FOREWORD

There are many definitions of the word aquaculture. Those concerned with the collation of statistical data concerning food production through aquaculture tend to be very specific; they embody the concept of stock ownership as well as its management, to distinguish between the harvest from capture fisheries and from farming. One simpler definition[1] of aquaculture is the "cultivation of plants or breeding of animals in water." Many different activities fall within this definition. The farming of aquatic animals and plants for direct or indirect human consumption is the field with which I am most familiar but it is clear that this definition of aquaculture would encompass many other activities, including the rearing of aquatic animals and plants for and within public and private aquariums and research facilities, the production of bait fish, and the hatchery and nursery rearing of stock intended for fisheries enhancement or restocking programs. In aquatic food production the word aquaculture has sometimes erroneously been used to imply culture in freshwater, while the word mariculture has been used to refer to culture in seawater. In fact, the word aquaculture embraces culture in all salinities, ranging from freshwater through brackishwater and full-strength seawater to hypersaline water.

The production of an aquaculture encyclopedia at this moment in history is particularly appropriate, since the positive and negative impacts of food production through aquaculture are frequently discussed by scientists not working in this specific field, by the media, and by the public. Often, such discussions are marred by misunderstandings about the various terms utilized. The public image of aquaculture is not always good. While some ventures have undoubtedly caused environmental and/or socioeconomic harm in the past, the emphasis now is on sustainable aquaculture, which implies responsibility. The FAO Code of Conduct for Responsible Fisheries includes many Articles which are specific or related to aquaculture. Many other attempts are being made to enhance the responsibility of aquaculture producers, which range from large commercial enterprises providing products for domestic and export markets to small-scale rural farmers seeking to produce family food and income. Attempts to mollify consumer concern for the environment through the "eco-labelling" of aquaculture products produced under responsible conditions are on-going.

The scale and importance of food production through aquaculture can be illustrated by a few examples:

- By 1996, more than nine out of every ten oysters, Atlantic salmon, and cyprinids consumed were products of aquaculture. Four out of every five mussels and three out of four scallops were cultured; 27% of all shrimp originate from aquaculture;
- In 1997 (the most recent year for which international statistics are available), global aquaculture production totalled 28.8 million tons of finfish, crustaceans, and molluscs for direct human consumption, worth US$45.5 billion; 7.2 million tons of seaweed (worth US$4.9 billion) were also produced;
- A considerable proportion of the harvest from capture fisheries is destined for the production of fish meal and fish oil, which are primarily used by the feedstuff industry. Capture fisheries production available for human consumption has been on a plateau or increased only slowly for many years;
- Aquaculture thus remains the major means of maintaining current per capita "fish" availability. It has been estimated that global aquaculture production will need to expand to 62 million tons by 2035 to maintain 1993 global average per capita consumption levels.

The *Encyclopedia of Aquaculture* will assist the many scientists, economists, sociologists, administrators, and politicians who are either directly involved in aquaculture itself or are concerned with resource use and environmental matters. The book will also be useful for those concerned with development and planning issues. In addition, this book provides information of relevance to those in the general public who consume aquaculture products, engage in recreational fisheries or keep aquariums, as well as those who belong to organizations concerned with animal welfare and environmental conservation.

The *Encyclopedia of Aquaculture* will thus serve as an essential handy reference book for a very wide audience, and its Editor-in-Chief and Editorial Board are to be congratulated on undertaking the task of producing this unique document. I hope all its readers will find it as useful as I shall.

MICHAEL B. NEW
Past President, World Aquaculture Society
Board Member, European Aquaculture Society

PREFACE

Aquaculture is the production of aquatic plants and animals under controlled or semicontrolled conditions, or as is sometimes said, aquaculture is equivalent to underwater agriculture (1). The term mariculture refers to the production of marine organisms; thus, it is less inclusive than aquaculture, which relates to both marine and freshwater culture activities.

A primary goal of aquaculturists has been to produce food for human consumption. Various species of carp top the list in terms of aquacultural production. Most of that production is in China, though India and certain European nations also produce significant amounts of carp. In North America, channel catfish farming is the largest aquaculture industry. Others of importance include trout, crawfish, and various species of shellfishes. Seaweed culture as human food is a major industry, particularly in Japan and other Asian nations.

Supplementing the human food supply is not the only goal of aquaculturists. Many of the species taken by recreational anglers are produced in hatcheries and reared to a size where they can be expected to have a good chance of survival before being released into the natural environment. Continuous stocking may be necessary in some bodies of water, while in others resident breeding populations may become established. Examples in North America are largemouth bass, northern pike, muskellunge, red drum, various species of trout, Atlantic salmon and Pacific salmon. Many of the fish produced for stocking purposes are reared in public (state or federal) hatcheries, but increasingly, private hatcheries are becoming a source of fish, particularly in conjunction with stocking farm ponds and private lakes.

