that remains largely unexplored (47). In contrast, the effects of chronic environmental stressors, such as chemical pollutants on embryonic development, gamete quality, hatching success, and larval quality are reasonably well established (59), although it may be difficult in many instances to ascertain whether the documented impairment occurred as a result of a generalized stress response or a specific action of the chemical stressor in question.

Behavior

Behavior patterns in fish important to aquaculture include feeding, avoidance, and aggressive behaviors, all of which can be affected by stress (19,60,61). As with other stress responses, initial behavioral reactions to a stressful event, such as avoidance of the stressor, may be to maximize chances of survival and, thus, are adaptive. However, in the face of continued or additional stress, behavioral responses may deviate sufficiently from normal to become deleterious, for example, decreased avoidance response ability or loss of appetite. Unlike other physiological responses that incur a time lag before they are detectable, such as blood-chemistry alterations, some stress-induced changes in behavior mediated directly through the CNS can occur and be observed in the fish almost instantaneously (19).

Major stressors encountered in aquaculture that can alter fish behavior include handling, transport, crowding, and poor water quality (19,60). For example, simply handling fish increases their susceptibility to being captured as prey (42,62–64) and reduces their ability to avoid other noxious stimuli (25). Normal social interactions such as aggressive or dominance behavior in captive fish populations can also be disrupted by stress (19,65).

A variety of adverse water-quality characteristics are known to affect fish behavior (19,60); while most of those documented are associated with environmental pollution, those with relevance to aquaculture are elevated ammonia, reduced dissolved oxygen, suboptimal pH, and altered thermal regime. Feeding behavior, in particular, is affected by altered water quality, as well as by physical stressors, such as handling, with the obvious responses being a cessation or reduction in feeding activity or loss of appetite (19,60). Endocrine mechanisms underlying stress-induced behavioral alterations in fish are not well elucidated, but at the level of the CNS, appear to involve monoamine neurotransmitters, specifically dopamine, norepinephrine, and serotonin (19,66). Notably, increased brain serotonergic activity is linked with subordinate behavior and reduced food intake in fish (67), suggesting one possible mechanism for reduced growth under stressful conditions in aquaculture.

Regardless of the mechanism, fish that are not feeding properly and subsequently not growing well in culture systems, or those hatchery fish incapable of effectively avoiding predators after being stocked, represent appreciable economic losses to the program.

APPROACHES FOR REDUCING EFFECTS OF STRESS

Over the long term, knowing that clear genetic differences exist in fish in their responses to stress has led to the possibility of selecting stress-tolerant strains for aquaculture (30). Although preliminary evidence is suggestive, research results to date have not definitively demonstrated a distinct consistent relationship between a reduced stress response and improved performance in growth or disease resistance. The potential also exists to improve fish performance and increase their tolerance to stress through the use of dietary supplements (68,69), but this is also a new research field.

In the short term, practical approaches for mitigating the detrimental effects of stress are relatively straightforward, employ common sense, and can be implemented at any time in the program. Guidelines and complete details are available elsewhere (45,70,71) and include, for example, (a) maintaining optimum water quality for the target species, (b) adhering to recommended loading densities, and (c) using established methods for disease prevention, including vaccination, water treatment, and facility and equipment disinfection. Healthy fish are more capable of tolerating stress than those whose health may be compromised because of poor husbandry practices.

Similarly, fish transportation methods should incorporate approaches designed to reduce stress and ensure that fish arrive at their destination in the best condition possible. Such methods employ the following: (a) proper oxygenation or aeration to provide adequate dissolved oxygen levels, (b) proper tank venting to prevent excessive carbon dioxide buildup, (c) appropriate in-tank water circulation and maintenance of water quality to reduce accumulation of toxic un-ionized ammonia, (d) prevention of overcrowding or overloading hauling tanks, (e) minimal use of out-of-water handling during loading and unloading, (f) addition of mineral salts to minimize osmoregulatory disturbance, and (g) possible use of anesthetics and other drugs to sedate fish in transit (45,70,71).

STRIPED BASS AND HYBRID STRIPED BASS CULTURE

CHRISTOPHER C. KOHLER
Southern Illinois University
Carbondale, Illinois

OUTLINE

The anadromous striped bass (*Morone saxatilis*) is one of four *Morone* species. The others are white bass (*M. chrysops*), yellow bass (*M. mississippiensis*), and white perch (*M. americana*). *Morone* spp. were originally placed in the family Percichthyidae, however, Johnson (1) placed them in their own family, Moronidae. The Names of Fishes Committee of the American Fisheries Society recently adopted the nomenclature suggested by Johnson. The striped bass is a major sport and commercial species native to the Atlantic and Gulf Coast of the United States, but stockings have expanded its range through much of North America as well as to other continents. When a reproducing population of striped bass was recognized in landlocked Santee Cooper Reservoir, South Carolina (2,3), fisheries biologists became interested in stocking striped bass in reservoirs to serve as a recreational sportfish and as a predator to control underutilized forage species. *Morone* hybridization programs were initiated in the 1960s. Efforts were aimed at combining the trophy fish potential of striped bass with the higher adaptability to landlocked, freshwater systems of its congenerics (4,5). Of the various crosses, backcrosses, and outcrosses made, only the striped bass X white bass cross gained wide acceptance (4,6–8). Striped bass and white bass hybrids were first made experimentally by Robert Stevens (South Carolina Wildlife Resources Department) in 1965 (9). The first cross, of the striped bass female with the white bass male, was initially called the original cross-hybrid striped bass, but is now referred to as the palmetto bass. The second, or reciprocal cross (of the white bass female with the striped bass male), is called sunshine bass (Fig. 1). Hybrid striped bass are still being used for recreational fish stockings, but interest in foodfish production emerged beginning in the late 1970s. Striped bass/hybrid striped bass is considered to be the fastest growing segment of the U.S. aquaculture industry (10).

Figure 1. The sunshine bass is a cross between a female white bass and a male striped bass. It is also referred to as the reciprocal cross-hybrid striped bass. The original cross, or palmetto bass, is similar in appearance to sunshine bass and is produced by crossing a female striped bass with a male white bass. (Photo by J. Rudacille.)

Production of food-size hybrid striped bass in the United States has risen from about 455,000 kg (1 million lb) in 1990, to over 4.5 million kg (10 million lb) in 1996 (11). Unless otherwise noted, the information that follows pertains to both striped bass and hybrid striped bass culture.

HISTORICAL PERSPECTIVE

The first hatchery for striped bass was built on the Roanoke River at Weldon, North Carolina in the 1880s (12). Ovulating females and running ripe males were collected on their spawning run, and then eggs and milt were stripped and mixed with water. The developing embryos were incubated in MacDonald jars much as they are to this day. It was not until the 1960s that aquaculturists were able to utilize nonovulating female striped bass. South Carolina Wildlife Resources Department personnel, led by Robert Stevens, developed procedures to induce ovulation in female striped bass that had undergone final gonad maturation (13–15). The department also initiated the production of hybrid striped bass by crossing striped bass with white bass (9) at the Monck's Corner Hatchery, South Carolina, in 1965 (9,16). Both crosses produced viable eggs, but poor survival was experienced with sunshine bass fry (7,9). From 1966 through 1973, production of hybrid striped bass was limited to palmetto bass. In 1973, Florida researchers began successfully culturing sunshine bass at the Richloam Fish Hatchery (17). Intensive rearing of one-day-old striped bass began in the mid-1970s at Southern Illinois University at Carbondale (18). Pond production of hybrid striped bass as a foodfish began in North and South Carolina around 1980 (19). Today, striped bass and both hybrid crosses are reared in ponds and in intensive systems. Rearing of larval sunshine bass is still problematic due to the smaller size of white bass eggs (20).

BIOLOGY AND ECOLOGY

Geographic Range

The anadromous striped bass has been stocked throughout much of North America. They were introduced to the coastal waters of California in 1879 (21) and were subsequently distributed along much of the Pacific coast. Stockings have been directed to freshwater impoundments since the 1960s (22), although marine restoration and enhancement programs have also taken place along the east coast (23).

White bass are also native to North America, and their range extends from the St. Lawrence River west through the Great Lakes (excluding Lake Superior) to South Dakota and the Mississippi and Ohio River drainages south to the Gulf of Mexico (24–26). Like striped bass, the range of white bass has been greatly expanded by stocking and now includes the Gulf and south Atlantic states, as well as New Mexico, Utah, Colorado (27), California (28), and Nevada (29).

Although natural hybridization between striped and white bass is conceivable (30), there are no known natural populations of hybrids in existence (31). Hybrid striped bass are artificially produced and stocked in freshwater impoundments to enhance recreational fisheries and to control forage fish populations (22). Hybrids are believed to have most of the positive recreational attributes of striped bass, while having the adaptability of white bass to varying environments (4,5). They are cultured for food in numerous states throughout the U.S., as well as in Israel, Taiwan, and the People's Republic of China.

Morphological Characteristics

Striped bass, white bass, and their hybrids have horizontal stripes laterally and an overall silver color with upper sides of olive gray shading to white on head and belly (24–26). The striped bass has an elongated body, which is laterally compressed and with the deepest part below the posterior portion of the spinous dorsal fin. The white bass body is robust, deep, and strongly compressed laterally and has similar coloring. The spinous dorsal and soft dorsal fins are entirely separate. Hybrids are intermediate of parentals in physical appearance and most meristic characters:

	Striped Bass	White Bass	Hybrids
• Lateral line scales	50 to 72	52 to 58	Intermediate
• Scales above lateral line	9 to 13	7 to 9 (usually 8)	Intermediate
• Soft anal rays	9 to 11	12 to 13	Intermediate
• Soft dorsal rays	12	12 to 13	12 to 13
• Teeth on tongue	2 patches	1 patch	Intermediate
• Parr marks	Present	Absent	Present

Fingerling white bass are easy to distinguish from fingerling striped bass, which have parr marks (7) and typically two tooth patches (32). Conversely, it is sometimes difficult to distinguish the young of white bass and hybrids of striped bass, including F_1, F_2 and backcrosses (33).

Age and Growth

Landlocked striped bass tend to initially grow faster than coastal stocks (21), but the latter grow considerably larger. Scott and Crossman (26) reported a striped bass caught in North Carolina in 1891 that weighed over 50 kg (110 lb). Striped bass are known to live more than 30 years (31), with females growing to the larger sizes (34,35). White bass grow considerably slower than striped bass, rarely exceed 2 kg (4.4 lb), and generally live no more than 9 years (20). Hybrid striped bass generally have superior growth rate to parentals (weight not length) in the first 2 years of life (8), but striped bass ultimately get larger (Table 1).

Food Habits

Newly hatched striped bass feed in schools on mobile zooplankton (31). Cladocerans and copepods are the primary dietary constituent during the early summer (49–51). Insects, other crustaceans and larval clupeids become more prevalent in late summer (49). Juvenile stripers usually switch to a piscine diet in autumn with soft-rayed clupeids being preferred (31,52).

Newly hatched white bass initially feed on rotifers and similar size organisms for two or three weeks when they reach a size that allows them to feed on microcrustaceans. Copepods and cladocerans comprise the bulk of the natural diet, at least through midsummer (41,53). However, insects were found to predominate in young white bass during spring in Beaver Reservoir, Arkansas (54). By midsummer, young white bass will switch to a largely piscine diet, provided forage fish are available in suitable size and abundance. Alternatively, the fish may continue to consume invertebrates (55). Adults are primarily piscivorous.

Hybrid striped bass food habits are initially very similar to their maternal parent (7). The larger newly hatched palmetto bass feed on cladocerans and copepods, while the initial food of sunshine bass consists mainly of rotifers. As adults, hybrid striped bass food habits are essentially equivalent to those of pure striped bass (56–59).

Natural Spawning

Female striped bass in the wild usually mature at age 4 years or older, while males usually mature at age 2 (60,31). Age at maturity is a function of size so those in warm waters mature earlier (31). Fecundity is a function of age, length, and weight (61). Most females produce between 110,000 to 220,000 ova/kg (50,000 to 100,000 ova/lb) of wet body weight (31). The spawning temperature for striped bass is typically between 13.9 to 21.1 °C (57 to 70 °F) (31). Striped bass are polygamous broadcast spawners in freshwater rivers (62). Ripe eggs range from 1.0 to 1.6 mm (0.03 to 0.06 in.) in diameter (63–65), are semibuoyant, and are fertilized when released into a current (26). Spawning times are highly variable (31). Hatching time is depends upon the

temperature, ranging from 29 h at 22 °C (71.6 °F) to 80 h at 11 °C (51.8 °F) (31). At hatching, larval striped bass average 3.1 mm (0.1 in.) TL in the wild (31), but are as large as 5.0 to 7.0 mm (0.2 to 0.3 in.) TL from laboratory-reared fish (66,67).

Female white bass in the wild usually mature when reaching 3 years old, while males generally mature a year earlier (41). The spawning temperature for white bass is typically between 14.4 to 18.3 °C (58.0 to 65.0 °F) (41). White bass migrate up tributaries when available and spawn in shallow waters on firm gravel or sand (24). They will spawn on any suitable shoreline structure in the absence of tributaries. Spawning occurs during both day and night, but spawning fish are most active crepuscularly (55). Eggs are adhesive, are demersal, and increase little in diameter when hardened by water (68). No nest construction or care is provided to the eggs that stick to gravel and vegetation. Mature white bass females can each produce several hundred thousand eggs, ranging in diameter between 0.61 and 0.68 mm (0.02 to 0.03 in.) at ovulation (4). Hatching occurs in about two days, with fry being approximately 3.0 mm (0.1 in.) TL (41).

Morone hybrids are not sterile and have bred with each other in the wild (69,70), as well as having been outcrossed with striped bass (71). No reports of natural hybrid outcrossing with white bass were found in the literature.

HATCHERY PHASE

Collection and Transportation of Broodstock

Striped bass broodstock are usually collected during spawning migrations in river headwaters above and below dams (72). Electrofishing, gillnets, and pound nets have been successfully employed (72,73). Electrofishing has been shown to be less stressful than gillnetting (74). The smallest males spermiating and females with secondary oocytes are preferred if the fish are to be maintained as broodstock. Striped bass in excess of 5 kg (11 lb) obtained from the wild do not adapt well to captivity (73). North Carolina researchers (73) recommend allowing females to resorb their eggs as an energy reserve to carry them through adaptation to dry feed. Males will generally spermiate the subsequent spawning season, whereas females may require two years before they produce good quality eggs (73). State hatcheries usually obtain all their striped bass broodstock from the wild and spawn them immediately.

Adult white bass can readily be caught by hook-and-line (75) or trap nets (72). Electrofishing can be used for capturing white bass, but with varying degrees of success. Many producers purchase their white bass broodstock from commercial fishermen on Lake Erie (20). White bass are usually hardier than striped bass, and are often spawned immediately after collection.

Ideally, hauling tanks should be filled with water from where the broodfish are collected. Salt (NaCl or synthetic sea salts) should be added to the water to raise the salinity to 8–12 ppt for striped bass (72) and 5 ppt for white bass (20). Depending on water temperature where the fish are collected, hauling tank water temperature should be 18.3 °C (65 °F) or less. Ice can be added if needed. The hauling tank should be equipped with pure oxygen regulated to maintain dissolved oxygen concentrations at a minimum of 7 ppm (76). Depending on fish condition and hauling duration, approved therapeutic treatments to control disease should be considered. The use of the anesthetic MS-222 during hauling does not appear to be necessary, but can be used at appropriate doses based on experience of haulers. Due to possible shifts in water pH when using MS-222, always buffer this anesthetic with sodium bicarbonate (500 ppm $NaHCO_3$: 100 ppm MS-222).

REARING FACILITIES

Training to Formulated Feed

Kohler et al. (75) demonstrated that adult white bass can be trained to accept and then be maintained on dry feed for over two years. They stressed that newly collected white bass should not be fed until all therapeutic treatments are completed. This delay assures that the fish will be hungry when feed is first offered and prevents habituating fish to ignore feed by presenting it to them when stress or disease agents impede their appetites. The fish are initially trained to formulated feed by hand-feeding moist pellets, which are prepared by mixing equivalent amounts of commercial dry trout feed [broodstock diet; 40 : 11 (% protein : % fat)] with raw gizzard shad, *Dorosoma cepedianum*, and a vitamin premix (coolwater fish; U.S. Biochemical, Cleveland, Ohio). Healthy white bass readily take this feed. By the second day of active feeding, a small proportion of the dry trout feed (floating) is mixed with the moist pellets. The proportion of dry feed is slowly increased in the diet until the fish accept 100% dry feed, a process usually completed in two weeks or less. This procedure should also work for striped bass. However, it may be necessary to feed striped bass pieces of fresh fish or even live fish if formulated feed is rejected after several days in captivity. Both white bass and striped bass tend to rapidly switch to dry feed once a few fish begin to accept the feed. Broodfish already trained to formulated feed can be placed with newly captured fish to accelerate formulated feed acceptance.

At the hatchery, striped bass and white bass broodstock should be placed for several hours in stress-recovery tanks containing salinities similar to those used for hauling. Salinity can be slowly reduced to 5 ppt by flushing. Both species seem to perform best in circular tanks, but can be held in rectangular tanks if necessary.

Domestication of Broodstock

A few efforts have been made to develop domesticated broodstocks of striped bass (77–80) and white bass (20,75,81). The difficulty with striped bass is the long time between generations, particularly for females. The shorter generation time of white bass makes this parental species a simpler candidate to domesticate (Fig. 2). Sullivan et al. (73) suggested that unless a producer is prepared
Figure 2. White bass broodfish are highly amenable to captivity and will readily undergo sexual maturation if held under proper photothermal regimes. (Photo by D. Russell.)

to maintain and propagate domestic broodstocks of both parental lines, the simplest solution may be to use captive striped bass males crossed with captive white bass females to produce sunshine bass. Consequently, the producer would not be burdened with producing and maintaining mature striped bass females. However, without the domestication of both sexes of striped bass and white bass broodstock, there will be no significant advancements made in terms of genetic improvement of heritable traits of the parental lines used to make the hybrids for the industry. Such domestication efforts are being carried out at various research centers and well-established hybrid striped bass commercial enterprises.

Controlled Spawning

Striped bass and white bass females are normally injected with human chorionic gonadotropin (HCG) to induce ovulation. Chorulon® is the recommended brand, because it was recently approved by the U.S. Food and Drug Administration for fish use. Recommended dosages for female striped bass are between 275 and 330 IU/kg (125–150 IU/lb) wet-body weight (4,5,8,14). Bonn et al. (5) stated that white bass females can be successfully induced to spawn at dosages between 1,000 and 2,000 IU/kg (500 and 1,000/lb). This was not a recommendation, but has been taken to be one. Recently, Kohler et al. (81) showed that HCG dosages as low as 50 IU/kg (110 IU/lb) are more efficacious. Accordingly, it appears that white bass should be injected at dosages similar to those commonly used for striped bass [i.e., 275–330 IU/kg (125–150 IU/lb) for females and 110–165 IU/kg (50–75 IU/lb) for males].

Only females in spawning condition — based on plumpness and/or visual examination of oocytes collected by a 3.0 mm (0.1 in.) outside diameter plastic catheter (68) for striped bass; or a 1.5 mm (0.005 in.) outside diameter plastic catheter for white bass (83) — should be injected with HCG. Reinjection of females with HCG usually results in abortion of eggs (68). However, multiple injections, using lower HCG dosages, have not been well examined. White bass males have been shown to continuously spermiate for several months when held at spawning temperature of about 16 °C (68 °F) (75). A monthly dosage of 100 IU/kg (45 IU/lb) is recommended if males are to be reused as broodstock over an extended period of time (20).

Before injection with HCG, the fish should be anesthetized with 50–100 ppm MS-222 with five times that amount of sodium bicarbonate to serve as a buffer. The fish can then be weighed, and the proper dosages administered intramuscularly just ventral to the first dorsal fin above the lateral line.

Production of palmetto bass can be problematic due to difficulties sometimes encountered in obtaining female striped bass in the late stages of ovarian maturation (84). The stress on broodstock associated with repetitive handling to check for maturation can impair reproductive performance and cause mortalities. To address this issue, researchers have demonstrated that a synthetic analogue of mammalian gonadotropin releasing hormone (mGnRHa) implanted in striped bass can reliably induce spawning (73,85,86). Commercial

application of this treatment awaits necessary studies to obtain regulatory approval.

Female striped bass and white bass should be checked for ovulation every 2 hours, starting at 16 hours post-HCG injection by lightly exerting abdominal pressure to extrude a small number of eggs. Oocytes can be staged for both species by using similar procedures described for striped bass (8,68). Ovulation generally occurs between 24−36 hours post-injection at 16−18 °C (60.8−64.4 °F), but a window of only 1−2 hours is available to obtain properly ripened eggs. In general, ovulation is indicated by the occurrence of clear, free-flowing, uniform-shaped, yellowish-tinged eggs with fully intact inner chorion surfaces. Ovulated females should be anesthetized with MS-222, as previously described. Ripe males usually do not need to be anesthetized because of the relative ease with which their gametes can be expressed.

Before manually removing the gametes, fish should be dried with a paper towel to avoid water contamination that might prematurely activate sperm. Eggs are removed from females by firmly exerting abdominal pressure starting just above and slightly posterior to the pelvic fins and progressing posteriorly and vertically toward the genital opening (Fig. 3). Semen can be expressed in a similar fashion. To avoid any contamination with urine, semen can be collected by inserting a Pasteur pipette in the urogenital opening and applying suction (75). It is advisable to collect semen from two or more males for fertilizing each egg batch to improve genetic heterozygosity. This also decreases the possibility of fertilizing eggs with low-quality semen (e.g., semen of low motility).

Figure 3. *Morone* are usually spawned by manually stripping gametes. Here, semen from a male striped bass is being stripped into a metal pan containing striped bass eggs. (Photo by G. Brown.)

The "wet" method for fertilization, in which semen is added to a mixture of eggs and water, is often used when males are stripped because urine often prematurely activates spermatozoa. Some hatcheries use a modified "wet" fertilization method, in which semen and water are added simultaneously to the eggs (33). The "dry" method, in which semen is mixed with eggs followed by water, should probably be limited to when semen is collected by a pipette. Regardless of the method employed, at least one minute of gentle stirring in a Teflon® pan (white bass eggs are adhesive) should be allowed for fertilization to take place (20).

Incubation Techniques

Embryos can be incubated in aquaria (5), Heath trays (75), or in MacDonald-type jars. However, in the case of white bass eggs, they cannot be incubated in jars, unless their adhesiveness is neutralized. Fuller's earth, silt, clay, starch, sodium sulfite, and tannic acid have all been used with varying degrees of success (33). Rottmann et al. (87) provided a detailed protocol (20) for eliminating adhesiveness of white bass eggs. Key elements of the protocol are the use of sodium chloride and urea to clear the embryos, so that developmental events can be seen, and tannic acid to reduce adhesiveness. Formalin-F can be used at 50 ppm to reduce fungal infections if hatchery water is being recycled through the MacDonald jars. Otherwise, concentrated bath treatments of 286−429 ppm can be used by injecting 2 to 3 ml (0.07 to 0.1 oz) of full strength formalin into the top of the shad tubes to provide a rapid flush treatment (33). Dead embryos usually turn opaque after 30 minutes and, when practical, should be removed.

Development is temperature dependent. At 16−18 °C (60.8−64.4 °F), the embryos will begin to hatch 36−48 hours post-fertilization and will usually be complete within another 24 hours (75). Depending on temperature, an additional 72−96 hours are required for the larvae to absorb their yolk sacs. Rees and Harrell (68) provided characteristics of various stages of development for striped bass, while white bass developmental stages were described by Yellayi and Kilambi (88) and Bayless (4).

POND PRODUCTION

Morone culture is divided into four phases: the hatchery phase as previously described; phase I in which larval fish are reared for 30−45 days; phase II, where fish harvested from phase I ponds are reared through the first growing season (6−9 months); and phase III, where fish harvested from phase II ponds are reared to market size in the second growing season. For a detailed description of these procedures see Harrel et al. (89), Harrell (90), and Hodson (19). Pond production procedures are similar for all *Morone* spp., except during phase I.

Phase I

The first foods of *Morone* are zooplankton with the smaller white bass and sunshine bass starting on rotifers, while striped bass and palmetto bass start on cladocerans

and copepods. Accordingly, successful phase I production requires a proper fertilization scheme to ensure that the right zooplankton communities are present in terms of quality and quantity. Prior to stocking, ponds should be drained, refilled, and fertilized with a mixture of organic fertilizers (cottonseed meal, alfalfa hay, and animal manure) and inorganic fertilizers (ammonium nitrate, 52%; and phosphoric acid, 32%). Organic fertilizers may be applied at 200 to 500 kg/ha (200 to 500 lb/acre), while inorganic fertilizers should be applied at 2.5 kg per ha (2.5 lb per acre). Pond filling and fertilization should take place 2 to 3 days to one week prior to stocking white bass and sunshine bass and two weeks prior to stocking striped bass and palmetto bass. This timing scheme ensures that rotifers dominate the zooplankton community when the former are stocked and that cladocerans and copepods prevail when the latter are stocked. In either case, inorganic fertilizers should be added weekly at the same rate as for organic fertilizers through at least 3 weeks poststocking. Additional organic fertilizer should also be applied on the third week poststocking at about 25 kg/ha (25 lb/acre). These are general recommendations, and the timing and quantities may need to vary depending on site characteristics.

The stocking rate is about 250,000 to 500,000 of 4-day posthatch fry/ha (100,000 to 200,000 /acre) for striped bass/palmetto bass and white bass/sunshine bass, respectively. Salmon starter feeds are usually provided at day 21 at 5 to 10 kg/ha (5 to 10 lb/acre) per day (fed three times per day). Progressively larger feed sizes and higher ration sizes should be used as fish grow. It is advisable to continue feeding some starter feed throughout phase I to ensure most surviving fish switch to prepared feed. Fish should readily be consuming no. 1 crumbles by the end of phase I. It is essential to maintain good water quality throughout this phase. Phase I generally takes 30–45 days when fish attain lengths of 2.5 to 5.0 cm (1.0 to 2.0 in.) TL and weigh about 1.0 g (0.03 oz). Survival in excess of 15% is considered good for white bass and sunshine bass, while striped bass and palmetto bass should exceed 45% (19).

Phase II

Harvested phase I fish should be graded to separate out runts (fish <2.5 cm or 1.0 in. TL). This is usually accomplished by holding fingerlings in raceways or tanks. Further feed training also takes place at this time. Larger fish should also be graded out, since they are likely to become cannibals. Stocking rate ranges from 20,000 to 30,000 fingerlings per ha (8,000 to 12,000/acre). Fish are initially fed no. 1 or no. 2 crumbles (40% crude protein) at 15–25% body weight daily in three equal feedings for the first month. Fish can be fed in two feedings thereafter at 15% body weight. The feed rate is gradually reduced to 3% body weight by fall. Near the end of phase II, fish should be able to consume no. 4 crumbles. Survival at the end of phase II should exceed 85%, and fish should weigh approximately 100 g (0.22 lb) or more. Phase II fish can be harvested and restocked for phase III in the first fall, or alternatively, the fish can be overwintered and then

harvested and restocked in the following spring. Runts should be graded out prior to restocking.

Phase III

Phase III fish are stocked at 7,500 to 10,000 fish/ha (3,000 to 4,000/acre). Fish are fed floating feeds of 36–40% crude protein at 3% body weight per day (usually in two feedings). Ponds should not be provided with more than 250 kg/ha (250 lb/acre) on a daily basis, even with supplemental aeration (91). Fish are harvested at the end of the growing season in late fall and should weigh 0.7 kg (1.5 lb) or more. The harvested fish can be stunned in super-chilled water and then packed on ice for delivery to the buyer.

INTENSIVE PRODUCTION

Striped bass and hybrid striped bass can be cultured in indoor recirculating systems (92). Researchers at Southern Illinois University (18) were the first to succesfully rear striped bass in such systems. That research was the basis for a striped bass hatchery on the Hudson River built by Commonwealth Edison Utility Company. Subsequently, commercial producers have used intensive systems to raise both striped bass (93) and hybrid striped bass (94). In fact, approximately half of all food-size hybrid striped bass grown in the U.S. are produced in intensive systems. The reader is referred to Hochheimer and Wheaton (92) and other contributions in this encyclopedia for more details on the use of such systems for *Morone* culture.

WATER QUALITY

Morone can be cultured in a wide range of water-quality variables (19). Oxygen requirements are slightly higher than that required for channel catfish, but are not as high as are needed for trout. Recommended levels for the major water quality variables are as follows:

Variable	Desirable
Dissolved oxygen	>4.0 ppm
Temperature	15–17 °C (77–86 °F) optimal
	16–32 °C (60–90 °F) growth occurs
	<10 °C (50 °F); >33 °C (93 °F) no growth
Alkalinity/hardness	>100 ppm CaCO$_3$
pH	7–8.5 optimum
	6–9.5 growth occurs
Ammonia	<1.0 ppm

The reader is referred to Boyd (90) for details on water-quality management.

NUTRITION

A review of micro- and macronutrient requirements of striped bass and hybrid striped bass appears in

Gatlin (91). The general recommendation for diet formulation from juvenile to market-size fish is as follows:

Composition	As fed basis
Protein	40%
Lipid	8%
Fiber	1.7%
Estimated available energy	3.3 kcal/g feed
Energy and protein ratio	8.25 kcal/g protein

Producers have successfully produced phase III hybrid striped bass with diets of lower quality. It is not advisable to use feeds with less than 36% crude protein. Broodstock diets should be high quality; salmonid diets in excess of 40% crude protein and 10% crude fat are sufficient.

DISEASES AND TREATMENTS

Morone are susceptible to most of the disease-causing organisms associated with aquaculture (97). Viruses have not been problematic. On the other hand, bacterial diseases are common, particularly columnaris and motile aeromonas septicemia (*Aeromonas* and *Pseudomonas*). Clinical signs may include exophthalmia (pop eye), hemorrhage in skin and fins, frayed fins, distended abdomen, bloody fluid in body cavity, and anemia (pale gills). Columnaris (*Flexibacter columnaris*) is also common, but is usually confined to skin, fins, or gills. Lesions on skin and gills, as well as frayed fins are the prevailing clinical signs. *Streptococcus* septicemia has recently been found in some striped bass operations (98). Stress from handling and movement seems to trigger this disease where *Streptococcus* is endemic (97). Clinical signs include darker than normal color, erratic swimming (spiraling), and curvature of the body. *Morone* reared in saltwater are susceptible to vibriosis (*Vibrio* spp.). The disease is usually stress related, and the clinical signs are similar to motile aeromonas septicemia. *Morone* reared in intensive systems are susceptible to mycobacteriosis (usually *Mycobacterium marinum*). Clinical signs include dark coloration, hemorrhaging in the skin, pale and granulanatous livers, as well as granulomas in the spleen, heart, kidney, and mesenteries.

Fish with any of the aforementioned diseases may also be afflicted with fungal diseases. White, cottony growths on their bodies is the classic sign of fungal disease.

Flagellated and ciliated protozoan ectoparasites can infect all *Morone* species and hybrids. Ichthyophthiriasis ("Ich") is the most problematic of these parasites. Clinical signs include small white spots on skin and gills, lethargy, gasping at the water surface, and excessive production of mucus. All protozoan parasites tend to cause discomfort and lethargy, and fish may go off feed.

Morone are also subject to being parasitized by gillworms, grubs, nematodes, crustaceans, and so forth. These are usually not life threatening, although grubs can render the fish unusable to human consumers.

Standard therapeutic treatments used in other fish are effective for *Morone*. However, in the United States there are no therapeutics approved by the U.S. Food and Drug Administration for *Morone*. Salt and Formalin F are commonly used to treat parasites. The producer is referred to veterinarians for all other treatments.

ECONOMICS AND MARKETING

Operating Costs

Once the production system and major equipment are in place, operating costs will primarily consist of cost for stocking (or hatchery production), feed, labor, utilities, and water-quality monitoring. Fry can be purchased for about US$0.01 each, while feed-trained fingerlings cost from US$0.15 to US$0.25, depending on quantity. Feed costs will range from US$0.44 to US$0.66/kg (US$0.20 to US$0.30/lb). An enterprise budget for a new 24 ha (60 acre) pond operation for hybrid striped bass is presented in Hodson (19), which is based on a US$1,000,000 beginning balance (US$250,000 equity and US$750,000 bank loan financed at 11% for 20 years). Once the first harvest is sold, monies from fish sales meet all fixed and variable costs and a positive balance occurs by the third year.

Marketing

Hybrid striped bass and striped bass appear to be equally acceptable in the marketplace. Even with the recent rebounding of the wild-striped bass fishery, the wholesale price of aquacultured fish has only slightly declined. Prices, on average, range from US$5.50 to US$7.70/kg (US$2.50 to US$3.50/lb) for whole fish on ice. Producers have not reported problems with respect to selling their product.

CONCLUSION

The commercial aquaculture of *Morone* has greatly advanced over the past decade. Hybrid striped bass are currently raised in many parts of the United States and also in many other areas of the world. The hybrid, in particular, is poised to become a global seafood delicacy in the twenty-first century.

SUMMER FLOUNDER CULTURE

DAVID A. BENGTSON
University of Rhode Island
Kingston, Rhode Island

GEORGE NARDI
GreatBay Aquafarms
Portsmouth, New Hampshire

OUTLINE

The summer flounder, or fluke, (*Paralichthys dentatus*) is a "left-handed" flounder (both eyes are on the left side) that ranges from Maine to Florida along the east coast of the United States. Commercial landings of this species have been in decline since the 1950s. The U.S. government has been funding research and development for aquaculture of summer flounder since 1990, and commercial hatchery production began in 1996. The biologically similar turbot (*Scophthalmus maximus*) is commercially cultured in Europe, and the
Figure 1. Commercial landings of summer flounder on the East Coast of the United States, 1950–1996 (National Marine Fisheries Service, 1998).

congeneric Japanese (or olive) flounder (*Paralichthys olivaceus*) is commercially cultured in Asia, extensively in public hatcheries for stock enhancement in Japan. Thus, successful models already existed for commercial culture of left-handed flounders and some techniques for rearing those species were readily adaptable to the culture of summer flounder.

The first attempts to spawn and raise summer flounder for both research and as a potential aquaculture candidate occurred in the 1970s (1,2). However, landings in the mid-1970s were close to the 1950s highs, so the need for cultured flounder was not yet apparent. In addition, rearing of larval marine fish was in its infancy at that time and the considerable advances that took place, primarily in Japan and Europe, in the 1970s to 1990s were necessary before the culture of summer flounder could take off. The U.S. National Marine Fisheries Service, through its Saltonstall–Kennedy grants program, funded the initial research in the early to mid-1990s that led to GreatBay Aquafarms establishing itself as the first commercial summer flounder hatchery and Mariculture Technologies establishing itself as the first commercial summer flounder growout facility. The

U.S. Department of Commerce, through its Sea Grant program, and the Department of Agriculture, through its Northeastern Regional Aquaculture Center, also began funding important summer flounder aquaculture research in the mid-1990s. At the moment, two hatcheries are in operation, along with four growout facilities. Thus, both the research and the production techniques described herein are in their nascent stages, compared with those of more established species like turbot and Japanese flounder. The research and development of the industry has recently been reviewed elsewhere (3).

BROODSTOCK

To this point, only wild-caught broodstock fish have been used for both research and commercial production. The hatcheries are in the process of domesticating broodstock and beginning selection programs. When captured broodstock are brought in to the hatchery, they require a few weeks to adapt to the tanks and begin feeding on nonliving food (either frozen fish or squid or pelleted diets). It seems best to allow them several months in the tank before spawning induction is attempted. Because
Figure 2. Broodstock summer flounder used for commercial production.

the species spawns during autumn, the environmental cues required for spawning are temperatures less than 18 °C (65 °F) and photoperiod less than 12 hours of light. It has been possible to induce spawning of lab-held broodstock fish in all months of the year by manipulation of environmental cues in association with hormonal manipulations. Once the female fish have gone through hormonal manipulation in the hatchery, they sometimes ripen in response to the environmental cues alone. A recent experiment (4) indicated that females will not ripen in response to environmental cues alone even after they have been in the hatchery for one year. On the other hand, males can be brought into ripe condition by manipulation of environmental cues only after one year in the hatchery.

Hormonal manipulation with injections of carp pituitary extract, originally described by Smigielski (1), has continued to be the most effective inducer of female spawning (5,6). However, the requirement for multiple injections (usually 2 mg/kg/d or 3.2×10^{-5} oz/lb/d) places great stress on the fish. Slow-release implants of GnRHa have therefore been used and are effective as long as the oocytes are greater than about 0.5–0.6 mm (2–2.4×10^{-2} in.) in diameter at the time of implantation (5).

Current spawning methods involve hand-stripping of the ripe fish, which is stressful to them and does not necessarily yield the highest quality eggs. Therefore, development of methods for volitional spawning are a top priority for research. Based on work with Japanese flounder, it is believed that volitional spawning requires stocking broodfish at very low densities; therefore, it is important to know that the fish chosen have the potential

to produce quality eggs and sperm. Another area of priority research is broodstock nutrition, about which we know nothing. The tendency is still to feed broodstock on a diet of frozen fish and squid. Anecdotal information suggests that egg and larval quality may be related to dietary changes.

HATCHERY TECHNIQUES

Fertilization and Incubation of Embryos

Milt stripped from males is usually not very abundant and is often collected by pipette so that contact of the sperm with seawater is avoided and the sperm are not activated (sperm are active for only about two minutes after seawater activation). A small amount is examined by microscope to verify sperm motility, and the full quantity is maintained dry (i.e., without addition of seawater) in a beaker on ice until the eggs are obtained. Small samples of eggs are also examined to determine their quality. Good-quality eggs are spherical and float; poor quality eggs may be misshapen and sink. Eggs judged worthy of fertilization are stripped from females into a dry basin or beaker. A female releases tens to hundreds of thousands of eggs. After a sufficient quantity of eggs has been obtained, seawater is finally added to the milt, which is then added to the eggs. The gametes are thoroughly mixed and allowed to settle for several minutes, during which time fertilization takes place. The embryos are then suspended in 34 (ppt) seawater in a cylindrical or cylindro-conical container in order to separate floating (good) eggs from sinking (bad) eggs. Frequent removal of the bad eggs will reduce the substrate for bacterial buildup and decomposition. Alternatively, one can transfer the good eggs to new vessels with clean seawater at frequent intervals. In any case, the embryo incubation period is relatively short and the larvae will hatch in about 60 hours at an incubation temperature of about 20 °C (68 °F). Although hatching is delayed by up to 12 hours, there is anecdotal evidence that larvae hatch more uniformly and are more vigorous when incubated at 16–17 °C (61–63 °F).

Larvae

Larvae are very rudimentary at hatching, with neither fully developed eyes nor digestive tracts. They exhibit very little swimming activity during the first two days and are normally observed hanging head down in the water column. Larvae can be readily transferred from their incubation vessels to rearing tanks up to 2 days after hatch (DAH). Optimal stocking density appears to be in the range of 20–30 larvae/L (75–115 larvae/gal) (6,7). Larvae survive better in conditions of "green-water" rearing (i.e., with algae added to the tanks) than in conditions of "clear-water" rearing (no algae) (8). The eyes and digestive tract are sufficiently developed by 3 DAH that the larvae can begin feeding on rotifers (*Brachionus plicatilis*) (9). The larvae reach the "point of no return" by 6 DAH (at 21 °C, 70 °F) to 11–12 DAH (at 12 °C, 54 °F) if they do not receive food (10). Particularly at high densities, the larvae may suffer severe mortality during the first 10 DAH, but that mortality is due to rearing conditions, rather than inability to initiate feeding. Alves et al. (11) demonstrated that replicate batches of larvae showed high variability in mortality among rearing chambers, but that all were feeding well up to the time of mortality. The tank microbiological environment most likely changes as feed types are changed. This change may introduce or provide the opportunity for opportunistic bacteria that stress or contribute to tank mortality. An increase in mortality is often seen during and following the transition of the fish from rotifers to brine shrimp nauplii (*Artemia* sp.) and then to a dry diet. The change in food is accompanied by a change in the bacteria associated with that food, thus exposing the fish to new microbes during a time of nutritional and physiological stress. Current probiotic research is oriented toward influencing the microbial fauna associated with the feeds, particularly the rotifers and *Artemia* sp., in a way that benefits the fish. Larvae can be reared at a wide range of salinities, although their tolerance to rapid changes in salinity varies greatly with age; and larvae grow better at 14 (ppt) than at 38 (ppt) (12). At the age of about 15–20 DAH, larvae can begin to ingest brine shrimp nauplii (*Artemia* sp.), so a combination of rotifers and brine shrimp is provided to them for a period of about one week. Feeding rates have been shown to increase from about 50 rotifers/larva/day at 6 DAH to about 300 rotifers/larva/day at 13 DAH and from about 50 brine shrimp/larva/day at 23 DAH to about 400 brine shrimp/larva/day at 47 DAH (13). Because those food consumption estimates were obtained in experiments with a 12L : 12D light regime and we assume that the larvae are capable of visually feeding only in the light, it would be wise to double the estimates of food consumption for larvae reared in constant light, as is the practice at GreatBay Aquafarms. As the larvae grow, they change from thin, elongated rudimentary larvae to deeper-bodied, bilaterally compressed larvae with more complex organ systems. About 4–5 weeks after hatch, they undergo the process of metamorphosis that ends the larval stage.

Metamorphosis

Metamorphosis in flatfish is one of the most spectacular examples of body reorganization among the vertebrates. In the case of summer flounder, the right eye migrates across the midline of the body to its juvenile position on the left side of the head, and the fish is transformed from a bilaterally symmetrical swimming larva to an asymmetrical settled juvenile. Meanwhile, the fins attain their juvenile configuration, and the digestive tract completes its development with the formation of a stomach. The process of metamorphosis, divided
Figure 7. Summer flounder larva with yolk sac.
Figure 8. Summer flounder larva nearing metamorphosis.

into stages of premetamorphosis, prometamorphosis, and metamorphic climax, is primarily under the control of the thyroid hormone and is highly correlated with growth rate (14); thus, fast-growing larvae metamorphose and settle to the bottom earlier than do slow-growing larvae. The result is that settlement of the juveniles occurs from about 35 DAH to about 65 DAH, and the wide range of sizes is conducive to cannibalism if grading is not performed. Francis (15) found that juveniles of about 55 mm ($2\frac{1}{4}$ in.) length could consume siblings up to about 40% of their own size. At both laboratory and commercial hatchery scale, one method of grading is simply to remove settled fish from the larval rearing tanks on a weekly basis and to place them in juvenile rearing tanks. Removal by siphoning is an effective technique, but a bit tedious and not 100% successful. One modification to the technique is to drain the tank into a larval collector or remove the swimming larvae with a bucket after a few days of thinning the tank by siphoning.

The development of a stomach during metamorphosis allows the fish to be weaned from live feed to commercially available formulated diets. Prior to metamorphosis, the larvae are unable to survive on formulated diets (16). Treatment of larvae with exogenous thyroid hormone accelerates development of the stomach (17), but larvae treated this way are still unable to survive any better on

formulated diets than are untreated larvae (16). Weaning appears to be more successful the longer the start of weaning can be delayed and the longer the duration of the weaning period (8). Nevertheless, weaning is still a period of unacceptably high mortality, and there is plenty of opportunity for research on both diet formulation and behavioral strategies to induce fish to consume the formulated diets. King et al. (18) recently found that 50% or 55% protein diets yielded better survival and growth during weaning than did a 45% protein diet.

NURSERY AND TRANSITION TO GROWOUT

Once the juvenile flounders have been weaned onto an artificial diet and reach a size of approximately 2 g (7.1×10^{-2} oz), they can be easily netted and graded into larger nursery tanks. At this stage the fish grow rapidly and care must be taken to manage the fish through the system, being sure to have available empty tanks into which the fish can be graded and moved as the densities increase. A simple box grader that floats in the tank works well with fish from about 2–5 g (7.1×10^{-2}–1.8×10^{-1} oz). After this size, a grading table may be more efficient. Commercial automatic graders for flatfish have recently debuted. Fish may have to be graded up to 3 times between the size of 2 and 10 grams (7.1×10^{-2} oz and 3.6×10^{-1} oz).

The nursery system may be either recirculating or flow-through with the choice being determined by the attributes of the site, regulatory climate, and economics. Either system will work well. Tanks may range from 3–6 m³ (105–210 ft³) and be of varying design: round, square, or raceways with rounded corners (D-ended). The tanks should be cleaned regularly and uneaten feed and feces removed as quickly as possible. Use of a self-cleaning tank design and drain system is advisable. Flounder, by virtue of their swimming on the bottom, help to move solids toward the drain. Oxygen levels in excess of 5 ppm should be maintained, preferably as close to 100% saturation as possible. Un-ionized ammonia should also be kept <0.015 ppm and nitrite <5 ppm. As a rule, saltwater fish are much more tolerant of nitrite than freshwater fish are. Salinity may range from 15 ppt to full strength at

Figure 9. Juvenile summer flounder in nursery tank.

35 ppt. Research is ongoing to evaluate whether these fish can be cultured in salinities less than 15 ppt, possibly less than 10 ppt. Other environmental criteria, such as alkalinity, turbidity, pH, CO_2, or heavy metals will be based on system technology employed, i.e., recirculating vs. flow-through and site-specific criteria. Some mode of culture water disinfection should also be employed, such as ultraviolet light.

As with other species of marine flatfish, such as turbot or Japanese flounder, the young fish are fed more frequently than older or larger fish. The 2 g (7.1×10^{-2} oz) fish may be fed to satiation up to 6 times per day, while a 10 g (3.6×10^{-1} oz) fish may be fed 4 times per day. Protein content of the feed should be 50% or better, while fat content should be <20%. Common marine fish diets range from 50 to 62% protein and from 11 to 19% fat. The protein is best if derived from fish and be >94% digestible. Weaning or starter diets may start at 300 microns (1.2×10^{-4} in.) in size and progress up through to a 2- to 3-mm (1/8 in.) pellet when the fish reach 5 g (1.8×10^{-1} oz). Summer flounder have a large mouth and prefer large pellets. By efficient grading, a fish culturist can maximize feeding efficiency by feeding the largest possible pellet acceptable to the population of the tank. At 20 °C (68 °F), one can expect to produce a 5 g (1.8×10^{-1} oz) fingerling in five months, at which point they could be transferred to a growout operation.

GROWOUT

The growout of summer flounder is in its infancy and optimum systems and procedures have not yet been established. Both recirculation systems and net pens are currently being investigated by different companies, some of which have received funding from the U.S. government for these demonstration projects. The fish seem to survive and grow well in both systems, but the demonstrations are ongoing and comparative data on biological and economic performance are not yet available. Comparisons of interest include (a) the growth performance and product quality of fish reared in more or less constant conditions in a land-based recirculation facility vs. those of fish reared in the highly variable temperature in a net pen and (b) the qualitative and quantitative differences in costs of production for the different systems. Researchers funded by the Northeastern Regional Aquaculture Center (NRAC) in the United States are currently assessing the survival, growth, behavior, and health of summer flounder reared in net pens with those of fish reared in recirculation systems. As of this writing, fish have not been maintained throughout the winter in net pens.

Specific environmental requirements are not known, but it seems likely that optimal growth will be obtained at temperatures around 20 °C (68 °F), which are characteristic of coastal waters in the northeastern U.S. during summer months. Growth at 10, 20, or 30 ppt salinity seems to be equivalent, at least for early juveniles (19). Since no specific summer flounder diets exist, fish in growout facilities are being fed diets similar in composition to those for turbot (50–55% protein, 12–20% fat). NRAC-funded research is also under way to identify nutritional

Figure 10. Recirculation system growout tank for summer flounder.

requirements of summer flounder and food conversion ratios (dry weight of feed offered/wet weight gain) of about 1.4 are being measured in those studies. Growth data on laboratory-reared summer flounder in a variety of laboratory-scale and production-scale systems over the years indicate that summer flounder exhibit growth rates very similar to those of turbot (19,20) (GreatBay Aquafarms, unpublished data; R. Link, Mariculture Technologies, personal communication). Thus, the average time for growth to market size is expected to be 24–28 months, at least prior to selective breeding programs, which may reduce that time. As this is being written, no cultured summer flounder have yet been brought to market. Fish currently being grown are targeted at the live and freshly killed markets for Asian and Asian-American consumers.

SUMMARY AND FUTURE EXPECTATIONS

The U.S. government funded both research and demonstration projects for the development of a summer flounder aquaculture industry during the 1990s. That investment has resulted in several fledgling companies engaged in summer flounder production, so far employing relatively few people. Knowledge gained from the turbot and Japanese flounder industries has been applicable to summer flounder production and has aided the rapid development of the industry. It is noteworthy that most of the companies involved in production include personnel who are making the transition from commercial fishing to fish farming. That trend may very well continue as the industry grows and increasingly strict limitations are placed on capture fisheries.

Hatchery production is reasonably stable, although continued research is necessary to reduce mortality and to bring down the costs of production. Problems of weaning and cannibalism at the nursery stage remain to be overcome and will also require more research. Growout production has not yet been well studied and the greatest amount of future research should be concentrated on this production phase, particularly in the areas of selective breeding and health management (e.g., breeding for rapid growth and disease resistance, and development of vaccines and diagnostic techniques).

The economics of production are still a question mark. The current costs of production require sale of product to the very expensive live and freshly killed markets. The size of that market and the acceptance of cultured products by the market have only been estimated at this point (21). The number of companies presently producing summer flounder or building production capabilities may be able to supply that market if they all reach projected production capacity. In the long term, production costs need to be brought down to the point where summer flounder can be produced for the U.S. retail filet market and for restaurants. The industry should establish a marketing strategy to identify cultured summer flounder as a high quality, safe, fresh seafood product that is continuously available at a reasonable price, not subject to seasonal variation in price and quality. With the continuing crisis in the world's fisheries and consumer demand for a well-accepted product like flounder, the future for the summer flounder industry should be bright.

INTRODUCTION

The Sunfish Family (Centrarchidae) includes 30 species (1) and is limited exclusively to North America. This family comprises the black bass (*Micropterus* spp.), crappie (*Pomoxis* spp.), and the bream (*Lepomis* spp.), as well as the genera *Amboplites*, *Elassoma*, *Enneacanthus*, *Centrarchus*, *Archoplites*, and *Acantharcus*. This family, especially the black bass, crappie, and bream, represents one of the most popular and widely known game fish groups in North America. Sunfish are widely sought by anglers because of their fierce tenacity when caught by hook and line; their firm, white flesh; and their favored status as "bread-and-butter fish" (2). In addition to their utility as sport and food fish, the lepomid sunfish species

are generally stocked as forage fish for predators such as bass in impounded waters. Few North American anglers are not familiar with these fish, and thus, their appeal and recognition are broad based. Bass, crappie, and bream have been cultured for the past 50 years primarily to provide fingerlings for stocking recreational ponds and lakes or for use in research. Recently, however, there is an increasing interest in culturing these fishes for human consumption and for use in fee-fishing operations. This entry addresses only the culture of species from the genus *Lepomis*, commonly referred to as bream, sunfish, sun perch, or simply panfish (see the entries "Black bass/largemouth bass culture" and "Crappie culture" for information on other members of the sunfish family).

SPECIES PROFILES

There are 11 species in the genus *Lepomis*, but only the bluegill (*L. macrochirus*), redear sunfish (*L. microlophus*), warmouth (*L. gulosus*), green sunfish (*L. cyanellus*), and their hybrids have been widely cultured as sportfishes. The centrarchids are perciform fish and thus, characteristically, have a spiny dorsal fin (with 6–13 spines), followed by a soft dorsal fin. The anal fin has at least 3 spiny rays at its origin, followed by numerous soft rays. The pelvic fins are located immediately beneath the pectoral fins and contain one spine and 5 soft rays. The caudal fin has 17 principal rays. Proper identification is critical to successful production, since the genus *Lepomis* readily hybridizes (3). The species profiles that follow are adapted from Etnier and Starnes (1).

Bluegill

The bluegill may be the most well known of all the sunfishes and is certainly the most popular with anglers and consumers alike. Originally distributed from the Great Lakes south to the Gulf of Mexico, it has been stocked throughout North America as a game fish. It is equally at home in lakes or streams, but is most abundant in shallow, eutrophic lakes and ponds. The bluegill is identified by its deep, laterally compressed head and body, and small mouth. The opercular flap is black, and individuals longer than 51 mm (2 in.) exhibit a dark blotch at the posterior base of the dorsal fin. The sides usually exhibit 8–10 sets of double-vertical bars that are chainlike in appearance. Body colors range from olivaceous to purple, with a white to orange belly.

Redear

The redear, like the bluegill, has been widely introduced throughout much of the United States and, perhaps, North America as a game fish and a companion to the bluegill in managed systems. Known by several common names such as "shellcracker" and "chinquapin," the redear prefers sluggish waters. It is identified by its olive-yellow to straw-yellow body with gray or dusky spots. The breast is bright yellow to orange, and the opercular flap is short with a distinct scarlet outside margin or spot.

Warmouth

The warmouth, also commonly called "goggle-eye" is an inhabitant of sluggish waters, typically preferring weedy structure or other debris such as logs, stumps, and brush piles. This species has not been widely used for stocking recreational waters, but is a common component of the panfish angler's creel in areas where it is abundant. Its primary importance to aquaculture has been in production of hybrids with the other primary species. It exhibits a dark olivaceous to brown body, with dark splotches on the sides and fins. The cheeks and opercula have 3–4 dark bars radiating posteriorly from the eye, and the eye is often reddish. The mouth is larger than that of the bluegill and the redear, and the body is not as dramatically laterally compressed as these species.

Green Sunfish

The green sunfish may be one of the most adaptable, abundant, and environmentally tolerant of the sunfishes, being found in a wide variety of habitats ranging from ponds and lakes to river systems. Characteristic colors of the green sunfish include a blue-green to dusky dorsum and sides, with a yellow to white belly. A dark basal spot is usually present on the posterior base of the dorsal fin. All fins are yellow to orange tinted, with occasional bright orange areas and white margins. Green sunfish are known to hybridize readily with other *Lepomis* species (3,4).

SUNFISH REPRODUCTIVE HABITS

An understanding of the reproductive habits of the lepomid sunfishes is vital to the successful production of fingerlings destined either for stocking recreational waters or for culture to adult stages. Breder (5) was perhaps the first scientist to observe and report extensively on the courtship and reproductive behavior of these fishes. Since that time, it has been clearly confirmed that sunfish are, in general, colonial nestbuilders and multiple spawners. Spawning begins in early to midspring and continues, to some degree, until early fall, depending upon the species and the geographic location (1,2,5–7). The general courtship ritual and nesting behavior are similar for all lepomids, with slight variations by species.

When the temperature first reaches the preferred range for the respective species, the male typically prepares a nest in shallow water. The depth at which these nests are constructed depends upon water temperature, which in turn depends greatly upon the time of year. In general, nesting will occur first in the warm shallows in early spring, and nesting activity will gradually migrate toward deeper waters (up to 2 m, 6 ft) as the shallows become progressively warmer. Nest building is done primarily by sweeping or fanning the caudal peduncle across a sandy or gravelly substrate to form a saucerlike depression, ranging from 51 mm (2 in.) to 156 mm (6 in.) deep and 101 mm (4 in.) to 303 mm (12 in.) in diameter, depending upon the size of the male. These sunfishes are colonial nesters (8) and a single colony, often called a "bed" by anglers, may contain as many as five dozen nests and cover several dozen square meters (1 square m = 10.8 square ft).

Once nests are constructed, the courtship ritual begins. The males, which are usually the more brightly colored gender, initiate a complex circling behavior around the perimeter of the nest, usually accompanied by a series of gruntlike calls (1,8–10). Females are attracted to the nest by the male and, after a short response ritual, deposit their eggs and depart. The males fertilize the eggs by releasing milt across the egg mass and then vigorously and aggressively defend the nest from invading predators, periodically fanning the nest to aerate the eggs. Egg incubation takes 1–6 days at temperatures above 21 °C (70 °F) (11,12).

BROODSTOCK

Broodstock selection is a critical step in the production of sunfish and their hybrids. Improper identification of the broodfish can lead to contaminated stocks of offspring, since these fish readily hybridize (3,13). Proper identification of both sexes is vital to successfully producing the desired offspring. Bluegill and green sunfish males in breeding condition are easily distinguished from females, but redears and warmouth sexes are more difficult to differentiate. Usually, experienced culturists can visually distinguish males from females based solely upon external characteristics such as color, body shape or size, distension of the abdomen due to enlarged ovaries, or on the size and shape of the urogenital sinus (14). Additionally, eggs or milt can usually be freely expressed from ripe broodstock. However, broodstock often are not ripe at the time of stocking and identification, so other methods have proven useful. Dupree and Huner (13) described a simple method of probing for eggs by using a 5–10 cm (2–4 in.) long capillary tube that is 1.1–1.2 mm (0.04–0.05 in.) in diameter. The tube is inserted into the urogenital sinus, then angled slightly back toward the tail and slightly to one side. With the application of light pressure, the tube passes through the oviduct into the ovary. A finger is then placed on the open end of the tube to seal the tube before it is removed for inspection. If no eggs are retrieved, the fish should be rejected as a broodfish. This is a simple procedure, but must be done with care to avoid damage to the fish.