The ornamental fish industry depends on animals caught in the wild and on those produced by aquaculturists. Most of the bait minnows available in the marketplace come from fish farms. Seaweeds are not only consumed by people as food, they are also a source of such chemicals as carrageenan and agar, which are utilized in everything from toothpaste and cosmetics to automobile tires. Squid and cuttlefish are not being produced to any extent as human food, but they are reared as a source of giant axons for use in biomedical research. An increasing number of potential pharmaceuticals are being identified from marine organisms. Culture of various species from a number of phyla, many of which have held little or no interest for aquaculture in the past, show promise as one means of meeting the demand for cancer-fighting and other types of drugs. A new, and potentially large aquaculture enterprise could be founded upon such species.

The roots of aquaculture can be traced back to China, perhaps as much as 4,000 years ago. Many nations have had some form of aquaculture in place for one or more centuries, but it is only since about the 1960s that scientists began to conduct research that brought the discipline to its current level of development. Since 1960, typical annual pond production rates have jumped from a few hundred kg/ha (one kg/ha is approximately equivalent to one pound/acre) to several thousand kg/ha. Much higher rates of production are possible in such water systems as raceways and marine net-pens, which are known as intensive culture systems. Ponds are generally considered to be extensive culture systems.

Improvements in production over the past few decades have been associated with the development of sound management techniques that include water quality and disease control, provision of nutritionally complete feeds, and the development of improved stocks through selective breeding, hybridization, and the application of molecular genetics technology. Many species that could not be spawned or reared a few decades ago are now being produced, because of technological breakthroughs, in large quantities by aquaculturists around the world.

Predicted peaking of the world's wild capture fishery at 90 million metric tons (about 99 million short tons) occurred in 1989 (2). Since that time global wild capture landings have been relatively stable. Given increasing demand for seafood, including freshwater aquatic species, and a stable to declining wild catch, the shortfall must come from aquaculture. As of 1992, about 18.5% of global fisheries output was attributable to aquaculture (3), and while aquaculture production is increasing, there is some question as to whether the growth of aquaculture can keep pace with demand.

In 1992, 88.5% of the world's aquaculture production came from Asia (3). Because of suitable growing conditions year round, the vast majority of aquaculture production comes from low temperate and tropical regions. Relatively inexpensive land and labor, accompanied by large expenses of undeveloped coastline with abundant supplies of water and few environmental regulations have contributed to the establishment of much of the industry in developing nations. Conditions are changing however. Many of the best areas for aquaculture have been taken, environmental stewardship is beginning to receive the attention of governments in many developing countries, and the once abundant supplies of high quality water are being fully utilized in many areas. Thus, the face of the industry is changing. Closed system technology, which includes continuous water treatment with little or no effluent, and the development of culture systems located in the open ocean are seen as technologies that will provide opportunities for virtually unlimited expansion of aquaculture. Much of the technology for closed and offshore systems has been developed, but in many instances employment of that technology has not translated into economic feasibility. As greater efficiencies in production are achieved, new species which have higher market prices are developed, and demand increases, the economic picture can be expected to improve.

The field of aquaculture encompasses many technical disciplines and trade as well as business management and economics. Knowledge of plant and/or animal breeding, animal nutrition, water and soils analysis, surveying, computer science, pathology, carpentry, plumbing, electrical wiring, welding, and bookkeeping are among the skills that are required on a working aquaculture facility.

A good aquaculturist is involved in every aspect of the activity, from reproduction of the parent organisms through rearing of the young, to final disposition, whether that involves direct sales to the public, sales to a processor, or stocking of public or private waters. The job of the aquaculturist is not completed until the consumer, whether a patron at a restaurant, a home fish hobbyist, or the angler who is using bait minnows, has received the produce of the aquaculture facility in acceptable condition.

The *Encyclopedia of Aquaculture* has been designed for use by both those who have some knowledge of the field or may even be aquaculture professionals, as well as for individuals who are interested in learning more about aquaculture, perhaps with the idea of becoming involved. Our intent is to provide information that is readily understandable by people who have at least some science background, without insulting professionals in the field. Some topics are mentioned or briefly summarized in several entries, but when a topic is only given cursory treatment the reader is referred to one or more additional contributions that provide more detailed information on the same topic.

The *Encyclopedia of Aquaculture* was written by experts from academia and government agencies and by practicing aquaculturists in the private sector. Entries are followed by bibliographies designed to document the information present, as well as provide readers with an opportunity to further explore each topic in more depth.

CONVERSION FACTORS, ABBREVIATIONS, AND UNIT SYMBOLS

SI UNITS (Adopted 1960)

The International System of Units (abbreviated SI) is being implemented throughout the world. This measurement system is a modernized version of the MKSA (meter, kilogram, second, ampere) system, and its details are published and controlled by an international treaty organization (The International Bureau of Weights and Measures).