Handling fish can be stressful to them, and every attempt should be made to reduce handling stress. In general, broodstock should be handled in cool water, which is conveniently available during the stocking season (late winter–early spring). Fish should be handled as little as possible, sedated when practical, and transported in well-oxygenated tanks. Thermal shock should be avoided at all costs. Ideally, sexes should be kept separate until the time for stocking into spawning ponds (13). This approach allows broodstock to be sexed in advance and held for a period of time in conditioning ponds to prepare them for spawning, eliminating or at least minimizing stressful handling, sexing, and sorting immediately prior to the spawning season.

Bluegills and redears should be at least two years old and 110 to 225 g (0.25 to 0.5 lb) for maximum productivity (15), while warmouth and green sunfish will spawn at much smaller sizes. Smaller bluegills and redears will spawn, but stocking rates should be increased to compensate for reduced fecundity and greater variability of spawn size, consistency; and success (15). Most culturists agree that broodstock should be stocked in the winter or at least by early spring (15,16) at the rate of 50–100 pairs/ha (20–40 pairs/ac). Sex ratios of broodfish in spawning ponds are typically 1:1 (14,17). Supplemental feeding of broodstock with a floating pellet is desirable as soon as the water temperature reaches a level where feeding activity is stimulated. Feeding rate should be 2–3% of body weight/day (14,15).

POND PREPARATION

Sunfish can be produced in many types of facilities and are often spawned in laboratory settings for research purposes (14,18,19). Most culture, however, is practiced in ponds of varying sizes, utilizing either open ponds or cages. In general, spawning ponds should be 0.6 to 1.5 m (2–5 ft) deep, with a smooth, uniformly sloped bottom to facilitate harvest of fingerlings. Pond size should be less than 1.2 ha (3 ac), although larger ponds have been successfully used. Drainpipes allow manipulation of water levels, and a water source (preferably ground water) is necessary to fill ponds and replace evaporative losses. Higginbotham (15) recommended that ponds be filled with well water at least 2–4 weeks prior to initiation of spawning activity. Ponds should be completely free of other fish species. Failure to completely remove resident fish populations is a common mistake that spells disaster for hatchery production. The presence of other sunfish can pose the risks of both hybridization and depredation, while the presence of other piscivorous species poses risk of depredation of the fingerlings and loss of a potential crop of fish. A plankton bloom should be established prior to spawning activity, using either inorganic or organic fertilizers, or some combination of the two (18).

Once water temperatures reach appropriate levels, spawning will be initiated. Warmouth and green sunfish are the first to commence spawning, with activity beginning at 21 °C (70 °F). Redear begin spawning when water temperatures reach 24 °C (75 °F), while bluegills do not spawn until temperatures reach 26–27 °C (78–80 °F) (4). Nest-building and territorial behavior for all species will commence at temperatures several degrees lower than optimum spawning temperature.

SPAWNING TECHNIQUES AND FINGERLING PRODUCTION

Except for limited manual stripping of gametes and laboratory fertilization, sunfish spawning in culture systems is done almost exclusively in ponds or other extensive facilities. Childers and Bennet (21) manually stripped gametes into petri dishes, mixing milt and eggs with water to accomplish fertilization. Fertilized eggs were placed into clean petri dishes containing aged tap water for water hardening. Fertilized eggs were then placed into aerated aquaria. When larvae became free-swimming

fry, they were transferred to rearing ponds. Toetz (22) conducted detailed studies on larval rearing of bluegill, reporting up to 79% hatch from a procedure modified from that of Childers and Bennett (21). Several investigators have successfully induced spawning in the laboratory or under simulated field conditions by manipulating temperature and photoperiod (14,21,23−26).

In pond spawning systems, broodstock are allowed to free spawn in ponds. Production of up to 375,000 fry/100 broodfish can be obtained, with an average of about 247,000 fry/ha (100,000 fry/a) (14,15). Once optimum conditions of temperature have been reached, and with good water quality, broodfish should produce offspring almost immediately. Fry should be observable soon after hatching, and a feeding program should be initiated. A fry powder or mash should be offered initially; then, as fry grow, the size of feed particles can be matched to size of the fish. With a feeding program, initial growth of up to about 2.5 cm (1 in.) per month can be obtained, with fingerlings reaching stocker size of 51−76 mm (2−3 in.) in 60−100 days (15).

HARVEST AND MARKETING

Harvest of small (<2.5 cm; 1 in.) sunfish is stressful to the fish, and thus most producers do not attempt harvest until the fish reach an average of 50 mm (2 in.). This is the most commonly stocked size for bluegills, redears, and sunfish hybrids. Transport for stocking purposes is usually delayed until the fall months when prevailing low water temperatures help minimize stress that may rise during handling and shipping. This also corresponds with the recommended time frame for stocking sunfish into small impoundments for recreational fishing (27−29).

Traditionally, sunfish have been cultured almost exclusively to produce fingerlings for stocking natural and manmade waters to enhance recreational fishing (14,16). Bluegills and redear sunfish have been the mainstay forage species stocked in combination with largemouth bass in small impoundments throughout much of the United State (30,31), providing not only forage, but also excellent sportfishing as well. Thus, most culture systems have concentrated upon fingerling production. These markets continue to expand, as the interest in recreational fisheries management, on both public and private waters, increases. Until recently, through various state and federal fish stocking programs (31), most state and federal hatcheries produced large numbers of sunfish for public distribution. However, increasing numbers of private hatcheries have developed which specialize in the production of game fish for stocking purposes. Simultaneously, many public hatcheries and state agencies have reduced or eliminated their programs for producing and distributing game fish to the public.

Recently, aquaculture interest in these fishes has expanded to include potential use as foodfish for human consumption (32) and for use in fee-fishing operations (33). Production of sunfish and their hybrids for human consumption will require culture of these fishes to adult sizes suitable for marketing to consumers, as well as conformity to several marketing criteria such as appearance, texture, flavor, and consumer recognition (34). Bluegill and redear, as well as at least a couple of sunfish hybrids, have a favorable combination of flavor, texture, firm, flaky, low-fat flesh (16) with good storage qualities (2), and strong consumer recognition and acceptance. Other considerations for sunfish as a marketable foodfish include biological criteria such as temperature and water quality requirements (35), growth rates (36−38), trainability to manufactured feeds (39−41), and fecundity and ease of spawning in captivity (17,23). The lepomids, in general, all meet these criteria. Specifically, bluegill and bluegill hybrids appear to best meet considerations for culture to adult sizes. The most common hybrid is the male bluegill X female green sunfish, which has a desirably high male : female sex ratio in the F1 generation. Other hybrids may hold potential despite variable sex ratios if techniques such as ploidy manipulation (42) can be perfected.

The interest in sunfishes and their hybrids as aquaculture foodfish candidates or for use in fee-fishing operations as an alternative to channel catfish has stimulated development of another production and marketing scenario. In this scenario, fingerlings would presumably be stocked at high densities, fed a manufactured feed, and grown to adult sizes suitable for marketing as foodfish (225−340+ g or 0.5−0.75+ lb) or to a minimum acceptable catch size of 110 g (0.25 lb) (43). Limited work has been conducted to define the potential that these fishes possess for these markets, but preliminary results appear promising. More emphasis has been placed on the culture of hybrids for this purpose (33,37,40) than for pure species populations, but it is anticipated that increasing consumer interest, especially in bluegills, will stimulate additional research into the propagation of these fishes for nontraditional markets. Research is needed in larval nutrition and in development of appropriate, economical growout procedures.

OUTLINE

The Sustainability Concept
Aquaculture Sustainability
Bibliography

The term "sustainability" is widely utilized with respect to the management and conservation of natural resources. One frequently hears the term used in conjunction with agriculture, fisheries, and, increasingly, aquaculture. Sustainability involves the establishment of production systems that can exist, at least theoretically, in perpetuity. There are various perceptions as to how sustainability can be achieved, but in most instances the concept is associated with limited inputs of nonrenewable resources.

THE SUSTAINABILITY CONCEPT

Sustainability is one of the buzz words of the 1990s. The concept is visualized in different ways by its proponents, with one of the most thoughtful definitions being put forward in a 1991 meeting (1) of the Food and Agriculture Organization (FAO) of the United Nations. The FAO definition of "sustainable development" involves the management and conservation of the natural resources of the world with an "orientation of technological and institution change in such a manner as to ensure the attainment and continued satisfaction of human needs for present and future generations." FAO goes on to indicate that such development will conserve "land, water, plant and animal genetic resources, is environmentally non-degrading, technically appropriate, economically viable and socially acceptable."

The concept of sustainability has been widely discussed with respect to agriculture, including forestry. The U.S. Department of Commerce's National Marine Fisheries Service has as one of its primary objectives building sustainable fisheries. This is in response to the collapse or declines in fish standing stocks due in large part to overfishing. There is increasing interest in how aquaculture can be developed in a more sustainable manner, and a book on the subject has been published (2). One aquaculturist defined "sustainable aquaculture" as that which leads to production of a crop with no net loss of natural resources (3).

AQUACULTURE SUSTAINABILITY

Total conservation of natural resources may be achievable in low intensity aquaculture operations. For example, subsistence culture, which provides a relatively safe place, such as a small pond, for the culture species to exist meets the sustainability objectives if it does not

include the use of inorganic fertilizers or prepared feeds. Subsistence aquaculturists often use organic fertilizers (manures, including night soil) and may feed agricultural waste products to supplement nutrition. Production levels are modest, ponds tend to be small, and water is supplied by runoff, springs, or surface water diversion. There is no pumping, aeration, or other use of electricity or fossil fuels.

Somewhat in parallel are extensive mollusc culture systems, such as those used for rearing oysters, which use natural reproduction to provide the young oysters and natural food (phytoplankton in the water column) to provide nutrition. The culturist may move young oysters from the location where spat settling occurred to another location for growout and may employ some type of predator control, but supplemental feeds are not used and water quality is not managed.

Most other forms of aquaculture require modest to significant inputs of natural resources, some of which are not renewable, such as the energy obtained from petroleum. The more intensive the system, the more inputs of resources it requires. For example, a pond system stocked at moderate density and receiving supplemental feed and sufficient inputs of water (which may or may not be pumped) to replace evaporation and seepage losses (see the entry "Pond culture") is clearly operating in a more sustainable manner than a closed recirculating water system that requires constant inputs of energy and the provision of complete feeds. (See the entry "Recirculating water systems.")

Developing culture systems that require significant infusions of natural resources may actually result in a net utilization of those resources. Rearing fish in a closed system within a metropolitan area will obviate the need for hauling the product long distances to market. Fuel, icing down or freezing a product, and refrigerating the trucks used to haul it represent net losses in natural resources that may offset, at least partially, added utilization of natural resources operating closed culture systems located close to the market. With increasingly heavy demands on land and water, along with the need to maximize production per unit volume of water, pressure to further intensify production from aquaculture facilities, particularly in developed nations is growing. Increased intensity is typically not compatible with increased sustainability because of socioeconomics. Balancing the goal of increasing sustainability with the need to generate a reasonable profit will continue to challenge aquaculturists.

It is often argued that aquaculturists should not employ high quality protein sources such as fish meal to produce other fish because the fish meal could be used more directly as human food. Some species that are currently used solely as sources of fish meal could be processed into surimi analogs (e.g., artificial crab), but the demand is not currently sufficient to warrant a major change in the approach to processing.

During the 1970s, the processing of low-priced fish (such as those used in fish meal) into fish protein concentrate (FPC), which was a tasteless white protein-rich powder grew. Adding one to two ounces (30 to 60 g) of FPC to a person's diet daily quickly overcame problems associated with malnutrition. FPC was promoted by the United States in its international development programs, but was abandoned when use of the product was banned in the United States (because it was made from whole fish). Developing countries became suspicious about a product that was illegal in the nation of origin.

Fish meal (and other animal proteins such as meat and bone meal) contain essential amino acid levels that cannot be matched by most plant proteins; therefore, many aquatic species animal proteins or plant proteins supplemented with purified amino acids are necessary in feed formulations. Research continues to find alternative plant proteins or feed formulations that will meet the nutritional requirements of various aquatic species while reducing or eliminating the need for animal protein. One example of a success utilizing that approach is the feed currently employed for the culture of channel catfish. A few decades ago much of the protein in catfish growout feeds came from fish meal. By the 1980s, fish meal content had been reduced to about 15%. Today, catfish in Mississippi are typically fed rations containing no more than 4% fish meal once the fish reach the advanced fingerling stage. Fry and small fingerlings have higher protein and amino acid requirements that can only be met with animal proteins.

Marine enhancement programs and ocean ranching move away from totally captive rearing to at least partial production that depends on resources available in nature. Reproduction and early rearing occur in hatcheries; but once the fish reach a size at which they have a reasonable chance for survival on their own, they are released into the natural environment for later capture. Input of some natural resources is greatly reduced as the bulk of the life cycle occurs in the wild, not in a culture facility.

Animals released for enhancement purposes will consume higher weights of food to reach the same size as their counterparts reared entirely in captivity. Food conversion ratios of 1.5 to 2.0 (one or two unit weights of feed will be required to produce one unit weight of growth) are commonly seen in aquaculture facilities, while it may take 10 units of natural food to produce 1 unit of weight gain in nature. Prepared feeds are specifically designed to meet the animal's nutritional requirements and typically contain only a few percent water, whereas the percentage of water in natural foods can exceed 90% and a combination of foods may need to be ingested to meet all the nutritional requirements. Aquatic animals living in the wild can be expected to utilize more food energy for foraging activities than their captive counterparts.

The major savings in natural resources come from the decreased energy associated with captive rearing systems (water pumping, aeration, and perhaps heating or cooling), growing or capturing the ingredients, and manufacturing the prepared feeds employed to rear many varieties of captive culture animals. Additional energy expenditures are required to construct the larger facilities needed to rear animals to market size and to operate the equipment and vehicles associated with construction and operation of such facilities. Those outlays are somewhat offset by the energy requirements for capturing enhanced species from nature, rather than from a pond, raceway, or net pen.

Aquaculturists are becoming increasingly aware of the need to limit the amounts of natural resources that are

consumed in conjunction with their activities and the potential environmental problems that can result from many forms of aquaculture. Nutrient and suspended solids loading into receiving waters from effluents are significant problems in some types of aquaculture. Various methods to control the quality of effluents, including the use of filtration systems, settling basins, and constructed wetlands are being employed by some culturists and are increasingly mandated by policymakers in some regions. Aquaculturists can also be more environmentally responsible by modifying feed formulations to reduce nitrogen and phosphorus losses to the environment (more complete utilization by the culture animals). The use of exotic species in aquaculture has been criticized by individuals and groups fearing that the nonnative species will escape and negatively impact native populations. Aquaculturists are taking increased care to ensure that exotics do not escape, particularly from facilities that have effluents which enter natural waters (as compared with those being recycled, used for irrigation, or that are put into sanitary sewers).

Most aquaculturists will steadfastly stand behind the view that they are conservationists and, as a consequence, are interested in the maintenance of environmental quality. While mitigating against environmental damage from aquaculture can be expensive, most aquaculturists recognize that it is to their long-range benefit to take appropriate steps. Many culturists in Japan learned that lesson the hard way when self-pollution caused both economic loss and stricter controls on the numbers and sizes of facilities that can be established within sensitive coastal areas.

Aquaculture may never achieve complete sustainability, but efforts are being made in many circles to approach that goal. With the growing human population around the world, the pressures to move toward sustainability and provide additional aquatic foods through aquaculture production will increase dramatically. How aquaculturists and policymakers respond to the challenge remains to be seen.

INTRODUCTION

Tank-based fish farming methods vary widely, and external pressures are constantly forcing improvements. Tank-based fish farms in the United States are especially challenged by lower farm-gate prices and by the implementation of new state and federal regulations that govern water use, the total maximum daily load (TMDL) of wastes, and/or the concentration of wastes discharged from fish farms. Therefore, better fish culture strategies and technologies are being adopted to reduce fish production costs, water requirements, and waste discharges. Culture tank design is especially important because it influences both physical and biological variables in fish culture (Fig. 1). The culture tanks are also the asset in which much of a farm's fixed and variable costs are invested, and they are the point of waste production and water use. A large portion of fish farm capital can go toward the purchase of culture tanks, of their water distribution and collection components, of support equipment (e.g., fish feeders, oxygen probes, and flow or level switches), and of the floor space that they require. Also, a large portion of fish farm operating costs can go into the labor required to manage culture tanks and control their waste discharge. Therefore, a large financial incentive exists to select the best culture tank, scale, and operating strategy to optimize fish farm profitability. This article discusses the design rationale, use, and cost implications of circular culture tanks, raceway tanks, and a new mixed-cell raceway-type tank. Several of the features, advantages, and disadvantages of each culture-tank design are summarized. First, however, this article briefly reviews how issues of culture-tank scale, carrying capacity, and stock management influence fish production and how rapid solids removal from the culture tank can affect waste management.

Scale Issues

The number and size of culture tanks is an important factor to consider during the design of the fish farm and of its stock-management plan. It is now becoming more common practice for fish farms to use few, but relatively large culture tanks to meet volume requirements. For example, Karlsen (1) described how more recent land-based salmon smolt farms in Norway use only 6 to 8 production tanks, many fewer than earlier farms used. No matter where the fish farm is located or what species the farm is producing, it often becomes readily apparent that fewer (maybe 6 to 10), but relatively larger, culture tanks can provide culture volume much more cost-effectively than can many (maybe 30 to 100), but correspondingly smaller, tanks. Also, the costs of miscellaneous equipment and labor decrease when a given culture volume can be achieved with a few large culture tanks rather than with many small tanks. Use of fewer but larger tanks reduces the purchase and maintenance cost of feeders, dissolved oxygen probes, level switches, flow meters/switches, flow-control valves, and effluent standpipe structures (2). Use of fewer but larger tanks also reduces the time required to analyze water quality, distribute feed, and perform cleaning chores (because the times are about the same for a large tank as for a small tank) (2). Also, the time and logistics of fish management in a large number of tanks can become quite costly.

However, the advantages achieved through the use of larger tanks must be balanced against the risk of larger economic loss if a tank fails for mechanical or biological reasons. There are also difficulties that could arise in larger culture tanks when removing mortalities, grading and harvesting fish, and controlling flow hydraulics (e.g., water velocities, tank mixing, dead spaces, and settling zones). Therefore, large culture tanks must be designed properly to allow for fish management and for control over flow hydraulics, as will be discussed.

Carrying Capacity Issues

Production in culture tanks can be boosted by increasing the culture tank's carrying capacity, which (in simplistic terms) is the maximum fish biomass that can be supported at a selected feeding rate. Dissolved oxygen is usually the first water quality parameter to limit culture-tank carrying capacity. The amount of dissolved oxygen available in fish culture tanks is dependent upon the water flow rate multiplied by the concentration of available dissolved oxygen (i.e., the inlet dissolved-oxygen concentration minus the minimum allowable dissolved-oxygen concentration). If there is no in-tank aeration
Figure 1. Rearing unit design is often dependent upon physical and biological variables, as has been illustrated by Ross and Watten (42). Solid arrows depict relationships demonstrated by research; dashed arrows depict hypothesized effects.

or significant photosynthesis, doubling the water flow through a culture tank will double the carrying capacity of the tank; however, moving more water through the culture volume is not always possible and often requires larger pumps and pipes or higher water-pressure requirements that can increase the farm's fixed and variable costs. Alternatively, supersaturating water with dissolved oxygen prior to use is popular and is often a more cost-effective method of improving the profitability of tank-based fish farms (3,4). For example, if we assume that a minimum allowable outlet dissolved oxygen concentration is 7 mg/L (ppm), increasing the dissolved oxygen concentration entering a culture tank from 10 to 16 mg/L (ppm) would triple the culture tank's available oxygen and thus triple its carrying capacity (if there are no other limitations). Supersaturating water with dissolved oxygen can be achieved cost-effectively with many different oxygen transfer devices, even in low-head applications (3,5).

Other fish metabolites, such as dissolved carbon dioxide, ammonia, and suspended solids, can limit culture tank carrying capacity when the level of dissolved oxygen no longer does so. Fish produce approximately 28 to 32 g (1 oz) of total ammonia nitrogen, 300 to 400 g (10–14 oz) of carbon dioxide, and 250 to 400 g (9–14 oz) of total suspended solids for every 1.0 kg (2.2 lb) of feed consumed. In terms of dissolved oxygen consumption, fed fish produce roughly 1.0–1.4 mg/L (ppm) of total ammonia nitrogen, 13–14 mg/L (ppm) of dissolved carbon dioxide, and 10–20 mg/L (ppm) of total suspended solids (TSS) for every 10 mg/L (ppm) of dissolved oxygen that they consume. Dissolved carbon dioxide and un-ionized ammonia concentrations can rapidly accumulate to toxic levels when fish consume large concentrations of dissolved oxygen without some form of ammonia or carbon dioxide control. Colt et al. (4) developed a method for estimating the carrying capacity of water when dissolved oxygen is not limiting. The method uses mass balances and chemical equilibrium relationships to predict the amount of dissolved oxygen concentration that fish can consume before the dissolved carbon-dioxide or ammonia concentrations limit further oxygen consumption. Accordingly, intensive fish farms can use the water flow without concern about ammonia or carbon dioxide limitations (in the absence of biofiltration and air stripping) up to a cumulative dissolved oxygen consumption of about 10 to 22 mg/L (ppm), depending upon pH, alkalinity, temperature, fish species, and life

stage (4). After reaching this cumulative oxygen demand, the water flow cannot be used again until the dissolved carbon dioxide and ammonia concentrations are reduced.

Stock Management Issues

Fish farm production can also be increased (approximately doubled) through the use of a continuous production strategy rather than of a batch-production strategy (6–9). The maximum economic productivity of the culture system can be obtained by year-round fish stocking and harvesting, because continuous production maintains the culture system at or just below its carrying capacity. Also, harvesting at a given size increases product value by regularly providing more uniform-sized fish for the market. In a full-scale production experiment, Heinen et al. (10) showed that rainbow trout (*Oncorhynchus mykiss*) stocked every eight weeks and harvested weekly could achieve a ratio of steady-state annual production (kg/yr) to maximum system biomass (kg), P:B, of 4.65:1/yr. This research demonstrated that continuous-production techniques can provide exceptionally high P:B rates. In practice, however, most commercial farms cannot operate at such high P:B ratios, and P:B ratios of 3:1 per year (or lower) are more common. Incorporation of stock management strategies that can increase the P:B ratio on a commercial farm would have a large and beneficial effect on production costs.

Continuous stocking and harvesting strategies also require the culturing of several size groups at the same time, frequent handling of the fish, and improvement in inventory accounting techniques, which can stress the fish (and increase labor costs if automated equipment is not used). To keep the cost of handling and grading fish (and the associated stress on the fish) to a minimum, convenient mechanisms for sorting the fish by size, counting them, and moving them to other locations should be incorporated into design of the culture tank and facility. Simply netting the fish out of the tank or using a net to crowd the fish for harvest or grading is an obvious solution. More sophisticated crowding and grading can also be achieved by using crowder and grader frames or gates that move down the length of a raceway or pivot around the center of a circular culture tank (1,11,12). Fish of small size can swim through the grader bars, while the larger fish are retained behind the gate. Use of crowder and grader gates is thought to be less stressful on the fish, because their use does not require handling the fish or moving them out of the water. Once crowded, fish can also be induced to swim through channels, pipes, or raceways to another location with relatively little stress. Crowded fish can also be moved rapidly to other areas by using more aggressive fish pumps or brail nets and cages, but these techniques should be used with care to avoid damaging fish.

Hand grading devices, such as box graders, are common at many hatcheries and have proven to work well on small farms, where the cost of automatic grading and counting equipment cannot be justified. At larger farms, however, labor and fish stress can be reduced by the wise use of automated grading and inventory tracking equipment. Commonly used automatic graders include mechanically driven belt graders and roller graders. These mechanical graders usually require removing the fish from water for a brief period as they pass through the sizing mechanism. Although mechanical graders can produce some stress and trauma, many of the established commercial mechanical grading machines are considered safe, reliable, and fast methods to sort large numbers of fish by size and count them. As with all new technologies, however, it is best to check with other fish farmers who have used the equipment before purchasing it.

There is a great deal of interest in affordable inventory tracking equipment because sampling fish with dip nets is labor-intensive and not extremely accurate. Exciting new technologies that use ultrasonics, infrared light, and video systems are now commercially available to estimate fish size distributions within culture tanks and cages. This type of inventory tracking equipment may sometimes also be used to track fish growth and feed conversion (if feed input and fish numbers are known) and to estimate the fraction of fish reaching harvest size.

Waste Management Issues

The concentration of waste discharged from most tank-based coldwater fish farms is relatively low under normal operating conditions; however, the large flow rates involved can make the cumulative waste load (i.e., total maximum daily load) discharged from fish farms significant (13–15). Consistently meeting strict discharge standards can also be difficult because cleaning routines for pipes, channels, and tanks can produce fluctuations in discharge flowrates and in the consistencies and concentrations of waste material. The distribution of the nutrients and organic matter between the dissolved, suspended, and settleable fractions affects the choice of method used and the difficulty of effluent treatment. The filterable or settleable solids contain most of the phosphorus discharged from tanks (50–85%) but relatively little of the total effluent nitrogen (about 15%) (13,16). Most of the effluent nitrogen released (75–80%) is in the form of dissolved ammonia (or nitrate, when nitrification is promoted). The variability in the nutrient and organic material fractionation between dissolved and particulate matter is largely dependent on feed formulation and on the opportunity for particulate matter to break apart, because the production of smaller particles increases the rate of nutrient and organic matter dissolution. Fecal matter, uneaten feed, and feed fines can be broken rapidly into much finer and more readily soluble particles by water turbulence, fish motion, scouring, and pumping. It is much more difficult to remove dissolved and fine particulate matter than larger particles. Therefore, culture tank designs, and operating strategies that remove solids rapidly and with little turbulence, mechanical shear, and opportunity for microbiological degradation are important in helping the fish farm meet discharge limits (to be discussed in more detail later in this entry).

CIRCULAR CULTURE TANKS

Circular tanks have been used widely in land-based trout and salmon smolt farms (Fig. 2) in Norway, Scotland, and
Figure 2. Circular culture tanks in one of the salmon-smolt production units at Target Marine Hatcheries in British Columbia. (Drawing courtesy of PRAqua Technologies, Ltd., Nanaimo, British Columbia, Canada.)

Iceland (1,17,18), as well as in North America and other parts of the world (11,12). Circular tanks used for salmonid production are generally large — usually between 12 and 42 m (40 and 140 ft) in diameter (although smaller tanks are used in hatcheries and on smaller farms). Diameter-to-depth ratios typically range from 3 : 1 to 10 : 1 (1). Circular tanks are also used for raising many species other than salmonids, including hybrid striped bass (*morone* sp.), tilapia (*Oreochromis* sp.), yellow perch (*Perca flavescens*), sturgeon (*Acipenser* sp.), walleye (*Stizostedion vitreum vitreum*), and red drum (*Sciaenops ocellatus*).

Circular tanks have several advantages that make them particularly attractive (2,19–21): they can provide a uniform culture environment; they can be operated under a wide range of rotational velocities to optimize fish health and condition; they can be used to concentrate and remove settleable solids rapidly; they allow for good feed and fish distribution; and they can permit designs that allow for visual or automated sensing and regulation of sinking feeds (22).

Relatively complete mixing of the water in circular culture tanks is necessary to prevent flow from short-circuiting along the tank bottom and to produce uniform water quality throughout the tank. The water exchange rate can then be set to provide the fish with good water quality throughout the entire culture tank, even when it is operating up to its maximum carrying capacity. The velocity of the water rotating in the culture tank must be swift enough to make the tank self-cleaning, but not faster than the desired fish swimming speed. The tank becomes self-cleaning at water rotational velocities that exceed 15 to 30 cm/s (6–12 in./s), which are adequate to create a secondary radial flow strong enough to move settleable solids (e.g., fish feed and fecal matter) along the tank's bottom to its center drain (20–24). To maintain fish health, muscle tone, and respiration, water velocities should be 0.5–2.0 times fish body length per second (25). For salmonids, the following equation can be used to predict safe nonfatiguing water velocities (26):

$$V_{safe} < 5.25/(L)^{0.37}$$

Here L is the fish body length in cm (in times 2.54) and V_{safe} is the maximum design velocity (about 50% of the critical swimming speed) in fish lengths per second. In circular tanks, water velocities are somewhat lower in a toroid region about the tank center, a circumstance that allows fish to select a variety of water velocities.

The self-cleaning effectiveness of the circular tank is also affected by the overall rate of the flow leaving the bottom center drain and how much the swimming motion of the fish resuspends the settled materials. Only about 5 to 20% of the total flow through the tank is required to flush settleable solids from the tank's bottom center drain, depending upon water exchange rate, because the water rotational velocity and the swimming motion of the fish control the transport of settleable solids to the tank's bottom center drain. This is the principle behind the use of dual-drain tanks to concentrate settleable solids (2). Therefore, the flow through the culture tank does not have to be increased beyond that required to support a selected carrying capacity, if the water inlet structure is properly designed.

The water inlet structure must be designed correctly to obtain uniform water quality, to achieve specific water rotational velocities, and provide for the rapid flushing of solids. According to recent studies (20,21) from the SINTEF Norwegian Hydrotechnical Laboratory, the tank rotational velocity is roughly proportional to the velocity through the openings in the water inlet structure at a given water exchange rate through the tank. The impulse force created by injecting the flow into the tank controls the rotational velocity in the tank and can be regulated by adjusting the inlet flow rate and the size, number, and orientation of the inlet openings (19). Injecting flow through an open-ended pipe creates poor mixing in the central toroid zone, much higher velocity profiles along the tank wall than in the central toroid region, resuspension of solids to all tank depths, and poor flushing of solids from the bottom (20,21). In contrast, distributing the inlet flow by using a combination of both vertical and horizontal branches can achieve uniform mixing in the culture tank, prevent short-circuiting of flow along the bottom, produce more uniform velocities throughout the tank, and more

effectively transport waste solids along the tank bottom to the center drain.

Circular fish culture tanks can be managed as "swirl settlers" when the bulk flow passing through the tank is discharged from a location distant from the settleable solids concentrated at the bottom and center of the tank. Ideally, the bulk of settleable solids will be transported out of the tank's bottom center drain by using only 5–20% of the total flow. Here, the majority of flow is withdrawn (relatively free from settleable solids) from an elevated drain. Dual drains have been used to help remove settleable solids from fish culture tanks since 1930 (24,27–32). Patents covering specific features of dual-drain designs have been awarded (33,34). A nonproprietary design, the "Cornell-type" dual-drain tank (Fig. 3), is a circular culture tank with a center drain on the tank bottom and an elevated drain part-way up the tank side wall (2). The separation of the two drains so that one is part-way up the tank side wall and the other is in the tank center makes the Cornell-type dual-drain tank easy to install, even as a retrofit on existing circular culture tanks. No matter which dual-drain design is selected, removing settleable solids from the bulk flow at the culture tank can have large economic implications — a reduction in capital cost as well as in space and water-head requirements (2).

The concentrating of settleable solids in the discharge leaving the bottom center drain in a dual-drain culture tank will depend largely on how rapidly fish fecal matter and waste feed settle. The settling properties of fecal matter and waste feed are influenced by several factors, including diet formulation. Feed pellets have been reported to settle at velocities ranging from 15.2 to 17.9 cm/s (6–7 in./s) (35); intact fecal matter can settle at velocities ranging from 2 to 5 cm/s (1–2 in./s) (36), but finer and/or less dense particles can be produced and may settle

at only 0.01 cm/s (0.004 in./s) (14), a speed that would not allow solids to concentrate effectively at the bottom center of dual-drain tanks. Research at the Freshwater Institute (Shepherdstown, WV) on solids removal within a Cornell-type dual-drain tank has shown that the mean total suspended solids (TSS) concentrations discharged through the elevated side-wall drain averaged only 1.5 mg/L (ppm), while the bottom drain discharge contained an average of 20 mg/L (ppm) TSS (S.T. Summerfelt, Freshwater Institute, unpublished data). This study was performed to determine how solids removal from the culture tank was influenced by hydraulic retention time (one and two culture-volume exchanges per hour), by diameter : depth ratio (12 : 1, 6 : 1, and 3 : 1), and by the percentage of flow discharged through the bottom drain (5, 10, and 20%). In that study, the tank contained rainbow trout at a density of 60 kg/m^3 that were fed 1% body weight per day. Others (32) have reported concentrating 91% of the fecal matter and 98% of uneaten feed within the bottom flow leaving dual-drain culture tanks.

A simple, fast, and reliable method that can be used to remove the occasional dead fish from the bottom-center drain should also be built in during the tank design, in order to decrease labor costs, reduce the spread of fish disease, and maintain water level in the culture tank (2). Dead fish are usually netted from the bottom drain, but automated mortality removal methods are sometimes used in relatively large and deep culture tanks.

RACEWAY TANKS

Raceways are the most common rearing-tank design prevailing in locations where aquaculture has tapped into huge groundwater resources. In these instances, the lay of the land allows for gravity flow from the water source
Figure 3. Details of a circular culture tank design used at the Freshwater Institute (Shepherdstown, WV) to concentrate settleable solids at its bottom center drain while discharging the majority of water flow (i.e., 80–95% of the total flow) through its "Cornell-type" side-wall drain. (Drawing courtesy of Red Ewald, Inc., Karnes City, Texas.)

through the raceways. Such is the case in Idaho, where some of the world's largest producers of rainbow trout are located (37). In Idaho, raceways are typically around 3–5.5 m (10–17 ft) wide, 24–46 m (80–155 ft) long, and 0.8–1.1 m (32–44 in.) deep (14). Raceways usually have a length-to-width ratio of 1:10, a depth <1.0 m (3 ft), and a requirement for a high water-exchange rate (e.g., one tank-volume exchange every 10 to 15 minutes) (38). Raceways used for warmwater species are typically much shorter, often only 7–13 m (23–43 ft) long.

Water enters the raceway at one end and then flows through the raceway in a plug-flow manner, with minimal back-mixing. The plug flow produces a concentration gradient along the axis in dissolved oxygen and in such metabolites as ammonia and carbon dioxide. The water quality is best at the head of the tank, where the water enters, and then deteriorates along the axis of the raceway toward the outlet. Oxygen is often the limiting criterion, so fish may congregate at the head of the raceway and cause an unequal distribution of fish density throughout the raceway. It is also more difficult to distribute feed throughout raceways than within circular tanks.

The velocity of water through the raceway is generally 2–4 cm/s (1–2 in./s), so a substantial amount of solids settles in the rearing area; however, these solids are slowly moved downstream through the rearing area by the swimming activity of larger fish (14,38). A series of baffles spaced at intervals equaling the width of the raceway and placed perpendicular to the flow can be used to create high water velocities (20–30 cm/s — 8–12 in./s) between the bottom of the raceway and the bottom edge of the baffle. The baffles allow solids to be swept continuously from the raceway (38); however, the Idaho Division of Environmental Quality reports (14) that baffles can be troublesome, because they must be moved to work the fish and can provide a substrate for biosolids growth in the summer.

In practice, raceways are managed on the basis of their oxygen requirements rather than their cleaning requirements (26). The velocity required to flush solids from unbaffled raceways is much greater than the velocity required to supply the oxygen needs of the fish. In a practical sense, raceways are incapable of producing the optimum water velocities recommended for fish health, muscle tone, and respiration.

Raceways are designed to minimize cross-sectional area and thus maintain as high a water velocity as possible, typically at least 2–4 cm/s (1–2 in./s). For this reason, many raceway systems are operated in series, with the discharge of the upstream raceway serving as the inflow water of the next one downstream. Hydraulic drops between raceways in series provide some reaeration. Long and narrow raceways are very convenient culture tanks for managing fish during crowding or grading. Crowders or graders can be placed in the raceway at one end and slowly worked down the axis of the raceway. Raceways can be constructed side by side, with common walls, to maximize the utilization of floor space and to reduce construction costs (Fig. 4). When constructed without common walls, raceways require 1.5 to 2.0 times as much wall length as circular tanks because of their large aspect ratio (L:W).

Figure 4. Raceways are often constructed side by side, with common walls. In some instances, the raceway units may be stair-stepped down a hillside, as shown at Leo Ray's fish farm (Buhl, ID), in order to provide some water aeration before serially reusing the flow in downstream raceways.

Circular tanks can also better handle the weight of the confined water structurally and can thus use thinner walls than rectangular tanks.

A quiescent zone devoid of fish is usually placed at the end of a raceway tank to collect the settleable solids that are swept out of the fish-rearing area (14,38). These solids-collection zones are the primary means for solids removal aimed at meeting discharge permit requirements at many large trout farms (14). The overflow rate recommended for capturing solids in the quiescent zone is <1 cm/s (0.4 in./s) (e.g., 0.01 m³/s flow per square meter of surface area). Settled solids should be removed from these quiescent zones as frequently as possible; settling zones are cleaned at least twice per month, and occasionally as often as daily (14). Prolonged storage allows for some nutrient leaching, solids degradation, and solids resuspension (due to denitrification and fermentation of the organic matter). Suction through a vacuum pump is the most common method for removing solids from the quiescent zone (14)

Figure 5. Some of the solids swept from a raceway's fish-rearing area can settle in quiescent zones, but the captured solids must be manually removed. Shown here is a quiescent zone being cleaned at the Pennsylvania Fish and Boat Commission's Big Spring Fish Culture Station (Newville, PA), where it takes about one day for a single person to clean all 80 of the hatchery's quiescent zones.

and sometimes also from the fish-rearing areas. Quiescent zones are also cleaned through a central drain after flow through the zone is temporarily stopped (Fig. 5). Even with efficient techniques, operating labor for solids removal has been reported to exceed 25% of the total farm labor (14).

MIXED-CELL RACEWAY TANKS

We have noted that circular tanks offer the advantages of elevated water velocities, uniform water quality, and good solids removal characteristics, whereas linear raceways make better use of floor space and facilitate harvesting, grading, and flushing operations. The crossflow tank is a recent hybrid design that incorporates the desirable characteristics of both circular tanks and linear raceways (39,40). Water is distributed uniformly along one side of a cross-flow tank (via a submerged manifold), and is collected in a submerged perforated drain line running the length of the opposite side. The influent is jetted perpendicular to the water surface, with sufficient force to establish a rotary circulation about the longitudinal direction. Comparative production trials with hybrid stripped bass (39), tilapia (40), rainbow trout (41), and

lake trout (42) have been positive, but application has been hampered by the need for the small-diameter, fixed, and submerged inlet jets and drain ports, as well as costs associated with rounding the lower side areas to streamline flow. The rectangular mixed-cell tank (43) avoids these problems while achieving the same overall objective: a hybrid tank design. Here, a standard raceway section is modified to create horizontal, counter-rotating mixed cells with cell length equal to vessel width (Fig. 6). Cells receive water from vertical pipe sections extending to the tank floor and positioned in the corners of the cells. Vertical pipe sections incorporate jet ports that direct water into the cell tangentially to establish rotary circulation. The pipe sections can be swung up and out of the water during fish crowding or grading operations. Water exits each cell through a centrally located floor drain. Hydraulic characteristics of the tank have been established and indicate that tank performance approximates that of a circular tank (mixed-flow reactor), both with and without fish present. Water velocities averaged 15, 12, and 12 cm/s (6, 5, and 5 in./s) for tank-surface, mid-depth, and bottom regions and were sufficient to scour and purge fecal solids. Cell interaction was significant with cell-to-cell exchange rates
Figure 6. Illustration of a mixed-cell raceway tank.

representing about three to four times the tank inflow rate. This characteristic contributed to the observed uniform distribution of fish throughout the vessel. Further, the energy requirement of the design was kept low [just 1.32 m (52 in.) of water head] through use of a large number of low-velocity inlet jets. Given that the tank's drain is similar to that of a circular tank, application of dual-drain solids concentration is feasible and desirable.

Bibliography

Temperature is one of the water-quality parameters most critical to the aquaculturist. Animals reared under aquaculture conditions are poikilothermic, so their metabolism is closely tied to the temperature of the water. Each species has a thermal optimum — the temperature (or temperature range) at which growth is optimized, and a thermal tolerance range — the range of temperature within which the species will survive. Aquatic animals tend to fall into one of three categories: warmwater, coolwater, and coldwater species. In general, the thermal optima for the three groups tend to be around 30, 25, and 20 °C (86, 78, and 68 °F), respectively. This entry is adapted from a previously published book (1) and is used with permission.

THERMAL REQUIREMENTS

Selection of an aquaculture species usually takes temperature into consideration, particularly when the site has been selected and the aquaculturist knows the type of water that will be used in the facility. Water temperature may fluctuate significantly in temperature on a seasonal basis, depending on the source of the water being used. Some culture species can survive a broad range of temperatures; others cannot. As indicated above, each species has a relatively narrow temperature range within which growth is optimum. Catfish, tilapia, striped bass, and trout provide good examples.

The original range of occurrence of the channel catfish (*Ictalurus punctatus*), for example, was from the Great Lakes region and the prairie provinces of Canada to the Gulf states of the USA (2). The species can thus survive water temperatures approaching freezing as well as those that rise above 30 °C (86 °F). Growth rate differs significantly from the North to the South; the optimum temperature generally accepted lies within the range from 26 to 30 °C (from 79 to 86 °F) (3,4), though a broader optimum (21 to 30 °C; 70 to 86 °F) has also been reported (5). Temperatures in that band may never be reached at the northern end of the fish's range, and,

in high latitudes, several years might be required for a fish to reach marketable size (about 450 g; 1 lb). In the southern United States, market size is generally reached in 18 months. If the temperature can be maintained within the optimum range at all times, the length of time from egg to market can be reduced by another 8 to 10 months. On the basis of its optimum temperature, the channel catfish is considered to be a warmwater fish (Table 1).

Table 1. Classification of Selected Aquaculture Species as a Function of Temperature Required for Optimum Growth

Optimum Temperature	Name
Coldwater invertebrate	Pacific oyster (*Crassostrea gigas*)
Coldwater fishes	Chum salmon (*Oncorhynchus keta*) Coho salmon (*Oncorhynchus kisutch*) Pink salmon (*Oncorhynchus gorbuscha*) Rainbow trout (*Oncorhynchus mykiss*) Chinook salmon (*Oncorhynchus tshawytscha*) Plaice (*Pleuronectes platessa*) Atlantic salmon (*Salmo salar*) Brown trout (*Salmo trutta*) Sole (*Solea solea*)
Coolwater fishes	Northern pike (*Esox lucius*) Muskellunge (*Esox masquinongy*) Striped bass (*Morone saxatilis*) Yellow perch (*Perca flavescens*) Walleye (*Stizostedion vitreum vitreum*)
Warmwater invertebrates	American oyster (*Crassostrea virginica*) Freshwater shrimp (*Macrobrachium rosenbergii*) Northern quahog (*Mercenaria mercenaria*) Southern quahog (*Mercenaria campechiensis*) Blue mussel (*Mytilus edulis*) Kuruma shrimp (*Marsupenaeus japonicus*) Tiger shrimp (*Penaeus monodon*) Blue shrimp (*Litopenaeus stylirostris*)
Warmwater fishes	Bighead carp (*Aristichthys nobilis*) Goldfish (*Carassius auratus*) Milkfish (*Chanos chanos*) Mud carp (*Cirrhina molitorella*) Walking catfish (*Clarias batrachus*) Grass carp (*Ctenopharyngodon idella*) Common carp (*Cyprinus carpio*) Sea bass (*Dicentrarchus labrax*) Silver carp (*Hypopthalmichthys molitrix*) Bigmouth buffalo (*Ictiobus bubalus*) Blue catfish (*Ictalurus furcatus*) Channel catfish (*I. punctatus*) Red drum (*Sciaenops ocellatus*) Yellowtail (*Seriola quinqueradiata*) Rabbitfish (*Siganus* spp.) Gilthead sea bream (*Sparus aurata*) Blue tilapia (*Oreochromis aureus*) Mossambique tilapia (*Oreochromis mossambicus*) Nile tilapia (*Oreochromis niloticus*)

Tilapia (most species of aquaculture being in the genus *Oreochromis*) are tropical fishes that can tolerate temperatures above those at which many warmwater species succumb. Tilapia are, however, not tolerant of cold water. Death generally occurs when the water falls below 10 to 12 °C (50 to 54 °F) (6–8). Growth is generally poor below about 20 °C (68 °F), and disease epizootics, extremely rare when the water is around 30 °C (86 °F), become very common when the temperature approaches the lower lethal range.

Rainbow trout (*O. mykiss*) represent a coldwater species that has a temperature tolerance range of from about 1 °C (34 °F) to nearly 26 °C (79 °F) (5). While rainbow trout and other salmonids can survive in relatively warm water, the optimum temperature range for rainbows is about 10 to 16 °C (50 to 61 °F). Growth is retarded at higher and lower temperatures.

Striped bass (*M. saxatilis*) can be considered a cool-water (also called midrange) species with respect to temperature tolerance. Striped bass survive a temperature range of from about 2 to 32 °C (36 to 90 °F) (5), but have an optimum range of from 13 to 24 °C (55 to 75 °F). Other species that are often considered to be midrange in terms of their temperature optima, such as northern pike (*E. lucius*), muskellunge (*E. masquinongy*), and walleye (*S. vitreum vitreum*), may actually be better classified as coldwater species, according to their optimum ranges (5).

Temperature-tolerant coldwater, coolwater, and warmwater species may exist in water bodies that lie in close proximity; two or three types may even coexist in the same water body. For example, the deep waters of reservoirs that feature primarily warmwater species may have sufficiently cold water at depth that coldwater species can survive through the summer under the thermocline or in proximity to cold springs. Coolwater species that are fairly adaptable to a wide range in temperature can also thrive.

Latitude, altitude, and water source are all factors that affect the suitability of a given area for various species of aquaculture interest. The relatively low latitudes in which the southern United States occur are generally conducive for the production of warmwater fishes, yet at the higher elevations in many southern states it is possible to produce coolwater and even coldwater fishes. Most southern states have trout hatcheries in them. Northern climates where coolwater and coldwater species predominate will have native populations of some warmwater fishes [e.g., channel catfish and largemouth bass (*Micropterus salmoides*)], and aquaculture of warmwater fishes may be possible in geothermal water or the effluent of power plants nearly anywhere.

Virtually all aquaculture candidates are poikilothermic. For reasons that are largely unknown but that undoubtedly entail genetic differences in enzyme systems among the various species, temperature tolerances and optima vary greatly. As a general rule, coolwater and coldwater fishes grow much more slowly than warmwater fishes, though that does not mean that warmwater fishes tend to be larger on average. There are many small warmwater fishes, just as there are large coolwater and warmwater ones.

There has been interest expressed in recent years in genetically engineering fish to tolerate, or even grow more rapidly in, water temperatures outside of the range in which those fishes are normally found now. For example, it might be possible, through the insertion of appropriate genes, to engineer a trout or salmon that can tolerate and grow well at 30 °C (86 °F) or a tilapia that will not succumb to disease and possibly experience mortality as the water temperature falls below 15 °C (59 °F). The latter would involve insertion of a so-called antifreeze gene. Certain polypeptides are present in the blood plasma of fishes that exhibit antifreeze protection. Presence of the antifreeze gene sounds impressive, and it is certainly of importance to tilapia culturists in certain regions where slightly more tolerance to winter minimum temperatures could mean the difference between success and devastating mortality, but presence of the polypeptides that allow fish to live at unusually cold temperatures can fail to impart as much as a one-degree advantage. Adult cod (*Gadus morhua*), for example, freeze at about −1.2 °C (29.9 °F), as compared with juveniles, which can tolerate −1.55 °C (29.2 °F), and as compared with fish like halibut and salmon, which lack the antifreeze polypeptide and generally freeze at −0.7 to −0.9 °C (30.8 to 30.4 °F) (9), though Pacific halibut juveniles have been found to survive temperatures below −1.0 °C (30 °F) (10).

Some success has been obtained not only in the transfer of a winter flounder (*Pseudopleuronectes americanus*) antifreeze gene into Atlantic salmon (*S. salar*), but also in the expression of that gene in a cross between a transgenic male and a normal female salmon (11). Better tolerance to low temperature could come from the transfer to Atlantic salmon of genes from other species that have higher concentrations of the antifreeze polypeptides (12). These kinds of alterations may soon become routine, but are they desirable?

One of the certainties associated with the practice of aquaculture is that, unless strict quarantine restrictions are imposed, culture animals will eventually escape into the natural environment. Restrictions have already been imposed on genetically engineered animals that ensure, to the extent possible, that the fish or their progeny do not escape into the wild. So far, transgenic animals of aquaculture interest have been developed and evaluated only in a research environment. If they are released for general aquaculture use, it will be very difficult to maintain the same stringent controls that are possible at research institutions.

It is difficult to know what the impact on native populations of warmwater trout or coldwater tilapia would be, but studies have shown that tilapia would compete with other species for nesting sites and would also compete with various species for food. At present, the threat of tilapia to native fish populations is low, because all but a very few locations in the United States are too cold in winter for tilapia to survive. While the aquaculturist might benefit from a cold-tolerant tilapia, native populations might suffer. Consideration of the welfare of native populations should supersede the interest of the aquaculturist in instances where the consequences could alter the natural ecological balance of a region.

THE INFLUENCE OF GENETICS AND AGE ON RESPONSE TO TEMPERATURE

While the tendency is to indicate that a species will respond to temperature stress in a predictable manner, the facts are that genetics can play a significant role and that different stocks of animals may respond differently to the same stressor. For example, coho salmon (*O. kisutch*) from six hatcheries responded differently to thermal increases of 1 °C/hr, as confirmed by measurements of changes in the critical thermal maximum tolerated by the fish (13). Similarly, it has been determined that a southern population of chinook salmon was better able to survive a challenge by high temperature than was a more northern population. (The southern stock would experience higher summer maximum water temperatures than would the northern stock (14).) The response was affected by fish size: Larger (and presumably older) fish survived the temperature challenge better than smaller fish.

The ability in Black Sea golden gray mullet (*Liza aurata*) to tolerate low temperatures increases with age until the fish reach sexual maturity, after which it goes back down (15). The relationship between age and temperature tolerance has not been well documented for most aquaculture species.

Genetic influences on the cold tolerance of tilapia have also been demonstrated. For example, *O. niloticus* from strains originating in Egypt, the Ivory Coast, and Ghana showed different lower lethal temperatures, ones ranging from 10 °C (50 °F) for the Egyptian strain to 14 °C (57 °F) for fish from Ghana (16). The Ivory Coast strain was intermediate (12 °C; 54 °F). The responses to low temperature were correlated with the normal ranges of temperatures at the geographic origins of the three strains.

RESPONSE TO SEASONAL PATTERNS IN WATER TEMPERATURE

The temperature of a surface water body typically fluctuates to one extent or another on a seasonal basis. The range of annual fluctuation tends to be maximized in temperate regions and minimized in Arctic and tropical ones. There are locations in temperate regions where temperatures approach the optimum for various culture species throughout much of the year. Surface waters in southern Florida and extreme south Texas, for example, can support good growth of warmwater species throughout most of the year. Temperatures are typically sufficiently warm to support tilapia survival during all but exceptionally cold winters. The climate in Hawaii is tropical and will support year-round growth of warmwater species. By contrast, the waters of Puget Sound in Washington and those off upper New England are sufficiently cold to support year-round salmon production. Parts of Alaska are subarctic and will also support year-round salmon growth.

There are instances wherein water that is unusually cold or atypically warm for a given region occurs. There are also places where water temperature does not fluctuate to any extent seasonally. Cold springs may reduce the extent of spring and summer warming in some surface waters;

geothermal water may be used to produce warmwater species throughout the year in regions where even summer water temperatures might otherwise be too low to allow for growth, or in some cases, survival of a particular warmwater species. Facilities producing tilapia and channel catfish in parts of Idaho where geothermal water is available are good examples. Similar, and also in Idaho, is the production of rainbow trout in the Hagerman Valley, where underground rivers of virtually constant temperature provide ideal year-round growing conditions. The water flows through raceways that have a short residence time shortly after it erupts from the ground, so there is little temperature change at any time of year.

Water that has had its temperature altered by the activities of humans can sometimes be used for aquaculture also. The best example is the warm water associated with fossil-fuel and nuclear power plants, but many other industries produce heated effluents that may be suitable for use in aquaculture, either directly or through heat exchange with water in the culture chambers.

Most species that are being successfully produced by commercial aquaculturists reach the market in less than two years; one year or less for growout is even more desirable. Tilapia can be grown to market size (about 500 g, 1.1 lb) in under a year in tropical regions or when geothermal or artificially heated water is available. Channel catfish can also be reared to the same size within a year if water temperature is constantly maintained within the optimum range for the species. In most parts of the United States where catfish are reared in waters that are subject to seasonal temperature fluctuations, growout requires about 18 months. In tropical regions it is easy to obtain at least two crops of penaeid shrimp annually; in temperate regions, however, one crop per year is typical.

Some species of commercial importance require two or more years to reach market size. Pacific oysters and Atlantic salmon are examples, with three-year production cycles from egg to market being typical, though selective breeding is leading to a reduction in the time required to reach market size in Atlantic salmon. Atlantic halibut (*Hippoglossus hippoglossus*) appear to require about three years for growout to a size of 5 kg (11 lb), which is considered to be market size for that species. One of the reasons for slow growth in halibut is related to their requirement for cold water.

At least modest reductions in the time required to produce marketable species in commercial culture and those of suitable stocking size in the recreational fish production arena may be possible as a result of improved nutrition, genetic manipulation, and aggressive culture system management. Research has already been initiated with respect to the introduction of growth hormone into fish. Yet, given the small initial size of the larvae and fry of aquatic species of aquaculture interest, there will be limits to how fast marketable animals can be produced. We are not likely to see fish or oysters reach the market in a few weeks as broiler chickens do, but we can anticipate some reduction in the growout period as technology advances. Maintenance of optimum temperature will be one key to reducing the period required for growout.

For most species, the maximum temperature experienced during the year is not within the temperature range optimum for most rapid growth. At temperatures both above and below the optimum range, growth rate decreases. Metabolic rate is reduced when the water temperature falls below the optimum range and increases when the temperature rises above that range. Low metabolism means reduced feed intake and slower growth. At temperatures above the optimum range, it usually happens that feed consumption rate increases to accommodate the higher metabolic rate, yet growth does not increase — and there is an economic impact associated with meeting the energy demand by providing more food, for no additional increase in rate of weight gain. As temperature approaches the upper tolerance point for a given species, metabolic rate begins to fall as various systems fail. Feeding activity declines, and, ultimately, death occurs.

Given a range of temperature, most species will select one that is within the optimum for growth, unless some mitigating factor is operating. For example, a fish that is approaching sexual maturity may select a temperature that is more suited to egg survival and development than one that is optimum for growth. In nature, aquatic animals can often make such selections because water bodies tend not to have uniform temperatures throughout. Thermal stratification and inflowing warm or cold springs provide opportunities for aquatic organisms to be somewhat selective in terms of temperature. In water systems in which temperature is controlled in some way, conditions may be more uniform.

Aquaculture ponds tend to have zones of temperature. Even a pond that is less than 2 m (6 ft) deep may partially stratify, and the shallow water around the edges of culture ponds is often considerably warmer during the day than is water in the middle, particularly on sunny days during summer.

SYNERGISMS WITH TEMPERATURE

The influence of temperature on the growth, metabolism, disease resistance, and survival of aquaculture animals may be influenced by various other parameters. While many of these synergisms have not been evaluated in any detail, and none has been examined across a broad range of aquaculture species, there is some information documenting at least a few of the factors that can interact with temperature and influence performance of aquaculture species.

The cold tolerance of *Tilapia aurea* at salinities ranging from 0 to 35 ppt has been examined (17), and it was determined that fish that were isosmotic with the medium survived lower temperatures than those for which the external medium was at a salinity higher or lower than that of the tissues of the fish. One implication of the relationship between temperature tolerance and salinity is that the species could be expected to have an extended range of distribution into estuarine waters as compared with into fresh water or marine waters (see the entry "Salinity" for further explanation).

Various other chemical parameters associated with the water can influence the temperature tolerance of aquaculture species. The ability of channel catfish to tolerate high temperature is reduced not only in the presence of ammonia (the un-ionized percentage of which increases with increasing temperature) but also when the fish are exposed to elevated nitrite levels.

EFFECTS OF TEMPERATURE ON DEVELOPMENT

Egg and embryo development are heavily influenced by temperature. A minimum temperature, below which larval development does not occur, has been identified for most species of aquaculture interest and importance. As the temperature increases above the minimum, the development rate also increases. However, once the temperature to which eggs or developing larvae are exposed rises above some level, which varies from species to species, abnormal development occurs, and the rate of mortality increases until it becomes total as the upper temperature limit is reached. The upper limit for proper development of eggs and larvae may not be as high as the temperature maximum that can be tolerated by later stages in the life history of the animals. A series of abnormalities can occur when temperature becomes too high during egg and larvae development. Some of the common ones in fishes are unusual numbers of vertebrae and tail abnormalities. A special condition related to development, temperature, and other variables in anadromous salmonids is smoltification, a physiological process that allows the fish to make the transition from fresh water to the ocean.

THERMAL SHOCK AND TEMPERING

Thermal shock results when aquatic animals are exposed to rapid changes in ambient water temperature. The stress associated with such shock may weaken the immune system and thereby reduce the resistance of the animals to disease. If severe enough, temperature shock can lead to death. The daily changes in temperature that occur as a result of daytime warming and nighttime cooling of the water within a culture chamber are usually small enough that no thermal shock occurs. An exception might be a small static tank or pond that is only partially filled; in such a case, daytime warming could be significant.

Thermal shock is most commonly associated with harvesting, live hauling, and transfer of aquatic animals from one water body to another. When aquatic animals are harvested at times of the year at which air and water temperatures are disparate, there can be a considerable amount of thermal stress that occurs during the harvesting process. When a pond is being harvested, the degree of temperature change can be significantly enhanced if the water level is greatly reduced. Total pond harvesting often involves seining, followed by reduction in water volume, followed by re-seining, and so on. Rather small volumes of water associated with harvest basins (or the immediate vicinity of the drain in ponds without harvest basins) may contain surprisingly large numbers of animals that

avoided the seine. While those animals are being collected, the water can warm or cool considerably, depending on season of the year. Heating of small volumes of water has been a more significant problem than cooling. In warm climates during summer or fall, the water temperature can rise several degrees in only a few minutes. The resulting stress may be acceptable if the animals are being hauled a short distance for processing, but it can be devastating when the affected fish or invertebrates are being moved for restocking. This type of thermal stress can lead directly to mortality or reduce the disease resistance of affected animals.

In addition to thermal stress associated with the final stages of pond harvest, there is often significant reduction in dissolved oxygen (DO). Low DO occurs because the water can carry less oxygen at saturation when it is heated and because the metabolism in the animals that are being harvested increases. The problem can be alleviated by adding copious amounts of new, oxygen-rich pond water to the drain area during the latter stages of harvesting.

Water in hauling trucks should be at approximately the same temperature as the water from which the aquatic animals are collected. In many instances, water from the culture chamber being harvested is used to fill the hauling tanks, thereby assuring a minimal initial change in temperature in most cases.

Whether a hauling tank or some other type of container is used for transporting fish, the temperature of the water is subject to change with time. Insulated boxes and hauling tanks are helpful in maintaining temperature, but it may be necessary to add ice to keep water within acceptable limits during summer if the boxes or hauling tanks are exposed to high temperature and direct sunlight.

Once live hauling has been completed, and before the animals are stocked, the temperature in the transportation tank and receiving water should be compared. If the difference in temperature is more than about $2-3\,°C$ $(4-5\,°F)$, though the conversion is not linear, the animals should be gradually tempered. For animals transported in tanks, common practice is to introduce water from the receiving site into the tank slowly, until the temperature within the tank equilibrates with that of the receiving water body. Tempering should not exceed a rate of more than a few degrees per hour, yet, in all instances, the process should be completed within 10 to 12 hr. Care should be taken to maintain a high level of DO at all times during the tempering process.

When fish are hauled in small containers such as plastic pails, plastic bags, or others that readily conduct heat, the containers can be floated in the receiving water body until the temperature of the water within the container equilibrates. This technique should not be used if a dramatic difference in initial temperature exists, because the rate of tempering may be too rapid and, therefore, stressful.

Rapid changes in temperature and exposure of aquatic animals to inappropriate temperatures sometimes cannot be avoided. It appears that such changes are less stressful to aquatic animals when the temperature is being changed toward, rather than away from, the thermal optimum of the species. Temperatures above and below the optimum can lead to increased rates of metabolism and to other physiological changes that can be detrimental. Whether tempering can be conducted more rapidly when the temperature change is toward the thermal optimum has not been well researched, but there is at least some circumstantial evidence to support that approach. When fish are exposed to heat stress in an almost completely drained pond during summer, rapid reduction in the temperature by adding cool water is often an effective means of avoiding subsequent mortality, even though the change in temperature may occur very rapidly.

Aquaculture animals can generally be handled without damage or severe stress in cool weather, but great care should be taken when handling them in the summer, particularly in temperate and tropical latitudes. Handling often leads to injury, and the high metabolic rate of aquatic animals in the summer may make them more active when caught, a condition leading to an increase in the incidence of self-inflicted injury. Also, bacterial activity is higher in warm as compared with cold water; thus, wounds are more likely to become infected during the summer than in the winter. An exception occurs in tilapia, which are quite disease resistant during summer but are extremely sensitive to various types of infections when exposed to cool water.

Animals that have been exposed to water temperatures above their normal optimum may be more vulnerable to parasitic and bacterial epizootics than those that have not, especially when exposure to unusually high temperatures is coupled with handling. It is generally a good idea to avoid handling aquatic animals during the summer insofar as possible. When it becomes necessary to handle animals during hot weather, they should be caught early in the morning, when the water has reached its coolest temperature of the day. Care should be taken to ensure that a high level of DO is maintained at all times. The animals should be handled gently and returned to the water as quickly as possible. If the animals are to be weighed, the operation should be accomplished in pre-weighed, water-filled containers; to avoid damage, animal density in the weighing containers should be as low as practicable.

OVERWINTERING

Most aquaculture is conducted in systems designed to operate under ambient water-temperature conditions. Outdoor aquaculture systems in temperate climates can vary in temperature from $4\,°C$ to over $30\,°C$ (from $39\,°F$ to over $97\,°F$), though there have been a few attempts to alter the normal pattern; among them are the use of geothermal water and the use of heated effluents. Heating or chilling production units in the absence of free or very inexpensive sources of heat energy has typically been unviable economically in commercial growout systems, though both heating and cooling have been used in conjunction with research laboratories, in hatcheries, and when animals are being held over the winter.

Maintenance of certain minimum temperatures through artificial heating during the winter is often necessary for tropical species being reared in temperate

climates. Various species of tilapia and certain species of penaeid and freshwater shrimp require supplemental heat during winter. Overwintering can be accomplished by maintenance of proper air temperatures in buildings used to house such species in static or recirculating systems. In flow-through systems, water heating can lead to significant and even staggering energy costs.

Overwintering is typically practiced in conjunction with the maintenance of broodstock, though young animals may also be held during winter for subsequent stocking and growout the following spring and summer. It is generally not necessary (or even desirable) to maintain the overwintering temperature at the optimum for the species involved, because the goal is to hold the animals, not have them grow. Thus, overwintering temperatures should be sufficiently low to slow the metabolic rate of the animals without stressing them and reducing their resistance to disease. For species such as tilapia, an overwintering temperature of around 20 °C (68 °F) may be appropriate. Fish at that temperature can be expected to eat a sufficient amount of food to maintain their body weight and can be expected to survive well.

The number of overwintered broodstock of species with high fecundity that spawn during spring need not be very high, so modest facilities can be used to house sufficient adults for fairly large growout operations. Species vary in their ability to accept crowding, but, for most species being reared commercially today, density limitations are usually not a factor as long as suitable water quality is maintained.

When a source of inexpensive heated water is not available, heated buildings, including greenhouses, are typically used for overwintering. Most commonly, the aquaculture animals are maintained in circular or linear raceways, though ponds covered by greenhouses may be practical in low-temperate regions where soil temperatures remain fairly high throughout the winter.

Stickney and Person (18) examined various ways of heating water before designing a heat exchanger used in conjunction with a recirculating water system. Such systems remove thermal energy from water that is of any initial temperature above freezing, thereby producing both a heat source that can be used to warm water and a source of cold water (the incoming water from which heat has been removed). Utilizing such a system could provide water suitable for the maintenance of both warmwater and coldwater species, if the temperature of the incoming water falls between the optima of the two types of animals.

TILAPIA CULTURE

Robert R. Stickney
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

Tilapia are a group of fish species that are among the most popular fishes being cultured around the world today (Fig. 1). Native to Africa and the Middle East, tilapia have been introduced throughout the tropical world and are also cultured in temperate regions, where protection against winterkill from cold temperatures must be provided. Tilapia exhibit various characteristics that make them

Figure 1. A blue tilapia (*Oreochromis aureus*) adult and small fingerling.

a desirable species for culture, such as rapid growth, ease of reproduction, and tolerance for both crowding and relatively poor water quality conditions. Also, tilapia can be reared on somewhat inexpensive prepared feeds and are resistant to diseases, unless stressed.

DISTRIBUTION AND TAXONOMY

Tilapia are freshwater fishes in the family Cichlidae that are said to have evolved from a marine progenitor. Much of Africa is dominated by cichlids. Various genera can be found in virtually every ecological niche; tilapia are known primarily as a group that has species which are herbivorous or omnivorous. The fact that tilapia feed relatively low on the food chain is among their attributes as culture species.

As previously mentioned, in addition to being native to Africa, tilapia are found in the Middle East. The fish in the biblical story of Jesus feeding a mass of people on only several loaves and fish is often believed to have been tilapia. Various species of tilapia are native to Lake Kinneret (the Sea of Galilee) and are considered highly desirable foodfish in Israel.

The introduction of tilapia into parts of Asia apparently began in the 1930s when *Oreochromis mossambicus* were imported to Java as an aquarium fish (1). During World War II, the Japanese distributed tilapia more broadly throughout much of southeast Asia, and today tilapia are considered native in many nations in Asia. Tilapia were first introduced into Caribbean nations in the 1940s and subsequently found their way throughout much of Latin America and into the United States. By the late 1950s, tilapia had become the main subject of aquaculture research at Auburn University.

Tilapia are not only produced as foodfish. In California, one species, *Tilapia zillii*, an herbivore, was stocked in irrigation canals to control aquatic vegetation. Tilapia have also been introduced into sewage lagoons to consume vegetation. Some of the more colorful species of tilapia have been marketed as aquarium fishes by producers of ornamental fishes. Many other genera of cichlids are also popular aquarium fishes.

Some tilapia species and hybrids can tolerate moderate to very high salinities. In recent years, interest has developed in the rearing of salt-tolerant tilapia in coastal ponds and marine cages. Interest for rearing tilapia in saltwater continues to be strong in the Bahamas and some Caribbean nations.

The tilapia of interest to aquaculturists were once all classified as members of the genus *Tilapia*. However, that changed during the 1970s when a taxonomist examined the situation and determined that most species of interest to the fish culture community should actually be placed in the genus *Sarotherodon* (2). Most of the world accepted the change, but the American Fisheries Society, which publishes a list of accepted names of fish that can be found in North America, did not. By the early 1980s, the taxonomy was reconsidered once again, and it was concluded that many of the species that had been placed in the genus *Sarotherodon* — again, including the most popular aquaculture species — should actually be placed in the genus *Oreochromis* (3). Once more, the American Fisheries Society experts initially failed to go along with the change, but have recently accepted it. However, the common name "tilapia" continues to be applied, regardless of the taxonomic status of these fish. Much of the world quickly accepted the changes in taxonomy, resulting in a mixture of scientific names during the years when some organizations accepted the changes and others retained the earlier taxonomy.

The most commonly reared species of tilapia are the blue tilapia, Nile tilapia, and Mozambique tilapia. Their scientific names appear in the literature as follows:

Blue tilapia	*Tilapia aurea*
	Sarotherodon aureus
	O. aureus (Fig. 1)
Nile tilapia	*Tilapia nilotica*
	Sarotherodon niloticus
	Oreochromis niloticus
Mozambique Tilapia	*Tilapia mossambica*
	Sarotherodon mossambicus
	O. mossambicus

Since the genus *Oreochromis* is now widely accepted around the world for tilapia, it is used here when scientific names are provided.

Various hybrid red tilapia have been produced and go by such common names as the Taiwanese red hybrid, Florida red hybrid, and Israeli red hybrid tilapia. The hybrids are composed of two- or three-way crosses, which may or may not include *O. mossambicus*. Crosses that include *O. mossambicus* tend to be more salt tolerant than crosses that do not include a contribution from that species.

Many other species of tilapia exist, some of which have been evaluated or employed as aquaculture species. However, the major emphasis continues to be on the species mentioned in this contribution. The Mozambique tilapia was once a widely cultured species, particularly in Asia, since it was the first tilapia introduced to that continent. However, many culturists have turned to blue tilapia and Nile tilapia as the primary species of interest, due to their better dressout percentages, later maturity, and more desirable color (Mozambique tilapia have a

large amount of dark pigment on their scales and a black peritoneum, which is seen as being undesirable). Mozambique tilapia continue to be reared extensively in Asia, though other species are gaining in popularity as well. Salt-tolerant red hybrids are cultured in coastal areas where they can be sold in markets competitively with red or silvery marine species.

Attributes of tilapia culture are as follows (4):

- tolerance to handling
- tolerance to crowding
- tolerance of poor water quality
- resistance to disease
- efficient conversion of natural and prepared feeds
- controllable reproduction
- good marketability
- rapid growth to marketable size.

CULTURE PRACTICES

Water Systems

In tropical regions, tilapia are most often reared commercially in earthen ponds (see the entry "Pond culture"). Ponds (Fig. 2) vary considerably in surface area, but most are no more than 2 m (6 ft) in depth and have slopes of 2 : 1 or 3 : 1. A well-designed tilapia pond should be equipped with a drain, to facilitate harvesting. Seines are also used for harvesting, but large numbers of tilapia are able to avoid capture by burrowing into the mud. After several passes of a seine through a partially drained pond, it is common practice to drain the pond completely and pick up the remaining fish by hand. This process can be protracted, however, since the fish may work their way to the surface and be subject to capture only after they have been buried for several hours. The fact that a fish which has been buried in the mud of a pond bottom for several hours will often recover with no apparent lasting effects after being placed in back in good-quality water is testimony to the heartiness of tilapia.

Tilapia can be reared in temperate ponds, but they should be harvested and marketed prior to the time that

the water falls below about 20 °C (68 °F), when growth generally ceases. Broodstock need to be overwintered at temperatures well above about 12 °C (54 °F), or else they may die. When maintained at cool, but nonlethal, temperatures, tilapia become more susceptible to disease than when they are maintained at their optimum temperature, which is about 30 °C (86 °F). Pond culture in temperate areas can result in one crop a year, while two to three crops a year can be obtained in tropical regions.

Although there has been some intensive tank and raceway culture of tilapia in tropical regions (Fig. 3), such systems are much more common in temperate regions. Intensive culture (Figs. 3 and 4) systems may be the flow through or recirculating type (see the entry "Recirculating water systems"). If a source of heated water is available,

Figure 3. Flow-through tank culture of tilapia in Idaho. The water source is geothermal.

Figure 4. Flow-through raceway culture of tilapia in Idaho. The water source is geothermal.

Figure 2. A tilapia pond in Jamaica, with the inflow line supplied by pumping water from an irrigation canal.

Figure 5. Concrete-lined saltwater pond culture of red tilapia at an experimental facility in the Bahamas.

tilapia can be reared year round (Fig. 5). Depending on the temperature of the available water and the ability of the culturist to alter the temperature to maintain the system within a narrow range of fluctuation, the tanks may be placed outdoors, or they can be housed within a greenhouse or another structure.

In the southernmost parts of Texas and in much of Florida, tilapia will survive many, but not all, winters without supplemental heating of the water. In more northern regions, however, winter temperatures are lethal annually. Yet, tilapia have been reared in such unlikely places as the high desert of Idaho and the prairie of North Dakota, where winter temperatures routinely reach $-34\,°C$ ($-30\,°F$).

Heating water can be a very expensive proposition, though aquaculturists have, in some instances, overwintered broodstock or even tried to grow out fingerlings in systems heated with oil, natural gas, or electric heating elements. The economics of using fossil fuels or electricity to heat water are highly unfavorable. Some inexpensive or, preferably, free source of heat is needed for economically successful commercial tilapia production in temperate regions.

In some regions, geothermal water is available from wells. While many geothermal wells are high in toxic chemicals, there are some hot aquifers containing very pure water that can be flowed directly into raceways or tanks containing tilapia. During portions or all of the year, depending on the temperature of the well water, it may be necessary to allow the water to stand in a pond for some period prior to exposing it to the fish, or to mix the incoming water with colder water to reduce the temperature. On the other hand, if the ambient geothermal water is at or near the optimum temperature for tilapia when it comes out of the ground, it may be necessary to provide supplemental heat during cold periods.

Artesian geothermal wells provide the best option, because no pumping is required when flow rates are sufficiently high. Some producers have to pump all of their geothermal water when there is no artesian flow, while others who have an artesian flow, but insufficient volume to supply their needs, may employ pumps to augment the flow.

A second option is to use warm wastewater from a power plant or industrial source. Coal, oil, natural gas, and nuclear power plants all produce large quantities of heated water as a result of electrical production. Many industries also produce copious amounts of hot water. In many cases, the warm water cannot be used directly, because it contains supersaturated gas levels (see the entry "Gas bubble disease") or toxins that have been added to prevent fouling within the facility producing the heated water. For example, power plants often flush condenser pipes with chlorine to remove fouling organisms. However, exposing fish to chlorinated water can result in total mortality.

Hot water from nearly any source, including geothermal water that may not be of a quality suitable for direct exposure to fish, can be passed through heat exchangers, which transmit the heat to the water in culture tanks. In some cases, power plants or other industries with large volumes of available warm water have been willing to work with aquaculturists in providing free or low-cost access to that water.

Reproduction and Hatching

While tilapia have a number of positive attributes that, altogether, are not shared by many aquaculture species (4), there are problems associated with their culture. One of those problems is early maturity, accompanied by slow growth of females and overpopulation of culture systems with submarketable fish. Mozambique tilapia, for example, mature as early as three months after hatching. Nile and blue tilapia typically do not mature until about six months of age. In both cases, maturity occurs well in advance of a size that can be sold in most markets. [Exceptions to the problem of marketing small, mature fish occur in nations where fish of 100 g (0.22 lb) or less can be sold].

The most common species of tilapia currently being cultured around the world are mouthbrooders. The males construct nests in pond bottoms (Fig. 6) and then go through courtship display behavior to attract a female. As the female extrudes her eggs into the nest, the males fertilizes them. The female then picks the eggs up in her mouth and retires, allowing the male to seek out additional mates.

Figure 6. Tilapia nests in a drained spawning pond.

Incubation of the eggs takes place in the mouth of the female and requires about one week. The fry remain in the mouth of the female through yolk sac absorption. When they begin foraging for food, the fry remain in a school near the female and will move back into her mouth if they sense danger. Thus, for two weeks or more, the female does not eat, since her mouth and buccal cavity are filled with eggs or fry.

A typical female can spawn as often as every 30 days, with the spawning season being virtually year round in the tropics, though studies have shown that a female usually does not spawn more than about eight times a year (5). Because of the high frequency of spawning, which requires that a considerable amount of the energy consumed by females go into egg development, and due to the fact that the female does not eat for two weeks a month during the protracted spawning season, growth of females is much slower than that of males.

Tilapia produce relatively small numbers of eggs — usually not more than a few hundred — during each spawning episode. Because of the high frequency of spawning, a brood pond stocked with a few hundred females per ha (2.4 ac) will, during the course of a spawning season, produce hundreds of thousands of fry and fingerlings. If the fry or small fingerlings are not removed periodically, competition for food can lead to stunting, even though, as the spawning season progresses, the number of fry observed decreases, apparently due to cannibalism by fingerlings. Because it is virtually impossible to collect all of the young fish without draining the pond, significant numbers of fingerlings are often found at the end of the growout period, even when efforts are made to remove fry or fingerlings periodically.

Tilapia fry will school for several days after leaving the protection of the female. The schools of fry tend to remain near the edge of the pond, at least in temperate areas, apparently because the water is warmest along the pond's margin. Schools can be dipped out with a fine-mesh seine for transfer to rearing ponds. Alternatively, entire brood ponds can be seined periodically to remove fingerlings.

Tilapia are not always reproduced in open ponds, even in developing countries. In some countries, small, very fine-mesh cages are used for spawning and fry rearing. These cages, called "hapas," allow the fish farmer easily to capture fry, since they are confined within a small volume of water (Fig. 7).

Tilapia can be stripped of their eggs and milt for egg incubation in hatching jars, or the eggs can be removed from the mouth of the female and hatched. Some hatcheries use one or both techniques, but natural spawning is the most commonly used method.

Several methods have been developed to avoid the problem of early spawning and overpopulation of stunted fish in growout ponds (5). One method involves hand-sexing, wherein trained individuals examine each fish individually, retain the males for stocking, and discard the females. The fish need to be about 60 mm (2.5 in.) long and near maturity before differences in the genital region of the two sexes can be detected visually. Mistakes are bound to occur, either in making the sex determination or in placing a given fish into the wrong container following

Figure 7. Hapas are often used in the Philippines and other countries to spawn tilapia and for early rearing of fry.

sexing. This method is also very labor intensive and time consuming.

Various species of predatory fish have been stocked in tilapia ponds to consume fry, so that the ponds do not become over populated. The predator fish should not become large enough to consume the tilapia that are intended for growout, of course. While this method can be fairly efficient if the proper number of predators is stocked, it does not eliminate the stunting of females' growth, however, since the females are still allowed to spawn and mouthbrood.

A third method of controlling reproduction has been to rear tilapia in cages placed in ponds. The theory behind this technique is that when the females spawn, the eggs will fall through the bottom of the cages, thereby eliminating the two or more weeks of nonfeeding that would occur if the females were mouthbrooding, as well as effectively eliminating fry and fingerling production. The method apparently works to some extent, but some successful spawning has occurred when females are able to gather fertilized eggs before the eggs can fall from the cage.

Some hybrid crosses are reported to result in all-male or nearly all-male offspring. There are some problems associated with using hybridization to produce all-male populations, however. First, since many species of tilapia freely hybridize and produce fertile offspring, a large percentage of the fish in culture today are undoubtedly cross-bred to some extent. While they may be called *O. niloticus* or *O. aureus*, they may, in reality, have some contributions from other species in their genomes. Thus, fish that have been identified as belonging to both species *A* and *B* might produce all-male populations on one farm when hybridized, but fish thought to be of the same two species on another farm may not produce a ratio of males to females substantially different from 1 : 1. Secondly, it is virtually impossible to avoid mixing the two species on a fish farm. No matter how much care is taken, fish will inevitably be placed in the wrong pond or other holding facility. Extensive genetic testing to retain pure species is possible, but is prohibitively expensive.

Sex reversal has become a widely used method of producing all-male tilapia populations. Various hormones

have been used by fish culturists to produce sex-reversed tilapia, with some form of methyl or ethyl testosterone being the most common. The standard technique is to dissolve the hormone (commonly used hormones have been synthesized and are readily available) in alcohol. The alcohol is then poured over prepared feed and allowed to evaporate, resulting in the feed being coated with small amounts of the hormone. [Methyl testosterone works well with 30 to 60 mg/kg of feed (30 to 60 ppm).] Immersion in hormone solutions has also been used for sex reversal (6). First-feeding fry are provided with the treated feed, usually for about three weeks. If the process is done properly, 95 to 100% male populations can be produced.

The most recent development involves the production of YY males — that is, males with two Y chromosomes (diploid males are normally XY). The process involves exposing normal male tilapia fry to estrogens (female hormones) to produce females that are XY instead of XX (3). When feminized males are bred with normal XY males, the offspring produced will have the following genotypes: 1 XX female: 2 XY males: 1 YY male. Mating YY males with normal XY females will result in all-XY-male offspring. Producing YY males requires extreme care in identification of the genotype of each fish produced from the pairing of feminized males with normal males.

Water Quality Requirements

Tilapia are generally resistant to degraded water quality. That resistance is one of the characteristics that make tilapia popular aquaculture fish. The basic water quality requirements of tilapia have been known for at least a few decades (7).

Temperature is a critical water quality variable for all aquatic animals. As previously indicated, tilapia growth ceases when the water temperature drops below about 20 °C (68 °F), and most species die at temperatures between 8 and 12 °C (46 and 54 °F). Optimum growth occurs at about 30 °C (86 °F), and the upper lethal limit may exceed 40 °C (104 °F) for at least some species. As the upper temperature limit is approached, feeding activity will decline and eventually cease. In most pond culture, maximum temperatures, at least in deep water, where a thermocline may form, will not exceed about 34 °C (93 °F), and tilapia will continue to feed and grow.

Tilapia are unusually tolerant of low levels of dissolved oxygen. When the supply of dissolved oxygen becomes depleted, tilapia are able to surface and skim the water surface, to run the upper microlayer of water, which is saturated with oxygen by diffusion, across their gills. However, long periods of exposure to low levels of dissolved oxygen, while possibly not lethal, will stress tilapia, and the fish may not feed during periods when dissolved-oxygen levels are very low. In many instances, oxygen depletions occur near dawn, as respiration causes the level of dissolved oxygen to drop throughout the night. Once photosynthesis begins in the morning, oxygen levels will rise and may even reach supersaturation by afternoon.

Most tilapia hatcheries, even those that produce fish for rearing in saline waters, use freshwater or water of very low salinity, although *O. mossambicus* has been known to spawn over a wide range of salinities (8), including those somewhat higher than full-strength seawater (35 ppt). Fry may not be tolerant of saltwater, but fingerlings of many species can be either directly transferred or acclimated to saltwater, and some can even tolerate hypersaline conditions. Some strains of red tilapia are salt tolerant and may even reproduce in saltwater (9).

Tilapia have a high tolerance for turbidity, grow well over hardness and alkalinity ranges commonly observed in ponds, and can tolerate relatively high levels of ammonia.

Nutrition and Feeding

Most species of tilapia are omnivores. First-feeding stages typically consume zooplankton, but may eventually convert to plant-only diets or mixtures of plant and animal diets. Tilapia have the ability to digest carbohydrates, including starches, so they can be fed diets low in, or even devoid of, animal protein and still grow rapidly. Tilapia will accept prepared feeds from first feeding, provided that the size of the particles is appropriate. In areas where the ingredients are plentiful and can be used economically, tilapia are often fed prepared feeds containing some animal protein (e.g., fishmeal), along with such items as corn meal, wheat meal, soybean meal, and cottonseed meal. Vitamin and mineral supplements may also be provided. Because of the ability of tilapia to use vegetable protein efficiently, prepared feeds tend to be considerably less expensive than the feeds used for carnivorous fishes such as salmonids.

In developing countries, a variety of alternative ingredients have been evaluated, some of which are in use. A partial list of nontraditional tilapia feed ingredients is provided in Table 1. In developing countries, prepared feeds routinely contain rice bran, which has a low protein content and is high in indigestible fiber.

Since tilapia have a general tolerance for poor water quality conditions, they are often produced in ponds that receive heavy inputs of organic fertilizers from such terrestrial animal sources as ducks, chickens, swine, and cattle. The technique of fertilization as a means of promoting natural algae and zooplankton production is widely practiced

Table 1. Nontraditional Dietary Ingredients that are Used or have been Evaluated for Use in Prepared Tilapia Feeds[a]

Alfalfa	Algae
Azolla meal	Brewery waste
Cassava	Cocoa cake
Coffee pulp	Copra meal
Cowpeas	Cracked rice
Duckweed	Groundnut
Leucaena leaf meal	Lettuce
Linseed meal	Macadamia presscake
Mango seed	Mustard oil cake
Palm kernal meal	Rapeseed (canola) meal, cake, or oil
Salt bush	Sesame meal
Sesbania	Silage grass clippings
Soldier fly larvae	Sugarcane bagasse
Sweet lupin	Sweet-potato meal
Sunflower seed meal	Tapioca

[a] From (10).

in developing countries where the ingredients required to produce good-quality formulated feeds may be unavailable or are prohibitively expensive.

Specific nutritional information has been developed for various species of tilapia; most requirements are similar among the species investigated thus far. A summary of the general nutritional requirements of tilapia is provided in Table 2. The actual lipid and carbohydrate requirements of tilapia have not been determined in detail. Research indicates that at least some species seem to require fatty acids in the linoleic (n-6) and linolenic (n-3) acid families (see the entry "Lipids and fatty acids"). Tilapia seem highly capable of digesting simple sugars and starches.

As with other fish, fry tilapia are fed to excess, perhaps as much as 60% of their body weight daily. The feed should be evenly distributed over the culture chamber, to ensure that the fish will not have to swim long distances

Table 2. General Nutritional Requirements of Tilapia[a]

Nutritional Factor	Requirement
Crude Protein Requirements (% of dry diet)	
Fry	35–40
Fingerlings	25–40
Amino Acid Requirements (% of dry diet)	
Arginine	1.13–1.18
Histidine	0.43–0.48
Isoleucine	0.80–0.87
Leucine	0.95–1.35
Lysine	1.43–1.51
Methionine	0.40–0.75[b]
Phenylalanine	1.00–1.05[b]
Threonine	1.05–1.17
Trypophan	0.28
Valine	0.78–0.88
Vitamin Requirements (mg/kg[c] of diet, unless otherwise indicated)	
Choline	None[a]
Pantothenic acid	6–10
Riboflavin	5–6
Vitamin B_{12}	None[d]
Vitamin C	40–125[e]
Vitamin D	375 I.U.[f]
Vitamin E	25–100
Mineral Requirements (% of dry diet)	
Calcium	0.70
Manganese	0.90
Phosphorus	0.45–0.50
Zinc	0.20–0.30

[a]From (10).
[b]The requirement is variable, depending on the level of cystine in the diet.
[c]mg/kg = part per million (ppm).
[d]Research has been conducted, but no requirement level could be established.
[e]The range may relate to the form in which the vitamin was incorporated into the diet, as well as to the method of diet manufacture.
[f]I.U. = international units.

in search of food particles. Juvenile tilapia are typically fed 3 to 4% of their body weight daily. The number of daily feedings employed by tilapia farmers is highly variable, ranging from one to several times daily. The most common feeding schedule involves two feedings daily. Demand feeders may also be used, which allow the fish to feed *ad libitum*.

DISEASES

In many culture situations, tilapia are remarkably disease free, as compared with various other aquaculture species. However, A notable exception occurs when tilapia are stressed. In temperate ponds, reduced water temperature is the most common stressor. Tilapia populations that may have shown no signs of disease for months will develop a variety of problems when the water temperature drops in the fall. The high-density conditions that exist in closed systems, which may also involve long periods of exposure of the fish to somewhat degraded water quality, have also resulted in disease outbreaks.

No viral diseases have been reported from tilapia reared in the Americas (11), but various other diseases have occurred. In other parts of the world, there have been a few reports of viral diseases associated with tilapia (12). Viruses observed to date include *Lymphocystis* sp., (a marine virus), a birna virus, and a rickettsial virus.

Numerous occurrences of diseases, due to fungi and crustacean parasites have been reported in cultured tilapia around the world (11,12). The fungus *Saprolegnia* sp., has been known to attack the skin and fins of tilapia that have been damaged during handling. That fungus is restricted to freshwater. Marine counterparts to *Saprolegnia* exist, but have not been reported to attack tilapia reared in saltwater. Other fungi reported include *Achya* sp., *Aphanomyces* sp., *Aspergillus* sp., and *Dictyuchus* sp. Crustacean parasites that have infected tilapia include *Argulus* sp., *Caligus* sp., *Dolops ranarum, Ergasilus* sp., *Lamproglena* sp., and *Lernaea* sp.

Bacterial infections of tilapia include *Aeromonas* sp., *Pseudomonas* sp., *Vibrio* sp., *Edwardsiella tarda*, *Flavobacterium columnare* (previously known as *Flexibacter columnaris*), *Mycobacterium* sp., and *Streptococcus* sp. Protozoan parasites that attack the gills and skin of tilapia include *Amyloodinium* sp., *Chilodonella* sp., *Epistylis* sp., *Ithyobodo* sp., *Ichthyophthirius multifiliis*, *Trichodina* sp., and *Tripartiella* sp. Internal protozoan infestations include *Eimeria* sp., *Myxobolus* sp., *Myxosoma* sp., and *Trypanosoma* sp.

The monogenetic trematodes *Cichlidogyrus* sp., *Dactylogyrus* sp., *Enterogyus cichlidonum*, and *Gyrodactylus* sp., have also been reported in cultured tilapia. In addition to those freshwater species, a marine monogenean, *Neobenedenia melleni*, has been reported in tilapia held in marine cages. At least one digenetic trematode ectoparasite, *Transversotrema* sp., has been reported in tilapia as well. Monogenetic and digenetic endoparasites have also been reported.

Treatment chemicals that have been effective with regard to the control of tilapia diseases include the following (12): acriflavin, to control bacterial infections of

eggs; formalin, to control parasites and external mono-genetic parasites; furanace, to control bacteria; malachite green, as a fungicide on eggs and a protozoan parasiticide when mixed with formalin; masoten, as a parasiticide; nitrofuran, oxolinic acid, and potassium permanganate, as bacteriocides; and salt (sodium chloride), to control bacteria, fungi, and parasites. Either each chemical is added to the culture water or the fish are exposed by dip or bath treatment. The antibiotics oxytetracycline and sulfamerazine have been incorporated in tilapia feed to control bacterial infections. While clearance for some of the aforementioned drugs and chemicals is still being sought, there are currently no therapeutic agents approved for use on tilapia in the United States.

MARKETING

Depending on the particular market, tilapia may be sold live, in the round, gutted, headed and gutted, or filleted. In tropical areas, tilapia tend to be sold in the round. Shoppers in developing nations, who often do not have refrigerators, will purchase and consume the fish the same day. Live tilapia and tilapia in the round on ice are sold in various ethnic markets in the United States and Canada. Live tilapia are, for example, often seen in Asian restaurants, where customers are able to select from an aquarium display the fish that they want to be prepared for their meal.

Headed and gutted tilapia for home consumption are popular in some markets. They may be sold fresh on ice or frozen. In the United States, shoppers often prefer filleted fish, so that they do not have to deal with scales, skin, and bones. However, the dressout percentage for tilapia fillets is not particularly high (approximately 33% for 500-g (1.1-lb) fish, slightly more for larger fish and fish that are carefully hand filleted, and perhaps no more than 25% for smaller fish). Fillets are also considerably more expensive than other forms in which tilapia are marketed, and fillets of other species may be less expensive, so marketing fillets can be a problem.

Tilapia are marketed as tilapia, St. Peter's fish, and under various other names. The name "tilapia" is becoming increasingly familiar to the buying public in the developed world. In the United States, the modest level of tilapia production that currently exists [in excess of 7,700 metric tons (7,700 short tons) in 1997] is augmented with high levels of imports (28,000 tons in 1997). The highest percentage of imports is from Taiwan. Other nations from which significant amounts of tilapia are imported are Costa Rica, Ecuador, Indonesia, Columbia, Jamaica, and Thailand (13).

REGULATIONS

In the United States and some Latin American nations, the exotic status of tilapia continues to be recognized and has led to regulations aimed at controlling the spread of the fish into the wild. Importation by and movement of tilapia within various nations are controlled through the regulatory process. Some species are allowed to be imported or moved, while others are restricted. Tilapia have been reared in most, if not all, of the states of the United States, as well as in Canada.

In states where the growing season is insufficient to produce a crop before winterkill occurs, production of tilapia is confined to greenhouses and other types of buildings where intensive culture is practiced and supplemental heat is available. Intensive culture, often in recirculating systems, is also practiced in areas where regulations prohibit culture in systems where the fish can escape (or be carried from one place to another by birds or other animals) and thereby invade public waters.

The following states have some type of restriction on tilapia culture: Arizona, California, Colorado, Florida, Hawaii, Illinois, Louisiana, Missouri, Nevada, and Texas. In those states, a permit may be required to culture tilapia, or tilapia can be reared only if the species of interest appears on a list of approved fishes. Before obtaining tilapia, prospective tilapia culturists should check with the appropriate government agencies to determine which, if any, permits are required.

TURBOT CULTURE

JOE MCELWEE
Galway, Ireland

OUTLINE

Fertilization
Diseases/Health
    Future Prospects

Turbot are large flatfish, circular in shape, with both eyes on the upper side of the head, and a large fan shaped flattened tail. They are dispersed throughout most parts of the seas that surround Europe, including the Caspian and Black seas. They are normally dark brown to black on the dorsal side and white on the underside. Their flesh is white and succulent in taste. They also have small lumps on the dorsal side, termed tubercules, which are believed to act as sensory organs, when they are buried in the sand. Turbot tend to habitate in up to 30 m (90 ft) of water and tend to meander between that depth and closer to the shore, depending on migratory and food patterns.

FERTILIZATION

The sexually mature fish tend to come into the shore to spawn around August and September as water temperature increases to circa 14−16 °C (57−61 °F). It is not uncommon for the dorsal side to change in color from dark to light brown, depending on the surrounding bottom habitat.

The females can produce up to three million eggs over a spawning period of 5−8 weeks and are, for the most part, larger in size than their male counterparts, with both male and female reaching sexual maturity in about four to five years, weighing from 4 kg (8.8 lb) upwards and averaging 3−4 kg (6.6−8.8 lb) in size at spawning. A female may spawn several times during this period, with up to 500,000 eggs per spawn. Fertilization is external, and, accordingly, the rate of success is variable, depending on prevailing tides and water currents. The fertilized eggs are suspended in the water column, and after consuming their yolk sac in the first two days, will start to seek out their food, which consists of *Artemia* and rotifers. Juvenile turbot are born bilaterally symmetrical with eyes on either side of the head, similar to salmonids, and will start to metamorphose circa day 25−30, to the flattened shape, with the left eye migrating to the upper side. Turbot will also start to descend to the sea-floor to assume their new existence and adjust to their new surroundings, in the sandy gravel benthos. As with any small living entity, the juveniles are prone to predation by larger demersal fish until they metamorphose properly, and can outmanouver predators in the open deeper waters. There may also be increased mortality levels, due to starvation and swimbladder deformities.

Since turbot feed on the bottom, they have adapted mouths quite large in proportion to the head size. In the wild, they can grow in size to 30 kg (66 lb) or more.

However, due to consistent overfishing, it's rare to catch one of that size. In relation to their body size, their gut cavity is relatively small and is located on the dorsal side, to the right of the head, as one would look at the fish from head on.

DISEASES/HEALTH

Like any animal living in natural or cultured conditions, turbot are susceptible to parasites (both internal and external) and diseases caused by both bacteria and viruses. There are a number of bacteria and viruses naturally present in the water, which, if the health of the fish is compromised, will take a quick and often deadly hold. Some bacterial problems will naturally dissipate through time, or if the fish's own immune is strong enough to fight it off. These will tend to occur through the lifespan of the fish as it forages for food or sustains flesh damage from skirmishes with potential predators, or in-house fighting. The turbot's own immune system is strong enough to generally fight off most bacterial problems. In intensive culture systems, the constant risk of infection is heightened, due to the numbers being stocked in such close proximity. The following are some of the bacterial affiliations common to turbot:

Vibrio's spp.
Pseduotuberculosis sp.
Furunculosis sp.
Streptococcus septicimic disease
Alteromonas sp.
Aeromonas salmonicida
Flexibacter sp.

Common treatments for bacterial problems in cultured regimes are the use of varying antibiotics in feed and immersion or bath treatments, again with an antibiotic chemical.

Viruses are naturally harder to fend off and can result in dramatic health problems and rapid mortalities in both wild and farmed stocks. While after time, fish in the wild may develop antibodies and a resistance. In intensive systems, vaccines are actively employed as a preventative measure. These are in constant development, due to the nature of viruses. Transmission of these viruses can be from direct contact with already infected stock or from other fish species. The following are some of the more prevalent viruses:

(1) Viral Heamoraghic Septicemia (VHS)
(2) Iridovirus/Rodovirus
(3) Rickettsial-Epitheliocystsis
(4) Paramyxovirus

There are a few others, but these are the major dangerous viruses that turbot contend with at present, and vaccines are being constantly being adapted to combat newer strands of viruses.

Turbot may also be afflicted by a number of other health problems that can be more attributed to environmental

and water quality problems and thus may arise commonly in farmed systems.

External parasites on the gills and skin can cause not only unslightly sores, but also give rise to bacterial and viral problems relatively quickly if not treated. Some of the main parasites that cause problems for turbot are the following:

Protozoa:
    Ciliates
    Trichodina spp.
    Cryptocaryon spp.
    Scyphydia spp.
Flagellates:
    Ichthyobodo necator
    Costia sp.
Microsporidia:
    Tetramiera brevifilum

Trichodina, a ciliate parasite, can settle in the gill lamellae or the skin surfaces. It can create sores if left untreated and respiratory problems within the gills. A variety of myxobacteria can also cause problems, and *Flexibacter* can lead to vibriosis and other serious ailments. These, for the most part, are easily treated and show evident physical damage prior to serious stages. Most are treated with tetracycline or quinolones (oxolinic acid and flumequine) and nitrofuranes and sulfonamides, by treatment in one-hour baths or inclusion in the feed.

Future Prospects

Turbot is a high priced delicacy in Europe at present and enjoys a niche market. It is cultured in a number of European countries in land-based pump-ashore systems, many using expensive filtration and heating facilities. Over the past few years, technology and biological advances have enabled hatcheries to successfully produce large numbers of juveniles, which are subsequently transported to grow out facilities. There is extensive detailed work being done with regard to genetic's and subsequent follow-up work with the sibling generations being reared.

There is a future for turbot farming, and as the market requires and demands more diverse and nutritionally healthy products, the rearing of different species should occur. As the fish species in the world are constantly being overfished, there is a huge opportunity in this area of the aquaculture industry.

V

VACCINES

LARRY A. HANSON
Mississippi State University
Mississippi State, Mississippi

OUTLINE

Vaccines are useful tools for increasing efficiency of fish production. The basic purpose of a vaccine is to enhance the immune system's ability to recognize a disease-causing infectious agent and therefore reduce the severity of a disease. Optimally, this results in better growth, reduced use of therapeutics, and decreased losses. One must consider the costs of administering the vaccine, its effectiveness, its potential side effects, and regulatory issues before the vaccine is developed for an industry and made commercially available. The aquaculturist must consider the same issues, since they relate to the unique characteristics of the specific production facility. For some diseases, the aquaculturist has several options as to the vaccine or vaccination methodology. There are five groups of vaccines: killed, subunit, live, genetic, and inducers of nonspecific defenses. Vaccines can be administered by injection, immersion, or incorporation into the feed. The focus of vaccine development is to maximize the immune response to the pathogen, while minimizing cost and negative side effects such as handling stress. Factors that influence vaccine effectiveness include the immune status of the fish; the quantity, form, and persistence of the antigen; and the route of antigen expression/uptake in the fish. Because of potential benefits and the complex characteristics of vaccines used in aquaculture, there have been a large research focus and several review articles and books written on fish vaccinology (1–5).

KILLED VACCINES

Killed vaccines are crude antigen preparations derived from the disease-causing agent. They are processed in such a way as to kill or inactivate the agent. This is the most common type of vaccine in aquaculture. This type of vaccine contains most of the antigens produced by a pathogen, and, at least for bacterial pathogens, is relatively inexpensive to produce. The pathogens are generally inactivated by using heat or a chemical, such as formalin. Because the agent is killed, storage of the vaccine and safety of the vaccine are generally of less concern than they are for live vaccines. Safety concerns for killed vaccines usually involve residual activity of toxins produced by a bacterial agent. The susceptibility of fish to bacterial toxins varies with species and age of the fish. In some killed vaccines, the protective antigen may not persist in the fish at a high enough level to induce a strong response. This may result in shorter duration or lower levels of immunity than those provided by live vaccines. This lower-level response can be enhanced by providing multiple exposures or by incorporating adjuvants into the vaccine. Adjuvants are substances that enhance the immune response of the fish to the antigens in the vaccine. These substances can change the physical characteristics of the vaccine, or influence the immune system directly, to improve the ability of the fish to respond to the vaccine (6). Another concern in the use of killed vaccines is the potential for the culture methods or the methods used to inactivate the agent to alter the form or quantity of a critical antigen, and therefore reduce vaccine effectiveness. Also, if the agent is an intracellular pathogen (like a virus), the killed vaccine will not induce as strong a cell-mediated immune response as would a live agent. Successful commercially available killed vaccines include vaccines for enteric red mouth disease for salmonids (7), furunculosis for salmon (8), and mono- and multivalent *Vibrio* vaccines for salmon and other marine fish (9). An inactivated vaccine for spring viremia of carp has been commercially produced (10) but is no longer available (11). Research has demonstrated the effectiveness of killed vaccines for enteric septicemia of catfish (ESC). Two ESC vaccines have been evaluated for commercial production: one conditionally licensed, the other fully licensed by the U.S. Department of Agriculture. Neither product is commercially available at this time (12). *Photobacterium damselae* bacterins for marine fish show promising results (13).

SUBUNIT VACCINES

Subunit vaccines are purified antigen preparations that consist of a single protein or portion of a protein that can induce a protective immune response in fish. Subunit vaccines have the advantage of focusing the immune response of the fish toward the specific antigen. They also allow the mass production of the specific antigen by chemical synthesis or biological expression systems. These characteristics are especially important in the establishment of practical vaccination systems against infectious organisms that are expensive to produce, such as viruses and parasites. Also, because the fish is not exposed to the entire array of antigens that the pathogen expresses, the serologic characteristic of a fish exposed to

a subunit vaccine would be different from that of a fish exposed to the pathogen. This allows for the differentiation of vaccinates from potential carrier fish in serologic assays. Subunit vaccines have the same constraints of killed vaccines; i.e., dosage, duration, and inefficiency in inducing cell-mediated immune responses. No subunit vaccines are commercially available for aquaculture at this time, but promising research indicates that subunit vaccines against several viruses will be effective. The A segment encoding VP2, VP3, and NS from infectious pancreatic necrosis (IPN) virus was expressed in the bacterium *Escherichia coli*, and lysates from this expression system that were used in immersion exposures also protected against IPN (14). Recent field trials have been performed on Atlantic salmon (*Salmo salar*) using injection vaccines containing *E. coli* expressed VP2 with encouraging results (15). Subunit infectious hematopoietic necrosis (IHN) vaccines have been produced from the viral glycoprotein expressed in *E. coli* that induce protection against IHN after immersion vaccination (16,17). This subunit vaccine has shown promising results in field trials (1). Also, maternal transfer of antibodies was demonstrated from broodfish that were given injection vaccinations of a similar subunit vaccine; these results indicate some protection of fry up to 25 days posthatch (18). Injection-administered subunit vaccines based on the glycoprotein of viral hemorrhagic septicemia (VHS) virus have been effective against VHS in laboratory trials (19).

LIVE VACCINES

Live vaccines are generally mutated strains of an infectious agent that have a reduced ability to cause disease and are referred to as attenuated. During vaccination, fish are infected with these attenuated agents and develop protective immunity that will provide protection when the fish are exposed to the virulent disease-causing agent. These vaccine agents can be developed by inducing mutations in the disease-causing agent by growing it in an unnatural host, exposing it to a mutagen, or using genetic engineering to inactivate certain genes that are involved in inducing disease. In some cases, a naturally occurring nonvirulent organism related to the disease-causing agent can be identified which will infect the fish and induce a protective response to the disease-causing pathogen. The effects of live vaccines are based on the ability of the agent to actively infect and replicate in the fish. This ability provides the persistence and dosage needed to induce a strong immune response even when using inefficient application methods. Additionally, the mode of infection is the same as in the disease-causing agent, allowing the induction of focused local immunity at critical locations and the induction of cell-mediated specific immunity in the case of intracellular pathogens. Disadvantages of live vaccines are related to storage and safety. Because the vaccine agent must be kept alive, storage conditions must be critically controlled. Improper storage, preparation, or application can result in vaccine failure. Safety concerns are related to the effect of the infectious vaccine agent on the physiology of the fish. Attenuated agents occasionally cause severe disease in

an immunosuppressed host, and they can cause mild disease and temporary immune suppression during the initial stages of the infection. This may lead to reduced feeding activity, reduced growth rate, and a predisposition to other diseases. Because of potential side effects from live vaccines, timing can be critical for the most effective and safest administration of these vaccines. Another factor that must be considered in the administration of attenuted agents that are derived from uncharacterized mutations is the ability of some attenuated agents to mutate back (revert) to a more virulent form in the host. Genetically engineered, live attenuated agents are generally designed so that reversion cannot occur. Another type of vaccine that shows promise for aquaculture is the vaccine vector. In this system, an attenuated, infectious agent is genetically manipulated so that it expresses protective antigens from other pathogens. In this type of system, one application of vaccine could provide protection against several pathogens. No attenuated agents are currently licensed for use in aquaculture, but laboratory studies have demonstrated effective vaccinations with attenuated live vaccines for furunculosis in salmonids (20), ESC (21,22), IHN (23), VHS (24), spring viremia of carp (10), and channel catfish virus disease (25,26). Vaccine vector potential has been demonstrated for attenuated *Aeromonas salmonicida* (27) and channel catfish virus (28).

GENETIC VACCINES

In 1990, it was shown that genes in purified DNA could be expressed when injected into the muscle of mammals (29) and that this expression could be used to induce an immune response to the gene products (30). Since then, research has been performed on a variety of fish and has shown that this methodology can be used in fish as well (31–33). The DNA injection method of vaccination induces an immune response to a specific protein or proteins encoded by the injected DNA and can induce a cell-mediated response. At present, vaccines of this type are not used in aquaculture, but they are used as tools for vaccine and immunology research.

INDUCERS OF NONSPECIFIC DEFENSES

When a fish is exposed to a pathogen, the focus of its physiology changes from maintenance and growth to defending itself from disease. Certain infectious agents or components of pathogens strongly induce this response, and these agents can be used to heighten the nonspecific defenses of fish at critical times. Cell wall components of fungus, gram negative bacteria, and acid fast bacteria have all been shown to induce nonspecific defenses and have been used to strengthen fish immunity or immune responses to vaccines in the form of adjuvants (6). Additionally, challenging a fish with an infectious agent that has a low ability to cause disease can induce a heightened nonspecific immunity. The nonpathogenic chum salmon reovirus has been shown to induce a response in rainbow trout (*Oncorhynchus mykiss*) that provides

protection against IHN (34). This induction of nonspecific defenses may be responsible for some short-term cross protection (observed after application of a vaccine) and can obscure true induction of specific acquired immunity in experimental vaccine trials. In the short term, this protective response can be useful, especially at early life stages, when the acquired immune system is not fully functional.

ROUTE OF ADMINISTRATION

Route of administration is largely determined by the type of vaccine available, the characteristics of the fish, and the severity of the problem. Most vaccines for fish are applied using an extensive application technique such as oral or immersion administration. This is generally the case because of the high numbers of fish that must be vaccinated, the relatively low value of the individual fish, and the stress-induced losses that are encountered when are uses injected vaccines.

Oral administration is accomplished through the incorporation of the vaccine in the feed. This method of vaccination eliminates stress-induced side effects, because the fish are not handled. However, oral administration is generally considered the least effective method of vaccinating the fish per application. Orally administered vaccines result in disproportionate application of the vaccine, due to disproportionate consumption of feed by the individuals in the population. Also, many antigens are not taken up by the gut or are poorly recognized by the immune system when absorbed via the gut. The low recognition of the immunogens is at least partially counteracted by the relative ease of application, allowing several applications sequentially over several days and thus providing antigen persistence.

Immersion vaccination is better for the equal distribution of the antigen within a population. Generally, the fish are netted or crowded and placed in a concentrated suspension of antigen for a short period of time and then released. All of the fish are exposed to the same amount of antigen. When killed or subunit antigen preparations are used, the fish absorb the antigen through the gills, skin, and gut. The persistence, concentration, and structure of the antigen influence the effectiveness of the vaccination on the fish.

In live vaccines, the agent actively infects the host, and replicates to provide the persistence and dosage needed to induce a strong response. Therefore, extensive methods of vaccination are generally used. Many of the live agents infect through the gut, making oral application of the agent feasible. However, more reliable dosing, ease in preparation, and maintenance of viability makes immersion exposure the most common method of application for live vaccine studies.

Vaccines administered by injection can provide the highest level of antigen in a single application. The formulation used can be an emulsion that slowly releases the vaccine, allowing for persistence. Practical routes of injection are intramuscular or intraperitoneal. Generally, intraperitoneal injections are used for food fish, since damage that could occur to the musculature from an intramuscularly administered vaccine would reduce the value of the flesh. Also, a larger volume of vaccine can be injected into the peritoneal cavity and retained after a single injection than by the intramuscular route. The negative aspects of injection vaccination are the manpower required and the stress induced by handling. Efficiency can be increased substantially by using an automated injection device or by setting up an assembly line with repeatable injectors. Nevertheless, individual handling and injection is practical only for fish that have high value and that are of a size that can be easily handled. In addition, extreme care must be taken when handling fish for injected vaccines. The fish must be anesthetized and processed quickly with minimal damage to the skin. Handling injury and induced stress is substantially higher when injected vaccines are given.

IMMUNE STATUS

The immune status of the fish is a critical parameter that determines the effectiveness of a vaccination. Vaccines work best in healthy, well-nourished fish that have a fully developed immune system and have not been environmentally or metabolically stressed. These conditions are often not convenient or practical to aquaculture operations. Often times, vaccination is desired at a very early stage in fish development. In fish species that have been evaluated, the acquired immune response is not fully functional until well after the fish have begun feeding. Also, the developmental stage at which effective vaccination can be done in fish is dependent on the type of antigen that elicits a protective response, and therefore will vary with the vaccine as well as the species vaccinated (35,36). In a broad sense, T-dependent antigens, like most proteins, are responded to later in developmental than are T-independent antigens (such as the complex sugar subunits of the lipopolysaccharides in gram-negative bacteria). If fish are vaccinated before they are developmentally mature enough to recognize the antigens, not only do they not respond, but they can develop an inability to respond to the antigen at a later date. This phenomenon is known as antigenic tolerance (a similar phenomenon known as anergy can occur if the immune system is overloaded with antigens and it is difficult to differentiate the two effects in developing fish). This phenomenon could result in a vaccinated fish population having higher losses than nonvaccinated fish during an outbreak of the disease that the vaccine was designed to prevent. Other metabolic factors that will affect vaccination efficacy are hormonally induced immune suppression due to smoltification in anadromous species and spawning and temperature-induced immune suppression. The timing of immunizations are critical for the desired effect. Generally, fish are thought to have a less sophisticated form of acquired immunity than mammals and birds. The boosting effect seen from giving fish multiple exposures to a vaccine is not as fast, as strong, or as long lasting as that seen in mammals. Also, this boosting should occur while there is a low persistent effect from the previous exposure. For best effect, boosting or primary exposure should be done within

one to three months of when the first outbreaks of the disease are expected to occur. If the disease usually occurs during periods of immune suppression, such as smoltification or spawning, the fish should be vaccinated three to four weeks before the immune suppressive event occurs so that residual humoral immunity can help protect the fish.

Finally, because the immune system is most effective in healthy nonstressed fish, the use of vaccination does not reduce the need for constant environmental management or allow the aquaculturist to push the productive capacity of the system. Reduced water quality due to overstocking and overfeeding will result in stressful conditions. If severe enough, the long-term stress response induced by the stress hormones will cause suppression of the immune system and seriously reduce the effectiveness of the vaccine.

NEGATIVE EFFECTS

Negative side effects of vaccinating fish can include reduced growth, reduced feeding, handling induced injuries, and stress-induced metabolic changes. Many of these side effects are simply the effect of the normal stress response due to the handling of the fish. These effects can be minimized by keeping physical handling to a minimum, keeping all surfaces that the fish contacts wet and smooth (preferably transported in a cushion of water), using anesthetics as soon as possible, avoiding temperature changes and maintaining optimal water quality throughout the operation. Supplementing water in recovery tanks with salt, magnesium, and calcium for freshwater fish during recovery will reduce osmotic imbalances induced by handling.

Other side effects are due to the makeup of the vaccine. Attenuated live vaccines are infectious agents, and certain components of killed vaccines induce the mediators of the immune system. The release of high amounts of these mediators into the bloodstream can temporarily switch the homeostatic focus of the fish from growth to induction of specific and nonspecific immunity. These mediators are the factors that induce fever and malaise in humans. In fish the effects of these mediators may result in a temporary reduction in feeding activity and a short term loss in feed conversion.

Another potentially negative result of using vaccines is related to the regulatory surveillance of pathogens. The induction of specific antibodies may result in the misidentification of populations of fish as endemic for a regulated pathogen when they are just vaccinated and not carrying the pathogen. The use of antibody specific assays such as serum neutralization and ELISAs for screening previously exposed fish can result in this false positive identification, which can in certain instances affect the marketability and transport of the fish. Alternatively, the use of modified live vaccines and subunit vaccines that have a different antigenic profile from the wild-type pathogen and antigen-based assays can be designed that can differentiate vaccinated fish from those exposed to the disease-causing agent.

BENEFITS

Benefits of implementing an effective vaccination program against a disease in endemic areas include not only the short-term effects of increased survival, reduced expenses on therapeutics, and increased growth, but also the longer-term effects of reduced medication induced antibiotic resistance of bacterial pathogens in the system and the potential for eliminating a pathogen from the population. The use of a vaccine can not only reduce disease induced deaths in a population but also it can reduce the amount of subclinical disease. Generally, when it infects a healthy host, a pathogen does not kill the host. Disease outbreaks that result in detectable mortality in a population are a small fraction of the total number of diseases that pass through the population. In aquaculture these diseases would generally go unnoticed or would be recognized as a temporary reduction in feeding behavior. These diseases can last for one to several weeks in the individual fish resulting in reduced feeding and weight loss. In more severe cases damage to vital organs can cause poorer performance and a predisposition to other pathogens in the environment. It has been shown that when fish in endemic areas were effectively vaccinated against enteric red mouth disease, or vibrio, they demonstrated significantly higher growth rates as well as better survival. The reduced need for antibiotics, in the case of effective vaccines against bacterial diseases, reduces the selective pressure on all of the bacterial pathogens in the system to develop antibiotic resistance. Therefore, over time, the aquaculture facility that effectively uses vaccination programs to reduce disease incidence is less likely to encounter problems from antibiotic resistance in the common bacterial pathogens in the system. Therefore, when an important bacterial disease outbreak occurs, the available antibiotics can be effectively used. The ultimate goal of a vaccination program is to reduce the incidence of the disease-causing pathogen in the population. This can be accomplished when the vaccination provides protective immunity that results in a substantially reduced ability of the pathogen to infect and to be shed from the host. Although vaccinations cannot induce protective immunity in all of the individuals in a population, if a large enough percentage of the population has protective immunity to the pathogen, the pathogen cannot maintain itself in the population (37). Thus, through a stringent program of vaccination and pathogen avoidance it is possible to cure an endemic population of the pathogen.

The decision to use a vaccine on an aquaculture operation is often not easy. The cost, management changes, risks, and benefits in using a vaccine are difficult to assess and are different for each operation. Often, the benefits are not clear cut; some vaccines reduce the incidence of a disease, but do not eliminate the disease. Also, user experience and skill and environmental effects can often confound the issue. Many managers will try a vaccine on a portion of the operation. This allows them to learn how to best incorporate the management tool into their production system and evaluate the vaccine's effectiveness before applying it to the entire system.

VIRAL DISEASES OF FISH AND SHELLFISH

YOLANDA J. BRADY
Auburn University
Auburn, Alabama

OUTLINE

INTRODUCTION

The effects of viral diseases of finfish and shellfish may range from little effect to catastrophic. Viruses may be present without detrimental effects, but when the environment deteriorates and fish succumb to environmental stressors, disease outbreak is usually the result. New viruses are being continually discovered and their effects on the host organism may not be fully known. Often viruses are detected in cell culture but detection is limited to the availability of compatible cell culture systems. Viruses have also been detected visually by electron microscopy and molecular techniques. As more interest in husbandry of new species arises, it is likely that more new viruses will continue to be discovered. Currently there are no effective treatments for viral diseases in fish and shellfish. Management practices must be used to prevent the introduction of viruses into a culture system or, once present, managed by manipulation of water temperature, good nutrition, and best management practices to keep viral disease outbreaks to a minimum. The following is a summary of descriptions of the major viral diseases in fish and shellfish.

ADENOVIRIDAE

White Sturgeon Adenovirus

White sturgeon adenovirus (WSA) was first identified in juvenile white sturgeon in the mid-1980s at a farm in northern California. Fish appeared lethargic, were anorexic and emaciated, and had pale livers and no food in the intestine. Mortality may reach 50% with this virus, however, no severe disease problems have been reported since 1986 (1,2).

BACULOVIRIDAE

Baculoviral Midgut Gland Necrosis

Baculoviral midgut gland necrosis (BMN) is classified as a type-C baculovirus and causes serious peracute epizootics in hatchery reared *Marsupenaeus japonicus* in southern Japan and in *Penaeus monodon* in Australia. There are no specific clinical signs except that the disease has a sudden onset with a high mortality rate of up to 98% (3,4).

Baculovirus Penaei

Baculovirus penaei (BP) is a type-a occluded baculvorus. It is also known as BP virus disease and nuclear polyhedrosis disease. Several strains are likely to exist based on different morphological characteristics of the virion, especially size. Distribution is widespread in cultured and wild penaeids in the Americas from northern Gulf of Mexico through the Caribbean to central Brazil. BP can cause serious epizootics in larval and postlarval juvenile stages, with an acute onset and high mortality rates. Epizootics range from chronic to acute with high mortality, however, presence of the virus may not always indicate disease. Severely affected mysis stage larvae and post larvae may exhibit a white midgut line through the abdomen. The principal clinical sign is the presence of tetrahedral occlusion bodies in the hepatopancreas and midgut epithelial cells. Hosts include *Farfantepenaeus aztecus*, *Litopenaeus vannamei*, *Farfantepenaeus duorarum*, *Litopenaeus setiferus*, and *Litopenaeus stylirostris* (5).

Cherax Baculvirus

Also known as baculovirus of blue crayfish and hepatopancreatic baculovirus of *Cherax* this was the first reported baculovirus in a decapod crustacean, described in *Cherax quadricarinatus* in Australia. First seen in Australia, then in second-generation crayfish cultured in California, the impact on the host is uncertain, since up to 52% of crayfish examined in Australia were infected but no distinct clinical signs were present. In California, infected animals grew poorly but mortality was not significantly higher than animals not infected (5,6). The virus was detected in hepatopancreatic tubular epithelial cells. Animals were in poor condition but were not experiencing unusually high mortalities. The disease occurs in juvenile, subadult, and adult crayfish (3).

Monodon Baculovirus

Monodon baculovirus (MBV) is classified as a type-A occluded baculovirus. It is worldwide in distribution, including the southeastern United States. The primary clinical sign is the presence of a single or multiple spherical inclusion body in the hepatopancreas and midgut epithelial cells. The virus causes moderate to heavy infections in the hepatopancreas and anterior midgut. Mortalities may exceed 90%, with clinical signs of reduced feeding and growth rates and increased surface and gill fouling due to epicommensals. Also present are lethargy, anorexia, and dark pigmentation. Severely affected larvae and postlarvae may exhibit a white midgut line through the abdomen. Species infected include *P. monodon*, *Fenneropenaeus merguiensis*, *P. semisulcatus*, *P. kerathurus*, *L. vannamei*, *P. esculentus*, *P. penicillatus*, *P. plebejus*, and *Metapenaeus ensis* (3,4).

Tau Virus of Crabs: Baculoviruses A and B, Subgroup C Nonoccluded Baculovirus

Tau virus causes hepatopancreatic lesions and destruction of epithelial cells. Decreased aggressive behavior is evident, followed by lethargy, anorexia, and death (3).

Species affected are *Callinectes sapidus*, *Carcinus maenas*, *C. mediterraneus*, and *Macropipus depurator* (4).

White Spot Syndrome Baculovirus Complex

At least three viruses have been described in the white spot syndrome baculovirus (WSBV) complex and have been reported in China, Japan, Korea, Thailand, Indonesia, Taiwan, Vietnam, Malaysia, India, and Texas. Natural infections were observed in *P. monodon*, *M. japonicus*, *Fenneropenaeus chinensis*, *Fenneropenaeus indicus*, *F. merguiensis*, and *L. setiferus*. The onset of disease is usually acute showing rapid reduction of feeding, lethargy, and loose cuticle with white spots, which are mostly apparent on the inner surface of the carapace. White spots represent abnormal deposits of calcium salts by the cuticular epidermis. In many cases, moribund shrimp display a pink to reddish brown coloration due to the expansion of the cuticular chromatophores. Mortalities may reach 100% within 3 to 10 days of the onset of clinical signs (3).

Yellow Head Virus (YHV) Disease, Yellow Head Baculovirus

Initially described in Thailand and probably widespread in cultured *P. monodon* in India and southeast Asia, YHV, along with mixed infection of TSV and WSBV, were observed in pond-reared juvenile *L. setiferus* from south Texas. Shrimp packing plants are thought to be the cause. Behavioral clinical signs include abrupt increase in feeding rate for several days, then total cessation of feeding followed by moribund shrimp swimming at the surface pond edge. The primary clinical sign is a bright yellow cephalothorax. Massive mortality begins by day three after feeding cessation. Also evident are white or pale yellow to brown gills (3,4).

BIRNAVIRIDAE

Eel Virus European

Eel Virus European (EVE) was isolated from European eels cultured in Japan and Japanese eels and tilapia in Taiwan. Clinical signs include rigidity with muscle spasms and congested anal fins, hyperplasia of lamellar epithelium, clubbed filaments, ventral petechiation, enlarged kidney, and ascites. EVE is found in cultured young European and Japanese eels. Disease occurs at 8 to 14 °C. Mortalities may reach 60% (2,7).

Infectious Pancreatic Necrosis

A subacute disease of salmonid fry and fingerlings, infectious pancreatic necrosis (IPN) or IPN-like viruses have been isolated from marnie and freshwater fish and invertebrates. Combined into the aquatic birnavirus group, IPN was the first proven viral disease of fish. IPN is found in 22 countries including North and South America, Europe, and Asia. Brook and rainbow trout are most susceptible, but virtually all salmonids are susceptible. Larger fry and fingerlings are the first to develop clinical signs. Externally infected trout have dark pigmentation, distended abdomen, exopthalmia, hemorrhages on ventral

surface and fins, and pale gills. Internally, there is general hemorrhage with obvious petechiae throughout the viscera, pyloric caeca, and adipose tissue. The spleen, heart, liver, and kidneys are pale. The body cavity is filled with a pale yellow fluid, and the posterior stomach contains gelatinous mucoid plug that is pathogomonic. IPN infections range from subclinical to acute with up to 100% mortality in trout populations. Optimum temperature is 10 to 15 °C. Survivors become carriers and shedding virus is seasonal (2,7–10).

FISH TUMOR VIRUSES

Over 50 types of fish tumors or tumorlike proliferations have been linked to viruses. Many of these have not been isolated or characterized and have only been visualized with electron microscopy (7,11).

HERPESVIRIDAE

Anguillid Herpesvirus

Also known as anguillid herpesvirus (HAV) 1, eel herpesvirus, and *Herpesvirus anguillidae*, HAV has been found only in limited populations of eels in Japan. Eels showed varying degrees of erythema on skin and gills. Optimum temperature for the disease is 20 to 25 °C (12).

Bifacies Virus of Crabs

Bifacies virus of crabs (BFV), also known as herpeslike virus of blue crabs (HLV), has been seen in *C. sapidus* and others on the east coast of the United States and possibly worldwide. The hemolymph fails to clot and is chalky due to viral lysis of hemocytes (3).

Channel Catfish Virus Disease

Channel catfish virus disease (CCVD) is an acute viral disease infecting juvenile channel catfish, *Ictalurus punctatus*, in most Southern states and worldwide where channel catfish are cultured. CCVD was first discovered in 1968 experimentally in fingerling blue catfish and channel × blue hybrids by injection. Brown and yellow bullheads are not susceptible. European catfish are also resistant. Clinical signs include distended abdomen, expothalmia, pale-to-hemorrhagic gills, and hemorrhage at the base of fins, throughout the skin, and on the ventral surface. Infected fish swim erratically, sink to the bottom, and respire weakly before death. Internally there is a clear yellow-colored fluid in the peritoneal cavity, general hyperemia and pale liver and kidneys, dark red enlarged spleen, no food in the stomach or intestine, and the presence of a mucoid secretion. CCVD usually occurs during the summer when temperatures are above 25 °C (2,7).

Epizootic Epitheliotropic Disease

Acute mortalitiy in juvenile lake trout in the Great Lakes Basin was caused by epizootic epitheliotropic disease (EED). The virus effected lake trout × brook trout hybrids.

Clinical signs include lethargy, erratic swimming, and hemorrhage in the eyes and mouth. Epithelial hyperplastic lesions and gray-to-white mucoid blotches develop on the jaw, inside the mouth, and on the body and fins. Secondary fungal infections develop in the eyes, fins, and body. Internally, infected fish have a swollen spleen. HAV is a significant juvenile disease in lake trout populations (13).

Fish Pox, Herpesvirus of Carp, Carp Herpesvirus, *Herpesvirus cyprini*

Carp pox has been reported in Europe, China, Japan, Korea, Israel, Malaysia, and the United States Common carp and koi carp are the primary hosts. Fish pox are benign, hyperplastic papillomatous growths on the epithelium of carp. Tumors are white to gray, elevated to 1 to 3 mm above the skin, and are commonly found on the head, fins, and body. Tumors are generally small, but may increase in size and then regress and disappear. Fish show no specific behavioral signs and usually no morbidity. Juvenile carp can suffer high mortality. Clinical signs include anorexia, distended abdomen, expothalmia, dark pigmentation, and hemorrhages on the operculum and abdomen. Young fish exposed to the virus may not show clinical signs for up to one year (2,7).

Goldfish Herpesvirus

Also known as herpesviral hematopoietic necrosis (HVHN), this virus was the cause of a severe epizootic in Japan with no apparent clinical signs. Not much is known about the virus (14).

Herpeslike Virus of Crabs

This virus causes extensive destruction of the bladder and antennal gland. No gross clinical signs have been reported. Species affected are *Paralithodes platypus*, *P. camtschatica*, and *Lithodes aequispina* in Alaskan waters over a large geographical range (3).

Herpes-Type Virus Disease of Oysters

A herpes-type virus was found in the eastern oyster, *Crassostrea virginica*, in the Piscataqua River, Maine. The virus was also seen in the Pacific oyster, *C. gigas*, in hatcheries in New Zealand and France. Clinical signs are pale digestive glands, which may be caused by poor conditions, elevated temperatures and crowding (3).

Salmonid Herpesvirus Type 1

Salmonid herpesvirus type 1 (SHV-1) comprises 10 herpesviruses isolated from trout and salmon. SHV-1 causes mild disease of rainbow trout. SHV-1 was first isolated in Washington State and later in California. Steelhead and rainbow trout are natural hosts, while chum salmon fry and chinook salmon are experimentally susceptible. Atlantic salmon and brook and brown trout are refractive. Clinical signs include dark pigmentation, experimental exposure, anorexia, lethargy, erratic swimming, exopthalmia, hemorrhage, pale gills, distended abdomen, and mucoid fecal casts. Internal signs include bloody gelatinous ascites, flaccid intestine, hemorrhagic liver,

mottled or friable liver, and pale kidneys. SHV-1 is of minimal importance and low pathogenicity (15,16).

Salmonid Herpesvirus 2, *Oncorhynchus masu* virus (OMV)

Salmonid herpesvirus 2 (SHV-2) causes mortality in juvenile masu and coho salmon and tumors on adult fish in Japan. In juveniles, the acute disease kills 30- to 150-day-old fish. Clinical signs include anorexic, exopthalmic, petechial hemorrhage on the body. Internally, infected fish have a mottled white liver and swollen spleen. Neoplastic tumors develop in survivors, primarily around the mouth but also sometimes on the operculum, body, and cornea. SHV-2 is a major problem in land-locked salmon populations and cage-cultured coho in northern Japan (17).

White Sturgeon Herpesvirus

Two types of herpesviruses have been isolated from white sturgeon and were designated white sturgeon herpesvirus-1 (WSHV-1) and white sturgeon herpesvirus-2 (WSHV-2). WSHV-1 was first reported in California sturgeon while WSHV-2 was detected in sturgeon from commercial farms in California and wild sturgeon in Oregon. No specific clinical signs for either viral disease have been described. Fish appear normal and continue to feed until death (2,18,19).

IRIDOVIRIDAE

Catfish Iridovirus

Catfish iridovirus (CIV) was first isolated from cultured black bullheads in France. Clinical signs include body and muscle edema, petechial hemorrhage, pale gills, and ascites. Disease occurs from 15 to 25 °C. Mortality may reach 100%. The full impact of this disease on cultured bullheads is uncertain (20).

Eel Iridovirus

An eel iridovirus (EV-102) was isolated from cultured Japanese eels in Japan. This virus was specific for Japanese eels since it had no effect on European eels also cultured in Japan. Clinical signs include depigmentation of skin and increased mucus. Mortality may reach up to 70% in three to five days at temperatures of 15 to 20 °C (7,21).

Epizootic Hematopoietic Necrosis Virus

Epizootic hematopoietic necrosis virus (EHNV) is thought to be the first viral disease of fish in Australia. The virus has been isolated from yellow perch and rainbow trout. Clinical signs include a slow spiraling behavior, dark pigmentation, anorexia, petechial hemorrhage of skin, fins, head, and internal organs, abdominal distension, swollen kidney and spleen, and mottled liver (22,23).

Gill Disease of Portuguese Oysters

Also known as gill necrosis viral disease, gill disease of portuguese oysters is caused by an iridovirus. This virus has been found in cultured *C. angulata* and *C. gigas* in Portugal, France, Spain, and Great Britain. Clinical signs include extreme gill erosion and yellow spots on gills that progress to brown discoloration indicating necrosis of the gill. Yellow or green pustules may occur on the mantle or adductor muscle (3).

Hemolytic Infection Virus Disease

Hemolytic infection virus (HIV) disease had been described in oysters, *C. angulata* and *C. gigas*, in France and Spain. There are no distinctive clinical signs, but atrophy and weakness of the adductor muscle has been observed (3).

Largemouth Bass Iridovirus

This is the first debilitating systemic virus reported from centrarchids. Moribund fish lose equilibrium and float at the surface. There are no external lesions but internally the swim bladder is greatly enlarged. The virus occurs around 30 °C and its significance is not yet known (24).

Lymphocystis Virus, Cellular Hypertrophic Disease

Oldest and best known of all fish viruses, the lymphocystis virus was first recognized as a disease in 1874, proposed to be of viral origin in 1920, and finally confirmed in the 1960s. The most widely distributed virus lymphocystis affects fish in North America, South America, Europe, Africa, Australia, and Asia. Lymphocystis has been reported in 11 orders, 45 families, and 141 fish species. Lymphocystis cells are large gray or whitish cells that appear singularly or grouped together in grape-like clusters occurring primarily on the fins and body. Lesions are most prevalent on the fins, head, and lateral body surface. Lymphocystis is a chronic, benign condition that rarely causes morbidity or mortality and occurs in all sizes and ages of fish. Lesions depend on temperature and appear 5 to 12 days at 20 to 25 °C or in up to 6 weeks at 10 to 15 °C (7,25,26).

Oyster Velar Virus Disease, Blister Disease

Oyster velar virus disease (OVVD) infects *C. gigas*. It is found in Washington State, however, it is believed to be more widespread in distribution where *C. gigas* is found. The virus causes infection of the velum and may cause up to 100% mortality in hatcheries. OVVD usually occurs from March to May, but can also appear in the summer and is seen in larvae more than 150 μm in shell length and more than 10 days old. Gross signs of the disease are blisters on the velum and a lack of cilia (3).

Sheathfish Iridovirus

Sheathfish iridovirus (SHV) was first isolated from cultured European sheathfish (catfish) in a recirculating system in Germany. Sheathfish fry show spiral swimming and general hemorrhage on the body and internal organs. Mortality may reach 100% (27).

Viral Erythrocytic Necrosis

Viral erythrocytic necrosis (VEN) is also known as piscine erythrocytic necrosis. VEN affects erythrocytes and a wide

variety of marine and anadromous fish. Reported in a variety of fish, primarily marine, its clinical signs include severe anemia, pale gills, colorless blood, and discolored liver. Hematocrits may be as low as 2 to 10% (28,29).

White Sturgeon Iridovirus

White sturgeon iridovirus was isolated in juvenile-cultured white sturgeon in northern California. Clinical signs include weakness, anorexia, and pale, necrotic gills. Internally there is no body fat, a pale liver, and an intestine void of food (2,30,31).

NODAVIRIDAE

Viral Nervous Necrosis Virus

Viral nervous necrosis virus (NNV) is also referred to as striped jack nervous necrosis virus (SJNNV). The virus was first seen in Japan in cultured striped jack but has also been seen in Greece, Martinique, and France in larval striped jack. A virus thought to be SJNNV was also reported from barramundi, groupers, other jacks, flounders, puffers, and a variety of marine fish in several geographic locations. Clinical signs include emaciation, enlarged swim bladder, spinal deformities, dark pigmentation, and exopthalmia (32−34).

ORTHOMYXOVIRIDAE

Infectious Salmon Anemia Virus

Occuring in Atlantic Salmon in Norway, the clinical signs for this virus are pale gills, exopthalmia, ascites, enlarged liver and spleen, petechial hemorrhage of the intestine, pale internal organs, and high mortality. Classification of the virus is not complete; however, it has tentatively been identified as an orthomyxoviridae (35,36).

PAPOVAVIRIDAE

Papillomaviruslike Papovavirus

This virus has shown up primarily in *C. virginica*, with unconfirmed reports in other species areas affected include Atlantic Canada, the eastern United States, and similar lesions in the western United States, Korea, and Japan. Clinical signs are mass hypertrophy of gametes and gametogenic epithelium. Host response is negligible, and there is generally low infection with no associated mortality (3).

PARVOVIRIDAE

Hepatopancreatic Parvovirus

Hepatopancreatic parvovirus (HPV) is seen in wild and cultured penaeids in Australia and in cultured penaeids in the yellow Sea area of China, in Korea, Taiwan, Philippines, Indonesia, Malaysia, Singapore, Kenya, Kuwait, and Israel. It is also seen in North and South America in *L. vannamei* and *L. stylirostris*. Clinical

signs are not specific but include whitish and atrophied hepatopancreas, poor growth rate, anorexia, increased gill fouling due to epicommensal parasites, occasional opacity of abdominal muscles, and secondary opportunistic bacteria such as *Vibrio* spp. (3,4).

Infectious Hepatopoietic and Hypodermal Necrosis Virus

Infectious hepatopoietic and hypodermal necrosis virus (IHHN) is also known as runt deformity syndrome (RDS). IHHN is widely distributed in culture facilities in North and South America and Asia and is also found in wild penaeids. Natural infections have been observed in *L. stylirostris*, *L. vannamei*, *L. occidentalis*, *F. californiensis*, *P. monodon*, *P. semisulcatus* and *M. japonicus*. *L. setiferus*, *F. duorarum*, and *F. aztecus* have been experimentally infected. IHHN causes acute mortality in juvenile *L. stylirostris*. Gross signs are not specific, but reduction of feeding and changes in behavior and appearance are noted. This disease is typically chronic in *L. vannamei* and linked to runt-deformity syndrome. Clinical signs in juvenile shrimp include bent or deformed rostrums, wrinkled antennal flagella, and rough cuticle (3,4).

Lymphoidal Parvolike Virus

Lymphoidal parvolike virus (LPV) has only been observed in Australia, although it is likely to be in the Indo-Pacific area or southeast Asia. LPV has been seen in *P. monodon*, *F. merguiensis*, and *P. esculentus*. No consistent clinical signs have been reported (4).

Parvolike Virus of Crayfish

Parvolike virus in freshwater crayfish, *Cherax destructor*, was the first systemic virus in freshwater crayfish and is indistinguishable from the virus that infects freshwater prawn, *Macrobrachium rosenbergii*. Crayfish are extremely moribund. Clinical signs include opaque musculature on the ventral surface of the abdomen (37).

PICORNAVIRIDAE

Chesapeake Bay Virus

Chesapeake bay virus (CBV) is also known as picornalike virus of crabs. This disease affects the blue crab, *C. sapidus*, and other crabs on the east coast of the United States (3). The CBV infection causes destruction of bladder epithelium, epidermis, gills, and neurosecretory cells of the central nervous system. Clinical signs include abnormal behavior and blindness (3).

Taura Syndrome Virus

Taura syndrome virus (TSV) is geographically limited to the Americas and was first recognized near the Taura River, near the Guyaquil Equador in June, 1992. Natural infections occur in *L. vannamei*, *L. stylirostris*, and *L. setiferus*. TSV causes high mortalities at PL 12 stage and older and is best known as a disease of the nursery phase. *L. vannamei* are affected within 14

to 40 days of stocking as postlarvae. Typically affected are small juveniles less that 5 g. The disease has two distinct phases: the peracute/acute phase and the chronic/recovery phase. In the peracute/acute phase, gross signs in moribund shrimp include expansion of the red chromatophores, giving an overall reddish coloration, with the uropod and pleopods distinctly red. These animals usually die during ecdysis. The exoskeleton is soft and the gut is empty. In the chronic/recovery phase, shrimp show multifocal melanized cuticular lesions similar to bacterial shell disease. Shrimp may or may not have soft cuticles and red coloration and may behave and feed normally. These shrimp are survivors of the peracute/acute phase. Losses may reach 95% in affected ponds. Survivors typically display survival rates of 60% to harvest size (4).

REOVIRIDAE

Catfish Reovirus

First isolated from healthy channel catfish during a CCVD survey in California, catfish reovirus (CRV) is considered insignificant because no significant pathology has occurred in experimentally infected channel catfish (38,39).

Chum Salmon Virus

Chum salmon virus (CSV) is a reovirus pathogenic to chum salmon, resulting in mortality and moderate to severe liver necrosis (40).

Golden Shiner Virus

The aquareovirus genus was formed to include reoviruses of fish and shellfish. Golden shiner virus (GSV) is the type species. In general, aquareoviruses exhibit little or no pathogenicity. GSV was first isolated from cultured golden shiners, *Notemigonus crysoleucas*. GSV appears to be confined to the southeastern United States and California. The virus has also been isolated from grass carp. Clinical signs include lethargic swimming and erythema on the back and head as a result of hemorrhages in the muscle and skin. Infected fish may hold fins close to the body and may be on the bottom of the tank. GSV can cause significant loss and may reach 75% when fish are stressed in holding tanks. The disease occurs in summer when temperatures are 25 °C or higher (41).

Grass Carp Hemorrhagic Virus

Grass carp hemorrhagic virus (GCHV) is a reovirus first reported in grass carp in China and is distinct from grass carp reovirus. Carp develop hemorrhage at the base of fins, operculum, and mouth, are exopthalmic, and have pale gills. Internally there is severe hemorrhage of the intestine. The disease primarily infects fry and fingerlings with up to 80% mortality and occurs during the summer when temperatures range from 25 to 30 °C (2,42).

Reolike Virus of Crabs

This virus occurs in a complex with a rhabdolike virus A. Death of crabs is caused by nerve and hemocyte dysfunction. Clinical signs include lethargy followed by paralysis. The hemolymph fails to completely clot (3).

Reolike Virus of Penaeids

At least two types of reolike viruses are known in penaeids. They are designated REO III and REO IV and are classified in the genus aquareovirus (REO I and REO II are found in other decapod crustacea). REO III is found in cultured *M. japonicus*, *P. monodon*, and *L. vannamei*. REO IV is found in cultured and wild *F. chinensis* in Asia. Clinical signs include lethargy, poor resistance to stress, eroded and melanized appendage tips, shell disease lesions, and black gills. The hepatopancreas is necrotic, pale, and atrophied. *M. japonicus* signs include poor growth rate, anorexia, lethargy, gill and surface fouling, and occasionally opaque abdominal muscle (3,4).

RETROVIRIDAE

Epidermal Hyperplasia

Also known as walleye epidermal hyperplasia and discrete epidermal hyperplasia, epidermal hyperplasia is found in adult walleye in Saskatchewan and Manitoba, Canada, and Lake Oneida, New York. Lesions are raised, which are clear translucent mucoid patches that appear on the body and fins. The virus seems to have little effect on the fish (7).

Walleye Dermal Sarcoma

Walleye dermal sarcoma (WDSV) was first described in 1947 from walleye in Lakes Oneida and Champlain in New York State. The virus produces spherical lesions that can occur anywhere on the body and fins of adult walleye. The lesions may be pink to white in color. Optimum temperature for tumor production is 10 °C. The disease usually does not cause mortality, but fish are rejected commercially (7,41,42).

RHABDOVIRIDAE

Eel Rhabdovirus

Several rhabdoviruses have been isolated from American eel and European eel. Clinicals signs are limited and the effects of these viruses are unclear (43,44).

Grass Carp Rhabdovirus

Grass carp rhabdovirus was first isolated in Hungary from healthy two-year-old grass carp. The role of this disease is still uncertain (2,45).

Infectious Hematopoietic Necrosis Virus

Infectious hematopoietic necrosis virus (IHNV) was first detected in fish from California to Washington State in the 1940s to 1950s. Originally thought confined to tributaries that flowed into the Pacific Ocean from California to Alaska, IHNV was later discovered in Minnesota, South

Dakota, Montana, West Virginia, New York, and Idaho. It was also reported in China, France, Germany, Italy, Korea, and Taiwan. Species susceptible are trout, chinook, sockeye, and chum salmon. Brook and brown trout are susceptible to a lesser degree than rainbow trout. Clinical signs in fry and fingerlings are lethargy, avoiding currents, moving to the edge of ponds or raceways, weak respiration, and swimming in circles. They also become extremely dark and have exopthalmic swollen abdomen, pale gills, and hemorrhage at the base of their fins, mouth, and body. Chevron-shaped hemorrhages are seen in the musculature. An opaque mucoid fecal cast trails from the vent. Internally, organs are pale with petechaial hemorrhage in the mesenteries, peritoneum, air bladder, liver, and kidney and pale yellow fluid is in the body cavity. Survivors may show malformed heads, scoliosis, or lordosis. Mortality can range from low to nearly 100% depending on species, age, size, environment, and virus strain. IHNV normally does not occur in water above 15 °C (47,48).

Pike Fry Rhabdovirus

Also known as red disease and head disease, pike fry rhabdovirus is an acute, highly contagious disease of cultured fry and fingerling northern pike and is found in the Netherlands, Germany, and Hungary, but not in the United States. Species affected include grass carp, tench, white bream, European catfish, brown trout, roach, and gudgeon. Two forms of the disease exist. Head disease affects swimming fry. Clinical signs include hydrocephalus, exopthalmia, and poor growth. Red disease occurs in larger fish. Clinical signs include hemorrhages along lateral trunk musculature, pale gills exopthalmia, abdominal distension, and ascites. Infected fish lose schooling behavior and become lethargic. Up to 100% mortality can occur at the optimum temperature of 10 °C (49,50).

Spring Viremia of Carp

Spring viremia of carp (SVC) *Rhabdovirus carpio* occurs primarily in Europe and has not been reported elsewhere even though carp are cultured worldwide. Species infected are common carp, goldfish, bighead carp, silver carp, and grass carp. External clinical signs include dark pigmentation, distended abdomen, exopthalmia, prolapsed inflamed anus, and pale gills. Internally, signs are general hyperemia with hemorrhages in the kidney, liver, and air bladder. Optimum temperature for the disease is 16 to 17 °C but the disease may occur at 12 to 22 °C. Spring viremia is an extremely important disease of cultured carp in Europe and may cause up to 70% mortality in yearling fish (2,7,51).

Stomatopapiloma Virus

Stomatopapiloma virus is also known as Cauliflower disease. Cauliflower disease is one of the earliest diseases thought to be of viral origin and was first recognized in 1910. Only European eels in northern Europe and Great Britain are affected (7,52,53).

Viral Hemorrhagic Septicemia

Viral hemorrhagic septicemia (VHS) is also known as Egtved disease. This is an acute, highly infectious disease of cultured salmonids in Europe. Cultured rainbow trout are most susceptible; brown trout are also a natural host. VHS has been considered a European virus until isolated from Washington State in 1988. VHS in salmonids occurs in three forms based on pathological changes and mortality patterns: acute, chronic, and nervous. Acute is the most serious form and is associated with high mortalities. Behavior of infected fish includes erratic and spiral swimming, exophthalmia, distended abdomen, dark pigmentation, and pale gills with petechial hemorrhage on the gills. Internally, signs include hemorrhages in the skeletal muscle, swim bladder, and swollen kidney and liver. VHS has subacute to chronic lower mortality. Internally, the liver is pale. There is a nervous stage with low mortality, but fish exhibit poor balance in swimming and are anemic. The optimum temperature for VHS disease to occur is between 8 and 12 °C and typically does not occur above 14 °C. Younger fish are more susceptible to disease, but as fish become larger, they gain greater resistance (54).

TOGAVIRIDAE

Erythrocytic Inclusion Body Syndrome

Erythrocytic inclusion body syndrome causes anemia in cultured Coho and Chinook salmon in tributaries of the Columbia River in Oregon and Washington. It is also reported in Canada, Chile, Ireland, Japan, and Norway. Chum and masu salmon can also become susceptible, but have mild infections. Clinical signs include primarily severe anemia and pale gills, and internal organs. No external or behavioral clinical signs have been reported. Mortality occurs due to severe anemia; mortality is due to secondary bacterial and fungal infections (54,55).

Lymphoid Organ Vacuolization Virus Disease

Lymphoid organ vacuolization virus disease (LOVV) is found in cultured *L. vannamei* and *L. stylirostris* in the Americas and Hawaii. There are no recognized gross clinical signs, and prevalence and pathogenicity of the virus is not known (3).

Vitamin Requirements of Fish

Vitamin Deficiency Signs in Fish

Hypervitaminosis in Fish

Estimating Dietary Vitamin Requirements of Fish

Factors that Influence Dietary Vitamin Recommendations

Summary

Bibliography

Vitamins are defined as organic compounds which are required in small quantities and not used as energy sources, but are essential for growth and maintenance and must be supplied in the diet. Vitamins were first

discovered through efforts to find cures for human and animal diseases. It has been known for millenia that some human conditions, such as night-blindness, could be cured by eating certain foods. Vitamin C deficiency signs, known as scurvy, were a major problem for sailors, whose diet on sailing ships was limited. The French explorer, Cartier, learned of a cure for scurvy from North American Indians, who extracted vitamin C from spruce needles. Lind, in 1753, wrote a book on scurvy for the British navy, in which he concluded that it could be cured by eating citrus fruits. This is how British sailors came to be know as 'Limeys'. Although certain foods were known to prevent or cure diseases caused by vitamin deficiencies, it was only through development and use of purified diets in the twentieth century that identification of vitamins and the establishment of dietary requirements was accomplished.

Although fish have been raised for thousands of years, vitamin deficiencies became apparent only when fish were raised exclusively on prepared feeds. In the 1920s, McCay and Dilley (1) attempted to identify the compound(s) in fresh meat that prevented anemia in trout. Twenty years later, folic acid and vitamin B12 were found to be the essential vitamins needed to prevent anemia in trout (2). Establishment of the essential vitamin requirements of fish could not be made until a purified diet was developed for fish. Through the research efforts of McLaren et al. (3), Wolf (4), and Halver (5), who continued to refine and develop purified diets for trout and salmon, the qualitative and eventually the quantitative vitamin requirements of fish were established. Purified diet formulations for trout and salmon continue to evolve as new information is developed on specific nutrient requirements of these fish and as purified diets for salmonids are adapted to other species of fish.

VITAMIN REQUIREMENTS OF FISH

All species of fish examined so far require the same 15 vitamins that are required by birds and mammals, including ascorbic acid, which is not required in the diet of most birds and mammals because they can synthesize ascorbic acid in their tissues. Based upon early studies of vitamins, in which they were extracted from foods, vitamins are classified as being fat soluble or water soluble. Originally, it was thought that there were two vitamins, one fat-soluble and the other water-soluble. Further research revealed that there was more than one active compound within each extract; eventually four separate vitamins were discovered within the fat-soluble fraction and 11 or more within the water-soluble fraction. The fat-soluble vitamins (A, D, E, and K) can be stored in the body, while the water-soluble vitamins supposedly cannot. Fish do have some capacity to store water-soluble vitamins, but the amount that is stored differs among the vitamins.

Vitamins have the same metabolic roles in fish as they do in other animals, and, in general, the required dietary level of those vitamins for fish is not substantially different from that for animals (Table 1). The fat-soluble vitamins are associated with vision (A), calcium metabolism (D), protection against free-radical lipid oxidation (E), and

Table 1. Vitamin Specifications for Salmonid Feeds (mg/kg)

Vitamin	NRC (1993) Recommendations[a]	Typical Added Levels in Feeds
Vitamin A (IU)	2500 (1500)	6000
Vitamin D$_3$ (IU)	2400 (200)	2000
Vitamin E	50 (10)	300–500
Vitamin K$_3$	R[b] (0.53)	10
Thiamin	1 (1.8)	15
Riboflavin	4–7 (3.6)	25
Pyridoxine	3–6 (3.5)	15
Pantothenic acid	20 (10)	50
Niacin	10 (35)	180
Biotin	0.15 (0.15)	0.6
Folic acid	1 (0.55)	8
Vitamin B$_{12}$	0.01 (0.01)	0.03
Inositol	300	130
Choline	1,000 (1,300)	1,000
Ascorbic acid	50	150[c]

[a]Values in parentheses are NRC (1994) recommendations for broilers.
[b]Required, but not quantitatively determined.
[c]When a stable and bioavailable source of vitamin C is used.

Table 2. Primary Functions of Vitamins in Fish

Vitamin	Primary Function
Fat-soluble vitamins	
Vitamin A	Normal vision
Vitamin D	Calcium metabolism, bone formation
Vitamin E	Cell membrane maintenance
Vitamin K	Blood clotting
Water-soluble vitamins	
Thiamin	Carbohydrate metabolism
Pyridoxine	Amino acid metabolism
Riboflavin, niacin	Hydrogen transport, amino acid metabolism
Pantothenic acid	Energy metabolism
Biotin	Energy metabolism, integrity of scales
Folic acid, vitamin B$_{12}$	Synthesis of nucleotides
Ascorbic acid	Collagen synthesis, intracellular antioxidant
Choline, inositol	Component of phospholipids

blood clotting (K). Water-soluble vitamins fall into two categories: the B-vitamins, which act primarily as cofactors for metabolic enzymes; and the other water-soluble vitamins (e.g., choline, inositol, and ascorbic acid), which have more complicated functions (Table 2).

VITAMIN DEFICIENCY SIGNS IN FISH

Vitamin deficiency signs in fish are related to the function of the vitamin for some vitamins but seemingly unrelated to function for others (Table 3). Deficiencies of all but two vitamins (B$_{12}$ and K$_3$) cause loss of appetite, usually as the first overt sign of deficiency. Loss of appetite (anorexia) is thus a sign of vitamin deficiency (not an exclusive sign), but one not specific to an individual vitamin deficiency. Because fat-soluble vitamins can be stored in the body,

Table 3. Primary Vitamin-Deficiency Signs in Fish

Vitamin	Anorexia	Primary Deficiency Signs
Vitamin A	Yes	Vision problems
Vitamin D	Yes	Impaired bone calcification
Vitamin E	Yes	Anemia, ascites, membrane fragility
Vitamin K	No	Anemia, prolonged prothrombin time
Thiamin	Yes	Hyper-irritability, convulsions
Riboflavin	Yes	Lens cataracts
Pyridoxine	Yes	Convulsions, erratic swimming
Pantothenic acid	Yes	Clubbed gills
Niacin	Yes	Skin lesions
Biotin	Yes	Muscle atrophy, skin depigmentation
Folic acid	Yes	Macrocytic anemia
Vitamin B_{12}	No	Anemia
Inositol	Yes	Distended abdomen, edema
Choline	Yes	Hemorrhagic kidney and intestine
Ascorbic acid	Yes	Lordosis, scoliosis, hemorrhages

long periods of feeding deficient diets are needed to cause deficiency for these vitamins, particularly in large fish. Fry and fingerlings have lower body reserves of vitamins, and this scarcity, coupled with their rapid growth rate, makes it easier to create vitamin deficiencies in them than in large fish. As an example, deficiency signs of pantothenic acid (clubbed gills) are evident after about 8–12 weeks of feeding a diet devoid of pantothenic acid in fry and fingerling salmonids (2), but 28–30 weeks of feeding are needed in larger fish (6).

Specific vitamin-deficiency signs are known for some vitamins, but not for others. Deficiencies of thiamin and pyridoxine cause neurological problems, manifested as hyperirritability in trout deficient in thiamin and tetany in salmonids deficient in pyridoxine. Pantothenic-acid deficiency causes a characteristic clubbing of the gills. Riboflavin deficiency is characterized by the presence of cataracts. Vitamin B_{12} and folic-acid deficiency cause anaemia, which can be distinguished by examining blood smears (2). Niacin deficiency causes skin lesions in rainbow trout exposed to ultraviolet radiation. Ascorbic acid deficiency is characterized by broken-back syndrome in channel catfish (*Ictalurus punctatus*) and rainbow trout (*Oncorhynchus mykiss*). Salmonids exhibit deformities of the gill cover as an early sign of ascorbic acid deficiency.

For vitamins such as choline, inositol, biotin, and niacin, specific clinical deficiency signs are observed only in cases of severe and prolonged depletion. In all cases of vitamin deficiency in fish, by the time clinical signs of deficiency are evident, the fish will not eat, and so it is nearly impossible to reverse the deficiency by diet supplementation. Thus, tests to detect subclinical vitamin deficiencies are important. Such tests typically measure the activity of an enzyme for which the vitamin is required as a cofactor. When enzyme activity decreases, the fish are in the early stages of vitamin deficiency, but the condition can usually be reversed by restoring or increasing the dietary vitamin level.

For a few vitamins, deficiencies can be induced when fish are fed semipurified diets lacking the vitamin, but, in practical diets and under controlled conditions, deficiencies cannot be caused, even when there is no supplementation of certain vitamins to the diets. For example, the clinical signs of biotin deficiency in rainbow trout are well described from studies in which semipurified diets were fed (2), but deficiency cannot be induced in rainbow trout fed practical feeds (7). Similar findings are reported in channel catfish fed practical diets (8). Intestinal synthesis of inositol has been demonstrated in channel catfish, making dietary supplementation with this vitamin unnecessary (9). Vitamin B_{12} is another vitamin for which intestinal synthesis is sufficient to supply the needs of some fish [e.g., Nile tilapia (*Oreochromis niloticus*) (10)]. Nevertheless, it is a good practice, under intensive farming conditions, to supplement the feed with a complete vitamin premix, in order to compensate for possible vitamin loss during feed processing and impaired intestinal synthesis of vitamins caused by the use of medicated feed additives in case of disease outbreak.

HYPERVITAMINOSIS IN FISH

Because fat-soluble vitamins are stored in tissues, excessive intake of these vitamins can cause health problems in fish. The occurrence of hypervitaminosis requires massive dietary vitamin levels. The maximum tolerable level of vitamin A in rainbow trout is 900,000 IU/kg, which represents over 130 times the average practical supplementation level for this species (11). Vitamin A hypervitaminosis symptoms in trout include growth depression, necrotic fins, pale liver, and mortalities. Similar levels of vitamin A (from *Artemia* by enriched 920,000–1,000,000 IU/kg) cause compression of vertebrae in larval flounder fed the brine shrimp at the time of notochord segmentation (12). Such extreme levels are unlikely to be encountered in production feeds. Furthermore, vitamin A is sensitive to heat and relatively unstable through feed processing and storage. The probability of observing cases of vitamin A hypervitaminosis in fish farming is therefore marginal. Massive vitamin D_2 supplementation (3.75 million IU/kg) increases circulating calcium in brook trout and reduces growth (13). In juvenile channel catfish, 50,000 IU D_3/kg impairs growth, although it does not alter calcium content in vertebrae (14). Although it is not well documented, it is suggested that excessive doses of vitamin K may lead to hypervitaminosis symptoms in fish. This danger does not seem to be the case for vitamin E, perhaps because it is widely distributed throughout all the lipids in the body.

ESTIMATING DIETARY VITAMIN REQUIREMENTS OF FISH

In the early years of vitamin-requirement studies in fish, requirements were estimated by feeding semipurified diets to groups of fish. The diets contained all known (at the time) essential nutrients at levels in excess of dietary requirements, except for the vitamin being studied; that one would be supplemented to diets at increasing levels. Researchers would feed these diets to fish, then measure

growth (weight gain), feed conversion ratios, survival, and, in some cases, vitamin levels in the liver or in blood smears. Absence of deficiency signs, both those clinically evident and those identifiable through histology, was also a response variable in these studies. From these data, the dietary requirement would be estimated. All early studies were conducted using small fish over relatively short experimental periods.

The early studies resulted in estimated dietary vitamin requirements that were in some cases much higher than those established for farmed animals or poultry. Part of this was the result of using liver vitamin levels as a response variable, but part was associated simply with the necessity for being safe. The rationale for this was that for hatchery salmon, at least, the cost of having a dietary vitamin deficiency was much higher in terms of lost production than was the cost of overfortifying the diets with vitamins.

Dietary vitamin-requirement estimates for fish became more accurate in the 1980s as a result of new, sensitive measures of vitamin status, most of which were based on the activities of vitamin-dependent enzymes (15). In addition, the expansion of fish farming, which made it the driving force in fish nutrition research, brought economic considerations, feed cost being a major one, to the forefront of fish nutrition research. Finally, improved semipurified diets made it possible to approximate more closely the growth rates seen in production settings (early semipurified feeds did not support such growth rates). The culmination of these advances is that vitamin requirements are now estimated more accurately, and at values more closely in line with those of other animals.

Recently, the attention of researchers has been focused on the relationship between the intake of several vitamins and disease resistance in fish. Extensive work in mammals has shown that vitamin nutrition plays a significant role in the development and function of the immune system. Vitamin C and vitamin E are potent antioxidants. They scavenge oxygen-rich free radicals and thus protect cells against oxidative damage. Studies show that an elevated vitamin C dietary level (1000 mg/kg) enhances cellular immune response (macrophage and lymphocyte functions) in rainbow trout (16,17). The response of the cells is correlated to their ascorbate content, which is related to the vitamin C intake. Enhanced phagocytosis and humoral immunity upon increased vitamin C intake is also observed in channel catfish (18). Infection trials further demonstrate the positive effect of high vitamin C intake on the resistance of channel catfish and Atlantic salmon (*Salmo salar*) to bacterial infections (18,19) and on resistance of rainbow trout to bacterial, viral, and parasitic infections (20–22).

Vitamin E prevents oxidation of polyunsaturated phospholipids in cellular and subcellular membranes. It also improves both humoral and cellular defenses in fish. Rainbow trout fed a diet containing vitamin E at 450 mg/kg (ppm) exhibit a significantly higher antibody response to vaccination and lymphocyte proliferation than do fish fed a diet supplemented with 45 mg/kg (ppm) (23). Rainbow trout experimentally infected with *Yersinia ruckeri*

exhibit significantly less mortality when fed a diet containing 806 mg/g (ppm) compared to fish receiving a diet with 86 mg/kg (ppm) (24).

Vitamin C and vitamin E requirements for optimal immune response are higher than the levels necessary for normal growth and prevention of deficiency symptoms. An appropriate dietary supplementation of these two vitamins as a prophylactic tool contributes to improving the health status of fish and to reducing losses due to infectious diseases.

FACTORS THAT INFLUENCE DIETARY VITAMIN RECOMMENDATIONS

Vitamin requirements of fish are influenced by several factors. First, there are species differences, as noted earlier. Second, there are differences associated with age, size, rearing conditions, and maturation. Third, dietary components can increase the physiological need for some vitamins — For examples, the presence of oxidizing fats in the feed increases the need for tocopherol (vitamin E) and possibly vitamin C; and egg white contains avidin, a compound that binds biotin, making it unavailable. Fourth, any leaching of vitamins from feeds that remains in the water for a period before being eaten by fish or shrimp increases the amount that must be added to feeds. In addition, any manufacturing condition that destroys vitamins must be taken into account, and the feeds must be fortified accordingly. Fifth, for pond-reared fish and shrimp, natural food supplies a portion of dietary vitamin needs. As the supply of natural food diminishes or the stocking density of ponds increases, vitamin fortification of feeds becomes more critical. Lastly, and most importantly, exposure to stressful rearing conditions, including exposure to pathogens, increases the requirement for some vitamins.

SUMMARY

Vitamins are essential nutrients in the diets of fish. Vitamins have the same metabolic roles in fish as in mammals and birds, and the dietary requirements of fish are similar to those of other animals. Vitamin needs increase when feeds contain oxidizing lipids, when fish are at an early stage of development or subjected to diseases or stressful rearing conditions, and possibly when fish mature.

VITAMINS SOURCES FOR FISH FEEDS

J. GABAUDAN
Research Centre for Animal Nutrition and Health
Saint-Louis Cedex, France

RONALD W. HARDY
Hagerman Fish Culture Experiment Station
Hagerman, Idaho

OUTLINE

Vitamin supplements for fish feeds must meet the dietary requirements of fish. Fish feeds are a challenging environment for vitamins, in part because of the conditions of manufacture and in part because of the fact that the pellets must remain intact in water for up to several hours before fish or shrimp consume them. Thus, vitamins must be provided to fish feeds in forms that can tolerate high heat and pressure during feed processing and conditions encountered during drying. Leaching of vitamins from pellets exposed to water is a major problem in raising shrimp or fish that consume feed slowly. The use of fish oil, which is rich in polyunsaturated fatty acids that are susceptible to oxidation, as the primary lipid source in fish feeds also must be considered when the chemical forms of certain vitamins are being chosen. Oxidizing lipids can destroy some vitamins unless they are protected. Most vitamins used to supplement fish and animal feeds are produced in forms that disperse well in feeds and resist destruction during pelleting and storage. However, few of the vitamins are completely stable in fish feeds. Thus, levels of supplementation must be chosen to account for the inevitable losses that occur in feed preparation and storage.

SOURCES, FORMS, AND ACTIVITY OF VITAMINS ADDED TO FISH FEEDS

Sources

Most vitamins added to fish feeds are produced by industrial processes, generally either chemical synthesis, fermentation, or a combination of both, rather than by extraction from natural sources, which is expensive and gives low yields. In addition, vitamins are manufactured in forms that are designed to flow evenly, mix well, and resist degradation during feed processing and storage. This is not a simple process, since optimal stability and full bioavailability are not necessarily compatible characteristics. Fat-soluble vitamins formerly were only available from natural sources, such as cod or shark liver oil. These vitamins generally occur in several active forms in nature, and the biological activities of these forms differ (Table 1). Today, vitamins A, D, E, and K are produced by chemical synthesis. Of the water soluble vitamins, most that are used in feeds are produced by chemical synthesis or by fermentation and are presented as vitamin salts or isomers. Often crystalline forms used in pharmaceutical products are produced by synthesis, while dilution products used in feeds are produced by fermentation.

Forms

Fat-soluble vitamins. Vitamin A is a chemically synthesized product that is enclosed in a beadlet to protect

Table 1. Relative Biological Activity of Different Forms of Vitamin E (1)

Vitamin E Form	Relative Vitamin E Activity (%)
Alpha-tocopherol	100
Beta-tocopherol	30
Gamma-tocopherol	15
Delta-tocopherol	Almost inactive
Alpha-tocotrienol	20
Beta-tocotrienol	5

against oxidation. Indeed, vitamin A is one of the vitamins most affected by the aggression of mill machinery. Beadlets typically contain a matrix such as cross-linked gelatin, with vitamin A dispersed throughout the matrix. Within the matrix the vitamin can be additionally protected by an antioxidant. Beadlets are then coated with a protective layer, such as corn starch, which improves handling. The form of vitamin A in such beadlets is vitamin A acetate. Several manufacturers produce beadlets containing both vitamin A and vitamin D. Stability of vitamin A beadlets through extrusion and three months of room temperature storage is approximately 80% at best and 40% at worst for different vitamin A beadlet products, the latter having no cross-linked matrix.

Vitamin D is added to feeds as a beadlet, enclosing cholecalciferol (D_3), or as a spray-dried product. The other form of vitamin D, ergocalciferol (D_2), is not used as a vitamin D supplement in animal or fish feeds. Antioxidant addition plus encapsulation within a beadlet provide protection of vitamin D_3 against oxidation. Typical stability ranges between 75–100% after extrusion and three months of room temperature storage.

Vitamin E is supplied to feeds as dl-alpha-tocopheryl acetate, which is an acetate ester of alpha-tocopherol. The acetate moiety is attached at the active site on the tocopherol molecule, thus preventing any other reactions from occurring that might result in loss of tocopherol activity. The most worrisome reaction in feeds is associated with oxidizing lipids, in which tocopherol donates a hydrogen atom, thus becoming a sacrificial antioxidant. The presence of the acetate moiety prevents oxidation, but also renders dl-alpha-tocopheryl acetate inactive with respect to antioxidant function in feeds. Once in the gut, the acetate moiety is enzymatically removed, restoring the antioxidant property to the tocopherol molecule. Vitamin E is relatively stable in extruded feeds when supplemented in the protected form, with no more than 10% loss after pelleting and extrusion.

Vitamin K is supplied as a menadione (K_3) salt. There are four forms of menadione salts used in feeds: menadione sodium bisulfite (MSB, 50% active K_3), menadium nicotinamide bisulfite (MNB, 43% active K_3), menadione sodium bisulfite complex (MSBC, 33% active K_3), and menadione dimethlypyrimidinol bisulfite (MPB, 45.4% active K_3). All are affected by heat, moisture, and the presence of trace minerals. After extrusion pelleting and three months of room temperature storage, between 20 and 50% of vitamin K activity remains.

Water-soluble vitamins. Thiamin (vitamin B_1) is commercially available as crystalline mononitrate or hydrochloride salts. Thiamin mononitrate (1 g thiamine = 1.088 g thiamine mononitrate) is typically used in animal feeds, while thiamin hydrochloride is typically used in liquid parenteral or oral vitamin products because it is more water soluble. Between 60% and 80% retention of thiamin activity is typically observed after feeds are extruded and stored at room temperature for three months.

Riboflavin (vitamin B_2) is produced as a crystalline compound or as a product of fermentation. The crystalline product is electrostatic and hygroscopic and does not distribute well when blended into a feed mixture. Its handling properties are significantly improved when it is formulated into a spray-dried powder. Riboflavin is relatively unaffected by extrusion pelleting and storage, with no more than 10% loss occurring after three months of storage of extruded pellets.

Pyridoxine (vitamin B_6) is typically added to feeds as crystalline pyridoxine hydrochloride, which is 82.3% active. Pyridoxine is relatively unstable, especially in premixes exposed to moisture (e.g., high humidity, and containing trace minerals). Up to 50% of pyridoxine activity in premixes exposed to abusive conditions can be lost after three months of storage. The stability of pyridoxine partly depends on the size of its crystal particles. Therefore, fine granular crystals have improved stability during feed processing compared to very fine crystals. Properly formulated pyridoxine is relatively stable during pelleting, with typical extrusion and storage losses of 10–20%.

Pantothenic acid is normally added to feeds as calcium d-pantothenate, which contains 92% of d-pantothenic acid. Calcium dl-pantothenate also exists, but has half of this activity because the l forms of pantothenate are not biologically active. Calcium d-pantothenate is relatively stable during pelleting and feed storage, with losses after extrusion and storage of no more than 20%.

Niacin is added to feeds as niacinamide and nicotinic acid, both having the same biological activity. Both forms are quite stable during extrusion, pelleting and storage, with losses generally 10% or less.

Biotin is added to feeds as d-biotin, the biologically active form. The isomer l-biotin has no biological activity. The activity of d-biotin products is 2% on a weight basis, and the stability of biotin during extrusion pelleting and room temperature storage for three months ranges from 70 to 90%.

Folic acid is synthesized and added to vitamin premixes as a dry dilution, either as a crystalline form or a spray-dried form. The crystalline form is electrostatic and tends to adhere to the machinery, while the spray-dried form does not and therefore contributes to a higher recovery of the vitamin in the feed. Stability of folic acid after extrusion and feed storage is relatively low, ranging from 50 to 65%.

Vitamin B_{12} is produced by fermentation and used in feeds as a dry dilution having 1% activity, on a weight basis. Vitamin B_{12} stability in extruded feeds after three months of room temperature storage ranges from 40 to 80%.

Choline is produced for feed use as a chloride salt, which is available as a dry dilution product having either 25, 50, or 60% activity on a weight basis or as a liquid having 70% activity. On a molecular weight basis, choline chloride is 86.8% choline. Choline is completely stable during feed pelleting and storage, but it is a hygroscopic substance and a strong base. Its presence reduces the activity of other vitamins, such as vitamin E and vitamin K when it is included in vitamin premixes. Thus, it should be added separately to feed mixtures.

Inositol is a hexahydric cyclic alcohol with several isomeric forms. The only isomer with biological activity is myoinositol.

Vitamin C, or ascorbic acid, was once the most problematic of all the essential vitamins with respect to stability in fish feeds. Crystalline ascorbic acid (100% active on a weight basis) is extremely susceptible to oxidation, and early tests with the Oregon Moist Pellet® indicated that within three days without frozen storage, all vitamin C activity was gone. Thus, feed was kept frozen until use, and coated forms (fat-coated, ethylcellulose-coated) more resistant to oxidation were used. In dry, pelleted fish feeds, approximately 20% of vitamin C activity remained after steam pelleting and storage, so feed formulators added five times more crystalline or coated ascorbic acid to ensure that enough remained to meet the dietary requirements of fish at the time of feeding. The use of extrusion pelleting in fish feed production introduced additional heat and pressure to the pelleting process, sufficient to melt the fat coating and otherwise accelerate the loss of ascorbic acid activity in fish feeds. Thus, conjugates were developed that added a functional group to the second carbon position of ascorbic acid, thus protecting ascorbic acid from oxidation. The first such product was ascorbate-2-sulfate, which was very stable, but had low biological activity to salmon (ca. 30%) and catfish (ca. 10%). The second such product was ascorbate-2-polyphosphate, which had full biological activity, but relatively low activity on a molecular weight basis, due to the relative weight of the polyphosphate moiety.

More recently, ascorbate-2-monophosphate has been developed, increasing the ascorbic acid content to ca. 49% on a molecular weight basis. This product, a Na/Ca salt of ascorbate-2-phosphate consists of ascorbate-2-monophosphate (equivalent to 33% ascorbic acid activity) and small amounts of ascorbate-2-polyphosphate (equivalent to an additional 2% ascorbic acid activity). It is in wide use in the fish feed industry today and exhibits less than 15% loss of activity in extrusion pelleting and three months of room temperature storage, compared to 70–90% loss of activity for ethylcellulose-coated or fat-coated ascorbic acid. For steam pelleted feeds, losses of crystalline ascorbic acid range from 30 to 70%, depending upon pelleting, drying, and storage

conditions, compared with less than 10% loss of ascorbate-2-phosphate.

ADDITIONAL FACTORS THAT INFLUENCE VITAMINS IN FISH FEEDS

Vitamins are affected by many factors associated with feed ingredients and feeds, but not all vitamins are affected equally. As mentioned earlier, vitamins are produced in forms that resist deterioration and loss of activity. Several processes are used in the manufacture of feed-grade vitamin products. These include encapsulation (beadlets), spray drying, coating, adsorption, compaction, and high-shear granulation. The formulation process affects the stability, handling, miscibility, and bioavailability of the vitamins (2). However well a vitamin is formulated, losses still may occur. The main factors that lower vitamin levels in premixes or feeds are moisture, oxidation, reduction, trace minerals, heat, light, and pH (low or high) (Table 2). Conditions of pelleting (temperature, moisture), length of storage, and the composition of the feed, particularly the presence of oxidizing polyunsaturated fatty acids affect vitamin stability (Table 3). In the case of vitamin premixes, the inclusion in the premix of trace minerals accelerates the destruction of vitamins, as many trace mineral ions act as catalysts of oxidation reactions, while oxides and hydroxides of metals increase the pH. The hydroscopic property of choline chloride increases moisture levels in vitamin premixes, thereby affecting stability of certain vitamins, notably vitamin K. The importance of these two factors is summarized in Table 4. Finally, some compounds added to fish feeds or present in ingredients can seriously inhibit or destroy vitamins. For example, thiaminases present in certain fish degrade thiamine, lindane (a common insecticide) is an antagonist of inositol, and sulfaquinoxaline inhibits vitamin K.

Because vitamins are affected by different factors, it is not possible to define a set of practical conditions favorable to all of them. Nevertheless, following a few simple rules will contribute to maximize vitamin stability and bioavailability in feeds: (1) select good

quality, protected vitamin products; (*2*) store vitamin premixes in a cool, dark, and dry room and reseal bags; (*3*) use good quality feed ingredients, particularly oils; (*4*) add vitamin premix to the mix after grinding; (*5*) use dry steam and lowest processing temperatures compatible with pellet quality; and (*6*) pack and store feeds with care.

MEASURING VITAMIN LEVELS IN FEEDS

Historically, most vitamins were measured by microbiological assay, both qualitatively and quantitatively. The development of high-performance liquid chromatography (HPLC) has reduced the use of microbiological and wet chemistry methods for vitamin analysis. Today, vitamins A, D_3, E, K_3, thiamin, riboflavin, niacin and ascorbic acid are determined by HPLC. Pyridoxine, B_{12}, pantothenic acid, biotin, and folic acid contents in feeds are evaluated with microbiological assays (3,4).

SUMMARY

The manufacturing conditions used to pellet fish feeds are abusive and result in destruction of many vitamins, unless they are supplemented in protected forms with good handling and miscibility properties. The use of these forms protects the vitamins against loss, but generally not completely. Thus, care must be taken to add sufficient amounts of vitamins to fish feeds to counter the inevitable losses that occur during manufacture and storage. Vitamins are added to feeds mainly as a vitamin premix, with the exception of choline chloride and ascorbic

acid, which are added separately to avoid combining these compounds with other vitamins.

WALKING CATFISH CULTURE

ROBERT R. STICKNEY
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

Walking-catfish (family Clariidae) have long been studied by zoologists because of their ability to survive for long periods out of water by breathing air directly. Walking-catfish were named for their ability to use their modified pectoral fins to essentially "elbow" their way across the land, often from pond to pond. The physiological and morphological adaptations allow the fish to either aestivate by burying themselves in mud like lungfish or to leave ponds that are becoming desiccated in order to find new bodies of water. Walking-catfish are also popular foodfish in many countries, not only the tropical regions to which they are native, but also in some European nations, where they are reared in recirculating water systems. The Netherlands has been actively involved in research and development. Walking-catfish have been reared in the United States primarily as aquarium fishes, but fears that they could escape and walk across land areas to invade various bodies of water — where they might displace more desirable species — prompted the prohibition of walking-catfish in the United States. There have been stories about walking-catfish eating dogs in Florida, though such rumors have never been substantiated and can probably be classified as urban legends.

DISTRIBUTION AND GENERAL CHARACTERISTICS

Walking-catfish are distributed throughout southeast Asia, including the Indian subcontinent, Africa, and parts of the Near East (1). In Asia, Thailand has been a leader in research associated with walking-catfish culture, as well as a leading producer nation. A considerable amount of research has also been conducted in India and the Philippines. Important species in Asia are *Clarias batrachus* (Fig. 1) and *C. macrocephalus*. There is also some culture of *C. gariepinus* and hybrids in Asia.

In Africa, walking-catfish inhabit tropical swamps, lakes, and rivers. Most of the interest by African culturists has been associated with the sharptooth catfish, *C. gariepinus* (other species have been recognized in Africa, but there is a view among some taxonomists that *C. gariepinus* is the only actual African species). *C. gariepinus* is found from the Orange River in South Africa to the Nile River. The species can also be found in parts of Turkey and is the species of interest to culturists in Europe. Most of the activity associated with walking-catfish culture in Europe is centered in the Netherlands (2). Markets have been established in Germany, Italy, and the United Kingdom, in addition to the Netherlands.

A few other species of walking-catfishes have also received the attention of aquaculturists. Among them are *C. fuscus*, *C. anguillaris*, *C. lazera*, and *C. leather*, reared in China. Research has also been conducted on hybrids between *C. gariepinus* and another clariid fish, *Heterobranchus longifilis*. However, there is not much information available on these hybrids and minor species, and they do not appear to be produced in large numbers as compared with the three dominant culture species.

Walking-catfish are tropical species. Growth occurs when water temperature is above 20 °C (68 °F), with best growth occurring in the range of 25 to 30 °C (77 to 86 °F). Because of the presence of an accessory air-breathing organ, walking-catfish are able to exist for hours out of water; they are often sold live on the streets in Asia from buckets containing fish with no water. Of more interest to fish farmers is the fact that walking-catfish can tolerate oxygen-depleted water and even survive in moist mud. Their propensity for leaving ponds and foraging on land, particularly at night, means that fences must be placed around ponds to keep the fish from escaping and taking up residence in the wild or at a competitor's culture facility. Vertical pond walls of earth or concrete are also useful in helping to constrain walking-catfish (Fig. 2). Walking-catfish are bottom feeders. They grow relatively rapidly and reach maturity after about one year at weights of 200 to 400 g (0.44 to 0.88 lb). As is true of other families of catfishes, the clariids produce a relatively small number of large eggs. Mature females typically produce from 2,000
Figure 1. Drawing of *C. batrachus*. (Original drawing by Cheryll Sorensen.)

Figure 2. Walking-catfish pond in the Philippines with vertical walls and fencing.

to 5,000 eggs that are round, yellowish brown in color, and range from 1.3 to 1.6 mm (0.05 to 0.06 in.) in diameter (2). Hatching occurs within 24 hours (1) when temperature ranges from 25 to 32 °C (77 to 90 °F).

Walking-catfish are not a major aquaculture commodity. In 1995, global production was about 89,000 tons (3).

COLLECTION AND CAPTIVE SPAWNING OF FRY

The simplest method of obtaining young fish for stocking is to allow them to spawn naturally and collect the resulting fry. Depending on species, walking-catfish spawn in nests constructed during the rainy season in the bottoms of ponds and rice fields or in holes in the banks of a body of water. Plant material may be placed in the nests to facilitate egg collection (4). Spawning generally occurs in 20 to 50 cm (8 to 20 in.) of water (1). The fry can then be removed from the nests with nets. This method of spawning and collection of fry is simple and does not require indoor facilities, use of hormones, or other technology that may be unavailable or prohibitively expensive in some regions.

Fish farmers in Thailand, prompted by a shortage of walking-catfish fry from wild spawns, began in the 1950s to employ methods similar to those used in the United States for spawning channel catfish. (See the entry "Channel catfish culture.") Instead of placing spawning containers in the ponds, Thai fish farmers dug suitable-sized horizontal holes in their pond banks, stocked pairs of *C. batrachus* near the holes, and were rewarded with a high degree of successful spawns (1). Fry could be collected in the usual manner from the nests, which were 20 to 35 cm (8 to 14 in.) in diameter and constructed about 1 m (3 ft) apart.

Pituitary hormone injections were found to be effective for inducing spawning in *C. macrocephalus* by Thai researchers who were employing the technique by the early 1970s. By utilizing the proper level of hormone, the fish could be induced to spawn well over 50% of the time within 14 to 16 hours following injection (1). Various other hormones, including human chorionic gonadotropin and leuteinizing hormone-releasing hormone or LHRH (see the entries "Hormones in finfish aquaculture" and "Reproduction, fertilization, and selection"), have in more recent years been shown to be effective at inducing spawning in walking-catfish (5). Pituitary extracts that are effective can be obtained from fish, such as carp, and from other animals, including chickens, toads, and frogs. To reduce the need for indoor broodstock spawning facilities, hormone injections and subsequent spawning activities can be undertaken in small cages placed in ponds.

After fertilization, eggs can be collected and hatched in troughs or jars. At present, Thai fish culturists produce *C. batrachus*, *C. macrocephalus*, and a hybrid composed of a cross between *C. gariepinus* and *C. macrocephalus*. Hybrid vigor is one positive result of such crosses. Other species of less interest to fish culturists have also been induced to spawn with hormones.

GROWOUT SYSTEMS

When fertilized eggs are incubated in hatcheries, the resulting larvae are often maintained through absorption of the yolk sac for about five days, then stocked in small earthen ponds (1). Troughs or circular raceways should be used for early rearing of fry. Sufficient oxygen levels should be maintained until the fish begin air breathing if, as some advocate, the fry are retained in the hatchery for several days after hatching (6). Fry have traditionally been maintained in ponds at high densities until they reach fingerling size, at which time they are restocked into production ponds or cages (1).

Production ponds are of various sizes and have depths that are typical of aquaculture ponds throughout the temperate and tropical world. (See the entry "Pond culture.") The difference is that the walls of the ponds may be more vertical than is the case with the standard aquaculture pond, and fences of about 50 cm (20 in.) may be constructed around each pond to prevent the fish from escaping (Fig. 2). While most production continues to be in ponds, flow-through raceways have also been employed in some places, including developing countries. Walking-catfish are most commonly reared in monoculture, though they have been polycultured with tilapia and are sometimes grown in rice-fish culture. (See the entry "Polyculture.")

Live and prepared feeds are commonly used in conjunction with walking-catfish farming, though many farmers depend upon fertilization alone. Organic fertilizers, including night soil, are commonly used, often in lieu of feeding with prepared rations. Organic fertilizers stimulate the production of natural food organisms. Manure may be carried to the ponds intermittently, or it may be continuously provided by rearing livestock in facilities constructed over, or immediately adjacent to, the fishponds. Apparently, there are no studies showing that manure ingested directly provides walking-catfish with some nutritional benefit, but there is evidence that dried poultry waste can be used in feeds to substitute for other ingredients in walking-catfish diets. Organic fertilizers commonly used in conjunction with the rearing of walking-catfish include manure from poultry, swine, water buffalo, and cattle. Ducks are a popular source of organic fertilizers

for ponds in various Asian countries and are also undoubtedly used to fertilize walking-catfish ponds. It is important in many parts of Asia and Africa to produce fish in facilities that involve little capital investment and only limited inputs, such as prepared feeds, which require significant expense. Subsistence culture is common, as are small family-operated commercial farms. Family farms can be operated in the absence of weekly or monthly payrolls. Ponds can be dug by hand or with the aid of livestock-drawn implements, natural spawning and fry collection eliminate the need for hatcheries, and the provision of organic fertilizers from other farm animals eliminates the need for purchasing feed or fertilizers. Relatively small fish are accepted by consumers in many countries, so walking-catfish can often be sold at sizes of less than 200 g (0.45 lb). If the fish can be sold at relatively small sizes, it is possible to produce three crops per year in the tropics.

WATER-QUALITY CONSIDERATIONS

As mentioned earlier, one of the characteristics of walking-catfish that make them desirable as aquaculture species is their tolerance of degraded water quality. They can be grown in ponds, which, at least during part of the time, have dissolved oxygen levels approaching or reaching zero parts per million. In the marketplace, one often sees live walking-catfish that have been maintained for several hours out of water. Even after lying out of water in the sun for several hours, the fish can be seen actively moving about.

Walking-catfish, like other freshwater catfishes, have limited tolerance to salinity. Salinities much above one-third strength seawater are not tolerated.

Because of the requirement of the tropical walking-catfishes for warm water, aquaculture activities in the Netherlands are centered around production in recirculating water systems. (See the entry "Recirculating water systems.") Among the water-quality variables that can cause toxicity in such systems is the buildup of ammonia and nitrite (NO_2^-) in the water. Walking-catfish do not appear to be more tolerant of nitrite than are channel catfish (family Ictaluridae) and are less tolerant than various other species of fishes and marine shrimp (5). Ammonia, particularly in the un-ionized form (NH_3), is highly toxic to fish, yet *C. batrachus*, which is intolerant of high nitrite, is quite tolerant of un-ionized ammonia (5) compared with channel catfish. The nitrification of ammonia by bacteria results in the production of toxic nitrite, which is then converted to low-toxicity nitrate (NO_3^-).

FEEDS, FEEDING, AND NUTRITION

Walking-catfish are omnivorous (7). They are aggressive and known to be cannibalistic. As first-feeding fry, they are normally provided with live zooplankton, though yeast has been used as a sole first feed for at least one species (5). Brine shrimp nauplii (*Artemia* sp.) are often used for several days, followed by cladocerans mixed with brine shrimp nauplii, and then cladocerans only. Monocultures of the mentioned zooplanktonic species can be grown, though it is much less difficult and requires little technology to rear natural zooplankton communities in fertilized tanks or small ponds. After a few days of providing live food, culturists can successfully convert fry to wet or dry prepared feeds.

In places where trash fish are readily available—for example, parts of Thailand—a mixture of 90% ground fish and 10% rice bran has been found to be readily utilized as food by walking-catfish fingerlings (8). Dry diets employing fishmeal, silkworm pupae, and various vegetable proteins have been used in feeding walking-catfish. Rice bran, while low in overall nutritional value, is widely used at some level in prepared feeds, largely perhaps because it is readily available and inexpensive. Rice and groundnut cake have also been mentioned as dietary ingredients. The protein requirement of walking-catfish is currently placed at about 40% (7), though there have been studies that placed the level 10% lower (3). Growth is better facilitated by animal protein than by plant protein. When the dietary crude protein level is 40%, *C. batrachus* have an optimum lipid requirement of between 7 and 9% (9). Little is known about the vitamin requirement of walking-catfish, though the ascorbic acid requirement of *C. batrachus* fry is about 70 mg/kg (70 parts per million) of their diet (10). The use of high levels of carbohydrate in conjunction with walking-catfish feeds remains questionable, as the ability of those fishes to utilize various types of carbohydrates has yet to be determined in detail.

DISEASES

Walking-catfish are not only extremely hearty and tolerant of degraded water quality; they seem also to have some resistance to aquatic animal diseases. Among the bacteria that have been reported in conjunction with walking-catfish under culture have been *Aeromonas hydrophila* and *Pseudomonas* sp. In the case of *A. hydrophila*, very high bacterial levels must be present in the musculature before lesions develop (11). Parasites of various kinds have been reported from collections of walking-catfish from natural water bodies.

WALLEYE CULTURE

ROBERT C. SUMMERFELT
Iowa State University
Ames, Iowa

OUTLINE

Walleye (*Stizostedion vitreum*) is a member of the perch family (Percidae), which, in Canada and the United States, includes sauger (*S. canadense*), yellow perch (*Perca flavescens*) and about 138 species of darters and logperch (1). Blue pike (*S. vitreum glacum*), presumed to be extinct, is a subspecies of walleye that once thrived in Lake Erie. Walleye presently occur in 32% of the freshwater habitat in the United States and Canada (2). Walleye are targeted as a sport fish in 34 states, seven provinces, and one territory (3). In the United States in 1996, walleye and sauger were fished by about 11% the 35.2 million U.S. residents 16 years old and older that fished in freshwater other than the Great Lakes and 36% of anglers in the Great Lakes (4). In 1990, walleye represented 16.3% of the total freshwater fishes captured by anglers in Canada (3), and

walleye are said to be "the most economically valuable species in Canada's inland waters" (5).

Wild-caught walleye, blue pike, and sauger were once a substantial part of the commercial fisheries of the Great Lakes, especially from Lake Erie, the Mississippi River, and many of the numerous glacial lakes of the United States and Canada. In Lake Erie, in the interval 1879–1959, the three congeners — walleye, sauger, and blue pike — contributed 13.7 to 18.3% of the total commercial harvest of fish. The blue pike harvest was 49.5 to 79% of harvest of the three taxa until they abruptly declined in the 1960s (6) (Fig. 1). Continued commercial exploitation of walleye from Lake Erie may have contributed to the extinction of the blue pike (7). Currently, an overwhelming majority of the commercial harvest of walleye in North America is from the Canadian shore of Lake Erie and many isolated lakes of western Ontario and the Canadian Prairie Provinces. In the United States, a small harvest is made on the Great Lakes by tribal fishers for subsistence purposes, and a few tribes support a small commercial market.

There has been interest in walleye culture for over 100 years; the 1900 *Manual of Fish-Culture* published by the U.S. Commission of Fish and Fisheries included a chapter on propagation of "The Pike Perch or Wall-Eyed Pike" (8). That *Manual* describes spawning and spawn taking, use of "swamp muck" to prevent adhesion of eggs, egg incubation, transportation of eggs, description of cannibalism (including some excellent photographs of cannibalism), and prey selectivity by first feeding fry when lake water containing zooplankton was used as the water supply. By 1948, public hatcheries of 44 States and the U.S. Fish and Wildlife Service distributed 596.4 million "wall-eyed" pike, 79.6 million "yellow" pike perch fry, and 485.4 million "unclassified" pike perch (9). If we presume that all of these categories are walleye, the total was 1.16 billion fry. That level of production seems to have persisted for forty years. A survey for production years 1983–1984, indicated a similar number of fry were stocked annually by state, federal, and provincial agencies in the United States and Canada (10).
Figure 1. Changes in harvest of walleye, blue pike (subspecies of walleye), and sauger from Lake Erie, 1900–1969 (data from Hartman 1973: Table 3).

AQUACULTURE POTENTIAL

Walleye is recognized as a species with substantial aquaculture potential (11). There is a market for all life stages from egg to adult. Presently, the objective of most walleye aquaculture, both public and private, is to produce fry and fingerlings for stocking. At this time, there are few growers of food-size walleye. Encouraging market factors that may lead to development of walleye food-fish culture include excellent reputation for the food-quality of walleye, its name recognition by consumers, a high retail price (>US\$16.48–21.89/kg, \$7.49–9.95/lb), and a small and shrinking supply of competitive sources of wild-caught walleye for the food-fish market.

Biological characteristics that are important for a decision on fish suitability for aquaculture include desirable reproductive traits, lack of cannibalism, suitable growth rate, acceptance of prepared food, tolerance of crowding and other hatchery conditions, disease resistance, and palatability (12).

Reproductive Traits

Public hatcheries have spawned, incubated, and hatched walleye for more than 100 years. Females have been striped of as many as 300,000 eggs, although the number varies with size of the female and the fecundity ranges from 55,000 to 88,000/kg (25,000 to 40,000/lb) (13). Walleye eggs are easily incubated in conventional hatchery containers. The "McDonald jars" are glass or plastic cylinders with parabolic bottoms. Large batteries of the jars are commonplace at state and federal hatcheries (Fig. 2). The number of days for incubation varies with the water temperature used at individual hatcheries, but it typically ranges from 12–21 days to the start of hatch and 3–7 days more for all eggs to hatch from a given hatchery container. The incubation interval can be extended to 42 days by manipulating the incubation temperature. First, the eggs are incubated at a minimum of 7.8 °C (46 °F) for 5 days for initial embryo development; next, the water temperature is lowered until the eggs are close to hatching; and finally, the temperature is increased to a minimum of 13.3 °C (54 °F) for hatching so the fry will be vigorous enough to shed the egg shell (14). The newly hatched larval walleye (prolarva) is about 7.4 mm (0.3 in.) in total length and has a large yolk sac, hence, the name yolk-sac fry (Fig. 3).

The annual reproductive cycle of gonadal and hormonal changes in walleye have been described (15); hormonal treatments (LHRHa and hCG) to induce oocyte maturation have been evaluated (16); and environmental manipulation (light and temperature) have been combined with hormonal treatment human chorionic gonndotropin) to induce ovulation in walleye about 10 weeks prior to natural spawning. These methods have been used by the Iowa Department of Natural Resources to advance spawning of walleye from normal interval in April to January or February (17). The early spawn extends the growing season in order to produce larger fall fingerlings than otherwise possible.

Figure 2. Large-scale, walleye incubation facility with many hatching jars. On hatch, the larvae swim to the top of the jar and go with the flow to a holding (catch) tank.

Figure 3. Newly hatched, yolk-sac fry (prolarva stage) of walleye.

Cannibalism

Walleye is a cannibalistic species; indeed, their first meal may be a sibling of about equal size (cohort cannibalism) (18). Cannibalism has been considered a serious problem in tank and pond culture of fry to fingerlings and during the 30-day interval of habituating pond-raised fingerlings (phase I fingerlings) to formulated feed (19,20). Nonetheless, cannibalistic tendencies vary with stocks (20). It may be reduced by genetic selection (21); and in intensive fry culture, it can be managed to insignificance by use of turbid water (22,23) and by providing adequate numbers of live brine shrimp (24). Frequent feeding and an adequate feeding rate are critical to prevent cannibalism. Nearly all walleye used by both public and private aquaculturists are progeny of wild-caught stock. For commercialization of walleye as a food fish, domestication, which seems to reduce the cannibalistic character of walleye, will be required, (25).

Growth

In nature, the major limits on growth are the abundance of prey and environmental temperatures. Assuming a minimum weight for a food-size fish is about 540 g (1.2 lbs)

in nature, walleye of this size are not typically seen until their fourth summer of life (26). In cage culture of walleye, where food is not limiting but environmental temperature strongly influences growth rate, walleye reach food-size in the middle or latter part of their third year of life (27), one summer earlier than in nature. In intensive culture where food is abundant and temperature nearly optimum, walleye can reach food-size in 16 months from hatch (28).

Acceptance of Formulated Feed

Techniques were developed almost 30 years ago to habituate pond-raised fingerlings to formulated feed in tank culture (29,30). When environmental conditions are right and low light intensity (31) or in-tank lighting (32) is used, small (35−70 mm, 1.4−2.7 in.) pond-reared fingerlings can be habituated to manufactured feed and raised to about 150 mm (6 in.), with about 90% survival of the initial stock for the intensive phase in practical culture conditions (32). First feeding fry readily feed on brine shrimp (*Artemia* sp.) nauplii (24,33) and they can be habituated to commercially available formulated feed (e.g., the Fry Feed Kyowa [FFK], Biokyowa, Inc., Chesterfield, Missouri) when requisite environmental conditions are provided (34).

Tolerance to Hatchery Conditions

With the exception of a single domesticated hatchery stock developed and maintained at the London Fish Hatchery, London, Ohio (25), nearly all walleye used in aquaculture today are progeny of wild stock. It is not surprising that offspring of feral walleye raised in hatchery raceways and tanks seem skittish and easily disturbed by overhead movement and hatchery activities (e.g., tank cleaning) (35−37). However, when low (<20 lux) overhead light (31) or in-tank lighting (35,37) is used, walleye of all ages are more tolerant of hatchery tanks. Subadult walleye seem to tolerate high-density culture; and, for short-term exposure, they are surprisingly tolerant of low oxygen and high temperature (28). Domesticated stock seem to show less response to fish hatchery conditions (32). Hybrid walleye, which are a cross between female walleye and male sauger, are quite docile and exhibit faster growth than walleye, at least as juveniles (35−37).

Disease

Walleye are susceptible, but not more susceptible than other cultured fish, to commonplace external protozoan parasites such as *Ichthyophthirius multifiliis* and *Trichodina* spp. (38). Columnaris disease (*Cytophaga columnaris*) is the most serious and commonplace bacterial disease of walleye (39,40). Columnaris infections often result from mechanical injuries when fingerling fish are harvested or handled at temperatures favorable to the bacterium (39). Environmental stress is certainly a significant factor contributing to an epizootic in walleye (40). To date, no viral infections have been found to cause epizootic mortality in walleye, but adult walleye are susceptible to several viral diseases of the integument: lymphocystis, epidermal hyperplasia, and dermal sarcoma (41−44).

Palatability

Cookbooks that include walleye recipes invariably provide very positive endorsements; for example, walleye "...one of the best eating of all freshwater fishes..." (45), and "...the walleye is one of the most delicious of freshwater fishes. Its snow-white flesh is both delicately and distinctively flavored, ..." (46). Walleye also have favorable name recognition in small, upscale, white-tablecloth restaurants, and have been on the menu of some national franchise chains. Given these facts and limited commercial supply, skin-on walleye fillets sell for more than cultured catfish, salmon, or trout. Surveys in 1990 and 1992 of retail, wholesale, and other firms that comprise the traditional marketing channel for fish and seafood products within the Midwest indicated that walleye had high marketing potential as foodfish (47,48). The scales and skin of walleye are 10.8 to 13.0%. Therefore, to avoid substantial economic loss at the retail level and for better presention in restaurants, walleye are generally sold scaled with their skin on (49). As a percentage of their body weight, female walleyes have significantly larger heads than males (12.9 and 9.8%, respectively). Thus, fillet yield of males is higher than females. The range in yield of two cohorts for scaled, skin-on fillets of male, Spirit Lake, Iowa walleyes was 43.2 to 44.5% for male and 39.3 to 41.0% for female walleye (49). Using an unweighted mean of 42% for Spirit Lake walleye (47), the fillet yield of walleye is similar to that of channel catfish (40−45%) and 10% higher than tilapia (32%) (50). A 540 g (1.2 lb) walleye is sufficient to obtain two 113.5 g (4 oz) skin-on fillets, and a 811 g (1.8 lb) walleye would provide two 170 g (6-oz) fillets (49).

STRATEGIES FOR WALLEYE CULTURE

Several types of culture systems are used for walleyes, such as

- Pond culture
- Tandem pond to tank culture
- Pond to tank to pond culture
- Cage culture
- Intensive culture
  - Fry to fingerlings
  - Fingerlings to food fish

Some topics have been more thoroughly researched than others; e.g., there is much more information on pond culture in drainable ponds than undrainable ponds because most state and federal agencies use drainable ponds, although the largest commercial production of fingerlings in the United States takes place in undrainable ponds in Minnesota. Also, nearly all research has been conducted or sponsored by natural resource agencies whose interests are in production of fingerlings for enhancement stocking, and only limited information has been published on the culture of walleye as foodfish.

POND CULTURE

Walleye harvested from ponds 30–50 days after fry stocking (typically between mid-June to early July) are called "summer fingerlings" or "phase I fingerlings" and have a total length of 32–76 mm (1.25 to 3.0 in.). Juvenile walleye raised to the end of the growing season (September and October) are called "fall fingerlings" or "phase II fingerlings"; they range between 100 to 200 mm (4.0 to 7.9 in.) total length. Pond culture of fingerling walleyes dates from at least the early 1920s (50). In 1948, pond production generated more than four million fingerlings (9). By 1983/84, more than nine million pond cultured fingerlings were produced annually by public agencies (10).

Pond culture of fingerling walleye is carried out in drainable and undrainable ponds. Drainable ponds are constructed with a levee on all four sides. Undrainable ponds are a diverse assortment of water bodies, including farm and ranch ponds, shallow natural lakes, marshes, borrow pit ponds, and dug ponds. Most fingerling walleyes produced in Minnesota are raised in natural prairie pothole and shallow lakes that do not sustain a fish population because of winterkill (51–54). Methodology for walleye culture in undrainable (54) and drainable (55) ponds was recently reviewed. Those references should be consulted for details of culture technology. The following is a summary of major issues concerning pond culture of walleye, with an emphasis on drainable ponds.

Variability

It has been said that pond culture of walleye fingerlings (i.e., survival and yield) is "plagued by extreme variability of results" (56), probably in reference to pond-to-pond variability within the same year. For example, in Ontario, within-year, pond-to-pond variation in survival ranged from 0.7 to 73% and yield ranged from 1.8 to 26.1 g/m³ (0.00012 to 0.0016 lb/ft³) (57). In a state facility in Ohio, 55% of walleye ponds within the same year had <10% survival, a problem reduced by carefully controlling N : P ratios with frequent addition of inorganic fertilizers (58,59).

Far less information has been reported on long-term variability at the same hatchery. In a 19-year interval at a state operated pond culture facility in western Nebraska, year-to-year variation in survival and yield (kg/ha) was greater than within-year, pond-to-pond variability (60). At an Illinois public hatchery with plastic-lined ponds, survival ranged from 55% to 91% from one year to another (61).

Pond Management

Management of drainable ponds includes pond preparation, scheduling pond filling in relation to the anticipated hatching date of walleye, stocking density and date after pond filling, fertilization (kinds, amounts, and application schedule), zooplankton inoculation, control of problem organisms (aquatic insects, clam shrimp and vegetation), water quality management (aeration etc.), and harvest methods (drain to catch-basin, drain and seine, or partial harvest with lights) (56).

Pond Preparation. If the time between draining and next production cycle allows it, the pond bottom may be seeded with an annual rye grass (62). If seeding is not done after the last harvest of the season, the ponds may be dried and disked; if needed, agricultural lime ($CaCO_3$) may be added to increase alkalinity. Caustic (hydrated) lime, $Ca(OH)_2$, may be applied after pond draining and harvest to kill parasites or problem organisms.

Pond Filling. Water supply for ponds may be from groundwater or surface sources. If ponds are filled from surface water sources, the water must be filtered with nylon screens or bags to exclude fish and fish eggs, tadpoles, and other problem animals. When ponds have been left empty over winter, filling is usually timed to the expected date that walleye eggs hatch and in relationship to strategies for zooplankton development. The time between pond filling and fry stocking varies from 1 to 28 days or "just before fry are ready to be stocked" (63), i.e., 9 days (64), 10 days (51), 2 weeks (65), and 4 weeks (66) after pond filling.

Once pond filling commences, most hatcheries fill ponds as quickly as the water supply will allow, which is usually 1 to 3 days. A staged- or gradual-filling process is a purposeful procedure to concentrate newly stocked fry and zooplankton, and it provides multiple hatches of zooplankton because new zooplankton hatches are stimulated by each increment in pond filling. Also, when zooplankton are abundant in the water supply, slowly filling the ponds will continually add zooplankton. Enhancing zooplankton by continuous addition of water has not been the subject of research, but it is inadvertently done when a continuous addition of water is used to replace water loss from evaporation and/or seepage. In one report, the addition of water was equivalent to the total volume of the pond every 10 days. The inflow water was from a surface source that contained about 500 zooplankton/L (1900/gal). The inflow represented 15% of the average density (360/L; 1368/gal) of zooplankton in the pond (60).

Stocking Density. Because they are more intensively managed, stocking densities in drainable ponds are substantially greater than reported for undrainable ponds. Fry stocking density in undrainable ponds by private producers in Minnesota typically ranged from 6,178 to 24,710/ha (2,500 to 10,000/acre), but 49,420 to 74,120 fry/ha (20,000 to 30,000 fry/acre) if the pond is aerated or known to be exceptionally productive (67). The Minnesota DNR typically stocks 7,410 to 24,710 fry/ha (3,000 to 10,000 fry/acre), and the Michigan DNR stocks 74,130 to 185,325 fry/ha (30,000 to 75,000 fry/acre) (68).

There is a substantial range reported in stocking density in drainable, production ponds at state, federal, and provincial hatcheries: 250,000/ha (101,736/acre) for plastic-line production ponds in Illinois (61); 250,000 to 375,000/ha (101,736 to 151,760/acre) in earthen ponds in Nebraska (60); 335,938/ha (135,952/acre) average for three hatcheries in Ohio (63); 410,000 to 494,000 fry/ha (166,00 to 200,000/acre) at a federal hatchery in North Dakota (64); and 600,000/ha (242,817/acre) at a provincial hatchery in Ontario (69). Generally, state and federal

hatcheries that use drainable ponds have higher stocking densities, more intensive management, and a smaller size at harvest than private hatcheries using undrainable ponds.

At a Nebraska state fish hatchery, an increase in stocking density from 250,000/ha to 375,000/ha in unfertilized ponds increased the numerical harvest of fingerling walleye from 153,509/ha to 228,647/ha without reducing survival (61.8% vs. 61.3%), mean fish size [36 mm (1.4 in.) vs. 33.5 mm (1.3 in.)], or yield (60). Yield was 52.0 kg/ha (46 lb/acre) at a stocking density of 250,000 and 57.2 kg/ha (50 lb/acre) at 375,000/ha (150,000/acre). Reduced yield and variability in returns of pond-reared walleye may occur when low fish densities allow zooplankton to overgraze algae, causing declines in both algae and zooplankton (59).

Commercially, the value of fingerling walleye varies by size and number; thus, an increase in number of fish harvested per unit area may be more important than an increase in yield (kg/ha). In most studies, fish size at harvest is inversely related to stocking density, survival rate, and number of fish harvested/unit area. When several ponds are stocked on the same date, but harvested over a 10 day interval, an inverse relationship in fish survival and length of the culture interval is evidenced, while there is a positive relationship between length of the culture interval and fish length at harvest (60).

Fertilization. The producer of phase I fingerlings may rely on natural fertility without supplemental fertilization, such as is typical of undrainable ponds. Generally, in drainable ponds, efforts are made to enhance survival and production by adding organic matter or inorganic fertilizers, or a combination of the two. Traditionally, organic fertilizers were preferred in walleye culture, especially in northern latitudes. A justification for this preference may have been based on results from early studies on pond fertilization for rearing walleyes. Research in Minnesota over 50 years ago did not indicate a positive correlation between total phosphorus and total nitrogen and yield of fingerlings in 66 walleye culture ponds (70); they concluded that "...basic fertility is not converted into a crustacean crop early enough in the spring to be available when most needed by the small yellow pike perch (i.e., walleye)." Thus, from that study and personal experience of many culturists, it has been widely held that algal populations are too slow to develop at low spring time temperatures when walleye fry are first stocked. With a short interval between pond filling and fry stocking, zooplankton foods of walleye develop more rapidly with organic fertilization. This view has been changing as noted below in the review of strategies for use of inorganic fertilizers.

Organic fertilizers that have been used for fertilization of walleye culture ponds include flooded rye grass, animal manures, ground hay, alfalfa pellets, alfalfa meal, soybean meal, and Torula yeast (55). The type and particle size of organic fertilizers is important because they affect both the rate of decomposition and the ability to stimulate development of microbial populations (71). Organic matter is used to nourish a microbial-detrital

(heterotrophic) pathway to fish production. Associated with the detritus is a complex community of decomposer organisms (bacteria, fungi, and many kinds of protozoa, but particularly the ciliates) and a diverse assemblage of small benthic metazoans that consume detritus meiofauna (nematodes, copepods, turbellarians, gastrotrichs, small annelids, hydrozoans, and larger invertebrates). The pathway from organic fertilizers to fish begins with decomposer microorganisms (bacteria and fungi) that are consumed by detritivores (e.g., infusoria, other detritus-feeding organisms), and their predators. Zooplankton and aquatic insect larvae that are eaten by walleye are either detritivores (i.e., heterotrophic organisms that consume organic matter) or predators on detritivores. Although organic matter also functions like a slow release fertilizer, releasing inorganic nutrients (N and P) that eventually stimulate algal production, it is seldom applied on the basis of its nutrient content.

A diverse complex of factors affect the abundance and composition of zooplankton communities in ways that are still unpredictable. Needed are experimental studies (74) to determine specific types and particle sizes of organic fertilizers and application schedules to optimize the abundance of particulate organic matter, its associated microbes, and zooplankton numbers and composition. Alfalfa, for example, is used as ground hay, pellets, or meal, and vary in particle size from large to small; smaller particles decompose faster and are food for zooplankton. A succession of experiments have been carried out at the White Lake Fish Culture Station, Ontario, to evaluate stocking density and fertilization regimens using organic and inorganic fertilizers (65,69,72).

Inorganic fertilizers stimulate an autotrophic food chain from algae to zooplankton. Autotrophic means "self-feeding," because algal cells produce their own carbohydrates ("food"). Synthetic inorganic fertilizers, which have a high concentration of nitrogen (N) and available phosphorus (P), are used to stimulate crops of small algae (diatoms, coccoid greens, and flagellates) that are eaten by zooplankton. Culver (58,59,63) described methods for measurement of N and P and the calculations needed to determine the precise amounts and mixtures of fertilizers to achieve a desirable N:P ratio. After pond filling, the inorganic concentration of N and P are raised to 600 mg [0.005 lb/gal] N/L and 30 mg [0.0002 lb/gal] PO_4-P/L and are maintained at those levels by weekly applications of liquid inorganic fertilizers. This procedure has the potential for improved management of algal abundance and algal community structure, as well as lower costs (exclusive of the costs for equipment, glassware, and reagents for determining N and P) for fertilizers.

A few experimental comparisons of organic and inorganic fertilization strategies for production of phase I walleye fingerlings have been reported. Jahn et al. (61) found that organic fertilizers were superior to liquid inorganic fertilizer in nearly every category of production of walleye in plastic-lined ponds; also, the inorganic fertilizers were said to promote poor water quality (e.g., high pH, low-dissolved oxygen). Soderberg et al. (56) compared walleye fingerling production in ponds fertilized

with periodic doses of alfalfa meal and Torula yeast with ponds fertilized with liquid fertilizer to maintain 600 µg/L of N and 30 µg/L of P. Differences in survival and yield between fertilizer treatment were not statistically significant, but the authors recommended the use of inorganic fertilizer treatment because it was less expensive and easier to apply. Tice et al. (73) carried out a similar experiment at the same production site in Pennsylvania. They also found statistically similar results with both treatments. Yield was 27% greater (47 kg/ha; 42 lb/acre) from ponds fertilized with organic fertilizers than from ponds fertilized with inorganic fertilizer (37 kg/ha; 32.9 lb/acre). Also, pond-to-pond variation (standard error) in survival and yield within treatments were greater in ponds treated with inorganic fertilizers. Fox et al. (74) compared production of fingerling walleye in ponds fertilized with a soybean meal slurry with production in ponds given the same dosage of soybean meal and supplemented with weekly applications of 8-32-16 (N-P-K) inorganic fertilizer. Although the difference was not statistically significant, walleye grew faster and biomass harvest was 42% higher in the ponds treated with inorganic fertilizers. These studies do not provide unequivocal conclusions regarding fertilizer strategies.

Bacterial decomposition of organic matter consumes oxygen, and oxygen depletion may cause fish kills; but oxygen depletion also occurs in ponds fertilized with inorganic nutrients (74). To prevent critically low oxygen from causing mortality, some production sites add aerated water (44,66,74) or employ oxygen diffusers (66) or a portable paddlewheel aerator (55) to increase oxygen concentrations.

Natural Foods. The first food of walleye may be diatoms (75), rotifers, and copepod nauplii (61,70); cyclopoid copepods (78); or small soft-bodied cladocerans (79). As they grow, walleye progressively switch to from copepod nauplii to small then larger cladocerans, especially *Daphnia* (69,76,77,79,80), and within three weeks, they are consuming immature aquatic insects, typically chironomid larvae and pupae (69,77,80). A sequence from copepod nauplii, to copepods, to small then large cladoceran species, and finally to chironomid larvae and pupae has been observed in gut contents of walleye fingerlings in production ponds in North Dakota and Nebraska (55). In that study, walleye did not consume diatoms or rotifers, even though rotifers were the most abundant zooplankton. Smaller copepods and cladocerans were preferred early in the culture season, but food preference shifted to large cladocerans (up to 2.0 mm; 0.08 in.) and then chironomids in the latter stages of the culture period for phase I fingerlings.

Zooplankton Inoculation. The purposeful addition of zooplankton (zooplankton inoculation, or zooplankton "seeding") to culture ponds is a potential, but largely unstudied, strategy to initiate a rapid increase in desirable zooplankton numbers. Zooplankton inoculation has been recommended for pond production of phase I fingerling striped bass (81). Zooplankton inoculation has special appeal for hatcheries in northern climates where the interval between pond filling and stocking is limited, water temperatures are low, and there is little time to optimize zooplankton populations by other means (71). Ponds filled with water from surface water sources (even filtered water) invariably contain zooplankton which serve as an initial inoculum for the newly filled pond. The kind, size, and abundance of zooplankton in a water supply will vary temporally. Quantification of zooplankton in a water supply was reported for a walleye hatchery in western Nebraska at 490 to 506 zooplankton/L (1862 to 1923/gal); and based on pond volume, the addition was 54 zooplankton/L (205/gal) in the ponds, or about 9.9 to 15% of the average zooplankton density in the ponds (60).

Daily (53) reported that the Minnesota Department of Natural Resources stocked amphipods (0.56 kg/ha; 0.49 lb/acre) into undrainable walleye culture ponds when amphipods were not present because "they provide important forage for the fish." Based on typical size of amphipods, they would not be suitable food for small walleye. An inoculum of cladoceran species too large for consumption by first feeding larval walleye may actually reduce walleye survival (77). Zooplankton stocking is limited by the ability to obtain large quantities of zooplankton of the right kind and size when needed. Skrzypczak et al. (82) described a system for larval culture of Eurasian perch (*Perca fluviatilis*) and pikeperch (*Stizostedion lucioperca*) that involved attracting zooplankton with lights into a fine-mesh cage and then pumping them to a fry culture cage. Certainly, zooplankton inoculation for walleye culture ponds requires considerably more research than has been reported to date.

Monitoring Growth and Survival. Walleye may be seined or trapped to monitor growth and to obtain an index of abundance (survival). Walleye have a strong phototactic response to light at 32-mm (1.3 in.) total length (83) and gradually become photonegative by 40 mm (1.6 in.). The attraction of walleye to light allows them to be captured in a light trap (55); the catch per unit effort (CPUE) in the light trap can provide a database that may be used to determine the status of the populations. Fish may be monitored to determine growth and presence of food in the gut, which can indicate the adequacy of the food supply and determine the need for additional fertilization and timing of harvest. It is also useful to examine fish for gas bladder inflation and incidence of parasitism. After the attraction of fingerlings to light wanes, nighttime seining is usually effective for sampling.

Problem Organisms. Predacious, aquatic hemipteran insects, such as backswimmers (Family Notonectidae) and giant water bugs (Family Belostomatidae), reduce survival of stocked fry; and the stout beak of notonectids is capable of a painful sting to personnel harvesting fish from seines. It has been common practice to control these insects in ponds by applying oil to the water surface (52).

Abundant clam shrimp are a nuisance in ponds used for production of fingerling fish because they clog screens during draining and they have been reported to reduce the production of fingerling northern pike (84,85).

Clam shrimp are branchiopod crustaceans; their chitnous exoskeleton resembles the valves of large ostracods or the shell of a fingernail clam (family Sphaeriidae, class Bivalvia). Clam shrimp densities as high as 4,488 m^2 (3,740/yd^2) have been reported in walleye culture ponds (85). Clam shrimp are not predators on fish—they consume detritus, diatoms, and green algae—but they compete for the same food resources used by copepods and cladocerans (85). Strategies for control of clam shrimp include: keeping ponds full of water over winter and not dried before stocking; flushing newly hatched clam shrimp nauplii with a fill-drain-and-refill strategy; sterilizing ponds with slaked lime (calcium hydroxide) at the rate of 2,000 kg/ha (1,760 lb/acre) to the moist pond bottom after fish harvest; and if regulations permit, applying insecticide trichlorfon (85).

Harvest

Fingerling walleyes may be harvested from undrainable ponds with traps or seines. The same gear may be use in drainable ponds, but they are usually harvested by draining water into a catch basin located inside or outside of the pond. Although drainable ponds may be partially harvested with seines or fyke nets, or seined during draining, most state and federal production hatcheries drain the ponds to a catch basin and harvest the entire pond in one day (55,64). If desired, walleye may be partially harvested over several days by using traps, seines, night harvest with lights, or a drain-and-seine procedure.

A night-harvest technique described for yellow perch (86) has been modified and used for harvesting walleye during the photopositive phase (56), which lasts until they are about 32 mm (1.3 in.) (83). A special advantage of the night harvesting technique is that fingerlings may be captured without the usual abundance of tadpoles and salamander larvae, which were a nuisance with daylight pond seining.

TANDEM POND-TANK CULTURE

Because it is difficult to raise many walleye to sizes >100 mm (3.9 in.) in ponds without the addition of forage fish, many public hatcheries use the tandem pond-tank culture method (i.e., extensive–intensive) to raise phase II fingerlings. Pond-reared fingerlings are transferred to indoor culture tanks where they are habituated to formulated feed. Thereafter, they are typically raised to 125–200 mm (5–8 inches). A variety of cultural factors have been studied, including stocking density, temperature, light, diet, and feeding frequency. There are two periods of high mortality in tandem pond-tank culture. The first occurs in the pond-culture interval, as is obvious by survival data from pond cultured fish. The second period of high mortality occurs in the intensive culture system during the first 21 days when fish are habituated to formulated feed (31). In earlier studies, survival through the feed-training interval varied from 20 to 60% (29,30,88,92), and 6.5 (89) to 84.3% in cages (93). Survival rates of 65 to 90% have been achieved in tanks in other studies (31,32).

A key element to successfully habituating pond-reared walleye to formulated feed includes starting with healthy fingerlings that have a good condition factor. Feed training should begin immediately after removal from ponds. Poor survival during the training interval will occur when fingerling fish have been held in a holding tank for several days before the feed-training interval begins. These fish usually refuse to feed and most starve. Also, rough handling when harvesting or during transport, especially at temperatures greater than 20 °C (68 °F), often results in high mortality from columnaris disease (39).

Cultural practices for successfully feed-training pond-reared walleye include: temperature (20 to 25 °C; 68 to 77 °F); low intensity (20 lux) overhead light or intank lighting; suitable feed quality; high initial feeding rate (10% body weight per day); frequent feeding (every 5 minutes, 18 hours/day); and initial densities of less than 3 kg/m^3 (0.19 lb/ft^3) of tank volume and maintenance of suitable water quality (31,32).

POND TO TANK TO PONDS

Phase I, fingerling walleyes harvested from ponds are often transferred to raceways and habituated to formulated feed. Nagel (88) returned feed-trained fingerlings to ponds where they were reared for several years to obtain captive broodstock.

A pond-to-cage-to-pond strategy was described by Coyle et al. (90) in which pond-raised, phase II fingerlings were over-wintered and, in early spring, habituated to formulated feed in cages in small (0.04 ha; 0.16 acre) ponds. In a 47-day interval (March 24–May 11), a yield of 47% "usable" survivors was obtained. Thereafter, the feed-trained fingerlings were released to ponds and fed once per day. Survival was 67% after 6 months (May 11–November 9) of culture. These findings suggested that if overwintered another year, a food-size fish may be produced in the third summer. Unfortunately, considerable mortality occurs in each of the several culture steps: between fry stocking and harvest of a fall fingerling; during overwintering fingerlings in ponds; training pond-reared fingerlings to formulated feed in cages; through the second summer; over another overwintering; and until the fish reach market size in the third summer. A serial multiplication of their survival data (0.83 × 0.45 × 0.673)—83% survival for overwintering phase I fingerlings, a feed-training success in cages of 45%, and survival to the end of the second summer of 67.3%—implies a cost of $2.28 to $3.50 for fingerlings at the end of their second summer. Raisanen (51) points out that for the private sector, the cost of a fall fingerling raised in undrainable winterkill ponds in Minnesota is likely to be $0.28 to 0.57 each based entirely on cost of fry, not including any production costs. Variable production costs include input for feed, feeders, cages, seines, labor, energy, and capital costs for land, ponds, and buildings. Unless the survival rates through each of the production phases can be increased, this cultural procedure is uneconomical.

Figure 4. Cage culture system for walleye tethered to raft in gravel quarry lake (89).

CAGE CULTURE

Cage culture of walleye has been in water-filled gravel and rock quarries, natural and artificial lakes, and farm ponds (93). Cages may be attached to rafts (Fig. 4), piers, or docks. Cage culture has been used to raise walleye fry to fingerlings (94), to raise a phase I pond-reared fingerlings to phase II fall fingerlings (150–200 mm; 5.9–7.9 in.), for enhancement stocking (95–97), and for culture of a food-size walleye (27,95).

Stevens (27) was the first to growout walleye to food size in cages, and Bushman (95) overwintered fingerlings in aerated cages for the purpose of growout to food size. Coyle et al. (89) overwintered fingerlings in a pond in north central Kentucky, then feed-trained the yearling walleye in cages. Starting with young fingerlings in midsummer, survival to fall is more successful when feed-trained fingerlings are used rather than training pond-raised fingerlings in cages to accept commercial feed (97).

When walleye are overwintered in cages in northern climates, aeration apparatus is required to keep the area around the cages free of ice (27,95). Overwinter survival of walleye fingerlings in cages was 40 to 60% in southern Iowa (27) to 93 to 98% in northeast Iowa (95).

Because fish growth rates are a function of water temperature, seasonal variation in water temperature in ponds and lakes will rarely be optimal for growth of walleye in cages or in pond culture; thus, it has not been proven to be an economical method to raise walleye to food size.

INTENSIVE CULTURE

High density, finfish culture in flowing water systems using single pass (one use), serial reuse (stair-step raceway system) or recycle systems are collectively referred to as intensive culture. High density (expressed as kg/m^3 or lbs/ft^3) is achieved by using a high exchange rate of water (single pass, reused, or recycled water) to supply oxygen and remove dissolved wastes (i.e., ammonia) from the culture tank. Recycle systems are designed to remove suspended solids and to nitrify ammonia to nitrates. Most intensive culture of walleye has been used to habituate

phase I fingerings to formulated feed with the purpose of growing them to a fall fingerling. Providing growth rates are sufficient and production costs reasonable, feed-trained fingerlings may be raised to a size for the food fish market in intensive culture.

One advantage of recycle culture is that it "closes" the production cycle. All aspects of culture, from holding broodstock, spawning, and culture to food size, can be done indoors under optimum conditions for growth. Also, intensive culture is an alternative for hatcheries that lack pond facilities and sites for cage culture and where space or water supply is a constraint. Advancing the spawning season 90 days to late January requires an indoor environment to hold and spawn broodfish, as well as for egg incubation and fry culture. Obviously, ice-covered ponds cannot be stocked with fry derived from an early-season spawn. Also, training fingerlings or fry to formulated rations is best accomplished in controlled conditions characteristic of intensive culture.

FRY TO FINGERLINGS

Twenty years ago the prospects for intensive culture of walleye fry seemed remote: "It is extremely speculative to suggest a culture method for walleye fry at this time, ..." (98). Major problems encountered in intensive fry culture were nonfeeding, noninflation of the gas bladder (NGB), clinging behavior, and interrelationships between these problem areas. Intensive fry culture is a now an effective production technology for large-scale production walleye fingerlings (98–100).

Advantages of intensive culture include control of temperature to enhance growth rates and extend the growing season. In intensive culture, growth rates can be accelerated or decreased by temperature manipulation to meet production schedules for fish of different size. Intensive culture is the only technology that can be used to raise fry produced by out-of-season (early) spawning. In nature, the growing season (i.e., the number of days when water temperatures are adequate for growth) is usually too short to raise a phase II fingerling to a target size of 150 to 200 mm (5.9 to 7.9 in.) by fall in ponds or cages. Fry produced by spawning in winter months cannot be stocked in ponds in the Midwest. Pond stocking begins in mid-April in Ohio (59) and western Nebraska (68), late April to early May in central Michigan (101), early May to early June in North Dakota (55,77), the third week of May in northern Michigan (104), and late May to early June in Ontario (65). Intensive culture of walleye fry in recycle systems has been used for intensive culture at sites as far north as near Gunton, Manitoba (98,99).

Methodology

Intensive culture of walleye from hatch to small fingerling requires careful attention to system design, environmental factors, feed and feeding, tank hygiene, and water quality, including the following factors:

- Culture tanks, such as size, shape, and color.
- Screens

- Surface sprays
- Aeration and pumping
- Light and temperature
- Stocking
- Feeds, feeders and feeding
- Tank hygiene
- Water quantity and quality

Culture Tanks. Many tank shapes and drain systems have been evaluated for intensive culture of walleye fry. Barrows et al. (102) proposed a tank-within-a-tank design to maximize screen size and to develop up-flow pattern to keep fry in suspension. Kindschi (103) described a similar apparatus that has a stainless steel mesh basket insert for a circular, cone-shaped tank. To maintain a high feed particle density, a cuboidal-shaped tank with an upwelling water circulation pattern was designed to resuspend formulated feed (34). In an experimental comparison, fry survival and gas bladder inflation for larval walleyes were higher in cylindrical than cuboidal tanks (107). Fry survival in a round-bottomed trough was 47% compared to 13% in a round tank with a hemisherical bottom (98). Moodie and Mathias (99) described a production-scale, trough-shaped tank with an upwelling current for intensive production of walleye fry. Conventional rectangular raceways (33) and cylindrical (circular) tanks (100–107) that are typically used in hatchery production of other fishes are effective for production-scale culture of walleye fry on brine shrimp (*Artemia* sp.) and formulated diets (Fig. 5).

Larval walleye are strongly phototactic (86). In tank culture, they are attracted to direct or reflected light, and they cling to the tank wall, drain screens, or any other surface that reflects light (Fig. 6). Their clinging behavior affects initial feeding, growth, and survival (22,23). Tank size, tank color, light intensity, and turbidity influence fry clinging behavior. A greater percentage of the fry will cling to the sides of smaller than larger tanks because the surface area per unit of tank volume of smaller tanks is larger than that of larger tanks. Corazza and Nickum (109) observed greater larval dispersal in tanks with gray walls than in tanks with white, yellow, or green walls. Most investigators now use black over lighter colors for the interior of culture tanks. Clinging behavior has been reduced by culturing fry in turbid water (22,23) or by using high-intensity (680 lux) overhead light (105).

Screens. The drain must be equipped with a screen with a mesh small enough to retain the fry. A screen not larger than 710 μm with no more than 53% open area is said to retain 3- to 5-day old larvae (110). Walleye fry produced out-of-season and fry of hybrid walleye, however, are small enough to pass through a 0.704 mm (0.03 in.) mesh, which implies that a somewhat smaller screen size is needed for these smaller size larvae. After 21 days posthatch, however, effluent flow and tank hygiene can be improved by switching to 1 mm (0.04 in.) mesh with 58% open area. In intensive culture, walleye typically grow about 0.67 mm/d (0.026 in./d) in the first 30 days, from 7.5 mm (0.3 in.) at hatch to 27 mm (1.0 in.) in 30 days (22,23).
Figure 5. Design features of production-scale walleye fry-culture tank (123). The fiberglass tank measured 123 cm across the top, 109 cm at the bottom, and 76 cm deep. In use, the water depth is 67 cm and the rearing volume 680 L. The tank is supplied with four surface sprays to enhance gas bladder inflation (123). The sprays are located about 20 cm above the water surface and directed 90° from the water surface.
Figure 6. Behavior of larval walleye in clear-water (left) and turbid-water culture (right). Larval walleye are strongly phototactic (83). In clear water, their attraction to light results in clinging of the larvae to the tank walls; but in turbid water, they disperse across the tank and orient to the water current (22,23).

Obviously, food must be smaller than the gap of the mouth, thus brine shrimp nauplii or particles of formulated feed will pass through mesh small enough to retain larval walleye. The 400 μm (0.016 in.) Fry Feed Kyowa (BioKyowa, Chesterfield, Missouri), which has a particle range 240 to 675 μm (0.009 to 0.026 in.) (105) and brine shrimp nauplii, in the range 200 to 250 μm (0.008 to 0.010 in.), will pass through the 700 μm (0.028) mesh that will retain fry. In an effort to reduce loss of feed particles, a 500 μm (0.02 in.) mesh has been used to retain FFK B-400 feed (34), and screens with openings of 200 μm (0.008 in.) have been used to prevent loss of brine shrimp nauplii (105).

Surface Spray. Larval walleye, in common with most fish, must penetrate the water surface to gulp air to fill their gas bladder (Fig. 7). Gas bladder inflation (GBI) was typically poor until it was discovered that a spray of water to the surface would enhance gas bladder inflation (106,107). Walleye typically inflate their gas bladder between 6 and 12 days posthatch. The gas bladder is first round but elongates quickly (Fig. 8). Oil film on the water surface of the culture tank causes noninflation of the gas bladder because larvae cannot penetrate the surface to gulp air for first filling of the gas bladder (108). Maximum thickness of the oil film on the water surface of fry culture tanks occurs when fish are 7 to 18 days posthatch. In the critical period when gas bladder inflation occurs, about 65% of the total oil thickness is derived from fish and 35% from the feed (109). A water spray to the tank surface removes the oil film and cleans the surface of feed and debris (106,107). In circular tanks with a circular flow pattern, the water passes under the spray head with each revolution of the water mass. It is important that the spray impacts the water surface with enough force to produce a slight depression in the water under the spray. About one spray per 5,000-cm² (775-in.²) of tank surface seems to be adequate.

Aeration and Pumping. Degassing and aeration of the water supply should be done before the water is delivered

Figure 7. Larval walleye (postlarval I) penetrating the water surface for first filling of the gas bladder (124). Gas bladder inflation is prevented by an oil film on the water surface that prevents surface pentration by the larva. (Photo courtesy of Phillip Rieger.)

Figure 8. Sixteen-day-old larval walleye showing fully inflated gas bladder. This 17-mm juvenile was cultured at a mean temperature of 18 °C (64.4 °F), 289 daily temperature units. (Units of scale are 1 mm.)

to the culture tanks. Compressors should not be used to aerate water destined for use in intensive culture of fry because they often contaminate the air with oil, which leaves an oil film on the tank surface and interferes with gas bladder inflation. In some hatcheries, an air line is placed around the center standpipe to keep fry from being impinged on the screen. However, this may cause undesirable turbulence, and fast rising air bubbles will even throw fry out of the water where they will stick to the side walls above the water line.

Light and Temperature. Fluorescent lights, flood lamps, and natural light are all acceptable, but a diffuse light source may deter fry from clinging to the sides of the rearing tank. Light intensities of 100 to 700 lx have been used. A light of 680 lx at the water surface is said to aid in achieving fry dispersal and attracting fry to the surface (33). Moore (100) recommended 100 to 100 lux (lx) for intensive culture of larval walleye with formulated feed.

Feed acceptance and survival is greater at 18.4 °C (65 °F) than at 12.8 °C (56 °F), with an optimum temperature 18.4 °C (65 °F) (99). A minimum water temperature of 12.8 °C (56 °F) is required to start walleye on brine shrimp (33). A constant temperature of 20 °C (68 °F) throughout a 30 day fry culture interval has also been used (100). To prevent water quality problems with a system having low water exchange rates, a constant temperature of 16 °C (61 °F) was recommended for the first 23 days when fry are fed with brine shrimp (24). A temperature protocol was proscribed that began with an initial temperature of 14 °C (57 °F), a sudden increase of 2.5 °C (5 °F) in the fifth day posthatch when feeding was started, and a gradual increase to 20 °C (68 °F) at 30-days posthatch (108).

Stocking Density. To reduce cannibalism, fry for stocking the same culture tank should be of similar age; that is, hatched within a short time interval, preferably within 12 hours, but not more than 24 hours. To reduce variance

in age, the tanks that receive fry coming from the hatching jars ("catch tanks") should be purged of all fish every day.

In large-scale production of walleye fry in intensive culture, stocking has been reported to be 15 (98), 19 (100), 20 (98), 21 (33), 40 (24,99), 56 (100) and 60 fry/L (57, 72, 76, 80, 152, 212 and 227 fry/gal) (24). Survival of fry through 23 days of culture at a stocking density of 40 fry/L (152 fry/gal) was 36.1% compared with 33.7% survival at a stocking density of 60 fry/L (228 fry/gal) when feeding brine shrimp (24). Using formulated feed, survival to 30 days was 47% at an initial stocking density of 19 fry/L (72/gal) and 23% at 56 fry/L (213/gal) (100). Moore (99) reported survival from 35 to 70% at 25 days posthatch with a stocking density of 40 fry/L (152/gal). Problems with cannibalism, poor water quality, and disease (bacterial gill disease and columnaris disease) seem to be directly proportional to increased density. Generally, however, even though survival rates decline with high density, yield of fingerlings can be much higher, thus increasing return on investment in tanks and hatchery space.

Feeds, Feeders, and Feeding. Larval feeding is not required until the yolk sac has been absorbed. Fry may be fed brine shrimp, then weaned to dry diets (24,33) or, as is more commonly the practice, started directly with formulated feed (22,23,98−100,102−104,106−108). Feed size, color, and texture have been considered the most important factors affecting acceptability. Failure of the fish to feed or digest the feed has been cited frequency as a major factor in the failure of walleye culture on formulated feeds. First-feeding walleye (postlarva I) have a mouth width of 0.7 mm (0.3 in.) and a gape of 1.5 mm (0.06 in.) (111). The mouth is large enough to cannibalize similar-sized siblings (cohort cannibalism) or to consume the 0.4-mm (0.016 in.) size common starter feed.

Nearly all research on formulated feed for intensive culture of larval walleye has been with the closed-formula diet Fry Feed Kyowa (FFK) B-series (B-400 and B-700) feeds manufactured in Japan and sold in the United States by Biokyowa Inc., Chesterfield, Missouri. The 400 and 700 represent approximate median particle sizes of 400 µm (0.4 mm) and 700 µm (0.7 mm) respectively (34). The manufacturer describes the B-series feeds as "krill-based," and they are more expensive than the FFK C-series, which the company calls a "minced-fish" feed. To reduce costs, a "phase" feeding strategy was proposed (106), which is starting first-feeding fry on FFK-B series (B-400), followed by transition to C-700 rather than B-700. Once on feed, feed sizes are gradually increased, from C-1000 (1.0 mm) to C-1500 (1.5 mm), then shifted to the 2 mm walleye grower diet, WG-9206 (112). The latter has been manufactured by Nelson and Sons, Inc., Murray, Utah. Colesante (33) feeds brine shrimp nauplii for 30 days, then starts feeding formulated feed ("New York State" diet) along with brine shrimp (period of "mixed" feeding) through 44 days posthatch.

Precise feeding of small quantities of fry feed is needed to prevent food deprivation. Excessive feeding that leads to water quality deterioration and higher incidence of bacterial gill disease. A variety of feeders have been developed. A hand-made scraper feeder using a

clock mechanism (115) is commonplace in many research laboratories. A commercial vibrator feeder is also used to dispense fry feed (34). In experimental studies in tanks with small capacity (circa 150 L; 39 gal), vibratory feeders cannot be regulated with accuracy or consistency (33,98). For experimental purposes, custom made feeders have been developed that deliver small amounts of feed more precisely than other types (100). A custom-made auger feeder has been used for practical, large-scale intensive culture of larval walleye in 679 L (170 gal) tanks (108).

Feeding rates for larval walleye with formulated feed have been based on fish size (99,108) or amounts needed to achieve a particle density of 100 feed particles/L; (380/gal) (98,100). Live brine shrimp have been fed at 800 to 1,000 nauplii per fish per day for the first 30 days then 1,300 nauplii/fish/day from 30 through 44 days posthatch when fish are habituated to formulated diets (33). Typically, feeding frequency for first-feeding fry with formulated feed is at 3 to 5 min intervals at least 22 hours/day, stopping only to clean the tanks (99,108). Survival has been poor when feeding was stopped for more than an 6 hours per day.

Tank Hygiene. Careful attention to tank hygiene is an essential component to successful fry culture (100,108). Cleaning regimens vary with each hatchery, but in feeding formulated feed, which is fed in excess to habituate the fry to formulated feed, the tank must be cleaned each day. A tank cleaning protocol may involve siphoning the bottom to remove waste food and dead fish, wiping biofilm from the tank walls, and removing the standpipe for pressure washing (108).

Water Flow. The prolarvae (yolk sac fry) are poor swimmers and do not feed; therefore, at this stage a low-water exchange rate may be used, being careful to maintain sufficient oxygen and avoid exceeding conventional standard for unionized ammonia [0.02 mg/L (ppm)]. Once feeding begins, however, the exchange rate should be increased. Exchange rates have not been evaluated and rates from the literature are not often given. In a research facility, exchange rates start with 0.5 per hour before feeding commences, and increase to 1.0 exchange by 21 days (108). In a production facility where brine shrimp are used as the only feed for 30 days, calculations of exchange rates based on tank size and inflow rates ranged from 0.44 to 0.81 per hour (33). Peterson et al. (24) reported an exchange rate of 0.3/hour for 1,200 (315 gal) tanks and a stocking density ranging from 40 to 60 fry/L (152 to 228/gal) using brine shrimp as the starter feed. Whatever the exchange rate, current velocities should not overtax the swimming ability of larvae.

Fingerling to Food Fish

Both extensive, intensive, and a tandem system of extensive-intensive culture systems can be used to raise food-size walleye: pond-to-tanks, pond-to-tank-to-cage and pond-to-cage, pond-to-cage-to-pond, and intensive culture of fry to food size. Substantial differences in production costs occur among these methods.

Pond to Tanks. Fry stocked and reared in ponds to midsummer and harvested as phase I fingerlings (32–64 mm; 1.3–2.6 in.) can be transferred to tanks to habituate (i.e., train) them to formulated feed. This culture strategy is common practice by public fisheries agencies to produce advanced fingerlings (phase II fingerlings) for fall stocking. Similar procedures may be used by commercial fish producers, but instead of stocking fish in the fall, the feed-trained fingerlings would be reared to food-size fish.

Pond to Tank to Cage and Pond to Cage. Phase I fingerlings (32–64 mm; 1.3–2.6 in.) may be transferred to tanks, habituated to formulated feed, then stocked in cages for growout to food size. Or, phase I fingerlings may be trained to accept formulated feed in cages and rearing continued in cages until they reach a food size. There are several constraints to cage culture. The major constraint is the slow growth of caged fish at ambient temperature. In Iowa, food-size walleye cannot be produced in cages until the middle to latter part of the third summer. The culture interval needed to reach food size is even longer in the colder climates. In Minnesota, a portion of cage-cultured walleye reached marketable size in three growing seasons, with the first year in ponds and two additional years in cages (120).

Pond to Cage to Pond. In this protocol, phase II fingerlings were overwintered in ponds and in spring were stocked in cages where they were habituated to formulated feed. After they were feed-trained, they were released to unconfined culture in ponds for further rearing to fall (90). In that study, at a site in Kentucky, the size of fish at the end of the second summer indicated they would not reach a food size until the third summer. The major impediment to this procedure for production of a food fish is the slow growth at ambient pond temperatures, whether at large or in cages in a pond. Also, considerable mortality occurs during the feed-training interval, two overwinter periods, and nearly three summers of culture. Stevens (27) reported similar growth rates in a pond-to-cage culture regimen in southern Iowa.

Intensive Culture: Fry to Food-Size. Culture systems for intensive fry culture have been described. Intensive fry culture allows production of a fingerling that is trained to formulated feed in 21 to 60 days. After fingerlings are habituated to formulated feed, they may be raised to food size in several types of single pass, reuse, or recycle systems. Several experimental trials have been conducted on intensive culture of walleye to food-size (116–118).

Intensive culture systems for rearing food-size walleye include single pass, serial reuse, and recycle aquaculture systems. The major constraint to single pass and serial reuse culture of walleye is the requirement for an abundant supply of water in a desirable temperature range for good growth (20 to 25 °C; 68 to 77 °F). Growth of walleye in intensive culture at temperatures less than 15 to 17 °C (59 to 63 °F) are economically impractical. Thus, the major constraint to general use of flow-through culture is availability of sufficient water sources with desirable water temperatures.

A detailed description of components of recycle culture system for walleye culture has been described (119). The advantages of recycle culture are the same for walleye as any other species: controlled water temperature and water quality (pH, DO); a 12-month growing season; low water requirements relative to production capabilities; a small volume of concentrated waste; and the ability to locate a facility close to major markets. In recycle culture, fish are stocked at high densities and raised on pelleted feeds, and there is an intentional effort to minimize the use of new water to ≤5% or less of total system volume per day. The effluent from the culture tanks must undergo several treatment processes before it is returned to the culture tank: clarification to remove solids; nitrification (biofiltration) to convert ammonia to nitrate; reaeration or reoxygenation; and disinfection by passing water through tubes with UV lamps or by ozone injection.

A survey of fish producers in the North Central Region indicated that 89% used ponds, but a surprising 14% used some form of recycle system to produce a variety of fishes (47,48). There are many recycle culture facilities in the Midwest and elsewhere that raise food-size tilapia, and others that raise hybrid striped bass. Moode and Mathias (98,100) described a recycle culture system for intensive culture of larval walleye on formulated feed at a site in Manitoba, Canada. A sensory evaluation of fillets from walleye raised in a recycle system was compared with walleye purchased from a market culture (122). In that study, the organoleptic qualities — those characteristics (aroma, flavor, and texture) that are evaluated by one's senses — of cultured walleye were equal to those of commercial, wild-caught walleye.

CHARACTERISTICS OF FOOD-SIZE WALLEYE

The most common market form of walleye is a scaled, skin-on fillet, but some consumers prefer skinless fillets because of the rubbery nature of the skin and taste problems that develop in frozen products from oxidative rancidity in the fatty layer under the skin. Dressed yield is essential for cost/benefit or break-even analysis for walleye food-fish production. A highly processed form of the fish (skinned fillets) results in more waste, higher processing costs per unit weight, and a more expensive final product.

Dressed yield is the percent of the live weight obtained for a specific processed product. The live weight to dressed weight relationships for different forms of a food-fish product strongly influences which form of the dressed product will be marketed as well as the overall economic feasibility for commercial food-fish production of that species. Obviously, yield of a dressed fish product affects the live weight of the fish needed to yield fillets of a commercial size.

Although a processing yield as high as 50% for walleye has been assumed (87), laboratory data by Flickinger (117) indicate a filleted yield of 42% (range 39 to 46%) for cultured walleye weighing 377 g (0.83 lb), and 45% (range of 39 to 46%) for wild-caught walleye of similar size. Yager et al. (122) reported variation in processing yield of skin-on fillets from different year classes, but the yield range was relatively small, 39.3 to 44.5% of whole body weight.
Figure 9. Intensively reared, 16-month posthatch, food-size walleye (28).

They found that males had consistently higher yield of skin-on fillets than females, as much as 5.3% greater in one year-class.

Assuming an average yield of skin-on fillets is about 42%, the live weight of a food-size walleye would be about 540 g (1.2 lbs) to obtain two, 114 g (4 oz) skin-on fillets (Fig. 9). An 810-g (1.78-lb) walleye would be needed to obtain two, 170.1-g (8-oz) fillets. Because body mass of walleye, as for most fish, increases in proportion to the cube of the length, it is reasonable to assume that the fillet yield as a percent of total body weight will increase with size. However, regression analysis of fillet yield on body weight for several cohorts, stocks within cohorts, and for as many as six age groups within the same cohort did not support the hypothesis (122). Body weight did not account for more than 6.6% of the variability of yield. Thus, within the range of fish size examined in that study, there was not a trend for the older (i.e., larger) fish to have higher processed yields.

In the Midwest, traditional food-size walleye fillets (scaled, but skin on) have been in three basic size groups: 114 g (4 oz), 170 g (6 oz), and 227 g (8 oz). Usually, a single 114 g (4 oz) fillet may be served for lunch, and one 170 g (8 oz) or two, 114 g (4 oz) fillets for dinner. Fillet size is of considerable importance in defining the size of fish raised for the food market. Obviously, if the market can be persuaded to embrace a 114 g (4 oz) fillet, perhaps labeled "pan-sized walleye," or "petite walleye" it will increase turnover time of the stock in the culture system and enhance profitability. With a 45% dressout yield, a fish that will yield two 114 g (4 oz) fillets would be about 504 g (1.1 lbs); a dress-out yield of 40% would require a fish of 568 g (1.25 lbs).

WATER HARDNESS

Gary A. Wedemeyer
Western Fisheries Research Center
Seattle, Washington

OUTLINE

Determinations of Hardness

Importance in Aquaculture

Management Recommendations

Bibliography

Hardness is the term used to describe the collective concentration of divalent ions that results when mineral salts are leached into water from limestone and other minerals in soils or rock formations. Hardness is expressed in units of mg/L or ppm (parts per million) of $CaCO_3$ equivalents and is due primarily to the carbonate and bicarbonate salts of calcium and magnesium. However, silica and dissolved metals such as iron and manganese may also contribute to a minor degree. Because aquatic animals and plants require calcium, magnesium, and carbonates (HCO_3^-, CO_3^{-2}) for normal growth and development, both hardness and alkalinity (see the entry "Alkalinity") have long been employed in aquaculture as important measures of water type and potential for biological productivity. Water low in hardness (soft) is usually also acidic, whereas harder water tends to be alkaline (basic).

In water from limestone aquifers, the total hardness and alkalinity values will often be similar, and both may be useful as a measure of buffering capacity. However, ground water can also be quite hard, but have little or no alkalinity. Natural waters can usefully be classified in terms of total hardness as follows (1): (a) soft, 0–75 mg/L (as $CaCO_3$); (b) moderate, 75–150 mg/L; (c) hard, 150–300 mg/L; and (d) very hard, 300 mg/L and above.

DETERMINATIONS OF HARDNESS

Historically, hardness was defined as the capacity of water to precipitate soap to form a scum and was measured by shaking standardized soap solutions with the water sample in question. However, this concept is not useful in aquaculture, so that, for biological purposes, total hardness is best calculated from the results of separate calcium and magnesium determinations (2):

Total Hardness (mg/L $CaCO_3$) = 2.497 [Ca] + 4.118 [Mg]

The simpler ethylenediaminetetraacetic acid (EDTA) titration method may also be used. An indicator dye is added, and the water sample is titrated dropwise with EDTA. When all the Mg^{+2} and Ca^{+2} ions present have been complexed by the EDTA, a color change occurs that marks the end point. The calcium hardness is sometimes also measured and expressed as mg/L (ppm) $CaCO_3$. For routine monitoring purposes, commercially available water chemistry test kits provide adequate accuracy and precision for both total hardness and calcium hardness determinations.

For aquaculture work, total hardness is most usefully expressed as mg/L (or ppm) $CaCO_3$ equivalents. However, a variety of other units may also be encountered. The calcium hardness is often expressed as mg/L Ca^{+2} instead of in $CaCO_3$ equivalents (1 mg/L $CaCO_3$ = 0.4 mg/L Ca^{+2}). In the aquarium industry, hardness is often reported as degrees of hardness (dH); either degrees of carbonate hardness (KH, from the German *karbonate*), or as degrees of general hardness (GH, calcium + magnesium). One unit (degree) of hardness (dH) = 17.9 mg/L $CaCO_3$. In the water softening industry, water hardness is often expressed as grains per gallon (1 gpg = 17 mg/L $CaCO_3$).

As evident from its name, the KH is a measure of the amount of carbonate, CO_3^{-2}, and bicarbonate, HCO_3^-, present and is only indirectly related to water hardness itself. Unfortunately, KH and alkalinity are often used interchangeably even though hydroxides, borates, silicates, and phosphates may also contribute to alkalinity. In seawater rearing systems, however, nearly all of the alkalinity is due to carbonate, and the values for alkalinity and carbonate hardness will be essentially equivalent.

IMPORTANCE IN AQUACULTURE

The total hardness (expressed as mg/L $CaCO_3$) of a water supply is an important environmental factor of which aquaculturists should be aware. As mentioned, aquatic plants and animals reared in aquaculture systems require calcium, magnesium, and carbonates for normal growth and development. Soft water is low in the calcium and magnesium needed for fish health, but can be tolerated by most species if dietary intake is sufficient. For example, both juvenile and adult salmonids and channel catfish (*Ictalurus punctatus*) can absorb the required amounts of Ca^{+2} and Mg^{+2} either from the water or from their diet. However, a minimum of 5 mg/L of calcium hardness is recommended to assure normal egg hatching and fry development (3). In addition, harder water reduces the physiological stress of fish culture procedures, such as handling, transportation, and disease treatments. On the negative side, hard water causes scale deposits that can clog pipes, air diffusers, and other submerged equipment.

Another important effect of water hardness on fish and invertebrate health is the protection it affords against the

toxicity of heavy metals, such as zinc and copper. In hard or alkaline water (>150 mg/L, pH >7), these metals form insoluble salts and precipitate out of solution rendering them less biologically available. For this reason, there is also less risk of fish toxicity when copper containing disease therapeutants or algicides are used. The criteria originally developed by Alabaster and Lloyd (4) for levels of copper safe for rainbow trout (*Oncorhynchus mykiss*) as a function of water hardness still serve as a useful guideline.

Water Hardness (mg/L as CaCO$_3$)	Safe Level (mg/L)
10	0.001
50	0.006
100	0.01
300	0.28

Salmonid fish may be slightly less susceptible in hard water to disease such as infectious pancreatic necrosis (IPN) and bacterial kidney disease (BKD), although the incidence may actually be inversely proportional to the water's ionic composition, rather than to hardness *per se* (5). Epizootic ulcerative syndrome (EUS), a disease affecting milkfish (*Chanos chanos*), and other warmwater fishes cultured in Southeast Asia, appears to be most severe in waters of low total hardness (6).

If necessary, water hardness (GH but not the KH) can be increased in ponds or aquaria by adding calcium sulfate. Calcium carbonate additions will increase the KH as well, but the proces is likely to be slow because of solubility problems. Calcium sulfate (gypsum) is relatively inexpensive, moderately water soluble, and does not cause areas of locally high pH if applied unevenly. Calcium sulfate in the form of gypsum, which is mined, rather than the calcium sulfate produced as a byproduct of phosphoric acid manufacture, should always be used because the latter may contain residual acid. To increase the hardness of the smaller volumes of water used in egg hatching or fry rearing, the required amount of calcium chloride can be inexpensively added to the incoming water supply using a drip system or metering pump.

MANAGEMENT RECOMMENDATIONS

As a guideline, water hardness in the range of 50–200 mg/L with a pH of 6.5–9 and alkalinity of 100–200 mg/L (as CaCO$_3$) is widely considered desirable for the intensive culture of both cold- and warmwater fishes and invertebrates (7).

INTRODUCTION

It has often been said that oxygen and ammonia, in that order, are the limiting factors in aquaculture production. Today, we have ways to treat these limiting factors. The biggest challenge to the aquaculturist is not the level of oxygen or ammonia, but how to treat hatchery effluents. Unless you are in the domestic wastewater treatment business, it is hard to justify the costs of secondary and tertiary treatments. For hatcheries to coexist in this world, aquaculturists must look to the future and apply these technologies. Therefore, aquaculturists must become skilled in the water and wastewater treatment processes. In this regard, managers and administrators should now be looking for ways to improve and use an important resource: water. For example, large cities use municipal wastewater to irrigate golf courses and parks. Water is a valuable resource, whether in pure form or in the form of wastewater.

WATER REQUIREMENTS

The demand for aquaculture products is rapidly increasing in the North American continent. This demand comes from people who fish for sport and from a viable market for aquaculture products. While the demand in North America may never reach that of Europe, it is steadily increasing. However, the oceans have limitations and cannot sustain the current need alone. Therefore, fish culturists must assume a role in meeting the demand. Europeans use every available source of water. For example, Germans rear eels in distillery wastewater. The Japanese use domestic wastewater to rear carp. Infact, every country in the world is engaged in some type of aquaculture.

Unlike some other continents, the North American continent has an abundant supply of water. For example, the Hagerman Valley, in southern Idaho, produces a large percentage of the trout in the United States. The spring waters in that area are rich in nutrients, ideal in temperature, and gravity fed to the hatcheries. However, all of the water is currently being used, and production is at an upper limit. What happens when the demand increases for this product? There are very few "Hagerman Valleys," and most of the good water sources have been already used. What does this situation mean to the present and future fish culturist? It means that they must produce more and be more efficient with available resources.

A statement by J.W. Atz (1) puts this thought into perspective and has a message for those who are concerned about the future of aquaculture:

> For more than 4,000 years, men have kept fish alive in ponds or tanks for food and pleasure. Fish culture has been practiced since the times of the ancient Romans and Chinese, and some of the methods used today are virtually the same as those devised centuries ago. Fish culturists have been much slower to take advantage of the benefits of science and technology than have their counterparts, the farmer and animal husbandman. This has been especially true of the maintenance and control of the water in which captive fishes must live. So poor has been the fish culturist's understanding of the complicated interactions between the fish and its water element that he has failed to recognize bad water as the underlying cause of most of his failures. Man's lack of understanding of the fish's way of life stems primarily from the fact he's a terrestrial animal, while the fish, still bathed in the fluid in which life itself arose, maintains the most intimate relationship with its surrounding. Evolution has provided fishes with limited homeostatic mechanisms, which are all too often overtaxed by the conditions they find ponds and hatchery troughs alike.

> Nevertheless, by locating his hatcheries and fish ponds near unlimited supplies of water, or by dealing only with species preadapted to polluted environments, the fish culturist has managed to be successful enough in the past, in spite of his ignorance. But water is fast becoming a scarce commodity, and in both Europe and America fish are now being reared in recirculated water. Moreover, the exigencies of mariculture and the mass culturing of new and more delicate kinds of fishes demands a degree of water control that the old-time fish culturists would never dreamed about.

If we look closely at our counterpart, animal husbandry, we can see the achievements that have been made in that field. Feed lots reproduce more animals in less space and at less cost. Waste is being recycled back to feed. The key word that separates aquaculture from animal husbandry is "environment." The person engaged in animal husbandry lives in the same environment in which he or she rears the animals. It is therefore much easier for that individual to understand and deal with a species with which he or she shares a common surrounding. The fish culturist, however, is faced with rearing a product in an environment that is foreign to him or her, an environment that can change its physical and chemical characteristics without the culturist's knowledge.

With today's rising energy costs, it is becoming more difficult to operate within the restricted environment known as water. Furthermore, there are certain options that remain, such as the many aspects of water treatment that are used in the domestic water and wastewater treatment industry.

Aquaculturists must not separate themselves from other disciplines. They must use the knowledge and technology that are found in the water and wastewater treatment industry. Then, and only then, can the aquaculturist progress and move into the next century.

According to the works of Burrows and Combs (2), there are five major aspects of any potential hatchery water supply: (1) quantity, (2) quality, (3) temperature, (4) environment (pathogenic or pathogen free), and (5) location.

Quantity

The quantity of water available must meet all of the hatchery's water requirements. Wheaton (3) lists four major needs that must be met for an adequate water supply: (1) evaporation, (2) seepage, (3) oxygen, and (4) waste disposal. In addition to the water supply for fish culture needs, a certain amount of water is needed for fire protection, irrigation, and use in residences.

Quality

The quality of water must match the requirements of the propagated species. Water can be "good" or "bad," depending on its use. Good-quality water is defined as water capable of supporting the desired species and of maintaining the sanitary conditions necessary to allow the harvested species to be used as intended. Under this definition, it is possible for raw municipal sewage to be considered good-quality water if algae are grown in it, processed, sterilized, and fed to animals. But this same water could be considered bad for human consumption, even after undergoing tertiary treatment.

Temperature

The water temperature must be within the optimum growth range for the desired species. Temperature is the most critical factor affecting respiration. Due to intensified fish culture techniques, fish are, at times, reared in less than optimum temperature ranges. The final result is a subquality product, or, worse, a product that experiences high losses throughout a production cycle. For hatchery operations, the water temperature must be within a range in which the species being cultured can survive and grow.

Environment

Disease prevention and pathogen control are critical in any type of hatchery operation. If a water supply meets all the requirements for a species, except for the ability to prevent and/or control disease outbreaks, then the water in a reuse system should be used only with adequate treatment. While it is generally economically unfeasible to treat all of the water in a single-pass hatchery, it may be possible to treat a portion of the total flow, such as in a reuse system, if all other requirements are met.

Location

The location of a hatchery is important in order to ensure that water is available for present and future needs. The site should be large enough to accommodate housing, water treatment facilities, and future expansion, as well as to meet fish-rearing needs. Accessibility to visitors and the security needs of the facilities during nonworking hours are also important considerations. Hatcheries are often located in very remote, as well as urban, areas.

Natural springs that meet all, or even just two or three, of the aforementioned aspects for hatchery sites are almost nonexistent in this day and age. If a body of water does not meet even one of these major aspects, it is not feasible for an open system. On the other hand, a body of water can lack two or more of the major aspects and still be feasible for a closed system. An open system is one in which water is continuously discarded and replenished from a natural source. An example of an open system is a single-pass hatchery. A closed system is one in which water is recycled and used again. A closed system can be completely closed, or it can be semiclosed. An example of a completely closed system is an aquarium. A semiclosed system is one in which some new water is continuously added to the recycled water and some of the water that has been recycled is discarded. A reuse hatchery, which is an example of a semiclosed system has been described by Owsley (4).

WATER TREATMENT

Filtering Systems

The importance of the aeration process cannot be overemphasized with respect to the design and operation of fish hatcheries. Oxygen is the controlling factor in pond loadings and is important to all aspects of hatchery operation. Piper (5) recommends for salmonids that, for every part of oxygen below saturation, the pond loadings are decreased by 5%. A good aeration system should provide a minimum level of 90% oxygen saturation.

One of the most important parameters for the aquaculturist to remember with respect to aeration is that air is 78% nitrogen and 21% oxygen. (Pure oxygen can be 98% or more.) Oxygen is critical to the survival and growth of fish and is just as critical to nitrification of bacteria in the wastewater treatment process.

Filtration can be classified into three general categories: (1) mechanical, (2) biological, and (3) chemical. Mechanical filtration is the physical separation of suspended particulate matter from the water. It is accomplished by passing the water solution through a suitable medium that traps the particles. Examples of mechanical filtration include sand filters (pressure and gravity flow), stationary screens, rotary screens, micro strainers, and diatomaceous earth filters. Mechanical filters usually exhibit a high head loss and require more energy to operate than biological filters.

Biological filtration is defined as the mineralization of organic nitrogenous compounds by bacterial action. It can be either aerobic or anaerobic. Aerobic biological filtration is called *nitrification*, and anaerobic biological filtration is called *denitrification*. Of the biological treatment methods studied for the removal of ammonia, nitrification appears to be the most efficient. The reasons for this are as follows: (1) high potential removal efficiency, (2) process stability and reliability, (3) easy process control, (4) small land-area requirement, and (5) moderate costs.

Nitrification is the oxidation of ammonia to nitrite and thence to nitrate by autotrophic bacteria, namely, *Nitrosomonas* and *Nitrobacter*. The two steps of the nitrification transformation are as follows:

$$\text{Step 1}\quad 2NF_3-N+3O_2 \xrightarrow{\textit{Nitrosomonas}}$$
$$2NO_2{}^- -N + 2H_2 + 2H^-$$

$$\text{Step 2}\quad 2NO_2{}^- -N + O_2 \xrightarrow{\textit{Nitrobacter}} 2NO_3{}^- -N$$
The nitrosomonas reaction is the rate-controlling step. The requirements for nitrification are the presence of ammonia, oxygen, nutrients, a low level of organic carbon, and a substrate for the bacterial to attach to. This substrate is called *medium* and is available in various forms. Some of the more commonly used media are oyster shell and rock, expanded shale, plastic rings, plastic beads, plastic saddles, porcelain saddles, styrofoam beads, and dolomite rock.

Chemical filtration is the removal of substances from a solution on a molecular level by adsorption on a porous substrate or by direct chemical oxidation. Examples of chemical filtration include ion exchange wherein a natural zeolite, such as clinoptilolite, is used as the resin for the adsorption of ammonia. Clinoptilolite is abundant in the southwestern areas of the United States and is common throughout the world. Carbon adsorption is another example of chemical filtration, as is foam fractionation. Air stripping, breakpoint chlorination, and ozonation are examples of chemical oxidation. Clinoptilolite may be the best filtration method available to the fish culturist.

Another type of filtration to be considered in hatcheries is hydroponics, which is the use of plants to filter nutrients from the water. This type of filtration can actually produce a crop from nutrients contained in wastewater.

Disinfection Systems

A number of disinfection systems are available to the fish culturist. Some work well, others hold promise, and still others have failed.

Ozone. Owsley (6) has reported on the use of ozone at Dworshak National Fish Hatchery (NFH). Ozone is a

three-atom allotrope of oxygen. It is a colorless gas and can be readily detected by its odor at very low concentrations. It is unstable and the strongest oxidizing agent commercially available. Ozone is produced by passing air or oxygen through a high-frequency electric field, which must be generated at the point of application.

Commercial ozone generators are available in many designs. Most use a high-voltage corona discharge system consisting of two surfaces separated by a space. High voltage is impressed across the space, and air or oxygen is passed between the surfaces, where the oxygen molecules are excited sufficiently to form ozone. Ozone can also be produced by ultraviolet (UV) radiation. However, UV radiation does not produce the quantity of ozone achieved by an ozone generator.

Although ozone is toxic to aquatic organisms and to humans, it is highly effective as a disinfectant, having about twice the oxidizing capabilities as chlorine and killing both bacteria and viruses on contact with equal effectiveness and speed. Ozone reacts very quickly as compared with compounds such as chlorine and is much less affected by pH and temperature than is chlorine. Unlike UV radiation, ozone is not limited by low-turbidity water, nor does it appear to leave harmful residues in water, such as chloramines, which are produced by chlorine.

Both organic and inorganic materials exhibit a demand for ozone. Ozone is used for removal of color, odor, and turbidity. In order to achieve the same disinfection level, water containing organic matter must be treated with a higher concentration of ozone than similar water without organic matter. Inorganic materials such as iron and manganese can be oxidized to the insoluble oxide forms by ozone, which decomposes back to oxygen. The decomposition rate is temperature dependent, rapidly increasing with increased temperature. Thus, an ozone destruction unit is basically a heater.

For many years, ozone has been widely used in Europe for water disinfection. Europe does not have the luxury of the abundant clean water that exists in the United States and Canada. However, even though the use of chlorine and UV radiation was more economical in obtaining clean water, we are finding that there are certain diseases that chlorine and UV radiation cannot effectively combat. One example is giardiasis, which is a disease that affects humans, and is caused by a protozoan, *Giardia lambia*, commonly found in high-mountain streams and lakes. Ozone will effectively kill giardia and its cysts, while chlorine is ineffective. An example of water treatment in an aquaculture facility is the treatment for a virus called *infectious hematopoietic necrosis virus* (IHN virus). Infectious hematopoietic necrosis is an epizootic virus

disease that causes high rates of mortality in most salmonids. Fish that survive may become carriers of the disease. Adult fish may become infected by disease causing organism, or may shed the virus during spawning. Natural transmission occurs primarily through water (7). External symptoms of fish with IHN include hemorrhaging under the skin, exophthalmia (i.e., protruding eyes), swollen abdomens, lethargy, darkening of skin color, and hemorrhaging at the base of the fins. Internally, the liver, spleen, and kidneys are usually pale. The stomach and intestine may be filled with fluid. The work at the Seattle laboratory of Wedemeyer et al. (8) indicates that ozone destroys the IHN virus at low dosages and low contact times (see Table 1).

Other aquaculture studies have shown positive results when ozone was used to treat water supplies. Ceratomyxosis, caused by the myxosporean parasite *Ceratomyxa shasta*, was controlled at the Cowlitz Hatchery in Washington (9). The Coleman National Fish Hatchery in California has had success using ozone for controlling whirling disease, caused by another myxosporean parasite, *Myxobolus cerebralis* (10). Ozone was found to be superior to chlorine for inactivating the bacterial fish pathogens *Aeromonas salmonicida* (furunculosis) and *Yersinia ruckeri* (enteric redmouth) and pathogenic viruses, including infectious pancreatic necrosis virus (IPNV), the causative agent of infectious pancreatic necrosis (11).

A study by Oakes et al. (12) at the Dworshak NFH showed that nitrite could be virtually eliminated by using ozone in reuse water. Williams et al. (13) determined the oxidation rates for ammonium, nitrate, and biological oxygen demand (BOD), separately and in combination, by using an improved contact-chamber design. The upflow design, which included an improved foam removal system, demonstrated good results in the study.

Foam can be a problem in an ozone system. Foam is made up of protein, suspended and dissolved solids, and organic and inorganic compounds. It is mainly found in the contact chamber, and most systems are designed with some type of foam removal system, such as a protein skimmer. Foam in incubation, especially during nursery rearing, can be a hindrance to fish culture operations. In nursery tanks, the foam prevents the starter feed from reaching the fish. A foam remover, such as Dow Corning antifoam FG–10, can be used to clear the water.

The feasibility of treating lesser quality water, as opposed to developing good-quality supplies, was studied at Coleman National Fish Hatchery in northern California (14). Four water supply systems were evaluated: wells, chlorination and dechlorination, UV sterilization, and ozonation. Table 2 summarizes the findings of that study, using UV sterilization as the base. At this facility,

Table 1. Ozone Dosages and Contact Times for Treatment of IHN Virus for Different Water Sources

Ozone Level (mg/L)	Contact Time (min)	Water Source at 10 °C
0.001	0.5 or 1.0	Phosphate-buffered distilled water
0.01	10.0	Soft lake water
0.01	10.0	Hard lake water

Table 2. Cost Comparison of Development of Good-Quality vs. Treating of Lesser Quality Water Supplies[a]

Water Supply	Construction Costs	Annual Operation and Maintenance
Wells	366	45
Chlorination and dechlorination	70	61
UV sterilization	100	100
Ozonation	94	36

[a]Use of UV sterilization is cost basis. All numbers are percentage of cost base.

ozonation was the logical choice to pursue, based upon cost-effectiveness.

As new systems are developed, ozonation will become more cost-effective. One new development, the aquatector (15), designed to efficiently add oxygen into water, could greatly alleviate, or even eliminate, the need for ozone contact basins. The aquatector uses microbubble technology that could improve the efficiency of adding ozone to water. This improvement would, in turn, reduce the size of equipment needed, as well as reduce costs. On-site oxygen-generating equipment can double the production of ozone and reduce costs accordingly.

As mentioned previously, ozone is a very toxic compound. Its toxicity is a function of time and concentration. The maximum allowable concentration for humans in an eight-hour day is 0.1 mg/L. Ozone can normally be detected in the air by the human nose in the range of 0.05 mg/L. It is very important that work areas be free of ozone. Ozone can be converted back to oxygen by using a heat system prior to discharging the ozone into the atmosphere.

Ozone is also very toxic to fish and must be removed from the water supply. Wedemeyer et al. (16) determined that the permissible safe exposure level of ozone for salmonids was 0.0002 mg/L. Several other studies have verified this level, while others have reported much higher exposure levels. The discrepancy between Wedemeyer's work and other studies is probably due to sampling accuracy and production vs. laboratory conditions. The conventional method of removing ozone is through the use of detention chambers. Since ozone has a short half-life, it can be removed by allowing the water to be held in a chamber for a period of time.

A faster, more economical way to remove ozone is to strip it out of the water by using packed columns (17). Removal efficiency of packed columns varies from 70% to 95%. Complete removal can be accomplished by using stripping towers (18). A stripping tower is a packed column that uses a countercurrent air flow. However, stripping towers raise the energy costs of removing ozone, due to the additional height and blower requirements. Carbon filters will also remove ozone very effectively, but will accommodate only small systems and are not as economical as packed columns or stripping towers.

Ultraviolet Light. Ultraviolet (UV) light, or energy in a wavelength of approximately 254 nm, has been shown to be effective in killing both bacterial and viral organisms.

Light in the UVB and UVC spectra are responsible for the majority of the disinfection and sterilization attributed to this type of system. High-quality bacteria-free water (99.9% removal) has reportedly been produced by using UV disinfection for low-turbidity supply sources.

Since UV light must effectively penetrate a water source in order to ensure that the shortwave energy is imparted to the biological organism, it is critical to ascertain that the water source entering the UV contractor is very low in turbidity and suspended solids and that turbulent conditions are maintained for adequate mixing. In order to achieve the necessary influent water quality, prefiltration is often recommended, to remove particulate matter capable of blocking light penetration and fouling the UV tubes.

The U.S. Environmental Protection Agency (EPA) has not recognized UV treatment as an allowable method of disinfecting potable water without another treatment used in conjunction with it, since it is impossible to develop a corollary concentration and detention time relationship to chemical oxidation. However, this does not mean that UV disinfection is not effective, only that it has not been widely used for treating water supplies destined for human consumption.

The use of UV energy to deactivate waterborne microorganisms in the aquaculture industry is a well-known and well-understood technology. UV systems have become an integral part of many aquaculture operations that provide disinfected water to areas of the hatchery and rearing operation where there is an established need to maintain control of fish pathogens (i.e., bacteria, viruses, molds, fungi, and protozoans). According to Caufield (19) the following are the advantage of UV radiation: (1) nontoxic, (2) adds nothing to the water, thereby preventing formation of toxic chemical residuals, (3) does not affect water chemistry, (4) is effective against a wide range of organisms, (5) can be designed to suit any flow rate, and (6) can be supplied with an automatic duty standby capability.

It is generally accepted that the germicidal nature of UV energy is the result of disruption of the microorganisms' DNA molecules by irradiation with wavelengths of 220–290 nm. With most organisms, this effect is maximized at 260 nm. It has also been shown that the survival ratio after UV treatment is related to the UV dose applied (normally reported in milliwatt seconds or millijoules per square centimeter — mWsec/cm^2 or mJ/cm^2, respectively).

The UV dose received by an organism is dependent on (1) the energy output of the UV source, (2) the flow rates of the water and the organism's residence time under the influence of the UV source, (3) the ability of the fluid to transmit the germicidal wavelengths, often referred to as *UV transmittancy*, and (4) the geometry of the radiation chamber.

In many cases, UV systems have been designed to provide a high kill rate for organisms that are easy to kill with UV radiation; such as *Escherichia coli*. *Escherichia coli* is a common bacteria found in wastewater treatment plants. A theoretical UV dose of 3.2 mJ/cm^2 will provide a 90% kill, or one log reduction. (The actual UV dose

Table 3. Dosages (in mJ/cm^2) of UV Required to Reduce Fish Pathogens[a]

Pathogen	90% Reduction	99.9% Reduction
Viral hemorrhagic septicaemia virus (VHS virus)	10	30
Saprolegnia (fungal disease)	13	39
Ichthyophthirius (white spot, or "ich")	40	120
Infectious pancreatic necrosis virus (IPN virus)	60	190

[a]*Source*: Blake, Ref. 20.

applied depends on factors such as UV transmittancy and TSS.) Table 3 shows the dosage of UV radiation needed to achieve a 90% and a 99.9% reduction of certain fish pathogens (20).

In many aquaculture applications, seasonal changes in water quality, due to a high concentration of undesirable organisms and high suspended solids or turbidity levels, affect UV treatment. These facts, together with a lack of accurate, continuous monitoring or validation of the UV system operation, have contributed to the poor performance of UV equipment, which was originally designed to treat consistently clear water. Over the years, several hatcheries including Dworshak National Fish Hatchery, have installed large-scale UV systems. However, as for as can be determined, Alaska's Trail Lake Hatchery, which used UV for posthatchery disinfection, is the only major facility in the northwest United States still using UV on a routine basis. The Trail Lake system (2,000 gpm) is working satisfactorily.

Chlorine. According to a report by Montgomery Engineers (18), chlorine is not a viable disinfectant alternative for most fish production facilities. Chlorination is the most common type of disinfection used for water treatment systems. Use of chlorine gas, HTH (hypochlorite), a chloramine, or other materials to produce a solution containing the oxidant is practiced by the majority of domestic water purveyors throughout the United States. Chlorine disinfection has been used on several aquaculture projects within the northwest United States, but has several inherent drawbacks. The most serious is the necessity to remove the residual chlorine prior to introducing the disinfected water into the fish hatchery in order to avoid the possibility of creating a toxic environment that would affect fish production. However, Wedemeyer et al. (6) and Bedell (21) found chlorine effective in inactivating both *C. shasta* and the IHN virus. The only large-scale facility in the northwest United States using chlorine disinfection in salmonids, Ore-Aqua, relies on careful control and constant monitoring, in combination with sufficiently large postchlorination storage to provide the extended detention necessary for dissipation of any harmful chlorine residual. Chloramines (ammoniated chlorine) are not suitable for aquaculture systems due to their known toxicity

to aquatic organisms and are not considered as a feasible method of disinfecting hatcheries.

Iodine. Iodine is a nonmetallic element with an atomic weight of 126.92. It is the heaviest of the members of the halogen group (i.e., chlorine, bromine, iodine, and fluorine). The halogens are a group of elements that form with metal compounds, such as common salt—sodium chloride. Iodine is the only halogen that is solid at room temperature. It is a shining blackish brown crystal solid with a specific gravity of 4.93 and peculiar chlorinelike odor. Iodine is always found combined and can be prepared from kelp or crude chile saltpeter. It is only slightly soluble in water.

Iodine and its compounds have been used in medicine since the early 1800s. The first use of iodine in water was in World War I for sterilization of water for troops. Iodine as a disinfectant for water supplies has been recognized for a long time, but it has never been feasible to use iodine in the same capacity as chlorine is used. However, iodine does have some advantages over chlorine as a water disinfectant. In the late 1970s, the Idaho Department of Health and Welfare recommended that the domestic water-supply treatment method at Dworshak National Fish Hatchery be changed from chlorine to iodine. This change was to combat a parasite, *G. lambia*, which is chlorine resistant.

Iodine is widely used in fish culture practices for egg disinfection. The term *iodophores* includes commercial forms of iodine, the two most common being Wescodyne and Betadine. Wescodyne is an iodine solution with a detergent base. Betadine is an iodine solution that contains povidone as the organic base. Both iodophores contain iodine as the active ingredient, but have different organic bases. Both are considered to be effective bactericides and virucides.

Since 1982, due to a severe infectious hematopoietic necrosis virus (IHN virus) problem at Dworshak, steelhead eggs have been water hardened in an iodophor solution each year to prevent the virus from erupting and infecting other fish. Based upon personal communications with Dr. Bob Busch, Director of Rangens Laboratory in Buhl, Idaho, iodine was selected to be tested using a continuous-drip method on a small group of fish from Brood Year 1989 steelhead egg production. Dr. Busch has been successful in reducing losses of rainbow trout due to IHN virus by applying a continuous dosage of iodine, between 0.3 to 0.5 mg/L, to rainbow trout fry and fingerling. Dr. Busch has also stated that iodine is an effective treatment against bacteria gill disease. This report was further substantiated by Jim Winton of the Service's National Fisheries Research Center in Seattle, WA. Dr. Winton was able to effectively kill the IHN virus in a laboratory setting at levels from 0.3 to 0.5 mg/L, which were the exact levels that Dr. Busch had reported. With these data, a pilot study was set up for the Dworshak hatchery (22).

Results of the test showed that iodine was not successful in destroying IHNV in the water, even with a continuous level of iodine present. Ozone-treated and control groups both showed very little signs of the virus. These results are based upon the literature and direct observation of fish.

Dworshak's water supply has a pH value that can range from 6.3 to 7.3 over a complete rearing cycle. Iodine is not a good viricide with this low-to-neutral pH range; however, it is a good bactericide. Second, the low level of iodine on a continuous exposure could have created a stress on the fish that may have initiated an IHN virus outbreak.

Further evaluation of iodine needs to be conducted at various levels of pH and water quality. Iodine does have the potential to help alleviate a serious disease problem in fish culture, such as the IHN virus, as long as the water is of good quality and has an adequate PH level.

Hydrogen Peroxide. Hydrogen peroxide is clear, colorless, and waterlike in appearance and has a characteristic pungent odor. A nonflammable substance, it is miscible with water in all proportions and is sold as an aqueous solution. The amount of hydrogen peroxide in commercial solutions is expressed as a percentage of the solutions weight. Thus, a 35% solution contains 35% hydrogen peroxide and 65% water by weight. Most industrial applications call for 35, 50, or 70% concentrations.

Hydrogen peroxide is not a particularly hazardous substance. It is considerably safer to handle and store than chlorine gas, which is widely used in wastewater treatment. It does not have the highly corrosive and dangerously toxic characteristics of chlorine. In fact, when properly handled and contained, hydrogen peroxide has been safely stored on street corners and the center strips of residential streets, where it is injected into sewer mains. At the same time, a basic understanding of the properties of hydrogen peroxide is necessary for proper handling.

The U.S. Department of Transportation classifies solutions of hydrogen peroxide as "oxidizers" (DOT yellow label). In addition, the chemical is a strong oxidizing agent, liberating oxygen and heat when it decomposes. In dilute solutions, the heat is readily absorbed by the water, but in more concentrated solutions, the heat raises the temperature of the solution and accelerates the decomposition rate. Hydrogen peroxide itself will not burn, but its decomposition liberates oxygen, which supports combustion. For water treatment, hydrogen peroxide holds much promise and as a by-product, it reverts back to oxygen. However more research needs to be done to evaluate the use of hydrogen peroxide in aquaculture.

Photozone. The simultaneous application of UV radiation with ozone can accelerate otherwise sluggish reaction rates significantly. Acceleration is brought about by catalytic formation of hydroxyl free radicals, which are stronger oxidizing agents than ozone itself. Ozone and UV radiation complement each other, requiring lower doses of ozone and better operation and maintenance of the UV radiation system.

Perozone. The simultaneous application of hydrogen peroxide with ozone can accelerate otherwise sluggish reaction rates significantly. Acceleration is brought about by catalytic formation of hydroxyl free radicals, which are stronger oxidizing agents than ozone itself.

Microfiltration. Microfiltration effectively cleans a water supply, but does not kill viruses or bacteria. Its use is limited to small flows of water, and it is generally used with a disinfectant.

Heat. Heat will destroy all bacteria and viruses, but it is not practical or economical.

Pure Oxygen. Although pure oxygen is not considered as a disinfectant, high levels of pure oxygen can relate to a clean environment and reduce the toxic effects of some bacteria and viruses.

SOLIDS REMOVAL

There are various methods of removing solids from the rearing space. They include, but are not limited to the following systems: (*1*) vacuum systems: These involve transfer of solids using a siphon device. These systems are very efficient when used in conjunction with baffles and screens. (*2*) mechanical systems: These range from swimming-pool cleaners to floor sweepers and are usually complex and difficult to use in a hatchery environment; (*3*) hydraulic systems: These drain the space while brushing and use hydraulic energy to remove the solids.

There are a number of systems and designs that are used to enhance removal of solids in a hatchery, including (*1*) baffles, as used in Michigan to promote the removal of solids from the upper end of a raceway to the tail end via a velocity concept, and (*2*) circular or square tank or pond designs for better solids removal with decreased flow.

The most important thing to remember with respect to the removal of solids is not to reduce the particle size of the solids, if at all possible. However, this requirement complicates the treatment process.

WASTEWATER TREATMENT

Effluent Treatments

The degree of treatment depends upon the receiving body of water. A recreational lake or small stream will require a higher degree of treatment than a large free-flowing river. The large river has a high rate of turnover, and the large volume of water can accept a higher nutrient load.

There are three types of treatment for wastewater: primary, secondary, and tertiary. Primary treatment includes sedimentation and clarification and can usually be expected to remove 50 to 60% of the suspended solids and 25 to 35% of the biological oxygen demand (BOD). Examples of primary treatment include settling ponds, lagoons, and clarifiers. Settling ponds and lagoons operate from detention time and require large volumes of space. These systems are effective for removing settleable solids. Insects and odors can be problems associated with ponds and lagoons. The efficiency of ponds and lagoons can be increased by aeration, which increases the settling efficiency of solids and reduces BOD by bacterial action. Aerated ponds and lagoons require less space than nonaerated ponds and lagoons, and aeration reduces odor and insect problems. A clarifier is a controlled settling

pond where the flow and solids removed are regulated in the design.

Secondary treatment uses conventional biological processes. Secondary treatment can remove up to 90% of the suspended solids and 75 to 90% of BOD. Examples of secondary treatment include trickling filters, biological filters, activated digesters, separators, and, ofcourse, filtration.

Tertiary treatment refers to methods and processes that remove more nutrients and contaminants from wastewater than are usually taken out by secondary treatment. Examples of tertiary treatment include microscreens, fine filtration, chemical filtration, air stripping, ion exchange, and hydroponics.

Other aspects of a hatchery water supply include fire and maintenance, domestic, and irrigation. Water is a scarce commodity in some areas and a valuable commodity in all areas. It should be used conservatively and wisely. Properly treated wastewater can be used on golf courses and parks. If hatcheries are to survive, fish culturists must be willing to make changes. They must start thinking about water and wastewater treatment as well as rearing fish. The time has come to merge water and wastewater treatment technologies with the technology of hatcheries.

OPERATION AND MAINTENANCE

Operation and maintenance go hand in hand. It is estimated that for every 100 man-hours of plant operation, at least 40 man-hours must be spent to maintain equipment in a water or wastewater treatment plant. A hatchery could be a combination of a water and wastewater treatment plant. The actual time spent depends upon the complexity of the plant and the age and type of equipment. Regardless of size or complexity, every hatchery must have a maintenance program.

A maintenance program may be as complex as necessary, but the maintenance requirements must be reduced to a fixed schedule. A gear box may require annual maintenance, whereas a pump may require daily checks and service. There must be specific tasks to do at specific times or else maintenance will be disorganized and cause equipment failures, which hatcheries cannot afford.

A basic maintenance management system may include equipment records, planning and scheduling, inventory control, maintenance personnel, maintenance guidelines, and a budget. Equipment records are vital for a successful maintenance program. Such records are used to keep track of the maintenance of equipment. The records will tell when equipment needs major overhaul or replacement. Records can also be used to keep track of costs and labor for equipment. The record system can take many forms, ranging from a log book to a card to a computerized system. Moreover, there are many available computer systems for water and wastewater treatment plants that are applicable for hatcheries.

Planning and scheduling preventive maintenance is the critical part of a good maintenance management system. It is based on the size and capabilities of the maintenance staff, quantity of work, and the time required to complete the work. A work schedule listing job priorities, work assignments, personnel, and timing is vital. The schedule may be divided into any convenient period of time: daily, weekly, monthly, quarterly, semiannually, or annually. Scheduling should take advantage of weather, seasons, low production, and flow periods. The biggest error is to perform preventive maintenance work as time permits. This practice is the direct opposite of scheduling and will cause problems. The manufacturers maintenance manuals are a good basis for preventive maintenance instructions and scheduling.

Critical and hard-to-get spare parts should be maintained. The manufacture's recommendations and work experience should help in determining which spare parts should be stored. Spare parts should be replaced immediately when they are used.

Only properly trained personnel may be expected to perform satisfactory inspections, repairs, and preventive maintenance. Even with properly trained maintenance personnel, some work will be beyond staff capabilities. Consultants or factory representatives may be called in to perform certain maintenance work. Some work must be sent out, such as an electric motor that needs to be rewound. Contractors may be used to perform infrequent and labor-intensive work. Trained personnel should have a knowledge of the functions and operations of the equipment as well as the maintenance procedure for the service to be performed. Specific skills are required in the operation and maintenance of mechanical and electrical equipment. As there is danger when dealing with electrical equipment, particularly when high voltage is involved, only a qualified electrician should be hired to maintain such equipment.

Maintenance guidelines can be found in the literature supplied by the manufacturer. Some may be known from operational experience. All information should be kept on record in a central location. Drawings and blueprints should also be kept at this location. A manual describing the preventive maintenance of the facility is a necessity.

All maintenance programs should have a budget for normal operations. Scheduled repairs and replacement of equipment and parts should be included. These costs should be part of the records for preventive maintenance.

Matching Water Sources to Aquaculture Products
Bibliography

Water has been dubbed the drink of the gods and the basis of life. It is little wonder that the source of water for an aquaculture facility is so important. Water sources can be from underground (groundwater), on the ground (surface waters), or above the ground (rain). Each source has unique water-quality parameters associated with it. A summary of the sources of water and associated parameters relevant to aquaculture is presented in Table 1. Many other topics in this encyclopedia also discuss various aspects of water quality and quantity. This entry is intended to provide an overview of water sources and a framework from which to judge their suitability for aquaculture.

GROUNDWATER

Groundwater refers to water that is contained in subsurface geological formations (1). It is brought to the surface either by pumping from a well or flowing naturally from a spring or artesian well. Water has a mass of about $1000–1028 \text{ kg/m}^3$ ($62–64 \text{ lb/ft}^3$) depending on salinity and temperature. To move a large mass of water needed for fish culture any great height or distance requires energy. Water sources that are located deep in the earth or at great distance from the farm will always be more costly than water that is free flowing or shallow (2). The impact that this will have on the economic viability of the farm depends on many factors related to species and site selection.

Because groundwater is contained far from the surface and can remain underground for millions of years, the water takes on characteristics that are related to the rock formations that the water is in contact with. Alkalinity, hardness, pH, dissolved minerals, and dissolved gasses (each of these topics are covered elsewhere in this volume) in groundwater can all be at very different levels from water that is in contact with the atmosphere. Oxygen and biological processes are limited underground, so ground water typically contains few pathogens and little oxygen, although carbon dioxide and argon gasses can be supersaturated.

Groundwater temperatures below 10 m (33 ft) are quite stable in a given location relative to surface waters. Temperature is moderated by the thermal mass of the earth, so groundwater tends to have a relatively minor seasonal temperature change. Groundwater varies with latitude, being warmer near the equator and colder away from the equator. For example, groundwater temperatures in the United States range from about 26 °C (79 °F) in southern Florida to 3 °C (37 °F) in northern Minnesota (1). In general, the average annual temperature of groundwater is a degree or two (°C) higher than the mean annual air temperature (3). In addition, groundwater temperature increases 1–5 °C (average about 2.5 °C) per 100 m depth (4). Higher increases may be due to local geothermal activity. If the groundwater is in proximity to volcanic activity, then it may be naturally

Table 1. Water Sources and Some Associated Water-Quality Parameters

Source	Quantity	Pathogens and Predators	Salinity	Temperature	Suspended Solids	Dissolved Oxygen	Other Dissolved Gasses	Total Gas Pressure	Metals	Oxidizers	Buffer (pH)
Groundwater	Generally stable, but may vary with season or year	Not usually a problem	Fresh to full strength seawater	Stable over the short term, can vary seasonally	Low	Low	Carbon dioxide, and argon can be high depending on geology	Can be above saturation variable	Iron and manganese may be a problem in water with low DO.	None	Depends on geology
Rivers, streams, and lakes	Streams and rivers variable, lakes generally stable, but can vary with seasons	Common and should be expected	Fresh	Variable short term and seasonally, varies more than groundwater	Varies, can be high during runoff events	Low to high variable	Generally low, but carbon dioxide can be high and variable if there is a lot of respiration	Same as above	Depends on industrial and domestic discharges in proximity to inflow lines	None	Depends on geology and source of water
Oceans, seas, and bays	Stable, although elevation can vary with tides	Common and should be expected	Brackish to seawater	Variable	Varies, can be high during runoff events and storms	Low to high, variable	Same as above	Generally below saturation at depth	Same as above	None	Generally well buffered, locally may reflect buffer capacity of rivers flowing into it.
Municipal water sources	Limited and expensive	Reduced, but not eliminated from source	Fresh	Variable	Low	Low to high	Low	Variable. Can be high in summer	Should not be a problem	Chlorine and/or ozone is often used	Depends on source and treatment
Rain	Highly variable	Low probability	Fresh	Variable	Very low	High	Low	Saturated	Depends on industrial air pollution upwind of catchment area.	None	Poorly buffered, can be acidic
Recirculation systems	Can intensify use of existing source.	Requires treatment, difficult to eliminate pathogens completely	Fresh to full strength seawater	Set by operator, stable	Depends on treatment	Depends on treatment	Carbon dioxide can be high	Generally not a problem, unless pump has a suction leak	May build up from feed	Ozone is often used to maintain ORP and kill pathogens	Highly buffered and controlled

heated by a geothermal source. Much of the trout industry in Idaho, USA benefits from geothermally heated water.

Groundwater is usually fresh, but saltwater aquifers also exist. Saltwater aquifers are common near the coasts, but can also extend for hundreds or thousands of miles inland. The salinity of the groundwater is variable. Discharge into freshwater canals or streams may be problematic if the site is located very far inland or in agricultural areas.

SURFACE WATER

Surface waters include streams, rivers, canals, ponds, lakes, seas, and oceans. Because they are exposed to the atmosphere and typically support diverse and abundant biological ecosystems, surface waters have different characteristics from groundwater. Surface waters can be fed either by rain or groundwater or both. Water quality parameters such as alkalinity, hardness, pH, dissolved minerals, and other factors will be somewhat dependent on the source. In addition, biological processes tend to change water quality and add competing organisms, pathogens, and predators. Biological processes tend to add acids to water, there by lowering pH and depleting alkalinity. They also tend to reduce dissolved compounds in water and lower the oxidative-reductive potential (ORP) of the water. Water temperature follows seasonal and local weather patterns, therefore surface water is more variable than groundwater.

RAIN

Rain is not usually a reliable source of water for aquaculture; however, in certain regions it can be. For example, many catfish (*Ictalurus punctatus*) raised in Alabama, are from ponds supplied primarily by rainwater (4). Rainwater may also be a useable supply for makeup in recirculation systems or other systems where a continuous high volume supply is not needed. Since rainwater contains almost no buffer and can be affected by airborne pollution, careful consideration must be given to its quality and dependability as a primary source of supply. In some cases, it may help reduce demand on other sources.

MUNICIPAL WATER SOURCES

Municipal water can originate from groundwater, surface water, or rainwater sources. While it may be convenient to simply hook up to a municipal-water source, there are two drawbacks. First of all, municipal water is treated to make it safe for human consumption. Typically, this includes treatment with strong oxidizers, such as chlorine or ozone, to kill human pathogens. These compounds are lethal to fish and need to be removed or treated to make the water safe for fish (see the entries "Ozone" and "Chlorination/dechlorination"). Second, municipal water is expensive and a limited resource in most areas. The use of municipal water for aquaculture is largely limited to

small-scale experimental systems, holding for live retail sales, or as emergency makeup for recirculation systems.

NATURAL OR REHYDRATED SEAWATER

Small amounts of seawater can be made from salt mixtures and freshwater (6–8). This might be sufficient for inland holding facilities, aquariums, or small research recirculation systems, but due to the expense and labor needed to prepare seawater, high-flow production aquaculture will likely need a large body of natural saltwater nearby. The advantage of making up seawater from salts is that very clean water can be made. This might be important for algae, zooplankton, egg, and larval culture, no matter where the facility is located. Also, if a seawater recirculation system is used with ozone as an oxidizer, then a salt mixture lacking bromine can be used to minimize hypobromide production. Hypobromides are toxic to many types of aquatic organisms (see the entry "Ozone").

RECIRCULATION AS A SOURCE

Just as recycling of paper and plastic can reduce the use of trees and petroleum resources, water recirculation technologies can reduce the demand on the water supply. Water recirculation can increase the flow to the culture units by 10–1000 times the flow of new water (9). The downside is the high capital cost of the treatment components.

Energy requirements may be greater or lesser than a single-pass system, depending on the amount of water that needs to be pumped in each system and the need for temperature adjustment. Temperature and other water-quality parameters can be adjusted in a recirculation system to suit the species and life stage of interest. This is a major advantage and may or may not offset high capital and energy costs and may offer higher growth rates. This advantage is particularly important with photoperiod and temperature-manipulated broodstock, egg incubation, and larval rearing. (For more information, see the many related topics about recirculating systems in this Encyclopedia.)

MATCHING WATER SOURCES TO AQUACULTURE PRODUCTS

What comes first, the water or the fish? Often, aquaculture projects come about from one of two situations. Either someone is knowledgeable about a species that they are hoping to culture and wants to find a site with a source of water to fit the species or has a site with an available source of water and is looking for a suitable species to rear. Water source and species selection are closely linked. If large quantities of water are involved, such as is the case with pond or flow-through culture, then it is very difficult and expensive to treat water beyond using simple screens and aeration. Pumping from deep wells, heating, or chilling large volumes of water is energy intensive, expensive, and unlikely to be economically or environmentally sustainable over the long haul. For all

these reasons, water quality from the source should be well matched to the environmental optima of the species to be cultured if the project is to be a success.

Temperature is often one of the most important factors when matching a water source and a culture species. Except for small water volumes used for egg or broodstock holding or for recirculation systems, attempting to significantly change the temperature of the culture water by heating or cooling is costly. Exceptions to this rule are geothermal or waste heat from a power plant to heat water, or possibly the use of deep, cold marine water for cooling warm water (such as is done at the Natural Energy Laboratory of Hawaii Authority site).

The amount of water needed for a fish production system will depend on the intensity of culture. In extensive systems, water requirements may be based upon management concerns, such as the time to fill a pond, or the amount water needed to makeup for evaporation or leakage. Larson (10) recommended that enough water be available for aquaculture ponds to fill in two weeks. Amounts needed for evaporation or leakage will depend on the area where the ponds are located.

For intensive systems, water requirements will be dictated by the first limiting water-quality parameter. Typically, oxygen is first limiting, followed by carbon dioxide and ammonia. A mass-balance approach can be used to determine water requirements for a given species and level of production. Conversely, this approach can also be used to determine the potential production levels of a given species for a known water source. The mass balance approach is very powerful and can be used to examine and identify which water-quality parameter is limiting for a given set of circumstances, and which water treatments will have the greatest impact on production (11).

The mass balance approach accounts for all inputs/ outputs and production/consumption of a compound of interest in a defined system. Compounds can get into or out of the system either predissolved in the water flow or they can transfer into the water once it is already in the system (form air, feed, light, and so on). Flow (Q, in volume/time, m^3/hr) in a system times concentration (C, in mass/volume, g/m^3) equals the rate of mass flowing (g/hr) into or out of a system predissolved in the water. Transfers (T), production (P), and consumption (R) are also rates in mass/time (g/hr). Transfers of mass into or out of the system come from or go outside of the system. For example, oxygen may be transferred into a system and carbon dioxide out of a system due to aeration. Compounds can also be taken up or released by the fish, bacteria, or some other internally generated activity of the system, to or from the water. Typically this relates to the biomass (B) of organisms contained in the system. For example, the consumption of oxygen by fish depends on the size and number of fish. Accounting for all the ins and outs and conversions that occur can be expressed mathematically. Mass is conserved, so the mass of a given compound into and out of a system is in balance, and this can be expressed in the equation below. The same approach can be used for energy, which is also conserved.

$$Q_{in}C_{in} + T + (P - R)B = Q_{out}C_{out}$$

where Q_{in} is the influent water flow (e.g., Lpm), C_{in} is the influent concentration of the compound in water (e.g., mg/L), T = transfer of the compound into (or out of, if negative) the tank (e.g., mg/hr), P = production of the compound in the tank (e.g., mg/hr/kg of organism), R = consumption of the compound in the tank (e.g., mg/hr/kg of organism), B = biomass of the organisms in the tank (e.g., Kg), Q_{out} = effluent water flow (e.g., Lpm), and C_{out} = effluent concentration of the compound in water (e.g., mg/L).

For example, if we have a spring that produces 100 m^3/hr of water at 15 °C (59 °F), and it contains 10 mg/L of oxygen, and we want to know the biomass of rainbow trout (*Oncorhynchus mykiss*) that can be maintained with this water, we can use the above equation to figure it out. We need to know what the trout will do to the oxygen in the water and what the minimum level of oxygen should be to keep our trout healthy. For this example, we will assume that the trout removes oxygen at the rate of 200 mg O_2/kg of fish/hr and requires a minimum of 5 mg/L to stay healthy (1). The concentration to keep the fish healthy will be equal to the outflow concentration since when it gets to that level, we want to get rid of it.

For our example the equation has the following values:

Flow ($Q_{in\ and\ out}$) = 100 m^3/hr or 100,000 L/hr
    both in and out

Transfer of oxygen (T) = 0 mg O_2/hr (we have no aeration in this example)

Production of oxygen (P) = 0 mg O_2/kg of biomass/hr (if there were plants or algae in the system then this might be a nonzero number)

Consumption of oxygen (R) = 200 mg O_2/kg of fish/hr

Concentration of oxygen in the inflow (C_{in}) = 10 mg/L (this is saturation at 15 °C)

Concentration of oxygen in the outflow (C_{out}) = 5 mg/L (set as the minimum acceptable level)

Plugging in the values:

$$Q_{in}C_{in} + T + (P - R)B = Q_{out}C_{out}$$

(100,000 L/hr · 10 mg/L) + 0 mg/L/hr
    + (200 mg/kg hr · B kg) = (100,000 L/hr · 5 mg/L)

Solving for B, (kg of trout)

$$B = 2500 \text{ kg (5500 lbs)}$$

The same exercise, repeated with each water-quality factor, can be used to determine the first limiting water-quality parameter. This approach can also be used to determine which water treatments will be necessary to increase production. In the foregoing example, the effect of aeration can be addressed by adding in a value other than zero for the production term. The calculations become more difficult when recirculation and multiple treatments are considered.

Surface water sources, especially those from established ecosystems, will contain pathogens and potential predators. Pollution may also be a concern for rain, surface, and groundwater sources that are in proximity to a pollution source. Various screens and sterilizers are available to reduce predators and pathogens, but treatments for pollution will depend on the nature of the pollution, and may not be treatable.

Regulations for the removal of water from either a groundwater or surface-water source exist at multiple levels in almost all countries. This is true for marine or freshwater sources. Additional regulations govern discharge of water from aquaculture facilities. Property owners should check with local authorities and government agencies regarding rights and permits for development of the water source.

WINTER FLOUNDER CULTURE

W. HUNTTING HOWELL
University of New Hampshire
Durham, New Hampshire

MATTHEW K. LITVAK
University of New Brunswick
St. John, Canada

OUTLINE

The winter flounder, *Pseudopleuronectes americanus*, is a right-eyed flounder (family Pleuronectidae) found along the east coast of North America from Labrador, Canada to Georgia, USA. The species is typically found on mud and sand substrates, at depths ranging from the shallow subtidal to 37 m (1). Maximum size is usually 2.25 kg and 65 cm, although they occasionally grow to over 3 kg (2). Among the flatfish species found along the coast of New England, winter flounder are the heaviest per unit length (3). The species has been exploited both commercially and recreationally for well over a century. Their stocks have been in decline over the past 20 years, and the species is currently considered overexploited (4).

The first propagation of winter flounder occurred in the late 1880s, at three government hatcheries located in Massachusetts and Maine, and operated by the U.S. Fish and Fisheries Commission. The work was undertaken in an effort to rebuild declining wild populations, and tens of millions of early larvae were released before the last of these hatcheries closed in the early 1950s (5,6). Although the success of those efforts was probably minimal due to the small size of the larvae released, some of the basic culture techniques developed through those efforts are still in use today.

Recent declines in the fishery, combined with a demand for high quality flatfish, have once again stimulated interest in the culture of various flounder species, including winter flounder (7). Although a pilot attempt to rear winter flounder in New Hampshire had only minimal success (8), advances since then, by a number of researchers, have improved the ability to culture this species. Researchers and culturists have also relied heavily on the wealth of information available on production techniques for other flounder species, including turbot (9,10), Japanese flounder (11), and summer flounder (12).

The purpose of this entry is to review what is known about winter flounder culture. Regrettably there are some topics for which little information is available (e.g., broodstock management, growout systems). In some cases, techniques come from our own recent studies, which are not yet published. Nevertheless, we are confident that the techniques work, and since we are anxious to give the reader the most recent information, we have included some of these results and observations.

COLLECTION AND MAINTENANCE OF BROODSTOCK

Currently broodstock are being kept by Huntsman Marine Science Centre in Saint Andrews, NB, Canada, and by Sambro Fisheries, Sambro, NS, Canada. Save for a few fish kept at Sambro that were grown by Litvak's laboratory in 1994–1997, these broodstock are wild caught. For the most part, researchers have relied on wild-caught adults to produce the early life-history stages needed for their studies (13–25). Brood fish are collected by trawl net, gillnet, fyke net, or by divers in the weeks preceding the natural spawning season, and returned to the laboratory. Ripe females are identified by their swollen ovaries, which indicate hydration, and spermiating males are identified as those which release milt upon slight abdominal pressure. Maintenance of captive adults for short periods of time is relatively easy. Although females fast during the spawning season, males readily consume clams, squid, chopped menhaden, silversides, clam worms, earthworms, and chopped capelin during the spawning season (16,26–29).

Wild winter flounder adults caught prior to spawning will usually undergo gametogenesis when provided with photoperiods and temperatures that are "normal" to their place and time. Spawning times vary from December to June, beginning earlier in the southern part of the fish's range and later in the northern parts of the range (30,31). Final maturation and spawning are commonly induced through hormonal manipulation. Smigielski (32) experimented with a variety of hormones, including human chorionic gonadotropin (HCG), pregnant mare serum gonadotropin (PMSG), deoxycorticosterone (DOCA), oxytocin, and freeze-dried carp pituitary extract. Smigielski's best success, in every case, was with freeze-dried carp pituitary extract, at doses of 0.5 or 5 mg/454 g female body weight. The extract was mixed in an isotonic (to fish blood) solution of sodium chloride as a carrier, and injected intramuscularly on a daily basis until spawning. Fish receiving the higher dose spawned after only three injections, while those receiving the lower dose required six injections. All but one female (which was later determined to be sexually immature) hydrated and spawned, and all resultant eggs and larvae were normal. Water temperature appeared to be a critical factor in producing ovulation, as the majority of fish did not hydrate at temperatures above 6 °C, even under hormonal treatment.

More recently, Harmin and Crim (33,34) conducted additional research on hormonal induction of maturation and spawning. Intraperitoneal injections of gonadotropic releasing hormone analog (GnRH-A), 20 μg per kg body weight, three times per week, resulted in a few females ovulating at temperatures as low as 0 °C, and accelerated ovulation and increased spawning reliability in prespawning flounders maintained at 5 °C. Harmin and Crim were able to induce spawning in February, which was three months prior to normal spawning season in their area (Newfoundland). Furthermore, egg and larval quality (as indicated by rates of fertilization, hatching, and larval survival) was good after this accelerated spawning. The researchers also observed that when using intramuscular implants of GnRH-A (100–120 μg slow release, or 40 μg fast release) there were rapid and predictable ovulatory responses from the fish.

Harmin and Crim (35) have also used GnRH-A injections to treat prespawning males. Maturing fish treated during winter (December/January), with a single injection of either 20 or 200 μg/kg body weight, showed increased levels of testosterone and 11 ketotestosterone within 12 hours and these levels remained high for several days. Single injections advanced spermiation in some individuals, but only small amounts (<50 μL) of milt were produced. By March, following GnRH-A treatment, all males were spermiating. In fish that were injected twice, there was a significant increase in sperm production and milt volume.

Although wild fish are easily collected and spawned in the laboratory, the development of a winter-flounder aquaculture industry will require the establishment of captive adult populations (broodstock) to produce a reliable supply of high-quality eggs. There are several disadvantages associated with the use of wild brood fish. Perry et al. (22) have shown, for example, in brood fish collected from areas that differed in habitat quality, that habitat affected the viability and health of resultant embryos and larvae. Fish from anthropogenically contaminated areas produced eggs with high incidence of chromosome damage and mitotic abnormalities. Similarly, brood fish collected from different spawning locations in Long Island Sound, CT, and Narragansett Bay, RI, spanning about 200 km, produced larvae with different mean sizes at hatching and different biochemical content (20). This was important, because there was a direct correlation between these variables and survival through the first month. In a related study (21), it was found that spawning time and female size affected the composition and viability of the eggs and larvae. Larger females produced larger eggs, and mean egg weight from the population decreased as the spawning season progressed. Therefore, large, early spawning fish produced the largest eggs, and these in turn had the highest viability.

COLLECTION AND INCUBATION OF EGGS

Collection

The fecundity of winter flounder has been described by a number of authors for a number of areas (2,36–38) and generally ranges from 100,000 to 3.3 million eggs per female, depending on female size. Ripe winter-flounder

eggs are spherical, range in diameter from about 0.71 to 0.96 mm diameter (39), have a specific gravity of 1.085–1.095 (40), and are adhesive (15). Thus, eggs form demersal clumps when extruded. Artificial fertilization is typically done using the "dry" technique, in which the ripe eggs are stripped from the female into a dry container. Typically all the eggs from a female are extruded by a single stripping. A mixture of milt and clean seawater is then added to the eggs, and the mixture is swirled for several minutes to ensure fertilization. Fertilization percentages are generally quite high and range from 78 to 93% (20,21). Because high egg mortalities have been attributed to clumping (15), the fertilized eggs are often treated with a diatomaceous earth solution to prevent them from adhering to one another. Newly fertilized eggs are spread into a polyethylene pan, then covered by a dense slurry of diatomaceous earth solution (50 g diatomaceous earth in 1 L of sterile seawater). The mixture is swirled for five minutes and then rinsed to remove excess earth (15). Litvak's lab has switched to Pyrex trays instead of polyethylene pans because plastic is prone to scratches, making them harder to disinfect after use and increasing the risk of bacterial outbreak. Alternatives to this procedure include the "plating out" of eggs into single layers on panels of either glass or fine plastic screening, which allows each egg more contact with the seawater (Klein-MacPhee, unpublished).

Very ripe females spawn volitionally when placed together with males in small (100 L) spawning tanks supplied with ambient (6 °C, 30 ppt) flowing seawater (25). No attempt is made to control photoperiod or temperature, but the amount of ambient light entering the spawning tanks is reduced by covering them with black window screens. Stocking ratio of males to females is 3 : 1. Depending on ripeness, the fish spawn within 1 to 10 days, and spawning always occurs at night. Although winter flounder are reputably batch spawners (30), our experience is that each female releases most of her eggs in a single spawning. Occasionally, however, smaller groups of eggs are released on subsequent days. After spawning is completed, the adults are removed from the tank. Eggs are allowed to clump and are then moved to 100 L tanks supplied with flowing seawater. This technique of volitional spawning usually resulted in very high (>95%) fertilization rates (Howell, unpublished). Although spawning behavior was not observed by King and Howell (25), the spawning behavior of captive winter flounder has been described (41).

Incubation Systems

A variety of embryo incubation systems have been used successfully. Smigielski and Arnold (15) used simple "incubation baskets," which were 15 L rectangular plastic containers into which windows, covered with 505 μm plastic screening, had been cut in the sides and bottom. Baskets of fertilized eggs were then incubated in flowing seawater troughs. Similar systems have been used by other researchers (16,20,22). Six-liter acrylic hatching jars, supplied with filtered seawater at ambient temperatures and salinities (4–6 °C; 31–33 ppt) have

also been used successfully (42–44). Static methods, in which embryos are incubated in small, temperature-controlled containers, and in which a portion of the water (25–50%) is periodically (every 1 to 3 days) replaced with filtered, ultraviolet treated seawater, have also been used extensively (24,45,46). Stocking densities of embryos in static systems have ranged from 40–1250 per liter (16,19,43). Litvak's lab incubates eggs at a density as high as 5000 per liter in Pyrex trays. These relatively low densities prevent ammonia buildup and oxygen depletion. With containers placed in a flowing seawater trough, Smigielski and Arnold (15) stocked eggs at 17,000–34,000 per liter. King and Howell (25) allowed entire egg masses to incubate in 100 L, flowing seawater tanks. Stocking density of eggs is estimated as 10,000–30,000 per liter.

Incubation Conditions

Winter flounder embryos are relatively eurythermal, but survival to hatching is generally higher at temperatures less than 10 °C. Williams (47) incubated eggs over a range of water temperatures from −1.8 to 18 °C and found that viability was high over a wide temperature range. Percentage of eggs surviving to hatch at low temperature (less than −1 °C) was variable, ranging from 0 to 79%. Survival to hatching was consistently higher than 75% for embryos incubated between 0 and 10 °C and consistently less than 75% for those incubated at temperatures between 10 and 15 °C. It was noted, however, that egg mortality may have resulted from microbial infection rather than directly from temperature. The upper lethal thermal limit was given as 15 °C. Buckley et al. (19) reported hatching percentages of 70–85% at 4, 7, and 10 °C, and noted that percentage was significantly higher at the lower temperatures. They also noted that hatching percentage was unaffected by the acclimation temperatures of the adults, which were 2 and 7 °C. Rogers (16) experimentally investigated various combinations of incubation temperature (3–14 °C) and salinity (0.5–45 ppt). She found that viable hatching was highest at 3 °C, lowest at 14 °C, and was similar at 5, 7, and 12 °C. Moreover, she found that temperature and salinity interacted, such that the highest viable hatch (78%) occurred at 3 °C over a salinity range of 15–35 ppt, while at temperatures above 3 °C, the optimal salinity range decreased to 15–25 ppt.

Embryonic development has been described (14) and is typical of other flatfish species. Rate of embryonic development is temperature dependent (16,47). Rogers (16) reported that time from fertilization to 50% hatching can last from 17 to 31 days (mean of 25 days) at 3 °C and from 5–10 days (mean of 7 days) at 14 °C. Near the end of the embryonic period, larvae move within the egg capsules, and this movement assists with rupturing the capsule at hatching (13).

Solutions of penicillin G and streptomycin (0.02 mg/mL of each) have been used prophylactically to disinfect embryos (24,45,48,51). These antibiotic solutions were added to the culture water 24 hours after fertilization, or periodically, as water in the cultures was changed.

LARVICULTURE

Development and Size

Good descriptions of larval development, from hatching to the end of the second month, are available (13,49). For a thorough review of the older literature on early life-history stages, the reader is referred to Martin and Drewry (50). Newly hatched winter flounder larvae range in total length from about 3.5 to 3.8 mm (13,45,46). Acclimation temperature of the adults, incubation temperature of the embryos, and geographic origin of the broodstock can affect both length and weight at hatching, as well as the biochemical composition of the larvae (17,18). Size at hatching affects survival potential, with larger larvae having a higher probability of surviving through the first month of life (19,20).

Time to yolk sac absorption is dependent on temperature, and generally occurs at 7 days posthatching (dph) at 12 °C (48), 9–10 dph at 5 °C, 12–14 dph at 4 °C, and 14 dph at 2 °C (17,19).

Larval Rearing Systems

Winter flounder larvae have been reared in static, flow-through and *in situ* systems. In static systems, which are used in research, but not aquaculture, the larvae are reared in containers with no flowing water. To prevent the buildup of nitrogenous waste products and to ensure adequate amounts of dissolved oxygen, a portion of the water is replaced either daily, or every second or third day. Generally, one-third to one-half of the volume is changed on each occasion. Because larvae that have been raised in static systems have been used for experiments, container sizes are relatively small, ranging from 0.4 to 40 L. The containers are typically dark walled and made of plastic or glass. Water used is typically filtered (0.45 μm) and sterilized by ultraviolet light. Antibiotics (an equal mixture of penicillin G and streptomycin) have been added (25 ppm) to static larval culture systems (42–44). Light aeration is provided, and overhead lights are used for illumination, which facilitates the visual feeding of the larvae. The advantage of static systems is that temperature is easily controlled by placing the container in a constant temperature room or water bath. An additional advantage is that prey organisms are not washed out of the system. Static systems have been used extensively (15–25, 42–45).

Flow-through systems, in which larvae are reared in 100 L circular tanks, supplied with 5 μm filtered, ultraviolet light-treated seawater at ambient temperatures and salinities (5–10 °C, 28–33 ppt) have also been used successfully (25). Flow rate to the tanks is 1–2 L (0.25–0.50 gallon) per minute. Loss of larvae is prevented by a high surface area, screened (80 μm) outflow that is located in the middle of the water column. The advantage of the flow-through system is its larger volume and improved water quality. Maintenance of desired prey levels is achieved by feeding the fish multiple times per day. Litvak's laboratory also uses a flow-through system, except they use an upwelling cylindroconical tank (48). Both experimental-sized (100 L) and production-sized cylindroconical tanks (1,000 L) have been used to successfully produce metamorphosed fish.

An *in situ* system to monitor the growth and survival of winter flounder larvae has also been used (52). It was a large (11.5 m³) open-mesh enclosure, suspended from a surface floatation collar, deployed in a subestuary of Narragansett Bay, RI. Mesh size (505 μm) was small enough to prevent the escape of the larvae and large enough to allow their natural food to enter. The system was stocked with 1,000 four-week-old, laboratory-reared larvae, and these were held in the enclosure for two weeks in April and May. Results of the experiment with this system were very encouraging. Physical conditions (temperature and salinity) within the enclosure were optimal, and prey (copepods, rotifers, polychaete larvae, barnacle nauplii, and cladocerans) concentrations were high (10–8700 per liter). Of the fish placed in the enclosure, 76.8% survived and all metamorphosed. Daily specific growth rate was 10.7% dry weight and 1.9% standard length. The advantage of this system is the ability to raise large numbers of larvae at relatively low cost. Perceived disadvantages are the lack of control of the rearing conditions (e.g., temperature, prey availability) and the danger of losing the system in storm conditions.

Photoperiod and Light Intensity

Downing and Litvak (unpublished data) found that there was no effect of light intensity (5 vs. 100 lux) on larval winter flounder growth and survival. Continuous light, however, significantly improved both growth and survival of winter flounder larvae (48). Larvae raised under continuous light showed a five-fold increase (50 vs. 10%) in survival to metamorphosis, compared with those raised under ambient photoperiod (48). The continuous light treatment also reduced the time to metamorphosis by five days. Both our laboratories now use continuous light in rearing winter flounder larvae (25,48).

Larval Stocking Densities

Because static systems have been used for experimental studies, the number of larvae stocked per liter has varied with experimental design. Numbers range from 2 larvae/L (44) to nearly 300 larvae/L (23). More typically, 10–40 larvae/L are stocked (19,25,42,43). In flow-through systems, stocking density is as high as 100/L (Howell, unpublished).

Green Water

The addition of cultured microalgae to larval rearing tanks ("green water" treatment) has been widely accepted as a technique for commercial marine finfish production. Cultured microalgae has occasionally been added to winter flounder larval culture systems as a "water conditioner." Species of microalgae used have included *Nannochloropsis* sp., *Isochrysis galbana*, *Dunaliella tertiolecta*, and *Tetraselmis souscii* (20,21,23,25,42,43). Buckley et al. (20,21) inoculated larval tanks prior to rotifer introduction with dense cultures of *Tetraselmis* sp. at a rate of 1 L per 36 L of aquarium water. King and Howell (25), working in static systems, determined that when

3 L (200,000 cells per mL) of *I. galbana* were added to 20 L larval cultures every third day, the larvae in green water grew significantly faster than those in clear water. The importance of microalgae to winter flounder larvae has been further documented in a recently completed experiment in which microalgal species (*Nannochloropsis*, *Dunaliella*, or *Tetraselmis*) were provided at 3 L of dense (200,000 cells/mL) microalgae per 36 L tank per day, for varying lengths of time (one to four weeks) following yolk absorption (Bidwell, unpublished). Results of the study indicated that larvae cultured in green water for at least two weeks had significantly higher growth rates than those provided either no microalgae (control) or those given microalgae for only one week. Moreover, the larvae provided with microalgae for at least two weeks were more completely metamorphosed after four weeks than those which received either no microalgae or microalgae for only two weeks. We strongly recommend the use of microalgae during larval culture.

Larval Feeding

Hatchlings spend the first several days feeding endogenously as they absorb nutrients from their yolk sac. First feeding occurs within one day of absorption of the yolk sac (19,53). Total lengths at first feeding range from about 4 to 4.4 mm, depending on adult acclimation temperature and larval incubation temperature (19). Winter flounder larvae are continuous, visual, daylight feeders (18). As with virtually all small marine fish larvae, first feeding winter flounder larvae require small (<200 μm) live food items. This need has been met by feeding the larvae the cultured rotifer (*Brachionus* sp.), field collected zooplankton, or a mix of rotifers and wild zooplankton. Feeding rates of rotifers range from 2000 to 5000/L/day (24,25,51).

A 1:1 or 1:2 mixture (wild plankton:cultured rotifers) has been used by Buckley et al. (20,21) and Klein-MacPhee (42,43), respectively. Feeding rates of these mixtures ranged from 1000 to 3000 prey per liter. The exclusive use of small (48–200 μm) wild zooplankton (principally copepod nauplii) has also been used successfully (17,18,25). Initial feeding rates ranged from 2000 to 2100 prey per liter. Larger sized (up to 500 μm) wild plankton are used as the larvae grow (17,25,45). King and Howell (25) found no difference in growth or survival between larval winter flounder fed wild zooplankton and cultured rotifers that had been enriched with the microalgae *I. galbana*.

Rotifers or wild zooplankton are typically given for the first four to five weeks of feeding, but the larvae need larger food particles as they continue to grow. In most instances, this need has been met by feeding nauplii of brine shrimp (*Artemia salina*) to the late stage larvae. *Artemia* feeding is typically started at four to six weeks after hatching (22,23,41–44,51); however, this is dependent on larval size and *Artemia* can be fed to the larvae as early as 21 dph (48). Klein-MacPhee et al. (42,43) tested commercially available brine shrimp from different geographical locations and found that the geographic origin of the brine shrimp affected the growth and survival of late stage (42–71 dph) winter flounder. They suggested that the poor performance of some larvae may have resulted from the presence of various pesticides,

which were relatively high in some of the brine shrimp strains tested. The differences may have also have been due to differences in the nutritional value of the different strains, particularly in the amount of long chain polyunsaturated fatty acids (e.g., 20:5n-3 series) that were present. In a related study Shauer and Simpson (44) found that *Artemia* are able to bioconvert short-chain fatty acids (18:2n-6, 18:3n-3) to longer chain forms (20:5n-3, 22:6n-3). Further, winter flounder juveniles accumulated the long-chain fatty acids, and were able to convert 18:3n-3 gotten from the *Artemia* to 20:5n-3 and to lesser extent, 22:6n-3.

Because cultured rotifers and brine shrimp may lack the essential fatty acids required for optimal growth and survival, many fish culturists, including those of winter flounder, enrich these live prey organisms. This is usually done through the use of commercially available emulsions (e.g., Selco™ products, Inve Aquaculture) or by feeding the rotifers and brine shrimp microalgal species that have the desired fatty acids.

The amount of food required by winter flounder larvae held at 8°C, from yolk absorption to metamorphosis, has been documented (18). It was found that (*1*) all larvae fed less than 100 prey/L died within two weeks; (*2*) the number of prey consumed increased curvilinearly with prey density, particularly in fish that were five to seven weeks old; (*3*) daily specific growth in dry weight was similar at prey concentrations ranging from 500 to 3000/L. Mean daily specific growth in dry weight was 5.72% at 500 prey/L, 7.68% at 1000 prey/L, and 8.62% at 3000 prey/L; (*4*) mortality rates decreased as prey density increased; and (*5*) complete digestion of gut contents occurred within 5–8 hours. In the same paper, Laurence developed a bioenergetic model that simulated the effects of a number of variables, including temperature, prey density, and larval size on the ability of larvae to obtain the food energy needed to meet the needs of experimentally determined growth and metabolism. Results of the model simulations indicate that (*1*) the amount of time feeding must change as the larvae develop, and this in turn is related to prey density. Depending on concentration, larvae need to feed from about 3 to 18 hours per day; (*2*) wild larvae need a minimum of 300–800 prey/L to meet their feeding needs within the 12 hour of light that is normally available to them; and (*3*) the theoretical number of nauplii or older stage copepods needed to be eaten per day increased with the dry weight of larvae (from about 25 to 200 nauplii, or from 2 to 16 older-stage copepods) over the size from first feeding to metamorphosis.

Larval Growth Rates

The growth of winter flounder, from hatching to metamorphosis has been extensively studied, and can be influenced by temperature (17–19), prey concentration (18), culture conditions (25), and nutritional quality of prey (42,43). Laurence (17) studied the growth of winter flounder larvae from yolk absorption through metamorphosis at 2, 5, and 8°C. Larvae were fed wild zooplankton (principally copepod nauplii) at a rate of 2000/L/day. Mean daily specific growth (dry weight) was 10.1, 5.8, and 2.6% at 8, 5, and 2°C, respectively. He also provided regression

equations that related larval dry weight to weeks after yolk absorption. Growth in mass was found to be exponential. Growth rates using different units of measurement are also available. Chambers and Leggett (45) reported that the average daily growth rate, from hatching to metamorphosis was 0.068 mm/day at 6.9 °C. King and Howell (25) reported specific growth rates (length increases per week) of larvae reared using different combinations of green and clear water and wild zooplankton and rotifers. Rates were 15.4% (green water/wild zooplankton), 14.2% (green water/rotifers), 12.2% (clear water/rotifers), and 9.6% (clear water/wild zooplankton). Bertram et al. (24) found that there was some variation in growth rates between individual larvae and that growth in length was nonlinear. Increase in length was rapid up to 30 days posthatch, then slowed, or even decreased at metamorphosis. In a related finding, Laurence (17) found that oxygen consumption increased as the larvae grew, decreased at metamorphosis, and then increased again. Jerald et al. (23) described the development of daily growth increments of otoliths and provided a growth equation (length) for laboratory-reared fish up to 50 days posthatch. The best fit of the growth data was achieved using a Gompertz-type curve. The length-weight relationship for laboratory-reared larval winter flounder has been reported (54).

Age and Size at Metamorphosis

Mean age at metamorphosis, which is functionally defined as the migration of the left eye to the right side of the head and loss of pigmentation on the blind side (45), has been reported by a number of investigators, and ranges from 49 to 64 days posthatch at incubation temperatures ranging from about 7–10 °C (17,18,23,24,45,46,51). At a higher mean incubation temperature of 15 °C, metamorphosis occurred from 26 to 33 days posthatch (55), while at a lower incubation temperature of 5 °C, metamorphosis was delayed until 80 days posthatch (17). Mean length at metamorphosis has also been reported by a number of investigators, and ranges from 6.1 to 10.1 mm total length (23,24,45,46,51). Laurence (17) found that all larvae maintained at 2 °C died before reaching metamorphosis. Length at metamorphosis is less variable than age at metamorphosis and that larvae that metamorphose at a later age do so at a larger size (45,46).

GROWOUT

Weaning of Juveniles

Lee and Litvak (55) used wild young-of-the-year winter flounder juveniles to develop a weaning protocol. They were able to wean wild juvenile flounder onto dry feed (BP Nutrition^TM, Aquaculture Research Centre, Stavanger, Norway) by cofeeding live *Artemia* over one week. In a study using recently metamorphosed laboratory-reared winter flounder juveniles, they further examined the weaning protocol and also tested two different diets: nonsalmonid and salmonid starter feed (56). The study found that the locally produced inexpensive salmonid pellet (Hi-Pro^TM, Corey Feed Mills, Fredericton, NB, Canada) performed as well as the specialty marine

dry pellet (Nippai SFI-3, CATVIS, Hertogenbosch, The Netherlands). However, they did see a slight decrease in growth rates immediately after the switch to dry diets, suggesting that there is room for improvement in their weaning protocol during this critical stage.

Juvenile Rations and Diets

Little information is available on how much food juvenile winter flounder need, and for this reason, fish in captivity are normally fed *ad libitum*. Juveniles fed a diet of chopped bivalve (*Mya arenaria*) siphons *ad libitum*, and held at 20 °C (4 °C above their normal seasonal limit) consumed between 193 and 973 mg food/day but lost weight because of the temperature stress (57). Fish at cooler temperatures (12° and 16 °C) consumed more food per day (1,118–2,088 mg/day) and gained weight. Maintenance ration was calculated to be about 1.5% wet-body weight per day at 12–16 °C, and gross caloric conversion efficiencies ranges from 13.9 to 36.8% (57).

Little work has been completed on juvenile diets. The only published work that we are aware of is that of Hoornbeek et al. (8), who found that wild-caught juveniles would feed on a bound mixture of frozen shrimp, herring meal and oil, and a vitamin premix. That diet was 38% protein. Research is currently being conducted at the Department of Fisheries and Oceans (Cheryl Hebb and John Castell, DFO Saint Andrews Biological Station, NB, Canada) on diet formulation for on-growing juvenile winter flounder. Winter flounder do not seem to have the capability to spare protein and require at least 50% protein in their diets. However, there have been promising results suggesting that winter flounder protein requirements may be partially satisfied with either a portion of soy meal or canola protein (John Castell, personal, communication). Clearly, the capability to digest and utilize plant protein would be a boost to winter flounder's potential for aquaculture.

Juvenile Growth Rates

Winter flounder juvenile growth rate compares well with other commercially grown flatfish (56). Daily specific growth rates of recently metamorphosed fish have reached 3.11% weight gain per day (Table 1). This high growth rate was maintained through their first year of growth (Casey and Litvak, unpublished data) in which the specific growth rate exceeded 2.8% per day. From this research, it is clear that the culture of winter flounder juveniles will have to be conducted in warm or heated water to be profitable. In a further study of photoperiod manipulation, Casey and Litvak (unpublished data) found that winter flounder juveniles, like larvae, grow fastest under continuous light.

Producing Adults

To our knowledge, winter flounder have yet to be grown from egg to market size in captivity. Growth to market size, which we assume would be about 30 cm total length, takes between two and four years in the wild, depending on latitude (30). Presumably this time could be shortened in an aquaculture setting, where fish would be provided with optimal diets and warmer year-round temperatures (8).

Table 1. Daily Specific Growth Rates for Juvenile Winter Flounder (*Pseudopleuronectes americanus*) Reared at Different Temperatures

Reference	Age (years)	Source[a]	SGR[b] (%lgt/d)	SGR (%wgt/d)	Temperature (°C)
Frame (57)	1	W	—	0.27	12
	1	W	—	0.47	16
	1	W	—	−0.23	20
Hoornbeek et al. (8)	0–1	H	0.09	0.21	1–15
		W	0.24	0.71	10–15
Lee and Litvak (55)	0	W	0.12	0.53	5.3
Lee and Litvak (56)	0	H	1.36	3.11	15.0
Casey and Litvak (unpublished data)	1	H	0.67	2.30	10.0
	1	H	0.82	2.81	15.0
	1	H	0.79	2.71	20.0

[a]H = hatchery; W = wild-caught tested in the laboratory.
[b]Specific growth rate = [ln(final weight) − ln(initial weight)]/time × 100%.

Adult winter flounders held in captivity and provided with *ad libitum* amounts of clams and cubed beef liver daily consumed 2% of their body weight per day. Gross caloric conversion efficiency ranged from 0.10 to 0.22 (27).

Growout systems, although not developed, will probably be similar to those used for other flatfish species, including land-based tanks or raceways and net pens. There is no reason to suspect that winter flounder could not be raised in recirculating systems. Litvak (unpublished observation) has conducted preliminary experiments on cage grow out of winter flounder. A plastic coated, wire mesh cage, with a flat bottom, was suspended from a 10 m octagonal collar. Winter flounder were placed in the cage in the fall and their weights taken in December. The greatest weight gain was 40% in this period. Fish grown in the cage were 1.8 times heavier than were wild-caught fish of similar size, suggesting that the yield (fillet weight) could be higher from cultured fish than from wild-caught winter flounder.

DISEASE AND PARASITES

Diseases and parasites of wild winter flounder have been reviewed by Klein-MacPhee (30). Because winter flounder spawn and hatch during a cold part of the year, disease problems do not appear to be as great as in some warmwater species. Prophylactic antibiotics are often administered to egg and larval cultures as a precautionary measure (42,43). Fin erosion of captive juveniles has been observed (56), and smaller individuals appeared to be more susceptible to this disease. Most mortalities of wild caught juveniles held in the laboratory for extended periods of time resulted from systemic bacterial infections and parasites (8). *Vibrio anguillarum* was isolated during the periods of heaviest mortality. Symptoms included the cessation of feeding, fin rot, and hemorrhagic areas on the ventral surface. The most effective treatment was mixing furazolidone into the feed, provided at a rate of 12 g/100 g of fish per day, for 10 days. Two myxosporidian parasites were also identified from these fish. In Howell's laboratory, cultured juveniles have occasionally developed an unidentified fungal infection. This has been effectively treated by placing the fish in a dilute (250 ppm) hydrogen peroxide solution for 20 minutes. Treatment is repeated three times over 10 days.

ECONOMIC VALUE AND PRODUCT POTENTIAL

Winter flounder market value varies seasonally, depending on quantities being harvested and on the size, catch location, and name given by the broker. Current price (May 1998) for whole winter flounder in New York City is between US$5.50 and US$6.00 per pound, which is more than $2.00 higher than either yellowtail flounder and cod. Winter flounder is also sold fresh dressed and filleted. Considering that this fish is eurythermal, euryhaline, and extremely hardy, it is an excellent candidate for the live fish markets of Asia and the developing live fish markets in North America. Another favorable attribute of the species is that it is very cold tolerant. Because they produce a set of antifreeze polypeptides (58), they survive even in ice-laden seawater at temperatures below −1 °C. For this reason, they are one of the few candidates for flow-through, or net pen aquaculture at high latitudes, particularly in Canadian waters. Attempts have also been made to transfer the antifreeze producing genes from the winter flounder to the genome of the Atlantic salmon, thereby making the salmon more cold tolerant (59).

YELLOWTAIL AND RELATED SPECIES CULTURE

Makoto Nakada
Nisshin Feed Co.
Tokyo, Japan

OUTLINE

INTRODUCTION

Since publication of a yellowtail (*Seriola quinqueradiata*) aquaculture review paper in the 1980s (1), yellowtail farmers have had a difficult time due to drastic declines in Japanese sardine resources and the stagnant economy in Japan. Farmers were able to maintain annual production of 140,000 to 160,000 metric tons until 1998 (Fig. 1). At the same time, more valuable species than yellowtail, such as amberjack (*Seriola dumerili*), goldstriped amberjack (*Seriola lalandi* or *Seriola aureovittata*), and striped jack (*Caranx delicatissimus*), which are members of the same family as yellowtail, were becoming more attractive to fish farmers, and the number of yellowtail juveniles stocked for aquaculture started to decline beginning in 1995 (Fig. 2).

Sudden decreases in the number of available juvenile yellowtail, called Mojako in Japan (Fig. 3), and significant drops in the price of cultured yellowtail in 1987 forced the fish farmers to increase production of red sea bream (*Pagrus major*) (Fig. 4). Although production costs increased with the rising costs of feed due to drastic declines in the volume of sardines caught in the waters around Japan and a poor supply of Mojako, the market price of cultured yellowtail was sluggish because of the economic depression. Thus, the number of yellowtail farms decreased to 1,815 by 1996 from 3,991 in 1977. Yellowtail culture, which used to be highly profitable (1), is facing difficulty today. Farmers are trying to introduce new species such as those previously cited to make fish farming more profitable.

High-density culture is becoming common practice to compensate for falling profits, which in turn stimulates pollution of the culture areas. It is recognized that under overcrowded conditions fish eat less, resulting in poor growth and increased susceptibility to diseases. Since the fish farmers have to use more expensive formulated feeds instead of raw fish, effective utilization of feed is essential and is a more environmentally friendly practice. In order to overcome these problems, the fish farmers are becoming aware of the importance of maintaining good records on stocking density. Many of them have begun to use personal computers to assist in farm management (2).

Use of formulated feeds with balanced nutrients made possible the production of high-quality fish with firm flesh and no fishy odor. The practice also creates a new demand for culture products for fillets used in various dishes in addition to sashimi. As consumption of cultured fishes increases, the public has become pickier about quality.

The wholesale prices of cultured yellowtail, amberjack, and red sea bream in Tokyo markets are shown in Table 1. The species bringing the highest price is amberjack, the meat of which maintains its brilliant color and firm texture longer than does yellowtail (3). Because of its high quality, amberjack usually brings a much higher price than cultured red sea bream and yellowtail at wholesale markets.

Another related species, goldstriped amberjack, is especially popular in the northern Kyushu area. Compared with yellowtail, it has less dark muscle. It gets the highest evaluation as a sashimi material, especially during the summer, because of low fat content (4). In 1997, 2.5 million large juvenile goldstriped amberjack, called Hiramasa in Japanese, were caught in the waters around the Goto Islands and cultured. The products are now being shipped to the Kanto area.

Techniques for artificial propagation of species related to yellowtail are almost completed at the Fisheries Experiment Station of Nagasaki and Mie Prefectures and the Japan Sea-Farming Association (5). Reproduction using cultured broodstock has been developed so that artificial propagation of the species on a commercial scale will soon be feasible (6).

CLASSIFICATION AND ECOLOGY OF YELLOWTAIL AND RELATED SPECIES

Even though they are all in the family Carangidae (7), each of the species of jacks being cultured in Japan has different characteristics and requires different culture methods (Table 2). Carangids are only a few of the many fish species being cultured in Japan (Table 3).

Yellowtail (*Seriola quinqueradiata*)

Yellowtail spawn offshore from southern Kyushu to the Chugoku area of the Sea of Japan. They migrate north to near Hokkaido, feeding for three to five years until reaching sexual maturity. Then they migrate south for spawning (8). From season to season, various sizes of yellowtail can be caught in different parts of Japan; therefore, special names are given to them in the different regions (9). Differences in migratory populations include growth rate and nutritional status (10). All juveniles weighing less than 50 g (2 oz) are called Mojako. Cultured yellowtail weighing less than 5 kg (11 lb) are called Hamachi, and those heavier than 5 kg (11 lb) are called cultured Buri (to be distinguished from wild Buri) (11).

Amberjack (*Seriola dumerili*)

Aquaculture of amberjack has been growing rapidly, and the species has become a rival of yellowtail. Amberjack are distributed throughout the world. In our research (12), we have found amberjack can grow faster with better feed efficiency than yellowtail if the water temperature is higher than 17 °C (63 °F). Amberjack have higher fat content and better flavor than salmon (13,14).

Goldstriped Amberjack (*Seriola lalandi,* or *Seriola aureovittata*)

The goldstriped amberjack is a new rival of yellowtail. Both goldstriped amberjack and amberjack, especially those weighing over 5 kg (11 lb), are known to sometimes cause ciguatera poisoning. If they are raised in a net pen and fed formulated feeds, they may not accumulate the poison. Before the culture of this species is pursued, it is important to make sure that cultured fish will not contain ciguatoxin (15,16).

Goldstriped amberjack is called Hiramasa in Japan and carries the scientific name *S. aureovittata*. That species may in fact be a synonym of *S. lalandi* (17). The total annual catch of goldstriped amberjack is less than either yellowtail or amberjack.

Horse Mackerel or Jack Mackerel (*Tracurus japonicus*)

Horse mackerel have an important position in Japanese aquaculture (18). Aquaculture of horse mackerel began in 1970 when a large number of wild fish were caught and stocked alive in a net pen (19). Horse mackerel raised solely on sardines contains 20 to 40% fat in their muscle tissue (20,21). Vitamin deficiencies and an improper protein : energy ratio caused poor survival. Based on a feeding experiment with horse mackerel conducted in Mie in 1974, a formulated feed was developed, and it is now possible to raise healthy horse mackerel having meat quality as good as the wild fish (Fig. 5).

Striped Jack (*Caranx delicatissimus*)

Many Japanese select striped jack as the best fish for sashimi. Striped jack culture started about 1963. At that time, experimental operations were initiated at the Fisheries Experimental Station and Fisheries Cooperative Association in Tokyo and Nagasaki and at Kinki University (22–24). Production of juveniles was attempted because the quantity of wild fish had declined. In 1984, Harada et al. (25) succeeded in their attempts to induce spawning with injection of an artificial hormone. After that, Takamatsu et al. (26) succeeded in natural spawning and hatching through thermal stimulation. Mass production of juveniles was not possible due to unstable spawning and poor fertilization rates. Murai et al. (27) thought that the quality of the eggs was influenced by stress experienced during attempts at artificial spawning. Subsequently, their research resulted in the development of techniques for stable juvenile production. In addition, they found that injuries to the body surface caused by rough seas and handling make the fish susceptible to infectious diseases and high mortality. Selective breeding has produced higher quality striped jack broodstock (Table 4).

In the 1990s, the juvenile production of striped jack in the Kyushu area was disrupted by iridovirus infections (VNN). Thus, there are still more problems to be overcome before stable production of striped jack can occur. Imaizumi et al. (28) from the Japan Sea-Farming Association are trying to maintain fingerlings that are free of virus.

Table 2. Comparison of Yellowtail and Related Species Cultured in Japan

English Name	Yellowtail	Amberjack or Great Amberjack	Goldstriped Amberjack or Yellowtail	Horse Mackerel or Jack Mackerel	Striped Jack
Japanese name:	Mojako: under 200 g, Hamachi: 200 to 5,000 g, Buri: over 5,000 g	Kanpachi, (Akahara)	Hiramasa	Maaji	Shimaaji
Scientific name:	*S. quinqueradiata*	*S. dumerili*	*S. lalandi* or *S. aureovittata*	*T. japonicus*	*Pseudocaranx dentex* (*C. delicatissimus*)
Market size:	Up to 6 kg for fillet, 3.5–4.5 kg for sashimi	3.5–5.5 kg for sashimi	Up to 4.0 kg for fillet and sashimi	80–200 g	0.8–2.5 kg for sashimi
Price (yen/kg)[a]:	600–900: Producer, 1,200–2,500: Consumer	800–1,300: Producer, 1,500–3,000: Consumer	700–1,200: Producer, 1,500–3,000: Consumer	400–700: Producer, 1,200–2,000: Consumer	1,000–2,000: Producer, 2,000–4,000: Consumer
Maximum size:	Up to 15 kg	Up to 70 kg	Up to 50 kg	500 g	Up to 20 kg
Rearing number in 1997:	$53,303 \times 10^3$	$17,200 \times 10^3$	$2,500 \times 10^3$	$35,901 \times 10^3$	$7,443 \times 10^3$
Juvenile supply:	Wild juvenile called Mojako	Wild juvenile mainly and prefeeding juveniles imported from China and Vietnam	Large juvenile of about 700 g caught in waters around the Goto Islands	Wild juvenile	Propagated juvenile

GROWTH

Performance of marine fish raised in floating net pens varies considerably. Exact weights of individual Mojako are not usually determined before stocking. At most, the total weight of the fish being stocked is determined and then divided by the estimated total number of fish to determine the average weight. The number of Mojako in each cage is estimated further by subtracting mortalities as they occur. Using those data, the daily amount of feed is calculated by the farmers. In my 30-year career, I have often encountered farmers who do not record the amount of feed offered in their net pens. This is why there are many cases where farmers cannot calculate a reasonable feed conversion ratio.

Effects of Water Temperature

Water temperatures vary in the areas where yellowtail culture is carried out (Fig. 6). In each region, yellowtail farmers developed a characteristic way of rearing by taking water temperature changes into consideration.

Representative growth curves with average harvest sizes, a summary of the environmental conditions required for yellowtail culture, and stomach evacuation times for yellowtail on various types of feed are shown in Figures 7–9. Information on the recommended feeding frequency for yellowtail is presented in Table 5. Depending on water temperature, Mojako can usually be stocked from April through July. Harvest size varies to some extent depending on mean annual water temperature.

In subtropical regions such as Okinawa and Kagoshima, the average water temperature range is from 20 to 24 °C (68 to 75 °F). Temperature remains within the optimum range for yellowtail for more than 75% of the year. By stocking young Mojako in these areas, it is possible to obtain more than 6 kg (3.2 lb) yellowtail within two years.

The range of average annual water temperature in the Kyushu area, which includes Kumamoto and Nagasaki, is 17 to 19 °C (63 to 66 °F). Temperature is optimum for yellowtail culture for about 50% of the year. Because of the shorter period when temperature is optimal, over 70% of the yellowtail reared in the Kyushu region are three years old at harvest.

The region where yellowtail can be grown but temperature is less optimal than the regions previously mentioned is the Honshu area, which includes Shizuoka and Yamaguchi. Average annual water temperature is 18 to 19 °C (64 to 66 °F), and temperature is within the optimum range only 50 to 60% of the year. More than three years are required to produce 6 kg (13.2 lb) yellowtail. A specific feature of this region is its short autumn, which provides the fish with insufficient time to prepare for winter. If the fish are pushed to grow rapidly during

Prefecture	Average Temperature °C	Ratio of Suitable Temperature %
Okinawa	24.5	86
Kagoshima	20.9	75

Figure 8. Optimum environmental conditions for yellowtails culture (data from Nakada et al., Nisshin Feed Co., Ltd.).

fall, high winter and early spring mortalities may occur. Therefore, yellowtail weighing from 3.5 to 4.5 kg (7.7 to 9.9 lb), a size range popular for sashimi, is produced.

In the Seto Inland Sea, the average annual water temperature is lower than 17 °C (63 °F), with less than 50% of the year being conducive to yellowtail growth. Temperature falls below 10 °C (50 °F) during the last two months of winter, at which time yellowtail may experience mass mortalities. To avoid the mortality problem, fish can be transferred to warmer areas such as Kochi and Miyazaki for overwintering. When the water temperature rises again in spring the fish may be returned to the Seto Inland Sea and reared to the size appropriate for use in sashimi. Another widely used approach is to stock large juveniles from other districts in the spring. It is then possible to produce fish suitable for sashimi within a growing season.

Juvenile Resources

The number of Mojako caught annually along with the number of yellowtail farmers is shown in Table 6. In 1966, the Fisheries Agency imposed regulations limiting the number of Mojako that can be caught annually for purposes of aquaculture to about 40 million in order to conserve the resource. Allocations are made to

each prefecture by the Japan Seawater Fishery Culture Association (29). Each prefectural government decides on the allowable period for catching Mojako and allots the number of fish allowed to be caught to the individual Federation of Fisheries Cooperatives in the prefecture. In 1977, the number of Mojako actually caught was about 45 million. The number has fluctuated between 30 and 50 million for about 20 years, but dropped to 25 million in 1997. Fish farmers were, however, able to maintain a total production level of about 150,000 t despite the decrease in available Mojako. The production in 1995 was the highest at 170,000 t.

Nisshin Flour Milling Co., Ltd., in response to the development of prepared feeds such as Umisachi and Otohime, produced the increased production related to high survival of Mojako. By using the proper prepared feed, it is possible to raise healthy Mojako that initially weigh less than 2 g (0.08 oz), which was not possible when raw minced fish was fed. Another reason for increased production of cultured yellowtail was the availability of imported Mojako from other countries to compensate for the decreased domestic supply. For example, over eight million Mojako were imported from Korea during the 1980s.

Recently, the domestic supply of Mojako showed a significant decrease, and a few million were once again imported from Korea. Juvenile amberjack are usually caught with Mojako and at one time the two species were cultured together. However, amberjack are vulnerable to the parasitic worm, *Benedinia*, and the parasites will spread to yellowtail. To avoid the problem, some farmers separated amberjack juveniles from Mojako and raised them separately.

The price of amberjack juveniles is 500 and 1,500 yen for fish weighing 50 and 600 g (2 and 24 oz). The high price has made possible commercial production of propagated juveniles. Japan, via Hong Kong, has imported wild juveniles caught in China and Vietnam since 1986.

Selection of Juveniles

Fry of yellowtail and related species inhabit seaweed that breaks away from the bottom. They feed on microorganisms and small fishes while drifting north with the seaweed. During the day they swim around the seaweed, and hide inside it at night. Small Mojako of 4 to 5 cm (1.6 to 2.3 in.) stay under or inside of floating seaweed. Larger fish 0.5 to 2 m (1.7 to 6.5 ft) swim below the surface. After reaching a size of 10 to 14 cm (4 to 5.5 in.), they disperse from the floating seaweed and swim toward the shore where they are caught in set nets (30,31).

Mojako feed actively at sunrise and sunset when swarms of zooplankton also can be seen. During daytime they feed on small fishes (32,33).

Propagation of Juveniles

The Japan Sea-Farming Association and several prefectural experimental stations have already established the techniques for artificial production of about 60 marine species (34). Significant quantities of juvenile yellowtail, amberjack, goldstriped amberjack, and striped jack have been developed by aquaculturists (35–38). Viable eggs are being obtained from both wild fish and broodstock cultured on high-quality formulated feeds. Hormone injections are necessary to stimulate maturation in many instances (39,40). By using mass-produced food organisms, such as rotifers and brine shrimp nauplii fortified with n-3 highly unsaturated fatty acids (HUFA) and formulated feeds, production of healthy fry is possible (41–43).

Domestication and Rearing of Mojako

Wild juveniles are weaned to prepared feed after capture and weak individuals are eliminated. They are then sold to producers who put them in net pens. Small juvenile yellowtail and related species are sensitive to feed deprivation. If a fishing boat catches Mojako far away from port, the fish will cannibalize one another in holding tanks (44). If fasted for more than three days, Mojako fail to adapt to prepared feed (45,46). It is well known that a prolonged fasting period before first feeding in net pens has a significant negative effect on later growth rate. If a good quality prepared feed is accepted while the fish are on the collecting boat, the problem can be overcome (47).

It is very important to obtain a good quality fish for stocking, whether Mojako or large-size juveniles. Careful observation to determine that the fish look and behave normally and careful record keeping with respect to the use of medications is important to document the health of the fish to buyers. Condition information for yellowtail of various sizes is presented in Table 7.

The improved technology both in domestication and transportation made it possible to import high quality juvenile amberjack at the size of 8 to 10 cm (3.1 to 3.9 in.) from China and Vietnam (48). Amberjack culture has been started around Tainan and Penhu-dao in Taiwan. In the near future, large-scale production there is scheduled to begin in floating net pens.

Problems associated with producing yellowtail and related species in warm waters include muscle parasites

Table 7A. Condition Factor in Various Stages of Yellowtail[a]

Growth Stage of Yellowtail	Average Body Weight (g)	Abnormally Fat	Fat	Normal	Thin	Abnormally Thin
Mojako	~200	20.0 over	16.0–19.0	13.0–16.0	10.0–13.0	Under 10.0

65.7	5,400	19.0
66.2	5,800	20.0

and ciguatera. In the waters south of Kagoshima, aquaculture of these species is not feasible because of parasitism with kudoa in the muscles and the internal organ (49). In some cases, cultured juvenile yellowtail, amberjack, and striped jack have been killed due to infection of iridovirus, which was originally introduced with wild juveniles imported from tropical areas (50). Unlike wild fishes, cultured fishes are vulnerable to diseases because they are always under a certain amount of stress.

WATER QUALITY

As the price of dissolved oxygen (DO) meters and salinometers has fallen in recent years, it became possible to measure such parameters conveniently at low cost. However, few farmers record the change of DO and salinity, probably due to the confidence in their intuition fostered by long experience (51). Annual differences in water quality (Fig. 10) over periods of several years provide some insight as to what farmers can expect, but spatial and interannual variations can be difficult to predict.

There can also be large differences in temperature from the surface to the bottom of the water column as shown in Figure 11. Tateishi, a colleague who stresses that measurement of the water temperature at the depth of 10 cm (4 in.) water each day at 0800 is not sufficient. He determined diurnal changes in vertical water temperature at a Nagasaki aquaculture site in August, 1984 (Fig. 12). The data clearly indicate that it is not a good practice to judge water quality from scanty data.

In order to develop an automatic feeder that responds to fish feeding activity, we devised a system that automatically inputs data into a personal computer. The daily change in vertical water temperature was continuously recorded, using our system at a yellowtail culture site in the Goto Islands, Nagasaki, from June 16
Figure 10. Annual difference of water temperature in the past 10 years in Wakayama (data from Fukaya et al., Nisshin Feed Co., Ltd., 1967–1976).
Figure 11. Seasonal change in the water temperature at different depths (measured by Tateishi; Nisshin Feed Co., Ltd., 1984–1985 at Floating Net Pen in Nagasaki).

to 20, 1992 (Fig. 13). At the same time, we determined diurnal changes of the depths at which yellowtail were swimming in a floating net pen (Fig. 14).

AQUACULTURE FACILITIES

Yellowtail culture started in 1927 when juvenile marine fishes like jacks, mackerel, red sea bream, black porgy, and young yellowtail caught in large set nets were released into embankment-type enclosures in AdoIke in Kagawa Prefecture. Fish culture in embankment-type enclosures and net enclosures depended on tidal flow through a few sluice gates for water exchange. Red tide episodes and oxygen depletions associated with poor water exchange, along with waste feed and fecal accumulations, caused heavy mortalities in such facilities (52).

Harada et al. developed net pens (8 × 8 × 8 m, 26 × 26 × 26 ft), which were less expensive than the previously described systems (53). This method has advantages such as a high water exchange rate, lower maintenance costs, and easier fish harvesting. Thus, net pen systems were adopted quickly and successively, and almost all the farmers use this system with various sizes of structures at present.

Net-pen culture requires frequent net exchanges because of biofouling that restricts water exchange. The problem was overcome through the use of tri-butyl tin (TBT) which was ultimately banned because of toxicity problems. New chemicals are now being sought as replacements.

As net pen culture developed, increasingly larger pens were used. Pens of 15 × 15 × 15 m (49 × 49 × 49 ft) are most commonly used, and the frameworks have changed from wood to metal and reinforced plastics. Even larger pens, up to 50 × 50 × 50 m (164 × 164 × 164 ft), are in use. For large fish like yellowtail, enough space for exercise helps them build firm muscle. Recommended

stocking density of yellowtail in floating net pens is shown in Table 8. Modifications must be made based on the environmental conditions at each aquaculture site. The use of large net pens makes for high-quality meat with proper fat level (54).

Selection of the Culture Area

A good area for young yellowtail and amberjack culture should have water temperatures higher than 22 °C (72 °F) as indicated in Figure 8 (55). In nature, yellowtail migrate

north and south along the coast of Japan and their body composition changes with growth and season. Fish cultured in net pens show similar tendencies to some extent. It is interesting to note that in winter feeding, activity and growth are depressed in the southeast area like Amami and Okinawa where water temperature remained above 20 °C (68 °F) (56,57). DO affects not only digestion and absorption of feeds but also fish health, with the effects increasing with density. Without sufficient DO, the fish become more susceptible to infectious diseases (58). Under the net pens, oxygen depletions may occur due to decomposition of accumulated waste materials. During autumn the oxygen-depleted layer may rise due to convection and cause oxygen depletions and associated mortalities in net pens. Eutrophication in culture areas can lead to the development of red tide phytoplankton blooms that have caused mortality at levels of thousands of tons of cultured fish annually.

FEEDS AND NUTRITION

Early yellowtail culture depended upon the locally available trash fishes as feed. In early times, only a few farmers started yellowtail culture depending solely on locally available trash fishes, and they enjoyed high profit without occurrence of severe disease and high mortality problems. As the culture technology was disseminated to various areas, demand for trash fishes exceeded production; and commercially available sardines, which were abundant and cheap, become a main feed. Supported by Government funds, freezing equipment became available in each area; and frozen sardines supported quick development of yellowtail culture thereafter. Formerly, minced frozen sardines were fed. Considerable amounts of food remained uneaten, resulting in deterioration of culture grounds. By using frozen instead of thawed fish, the deterioration problem has been alleviated considerably. However, it became apparent that use of sardines as the sole feed for yellowtail led to nutritional disorders because of unsuitable protein and energy levels. Miyazaki (59) found that the use of frozen fish did not cause any ill effects and was better than feeding thawed sardines. The use of frozen fish alleviated deterioration of the feed and reduced environmental pollution. Body components of sardine, especially fat content, changes drastically along with seasons and harvest areas as shown in Tables 9 and 10. Fat content also differs among the Pacific Ocean stock and the Japan Sea stock as illustrated in Figure 15 (60–71).

While a good system for distributing sardines was developed that made them readily available to fish farmers, there was no control over their fat content. Sato et al. (Nisshin Nasu Feed Research Laboratory, unpublished data) found a high linear correlation between moisture and fat content of sardines landed at Kyushu, Sanin, and Kushiro. The amount of water and fat in the bodies of sardines is highly negatively correlated (water and fat equation in sardine; $y = -1.138x + 90.121$, x: moisture 57–74%, y: crude fat 25.3–59%, $n = 35$, $\gamma = 0.9702$). Thus, fat content could be estimated roughly by measuring moisture content more simply than by direct fat measurement. A more simple method is available to small-scale farmers. In Table 11, a simple estimation table is provided.

In 1979, the Fisheries Agency started a large project to develop a moist pellet diet adequate for yellowtail culture to prevent pollution coming from marine

aquaculture. However, introduction of the moist pellet to yellowtail culture failed until the early 1990s, mostly due to an abundant and extremely cheap supply of domestic sardines. At that time, fish farmers finally became conscious of the severely damaged environmental conditions around their aquaculture grounds. In 1988, a new type of dry pellet diet produced by extrusion was found to be useable in yellowtail culture.

Improvement in fish feeds has been important to the development of aquaculture (72). World production of fish meal and fish oil has fluctuated drastically so the supply of those ingredients, which are important to aquaculture, is very unstable (Fig. 16). Thus, further improvement in fish feeds, including use of alternative protein sources, has been undertaken.

The quantity of formulated feed used for yellowtail culture has increased almost linearly (Table 12). Yet more research is needed to develop dry pelleted feed and appropriate feeding techniques and to evaluate the use of inexpensive feed materials (73–75). The Fisheries Agency of Japan has been promoting development of high-quality formulated fish feeds. The Japan Fish Feed Association is involved in that effort with the help of researchers from universities and fisheries experimental stations (76). Various substitutes for fish meal can be used to decrease the amount of fish meal and fish oil in yellowtail feeds by half without adverse effects (77–79).

If fish are fed only Japanese anchovy for a long period of time, feeding activity decreases and mortality results due to vitamin B_1 deficiency. The problem can be avoided if a vitamin mix is added to the diet. Not only is vitamin B_1 added, but also vitamins C and E to prevent oxidation and fat deterioration.

Feed efficiency from minced raw fish can be improved almost twofold by adding certain binding agents; and daily feeding rate can be reduced by 20% to 30%, accompanied by a better feed conversion ratio and reduced water pollution (Table 13). The use of the right feed in the appropriate

amount is a very important factor for efficient and sustainable production. We have also recognized that this practice can improve cultured fish quality. Comparison of feed costs for yellowtail culture on various feeds can be seen in Table 14.

When raw fishes were used as the primary feed material, it is difficult to predict fish growth precisely because nutritional composition of the feed varies significantly. As information on the protein and vitamin requirements of yellowtail are developed (80), production of various types of moist pellets and formulated feeds becomes possible. Now that the production cost for yellowtail fed moist pellets or formulated feeds is less than that with raw fish, many feed makers and pharmaceutical companies have started to produce fish feeds.

If defatted and dried fish meal are used in aquaculture, fish feeds may have an insufficient lipid content in the absence of added fat (81). During the 1980s we recognized that if the ratio of formulated feed to moist pellets offered to yellowtail was increased, growth of young yellowtail deteriorated due to a decrease in protein:calorie ratio in the moist pellets. During the same period, it was common practice to provide supplemental oil in feeds used for the rearing of freshwater fishes; but the same oils could not be used for the marine species since there are significant differences in the fatty acid requirement

Table 14. Comparison of Feed Cost for Yellowtail Culture by Type of Feed

Type of Feed for Yellowtail	Growth Stage and Average Body Weight (g)	Unit Cost of Feed (yen/kg)[a,b]	Feed Conversion Rate	Production Cost (yen/kg)	Remarks
Minced raw fish sand eel	Mojako: 5–50	125	8.4	1,050	High stable quality, but high leaching
Minced raw fish spotlined sardine	Mojako: 5–200	60	16.3	978	Unstable quality and high leaching
Minced raw fish spotlined sardine	Hamachi: 50–2,000	65	12.1	787	Unstable quality and high leaching
Minced raw fish + binder	Hamachi: 50–2,000	70	6.8	476	Decreased leaching problem
Round raw fish + supplement	Hamachi: 500–2,000	60	7.6	456	Economical, but small harvest
Round raw fish + supplement	Buri: 1,000–8,000	60	8.1	486	Economical, but small harvest
Moist pellet; MP					
MP50 (50[a]: 50[b])	Mojako: 5–200	105	2.6	273	Technical difficulty in feed production
MP30 (30: 70)	Hamachi: 50–2,000	88	4.1	361	Economical and good for fish healthy
MP0 (0: 100)	Hamachi: 500–2,000	64	6.3	403	Low feed cost, but unstable quality
MP100 (100: 0)	All season for medication	140 + medicine	2.4	336 + α	Used especially for medical treatment
High fat dry pellet (C-fat more than 12%)	Mojako: 5–200	170	1.8	306	Highest performance until the end of August
High fat dry pellet (C-fat more than 12%)	Hamachi: 50–2,000	160	2.7	432	Suitable feed for least feeding rate during winter season
Extruded pellet	Mojako: 5–200	230	1.1	253	Highest growth and economical performance
	Hamachi: 50–2,000	180	1.6	288	Low feed conversion rate during winter season
	Buri: 1,000–8,000	170	2.7	459	Low feeding efficiency for large size yellowtail

[b]Frozen sardines; 60 yen/kg, feed oil; 170 yen/kg.

between freshwater and marine species. We developed a feed oil suitable for marine species that was tested in commercial production trials with yellowtail and produced fish similar in lipid composition to wild fish. However, the quality of oil containing high levels of HUFA vary, so the Society of Aquaculture Feed Oil Investigation has set up standards of feed oils recommended for aquaculture diets (Table 15). In the future, fish meal, which is a major protein source in formulated feeds, will be replaced by soybean meal or poultry meal and a certain amount of fish oil will be added along with soybean oil or coconut oil.

Extruded pellets formulated to contain more than 20% fat are efficiently utilized by yellowtail. By using extruded pellets, farmers have achieved feed conversion ratios (dry weight of feed offered/wet weight of body weight increase) as low as 1.2 during the production of one-year-old fish. Satisfactory growth has also been achieved during the second year using the same type of feed if temperatures

Table 15. Standard Feed Oil Recommended for Aquaculture Feed[a]

Factors	Specifications
Components:	Main fatty acids and glycerin ester
Color:	Yellow and yellowish brown
Condition:	Liquid in normal temperature
Smell:	Fishy odor, but not putrefaction smell
Acid value:	Max. 2.0
Iodine value:	130–160
Peroxide value:	Max. 10 meq/kg
Unsaponifiable matter:	Max. 5.0%
Water and other:	Max. 1.0%
Vitamin A:	~500 IU/g
Vitamin D:	~100 IU/g
Vitamin E:	~30 mg/100 g

[a]Specification standard of the Society of Aquaculture Feed-Oil Investigation, Riken Vitamin Co., Ltd.

are optimal. After the water temperature falls in winter, feeding activity diminishes and the fish do not consume sufficient calories for growth.

Yellowtail larger than 3 kg (6.6 lb) prefer raw fish to extruded pellets; and it is difficult to attain daily feeding rates of 2% on extruded pellets, especially during winter. The author thinks development of an extruded diet that contains more than 25% fat will be required for the economical production of yellowtail larger than 3 kg (6.6 lb), especially during periods of low water temperature.

DISEASES

If it turns out to be profitable, people will copy those who have been successful. This adage is true in fish culture so that the same kind of fish is often overproduced in a given area, which can lead to outbreaks of diseases and pollution (82). The importation of wild fry, fingerling, or juvenile fish is also a source of disease (83). In Japan, 13.9 billion yen were spent on medications for use in fish culture during 1997. Kagoshima spent 2.9 billion, with lesser amounts spent in Ehime, Kochi, and Kagawa with the amount spent falling proportional to the fish farming activity in those areas (84). The types of medications purchased annually changes based on the situation and in response to the occurrence of drug resistance (85).

Disease is usually not a problem during the initial phases of rearing a particular aquaculture species. It becomes a problem when several people try to raise the same fish in floating net pens within proximity to one another. The fish will become more susceptible to disease if fed too much and maintained in overcrowded conditions. Moreover, deterioration of the environment and nutritionally deficient feeds will aggravate the situation (86).

Nishioka et al. (87) compiled information on the occurrence of disease during juvenile production of marine fishes from 1989 to 1994. Incidence was as follows: viruses, 24%; bacteria, 23.7%; mycotic granulomatosis, 14.6%; parasites, 2.4%; and unknown, 35.2%. A large portion of the unknown category can be explained by the fact that target organisms were extremely small and the techniques for juvenile production remain to be perfected.

In order to prevent fish disease, it is necessary to maintain a healthy environment and, based on experience, predict when and what kind of diseases might be anticipated under existing conditions (88). If conditions indicate the potential for a disease epizootic, stocking density can be reduced and feeding can be curtailed. We have observed increases in the level of *Enterococcus seriolicida* in the waters around fish farms before epizootics.

Recently observed mass mortalities can be attributed to several factors (89). Environmental and nutritional stress increased the need for supplemental vitamin C and vitamin E, which can be supplemented in the diet. The most serious problem in recent years has been Iridovirus infection introduced from Southeast Asia. It causes mass mortalities in yellowtail (90) and striped jack (91,92).

Records of the amount of feed consumed and numbers of mortalities should be kept to help determine when an epizootic is occurring. Books are available to assist farmers with diagnosis of specific diseases (93–95).

The most common disease in yellowtail, *E. seriolicida*, is diagnosed by simply identifying Gram-positive bacteria by using STAN agar (96). For diagnosis of Pasteurellosis, a specific iodine solution is dropped on the spleen obtained from a sick fish. Infection with Iridovirus is confirmed by presence of abnormally hypertrophic cells from the spleen.

Mortality in cultured yellowtail can be divided into four major categories: (*1*) physical damage from handling and transportation and from contact with netting during storms and strong tides, (*2*) turbidity and pollutants, (*3*) nutritional deficiencies and the feeding of oxidized raw fish and nutritionally inadequate feeds, and (*4*) diseases. Disease often occurs in response to one or more of the other four factors. An important publication on controlling fish disease is being published by Sano (97).

For treatment of bacillus diseases, the Ministry of Agriculture Forestry and Fisheries approves 25 kinds of drugs for aquatic species. Japan has a system in which any person or officials of prefectural government may be trained and obtain a license to diagnose and treat fish diseases. Several trade publications have published special issues on the subject of disease treatment, which are used by fish farmers (98). Hara described the research needed to establish a program in marine medicine (48).

The first important step for disease treatment is to remove the causative factor. In order to prevent recurrence of the same problem in the future and to identify the actual causes, detailed records should be kept when mass mortality takes place. Also, daily management records and treatments used during epizootics should be kept.

Removal of dead fish is the first step in the prevention of further spread of disease. Both sick and dead fish should be removed from affected net pens. The amount of feed consumed in net pens where disease has occurred should be kept. Sick fish will not feed as well as healthy fish, and it is usually necessary to reduce the feeding rate to 60 to 70% of normal.

Methods for mixing medication into feed depend on feed type. For dry pellets, the medication can be dispersed in water or oil in advance, and then the solution is poured over the feed. For moist pellets, the medicine should be well mixed with the other feed material and then extruded. In both cases, it is necessary to make sure the proper amount of medication is uniformly included in the final feed. Drying the surface of pellets or coating them with oil will decrease leaching of the medication. The medicated feed should be offered quickly to the entire net pen. If fed slowly, only active fish will consume the feed.

MANAGEMENT TECHNIQUE

Proper management is critical to any fish culture operation. Overfeeding results in poor quality meat and unhealthy fish. Also, overfeeding pollutes the growout area and can promote the occurrence of red tide outbreaks that can result in mass mortality. In order to escape this

vicious circle, raising fish at the proper stocking density and providing them with the proper amount of feeding are critical.

Best management practices include maintaining daily records of fish health, feeding activity, and environmental quality (Table 16). The determination of water quality can be made with the assistance of the latest analytical equipment, but the final judgment has to be made by humans. On large farms, managers may be assigned to particular sectors. For instance, a manager for the feeding sector has the responsibility for determining the right amount of feed to provide in each net pen using his intuition. The overall manager has to confirm by checking the daily records that the feed manager is properly performing the feeding. The same would be true of other sectors, such as disease and water quality.

Proper feeding level relates to sea condition. Only people who watch the sea every day can properly evaluate the environmental conditions. The water quality depends on weather, tide, and wind velocity.

With the use of an underwater camera, the swimming activity of fish in a net pen can be documented and unusual behavior of individual fish observed. An accurate judgment as to whether a few diseased fish and mortalities represent the whole group of fish in a net pen is critical. If the wrong conclusion is drawn, the result could be either mass mortality or a waste of money on medication.

Table 16. Daily Record for Management, for Estimation of Fish Health, Feeding Activity, and Environmental Conditions

Period	Start	10th Day	20th Day	End of Month

Another important practice is to check for fish that are not healthy and may be swimming around the corners of the net pen. This can be done with an underwater mirror before and after each feeding. Observations of swimming speed of individual fish while feeding, swimming activity of the group, and fish color are also important.

The feeding activity of the fish is the clearest indicator of their health. In order to determine what portion of the fish in the net pen are participating in feeding and how vigorously they feed, daily measurement of the time spent feeding a particular net pen can be used. Thus, not only total amount of feed being used but also the time spent in offering the feed to each pen should be recorded. Table 17 shows a management record of the intermediate rearing of yellowtail as an example of feeding. For estimation of the final total weight, feed conversion ratio plays a vital role.

The major reason why the growth potential of properly fed fish is not fully realized is that stocking density has exceeded the carrying capacity of the system. Technical keys to proper rearing are shown in Figure 17. An optimum density and proper feeding rate are musts for economical production. If rearing records are accumulated at a particular site for at least three years, the optimum stocking density and feeding rate for maximum growth

and feed efficiency relative to season and fish size can be estimated. Table 18 shows the proper daily feeding rate calculated from the results of actual Mojako rearing data from 1986 to 1993. Figure 18 shows recommended daily feeding rate by size for yellowtail with the use of extruded pellets. Recommended calorie : protein ratio by season and size of yellowtail is shown in Table 19.

SHIPMENT OF THE PRODUCT

The strongest competitor for cultured yellowtail is not pork or beef; it is wild small Buri, 50 to 60 cm (20 to 23 in.) in body length, which are caught in set nets. If a large quantity of young Buri are landed at one time, their market price drops as low as 200 to 300 yen/kg (91 to 136 yen/lb), while 800 yen/kg (364 yen/lb) or more is a lowest price for cultured yellowtail. Moreover, amberjack, goldstriped amberjack, striped jack, and jack mackerel are becoming competitors in recent years.

The market for cultured fish can be divided largely into that for high-class Japanese restaurants that deal mainly with live fish, wholesale stores and supermarkets dealing with fresh and frozen fishes, and direct delivery of fillets processed to the individual restaurant and home

(99). Fish farmers are having difficulty making a profit due to the stagnant economy and excessive competition among themselves.

Recently, direct delivery from the producer to the consumer has begun. The Internet, mail, or fax can be used to order the merchandise and reliably collect the money. Producers maintain lists of reliable customers and can estimate future demands. The consumer has recognized the difference in quality of the product, so this type of delivery system has a promising future and could help stabilize fish farming.

In order to maintain high product quality, the fish should be fasted before harvesting. The main purpose of fasting is evacuation of the ingested feeds as they may contribute to rapid deterioration in fish quality as well as lead to increased oxygen consumption and water pollution due to vomiting feed during transportation.

In order to keep product freshness as long as possible, fish should be killed immediately after being taken from the water by severing the medulla oblongata. They should be bled by cutting the caudal artery with a knife. If it is impossible to treat the fish individually they should be dumped into a tank with a large amount of chipped ice. If the moribund state is prolonged or the fish are shipped without enough chilling, rigor mortis will start earlier and reduce product quality (100).

PRODUCT QUALITY

Yellowtail were once sold strictly by weight, but consumers have become pickier about product quality, so the farmers have started to produce higher quality fish. Currently, a special brand of cultured yellowtail will fetch a higher price than the ordinary products. Having stable quality of product by discarding the second grade fish and paying special attention to maintaining freshness has become highly valued by buyers. At supermarkets and retail fish stores, sales have been expanded through the marketing of special brands produced by such organizations as the Kagawa and Kagoshima Federation of Fisheries Cooperatives.

The quality of fish deteriorates much faster than that of land animals. Therefore, it is vital when dealing with fish to get the product to consumers quickly after harvest. The fish meat can be served as sashimi for about three days in cold storage, depending on rearing conditions and treatment after harvest. Rapid killing, bleeding, filleting, and proper packaging and refrigeration can lead to excellent yellowtail (101). Amberjack and goldstriped

Table 19. Proper Calorie/Protein Ratio of Feed by Season and Size of Yellowtail

Growth Stage	Average Body Weight (g)	Season	Month	Recommended C/P Ratio, kcal (kJ)[a]	Nutrient, kcal/g (kJ/g)
Mojako	0.2–10	Catching and acclimation	April–June	60–80 (251–335)	Crude protein, 4.5 (18.8)
	10–200	Acclimation and rearing	April–August	80–90 (335–377)	Crude fat, 8.0 (33.5)
Hamachi	100–800	High temperature period	May–September	90–100 (377–418)	Carbohydrate, 2.3 (9.6)
	500–2,500	Low temperature period	September–March	100–120 (418–502)	
Yellowtail	800–5,000	Rising temperature period	March–September	120–140 (502–586)	
	3,000–	Descending temperature period	September–	140–160 (586–669)

[a]Manufactured by Nisshin Flour Milling Co., Ltd.

Figure 18. Daily feeding rate for yellowtail using extruded pellet (Umisachi; Nisshin Flour Milling Co., Ltd.) (data estimated from Field Hamach Rearing Data 1986–1993 by Nakada et al., Nisshin Feed Co., Ltd.).

amberjack are more popular than yellowtail because they can be kept for more than three days under refrigeration without losing their flavor, color, and firmness. Currently, demand for them exceeds the supply.

ECONOMICS

As the cost analysis in Figure 19 shows, the gross profit for the past 10 years has not been good compared to previous years because the total income declined due to low prices. In addition, the proportion of total expenditures dedicated to the cost of juveniles has increased. Feed cost is also

increasing because of a drastic decline in the sardine resource around Japan. It is not clearly shown in the figure, but total production has changed little even though the number of fish farmers is declining. This indicates that some farmers have expanded their production.

FUTURE NEEDS

The production of better quality juveniles that show good growth rates and less vulnerability to diseases through selective breeding is an urgent need of the yellowtail culture industry. To accomplish that task, different strains

10,000 Yen	Total Income	Feed Cost	Juvenile Cost	Labor Cost	Depreciation	Miscellaneous	Gross Profit
1992	9,321	4,008	1,585	280	373	1,305	1,864
1993	9,641	3,542	1,957	186	373	1,119	2,144
1994	9,061	4,754	1,957	186	373	1,119	839
1995	8,748	5,861	1,487	262	437	1,225	(524)
1996	11,363	5,113	2,386	227	455	1,449	1,733
1997	13,500	5,670	2,700	135	405	1,485	2,835
Figure 19. Cost analysis of an actual yellowtail Culturist (Statistics and Information Department, Ministry of Agriculture, Forestry and Fisheries).

of yellowtail have to be collected to select the best strain for developing the required brood stocks.

In the past, no one thought about culturing marine species on land because of the high initial cost for facilities, but it now may be a feasible approach. First of all, the fish can be raised in water, the quality of which can be controlled by humans. Under well-controlled conditions, the fish may have fewer disease problems and exposure to pollutants can be avoided. Artificial seawater systems that perform better than natural seawater systems for larval production have been developed (102). Techniques for closed systems and automatic feeding systems are improving day by day (103). Moreover, it can be predicted that people will more readily consume cultured fish if they know that the fish have not been medicated.

Finding suitable heat sources to control water temperature remains a problem. If culture of yellowtail and related species becomes possible on land without polluting coastal areas, it will be a welcome approach for producing high-quality protein to supply an ever-increasing human population (104).

The author developed a moist pellet for yellowtail 10 years ago and has also developed a formulated feed. However, we do not have proper countermeasures for declining productivity of the fish in the growout regions or for controlling disease in intensively cultured fish. For economical and sustainable fish culture, it is indispensable to maintain an optimum stocking density based on carrying capacity. It is also important to prevent the spread of infectious diseases. Hirata and his colleague's (105) proposed developing a distribution graph of DO concentrations around culture areas to aid in proper management. Recently, real time information on the dissolved oxygen and water temperature of particular areas became available through the respective Fisheries Experimental Station and Fisheries Cooperative Association.

In order to alleviate the environmental problems associated with marine fish farming, various measures, such as dredging accumulated sediment from the bottom of the sea, using chemicals to stimulate decomposition of organic materials, prohibiting the use of minced raw fish, and prohibiting the culture of large yellowtail in favor of culturing smaller, less polluting fish, are appropriate. Moreover, increasing the propagation of lugworms, which consume organic material in the mud, and cultivating algae in close proximity to fish pens should be emphasized. The algae absorb dissolved nutrients last from feed and excreted by fish. The comprehensive utilization of natural productivity may be a direction of aquaculture in the future (106).

It is time to think about a comprehensive culture approach that utilizes the natural purification ability of the environment. Such an approach may involve polyculture not only of several species of fishes but also of crustaceans and algae (107).

OUTLINE

Plankton makes up the primary and secondary food chains in most bodies of water and is generally passively floating, or weakly swimming, minute animal or plant life. Zooplankton is considered the animal portion of plankton, whereas phytoplankton is considered the plant portion of plankton. Zooplankton generally feed upon phytoplankton. Thus, phytoplankton is referred to as the base of the food chain. Phytoplankton are considered autotrophic, because they can produce their own food from a carbon source, a simple nitrogen source, and sunlight. Heterotrophic organisms require more complex organic compounds of carbon and nitrogen to sustain life and often feed upon the autotrophes. Heterotrophic production of microorganisms, such as bacteria and protozoans, helps to provide feed for zooplankton. Zooplankton are also considered heterotrophic, and they feed upon autotrophes and other heterotrophs. Zooplankton, in turn, provides an important food source for larval fish and shrimp in natural waters and in aquaculture ponds. Zooplankton populations can be increased through fertilization management and can be harvested with plankton nets or by other means.

Zooplankton can be harvested and fed to fry, or, if fry or postlarval shrimp are stocked directly in the pond, they will prey upon the zooplankton, which thus provide an important natural food source. Although bacteria and protozoans also play important roles in the diet of larval fish and crustaceans, zooplankton is naturally their major food source until the larvae reach a certain size. The dominant zooplankton groups in ponds include Rotifera (rotifers) and Copepoda (copepods), a subclass of Crustacea; these groups remain the preferred prey for shrimp and fish. The most common zooplankters used in aquaculture are rotifers, cladocerans (water fleas), copepods, tintinnid ciliates, and, most importantly, Artemia (brine shrimp).

ROTIFERS AS LIVE FEED

The rotifer Brachionus (see Fig. 1) is one of the most important zooplankters and food organisms for the mass cultivation of larval fish in hatcheries around the world. Brachionus plicatilis is the most common species used. B. plicatilis is a euryhaline species and is extensively used as a first food for larval fish, because of its size, mobility, and nutritional value. The culture and use of B. plicatilis as food for larval fish were first developed and studied in Japan in the 1950s. Rotifers were investigated first because their blooms caused problems with oxygen levels in eel production ponds. Later in the 1950s, researchers in Japan discovered the use of rotifers as food for marine fish larvae, and the technology spread rapidly. In 1965, rotifers were first used to feed the commercially important Red Sea bream. In the late 1960s, rotifers were cultured on baker's yeast, but the commercial use of yeast as a culture medium did not spread until the 1970s. Since then, many different methods for culturing the rotifer have been developed and used. Presently, more than 60 species of marine finfish are cultured worldwide using the rotifer as live food. The developmental phases of rotifer technology are as follows:

- Introduction as feed
- Development of mass culture
- Evaluation and improvement of nutritional value
- Development of biological and genetic information
- Nutritional requirements
- Environmental control
- Automation

B. plicatilis is well suited to mass culture because of its life cycle. It is a planktonic filter feeder which feeds on organic particles that are brought to its mouth by the movements initiated by the corona, which is a ciliated organ on the head region that characterizes rotifers and serves as a means of locomotion.

B. plicatilis varies in size, depending on strain and culture conditions. Adult sizes range roughly from 100 to 300 μm (0.0039 to 0.01 in.) in length, including the egg mass on females. Strain selection is important, because reproduction rate, size, and optimum culture conditions (temperature and salinity) can all vary with strain. Two of the best known strains or morphotypes of B. plicatilis are the large (L-) and small (S-) types. The mean dry weight of the L-type is 0.33 μg/rotifer (0.000000009 oz/rotifer) and of the S-type is 0.22 μg/rotifer (0.000000006 oz/rotifer). The size range of the S-type is usually 126–172 μm (0.005–0.006 in.) in length, and the size range of the L-type is 183–233 μm (0.007–0.009 in.). Rotifers may tolerate 0–60 ppt salinity, but most production facilities indicate that 1–20 ppt is the optimum salinity range for the best growth and reproduction rates.

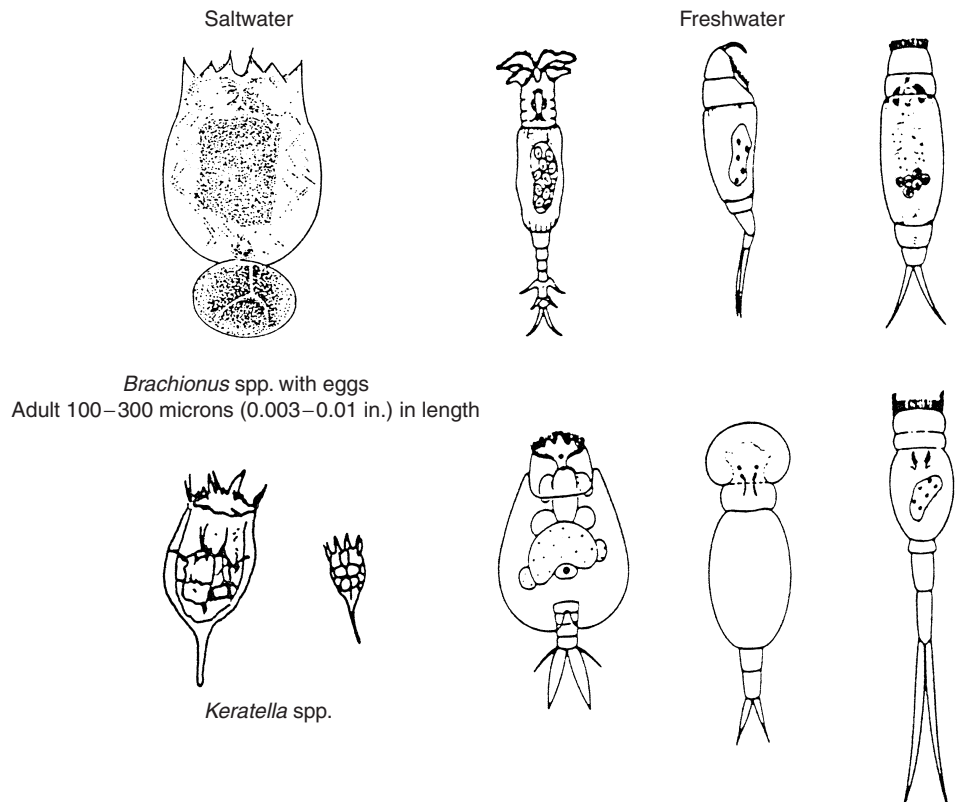

Figure 1. Rotifers. [Figure modified from (1) and (16), with permission from W.H. Freeman & Co., New York.]

There are many freshwater rotifers. The S-type rotifer is most commonly cultured outdoors. Temperature, salinity, and feed concentration all affect the rate of growth of rotifers, but temperature is the most critical factor affecting growth. The most suitable temperature range for the strains described previously is 28–32 °C (82.4–89.6 °F). Above 28 °C (82.4 °F), the salinity and size of the strain are not very critical, but the density of feed is very important. Below 28 °C (82.4 °F), the bigger strains grow faster than the smaller ones. Decreasing the salinity to 10–20 ppt increases the growth rate of both strains.

Stock rotifer cultures are used as starter cultures to initiate production in larger culture containers. The cultures should be maintained in a separate area from mass culture tanks, to prevent contamination. Stock rotifer cultures can be maintained in 1- to 2-L (0.2641 to 0.5283-gal) flasks, fed algae at 24–25 °C (75–77 °F), and placed within a light cycle of 12 hours of light followed by 12 hours of dark. The cultures are maintained in a slightly cooler environment to slow down growth and development during the stock culture period, which allows for better water quality and less maintenance. The culture should be restarted periodically (at least every month, and more often if environmental factors are poor).

Rotifers have broad nutritional requirements. They ingest many types of feed, including bacteria, as long as the size of the particle is appropriate. Rotifers also require vitamin B_{12} and vitamin A. However, the nutritional requirements of larval fish are more specific. Watanabe et al. (2) determined that highly unsaturated fatty acids (n-3 HUFAs), especially 20 : 5n-3, are essential for survival and growth of marine finfish larvae. While some species can synthesize long-chain HUFAs from short-chain HUFAs, many marine fish cannot. This is why certain feeds containing HUFAs can be as valuable as rotifer feed. Depending upon the food source, the proximate composition of rotifers consists of 52–59% protein, up to 13% fat, and 3.1% n-3 HUFAs.

There are many recognized culture methods for rotifers, both extensive (low-density culture) and intensive (high-density culture). An early method involved daily tank transfers of rotifers to fresh tanks of the same size after most of the algae was consumed. Following this procedure, batch, semicontinuous, continuous, and feedback culture techniques evolved. Each system has advantages and disadvantages. Batch culture is the most reliable method, but the least efficient. Semicontinuous culture is less reliable than batch culture, but more efficient; however, the former allows buildup of wastes, causing contamination. Continuous cultures are the most efficient and consistent, but are maintained under strictly defined conditions and are almost always "closed" and kept indoors, limiting the size and increasing the cost of operation. Another technique is the "Galveston method," in which rotifers are cultured in an open shed with unfiltered seawater and toruluse yeast as food. Rotifers are also grown in tanks that are 0.5-m (20-in.) deep and are harvested with skimmers. The feedback system, developed in Japan, uses wastes from rotifer culture (treated by bacteria and the nutrients retrieved) as fertilizer for algae cultured in a separate tank. The Japanese consider this method to be the most efficient and reliable technique.

The highest fecundity of rotifers (21 offspring/female every week) has been reported to occur when the

rotifers were raised on a pure diet of *Isochrysis galbana* (Tahiti strain) at a temperature of 20–21 °C (68–69.8 °F). Lubzens (3) and Arnold and Holt (4) have described methods of culturing rotifers, including techniques using baker's yeast and emulsified oils; algae (*I. galbana*), yeast, and emulsified oil; algae as a sole nutrient source; algae and rotifers together; and outdoor culture of rotifers. Rotifers are excellent feed for larval fish because they are small, slow swimming, can be grown in high densities, and have a high rate of reproduction. But their nutritional value can vary widely, greatly affecting larval survival and growth.

Rotifers can be enriched with fatty acids and antibiotics and are used to transfer those substances to fish larvae. For example, larval red drum (*Sciaenops ocellatus*) begin feeding on the third day after hatching (earlier if temperatures are high, later if temperatures are low), with the development of their mouth parts. Rotifers are fed to fish at this time at a rate of 3 to 5 rotifers/mL (0.034 fl. oz) until the larval fish can consume larger foods. The optimum food density varies between fish species and larval stocking densities. In comparison, when they first begin to feed, larval mullets (*Mugil* spp.) require a food density of 10 rotifers/mL (0.034 fl. oz) for densities of 25 to 50 larvae/L (33.8 fl. oz). Because the nutritional value of rotifers decreases when the rotifers are held for over six hours, it is best to feed them to fish at least two times per day, or whenever the rotifer density drops below a designated number per mL (0.034 fl. oz). For example, in red drum larval culture, feeding occurs when the rotifer density drops below 3 rotifers/mL (0.034 fl. oz).

Variations in feeding techniques occur between species of larval finfish, but generally, rotifers are fed to fish larvae as soon as the larvae have developed mouth parts [for example, 2 days after hatching for the striped mullet (*Mugil cephalus*) and, as described earlier, 3 days after hatching for the red drum]. Since one fish larva can eat as many as 1,900 rotifers/day, from 13,300 to 57,000 rotifers are needed to feed one fish larva through this period (depending on the species of fish and the size of the rotifers). Most producers estimate that three times this amount of rotifers are actually eaten (1,900 × 3 = 5,700 rotifers/day are fed per larva). Therefore, as many as 39,900 rotifers (for a 7-day period), or as many as 171,000 rotifers (for a 30-day period), may be required to feed one fish larva. However, too many rotifers present in the tank can cause the fish to ingest so much that assimilation becomes a problem.

In the past, red drum larvae were generally fed rotifers from day 3 posthatch to day 10 and then were fed *Artemia* (another zooplankter) nauplii from day 11 to 15. Weaning larvae from rotifers to *Artemia* was commonly practiced in the industry for better larval survival. More recently, red drum larvae have been weaned to artificial diets earlier in their life by cofeeding them rotifers and artificial diets (5). The protocols for feeding red drum larvae change with time and are moving away from the dependence of feeding live feeds.

If striped mullet (*M. cephalus*) larvae are fed rotifers, the quantities to use are 5 to 20/mL (0.034 fl. oz) starting on day 2 posthatch and continuing until day 40. For most marine finfish species that are reared indoors, weaning of fish from live rotifers and *Artemia* to dry food should begin a few days before transformation and finish by the time the fish are juveniles. The timing of this transition might be done in three days or take as long as two weeks, but should be done gradually. The size of food particles should be the largest that can easily be swallowed by the fish (one fourth to one half of the fish's mouth width). Starter feeds should contain 50–60% high-quality protein. Thus, the rotifer is an excellent starter feed, as it is high in good-quality protein.

Rotifers were fed to larval shrimp during the early developmental stages of shrimp aquaculture, but, for the most part, their feeding has been discontinued in modern intensive hatcheries. Larval shrimp are fed algae, and then *Artemia* and artificial diets in saltwater culture, whereas freshwater shrimp are started on *Artemia*. Most shrimp hatcheries have done away with the added step of rotifer culture.

Keratella is another genus of rotifer found in salt water (see Fig. 1), but it is not used indoors as commonly as *Brachionus*. Other freshwater rotifers can be seen in Figure 1 as well.

COPEPODS, CLADOCERANS, AND TINTINNID CILIATES AS LIVE FEED

Copepods are common zooplankton in both freshwater and brackish water and are a natural food for many finfish and crustacean larvae and juveniles (see Fig. 2). In the field, most marine larvae feed on copepod eggs and nauplii during the first few weeks of life (6). Only a few copepods, such as *Tigriopus japonicus*, have been mass cultured successfully, and even the technique for their culture employs the combination of rotifer culture and the use of baker's yeast or omega yeast as feed. The amount of yeast used to produce the copepod and rotifer combination outdoors is fairly high. At Florida State University, Nancy Marcus has cultured copepods in the laboratory under conditions designed to induce diapause egg production. In the last two decades, Marcus and others have shown that many coastal planktonic copepods spend a portion of their life in the sea bed as resting eggs (7). The eggs have been collected, incubated, and hatched to obtain nauplii to feed larval fish and crustaceans, but the technique for their culture has not been developed for commercial use.

Dr. G. Joan Holt at the University of Texas Marine Science Institute's Mariculture Research Center has been researching the possibility of using copepods as a feed source for marine ornamental fish and of using copepods to make a better larval diet. Results thus far are promising, but there is still much work to be done before copepods can be used for more than supplemental feeds. Culture and harvest techniques still need to be developed so that the copepods can actually substitute for currently used feed methods and be considered commercially viable. Marine organisms such as the pygmy angelfish (*Centropyge argi*), spotfin hogfish (*Bodianus puchellus*), yellowtail snapper (*Ocyurus chrysurus*), cubbyu (*Pareques umbrosus*), and cleaner shrimp (*Lysmata ambionensis*) have all been spawned in the laboratory by Dr. Holt, but larval rearing

Cyclops   *Diaptomus*

has been the bottleneck. According to Dr. Holt, easily cultured zooplankton such as rotifers and brine shrimp, along with artificial diets, have been unacceptable as the first feed for those organisms. However, copepods have been a suitable first feed, but using wild-caught zooplankton is time consuming, and species composition is not easy to reproduce.

A major hindrance to the cultivation of marine tropicals has been the inability to rear the larvae of most species of reef fish. The greatest success has been with substrate spawners, such as damselfish [*Dascyllus albisella* (Gill) and *D. aruanus* (L.)] (8). These fish have relatively large eggs and receive parental care during embryonic development, unlike most marine ornamentals, which produce tiny planktonic eggs and provide no parental care.

Mass culture of copepods has not yet been adopted for full commercial use, but it does offer future potential, because copepod eggs can be collected in large numbers and stored for months, like *Artemia* and rotifer cysts. It has been shown that photoperiod and temperature determine,

in large measures, the production of copepod resting eggs and that laboratory production of those eggs is possible, but has not yet proven to be economically feasible. It is hoped that copepods, as a food source, can improve the culture of species such as red drum, by reducing the size variability and the mortality rate. Copepods have not been used extensively in aquaculture because wild zooplankton are not a reliable source, and the species that have been cultured require continuous attention. Copepods also have a reputation in aquaculture as being difficult to maintain on a continuous basis. Most of the studies conducted on copepods as potential food sources for finfish have relied on wild net-collected plankton (9). This approach has generally resulted in good growth and survival of the fish and has shown that when offered mixed-plankton diets, young turbot (*Scophthalmus maximus*) larvae consumed more copepod nauplii than rotifers and preferred copepod nauplii, due to the differences in size and swimming patterns of the two prey types.

Stottrup and Norsker (10) reported on the production and use of copepods, especially harpacticoids, in marine

fish culture. They also mentioned the potential of using resting eggs of copepods, similar to the method currently practiced with *Artemia*. Other studies have relied on laboratory-cultured copepods for use as live feed. Klein Breteler (11) reared copepods in vessels as large as 100 L (26 gal) for experimental purposes and suggested that the copepods could be useful food items for mariculture. Stottrup et al. (12) described a 450 L (118 gal) system for rearing *Acartia tonsa* and reported that the system would provide 250,000 nauplii per day for fish larvae cultures. According to Watanabe et al. (2), the Japanese have routinely cultured the copepods *Tigriopus* and *Acartia* for rearing fish larvae approximately 7 mm (0.28 in.) in length. Kraul et al. (13,14) compared the growth and biochemical composition of mahimahi (*Coryphaena hippurus*) larvae that were cultured in 700 L (185 gal) tanks and fed brine shrimp, rotifers, and the copepod *Euterpina acutifrons*. Larvae fed copepods survived better under stressful conditions. More recently, Sun and Fleeger (15) have described a system for the mass culture of a benthic marine harpacticoid copepod, which, they suggested, would be useful for aquaculture.

Herbivorous copepods are primarily filter feeders and typically feed on very small particles. But they have the ability to feed upon larger particles, which gives them an advantage over rotifers. Copepods can also eat detritus, called "marine snow" (16). Copepods differ from *Artemia* (brine shrimp) and rotifers in that they lack the ability to reproduce asexually. Copepods mate sexually after maturing, and the female produces between 250 to 750 fertilized eggs, depending on the species and the size of the female. Unlike rotifers, which have a small brood size of 15–25 per female and exhibit rapid development, with life spans of 5 to 12 days, the life span of a copepod can range from 40 to 50 days and has a longer generation time (1 to 3 days for rotifers vs. 7 to 12 days for copepods).

A cylindrical shape characterizes copepods, with a trunk composed of 10 segments, consisting of head, thorax, and abdomen. Adult copepods have body sizes ranging from 0.5 to 5.0 mm (0.01 to 0.19 in.) (16). The larval stages consist of six naupliar and 6 copepodite stages. The main suborders of copepods found in brackish water ponds are calanoids (*Acartia*, *Calanus*, and *Pseudocalanus* spp.), harpacticoids (*Tisbe* and *Tigriopus* spp.), and cyclopoids (see Fig. 2 for shape differences between these copepods).

Other copepods considered to be promising species for mass culture are as follows: *Acartia clausi*, *A. longiremis*, *Eurytemora pacifica*, *E. acutifrons*, *Oithona brevicornis*, *O. similis*, *Pseudodiaptomus inopinus*, *P. marinus*, *Microsetella norvegica*, and *Sinocalanus tenellus*.

Cladocerans, or water fleas (see Fig. 2), such as *Daphnia magna*, have been cultured as live food. Pennak (17) has discussed the life history of cladocerans. Other cladocerans considered to be promising species for mass culture are *Evandne tergestina*, *Penilia avirostris*, and *Podon polyphemoides*. The cladoceran *Moina macrocopa* has been used in Southeast Asia as feed for sea bass fry immediately after weaning from *Artemia* sp., and prior to feeding minced fish flesh. During this period, sea bass, being a catadromous species (i.e., a species that moves into

freshwater for a portion of its life cycle), may be reared at lower salinities, to allow feeding of freshwater zooplankton; but this practice is not commonly used and has not proven to be viable on a commercial scale. Many laboratories use *Daphnia* as the invertebrate of choice for conducting toxicity tests, because it is easy to culture and maintain in the laboratory. Cladocerans are mainly freshwater zooplankters, do not tolerate salinities higher than 3 ppt, and are generally not found in brackish water ponds (16).

Tintinnid ciliates, which are consumed by larval fish and crustaceans in the wild, have also been considered to be promising candidates for mass production. However, since the technology for mass production of rotifers is well established and microparticulated diets are being cofed with rotifers or have been developed to partially substitute for live food, the role of copepods, cladocerans, and tintinnid ciliates in aquaculture is not as important as that of rotifers.

ARTEMIA AS LIVE FEED

Artemia (brine shrimp) are probably the most important and most widely used zooplankter in aquaculture. Brine shrimp eggs, or cysts, are easily purchased and hatch readily when placed in seawater overnight. Before the eggs are placed in seawater, they are generally exposed to active household bleach for a specified period of time. This process is called *decapsulation*. Decapsulation disinfects and softens the shell and makes it easier for the nauplii to emerge from the eggs. Once brine shrimp nauplii have hatched, they can easily be separated from the shells and other debris and are then fed to the fish or crustacean larvae being cultured. The ease of feeding *Artemia* nauplii to cultured animals and the superior nutritional value of *Artemia* ensure that brine shrimp will be used in hatcheries for many years to come. However, artificial diets are slowly being developed that may substitute for *Artemia* in the future.

MAINTAINING ZOOPLANKTON IN TANKS AND PONDS

Zooplankton blooms can be managed indoors and outdoors in tanks and ponds by fertilizing the water with organic products, such as manure, cottonseed cake or meal, fatted soybean meal, and so on. It is important not to remove the fat in the soybean meal, in order to have proper results with zooplankton blooms in ponds. The fertilizer acts to stimulate phytoplankton growth and density, which are in turn fed upon by zooplankton. Zooplankton also feed upon the organic matter of the fertilizer itself. Survival and adequate growth of cultured finfish and crustaceans in tanks or ponds are strongly dependent on the availability of suitable live food organisms of the proper size and in sufficient numbers. The presence of zooplankton ensures the initiation of feeding by larvae or fry and subsequent growth and survival during the rearing period of the juvenile crustacean or fingerling stage of finfish.

In ponds, live zooplankton can be caught with a plankton net (18), pulled from the bank or towed from a boat

(19) or harvested by using a low-volume impeller pump that concentrates the zooplankton in a net (20). All of these methods are inefficient and labor intensive, and the impeller pump mutilates some zooplankton (21). Although large-scale harvest of zooplankton from marine environments has been successful (22), the bulky harvesting apparatus may not be suitable for use in small hatchery ponds. Graves and Morrow (21) modified a Fresh-Flo propeller-lift pump (model MD, 1/20 hp, Fresh-Flo Corp., Cascade, WI) originally designed for aeration to make a zooplankton harvester (see Fig. 3). After modifications, the pumping capacity was 178 L/min (47 gal/min). Pumped water was discharged into a $0.91 m \times 0.45 m \times 0.45 m$ (36 in. $\times$ 18 in. $\times$ 18 in.) floating Saran basket with 0.5-mm (0.02 in.) mess apertures. Harvesting zooplankton at night with a light was the most effective collection method (21), and only the size of the catch basket appeared to limit the amount harvested. Harvest periods longer than six hours resulted in clogged basket meshes and losses of zooplankton due to overflows from the catch basket. With one catch basket, up to 2.7 kg (6 lbs) of live zooplankton can be harvested at night from fertilized ponds. A larger mesh of 2 mm (0.08 in.) placed in front of the smaller meshed nets allowed passage of most zooplankton, but retained undesirable aquatic insects. The system provides zooplankton for feeding and for inoculation.

A zooplankton tube sampler (see Fig. 4) (23) or a plankton net can be used to assess zooplankton
Figure 4. Zooplankton tube sampler. From (23), with permission from *The Progressive Fish-Culturist*. All measurements are in inches.

populations in ponds. The tube sampler is used by rapidly lowering the vertical tube to the desired depth. The check valve is self-operating, opening when the sampler is lowered and closing immediately when the sampler is raised, trapping a known amount of water. The sample is released by lifting the check valve with a finger. A sample can be concentrated by straining it through netting of the appropriate mesh size.

Zooplankton may be sampled from a pond with a Wisconsin-style plankton net, which may be obtained from Wildco Supply Company, Saginaw, MI. This sampler is available with either 80 μm (0.0031 in.) or 153 μm (0.006 in.) nitex netting. The smaller mesh is recommended for retaining rotifers and copepods. Plankton net-sampling methods have been standardized by the American Public Health Association (APHA), and oblique tows, in which the net is lowered to some predetermined depth in the pond and raised at a constant speed for a known distance, allow the sampler to estimate the amount of zooplankton in a pond.

As in microalgae production, indoor zooplankton production costs are high. The ratio of rotifer biomass to target species is generally 3 : 1. The estimated cost of rotifer mass production using large-scale batch methods is US$4.50/1 million rotifers. Of these production costs, 72% is for feed (50% for live algae, 22% for yeast). Continuous cultures using chemostats offer future promise for improving indoor rotifer mass culture economics, but at the present time, these systems are still very expensive to operate, remain in the research and development phase, and are not commercially viable. As with most indoor-versus outdoor comparisons, the outdoor production of zooplankton is less expensive, but, for reasons associated with climate, may not always be possible.

Figure 3. Diagram of modified propeller-lift pump for harvesting zooplankton. From (21), with permission from *The Progressive Fish-Culturist*. All measurements are in inches.

POND MANAGEMENT FOR ZOOPLANKTON

Management of ponds for zooplankton may require fertilization, liming, chemical treatment, and inoculation. Most healthy water sources have an abundance of zooplankton, but the ability of water to support the zooplankton depends on the availability of nutrients for the food chain. The water source generally has a variety of zooplankters. The types of zooplankton in a pond can be controlled with the use of chemicals. For example, low concentrations of organic phosphorus acid esters kill cladocerans, but do not affect rotifer populations (24). Most ponds are fertilized with either organic or inorganic fertilizers or a combination of both. Good organic fertilizers are alfalfa, cottonseed meal, fatted soybean meal, and manure. Combining the two types of fertilizers (i.e., organic and inorganic) promotes a diverse autotrophic and heterotrophic microbial community, necessary to improve zooplankton abundance. Phytoplankton, the base of the food chain, require inorganic nutrients, carbon dioxide, water, and sunlight to produce their own food. The key nutrient in regulating phytoplankton or autotrophic production in freshwater is phosphorus, whereas nitrogen is generally considered the limiting nutrient in brackish water. Inorganic fertilizers promote phytoplankton growth, and organic fertilizers and their decomposition promote the heterotrophic production of microorganisms, such as bacteria and protozoans, that help feed the zooplankton.

There are numerous fertilization regimes that have been used by pond managers for years, but the most successful ones generally provide a way for the fertilizer to solubilize quickly, disburse rapidly and evenly, and generally have a low carbon-to-nitrogen ratio or, in other words, a $10-20:1$ N:P ratio. Other information on fertilization and zooplankton can be found in (25–36). Additional information is also available on pond management (37,38), fertilization (39), liming (40), chemical treatments (41), inoculation (42), and zooplankton identification (43,44).

INDEX

Page references in **bold** type indicate main articles. Page references followed by italic *t* indicate material in tables. If a main article appears as a subheading, there may be additional index terms at the main heading location of that topic. Countless disease agents and diseases are discussed in the context of specific cultured species. A complete list of every species covered in a main article is contained in the index entry "Aquaculture (of specific organisms)".

A COMPREHENSIVE, ONE-STOP REFERENCE TO THE SCIENCE, TECHNOLOGY, AND ECONOMICS OF AQUACULTURE

Technological advances, coupled with the mounting pressures of global food production, have dramatically changed aquaculture in recent decades. And while there has been an explosion of books and articles on its different facets, none of these provide a single comprehensive reference to this evolving and fascinating field. With an emphasis on current trends and sustainable practices, the *Encyclopedia of Aquaculture* presents complete A-to-Z coverage for a multitude of scientific, technical, and economic topics encompassed by the discipline. From abalone to zooplankton culture, over 150 timely and authoritative entries explore such areas as:

- Primary species being cultured worldwide, as well as species under development

- Echinoderms, molluscs, crustaceans, and finfishes

- Aquaculture for food, research, bait, aquariums, and endangered species recovery

- Management techniques for water and feed quality as well as disease control

- Different aquaculture systems—from pond production to marine net-pens

- Environmental issues and the economic feasibility of closed and offshore systems

- Business plans, marketing, and sales

Complete with photographs, illustrations, and graphs as well as references to the extensive literature, the *Encyclopedia of Aquaculture* is a handy, easily accessible resource for scientists and professionals in aquaculture as well as individuals wishing to expand their knowledge of the field.