SI units are divided into three classes:

BASE UNITS		SUPPLEMENTARY UNITS	
length	meter[†] (m)	plane angle	radian (rad)
mass	solid angle	steradian (sr)	kilogram (kg)
time	second (s)		
electric current	ampere (A)		
thermodynamic temperature[‡]	kelvin (K)		
amount of substance	mole (mol)		
luminous intensity	candela (cd)		

Quantity	Unit	Symbol	Acceptable equivalent
volume	cubic meter	m^3	
	cubic diameter	dm^3	L (liter) (5)
	cubic centimeter	cm^3	mL
wave number	1 per meter	m^{-1}	
	1 per centimeter	cm^{-1}	

In addition, there are 16 prefixes used to indicate order of magnitude, as follows:

Multiplication factor	Prefix	Symbol
10^{18}	exa	E
10^{15}	peta	P
10^{12}	tera	T
10^9	giga	G
10^6	mega	M
10^3	kilo	k
10^2	hecto	h[a]
10	deka	da[a]
10^{-1}	deci	d[a]
10^{-2}	centi	c[a]
10^{-3}	milli	m
10^{-6}	micro	μ
10^{-9}	nano	n
10^{-12}	pico	p
10^{-15}	femto	f
10^{-18}	atto	a

[a]Although hecto, deka, deci, and centi are SI prefixes, their use should be avoided except for SI unit-multiples for area and volume and nontechnical use of centimeter, as for body and clothing measurement.

For a complete description of SI and its use the reader is referred to ASTM E380.

A representative list of conversion factors from non-SI to SI units is presented herewith. Factors are given to four significant figures. Exact relationships are followed by a dagger. A more complete list is given in the latest editions of ASTM E380 and ANSI Z210.1.

[†] The spellings "metre" and "litre" are preferred by ASTM; however, "-er" is used in the *Encyclopedia*.

[‡] Wide use is made of Celsius temperature (t) defined by

$$t = T - T_0$$

where T is the thermodynamic temperature, expressed in kelvin, and $T_0 = 273.15$ K by definition. A temperature interval may be expressed in degrees Celsius as well as in kelvin.

OUTLINE

INTRODUCTION

Abalone are herbivorous marine gastropods represented throughout the world's oceans by about 70 species. Abalone have traditionally been a highly prized seafood item, and they were used more than 5,000 years ago by Native Americans along the Pacific coast of North America for food and for the manufacture of shell implements and mother-of-pearl decorations. The earliest fisheries occurred in China and Japan around 1,500 years ago; and within the past 50 years, fisheries have developed in every country with an exploitable abalone resource. Efforts to manage these fisheries have often been unsuccessful due to a lack of knowledge of population dynamics and the upswing in poaching as harvests declined and the abalone became increasingly valuable. Today, most wild abalone populations are being harvested at or above maximum sustainable yields. This situation provides an excellent opportunity for abalone farming, and considerable effort is underway throughout the world to establish abalone farms.

ABALONE CLASSIFICATION AND BIOLOGY

Abalone are in the phylum Mollusca, a predominantly marine phylum that includes other cultured species such as clams, oysters, and scallops. They are members of the class gastropoda which includes snails. All members of the class are univalves, having one shell, unlike the bivalve oysters and clams which have two. All abalone belong in the family Haliotidae and are members of the genus *Haliotis*.

The prominent shell of the abalone encases the animal and the large centrally located muscular foot that is used to clamp tightly to hard surfaces (Fig. 1). In attached abalone, water enters under the shell, passing through the mantle cavity and over the paired gills before exiting through respiratory pores in the dorsal surface. In the head region, the eyes are located on extended eyestalks; and two enlarged cephalic tentacles extend anteriorly (Fig. 2). The mouth is at the base of the head region and houses a rasp-like radula which is used to scrape food from hard surfaces or consume macroscopic algae. The mouth leads to the esophagus and connects to the gut located between the muscular foot and the shell. The gut wraps around the foot opposite the gonad and terminates in the mantle cavity where waste material is released to exit through the respiratory pores.

A thin mantle and epipodium circle the foot. In a resting animal, small sensory tentacles on the epipodium are visible protruding from the shell periphery. Prominent gonads are visible arcing around about one third of the foot toward the rear of the abalone. The gonads release mature gametes into the mantle cavity where they are broadcast out through the respiratory pores.

The abalone heart is located near the mantle cavity and pumps oxygenated blood from the gills into the foot via two arteries. From there it is distributed via smaller and smaller arterioles to the organs. Returning blood is collected in a sinus located in the muscular foot and flows in veins back to the gills. The location of these arteries, veins, and the blood sinus in the foot make abalone extremely vulnerable to even small cuts in the foot muscle, which can cause them to bleed to death.

Cultured Species

Of the approximately 70 species of abalone in the world there are only 10 that support large commercial fisheries.

Figure 1. Red abalone (*H. rufescens*) showing prominent muscular foot (35 mm color side).
Figure 2. Dorsal view of abalone internal organs with shell removed (California Department of Fish and Game).

Six of those are currently grown in significant numbers. The primary regions where culture is underway are indicated in Table 1 (1). The shell lengths listed are for large wild animals while most cultured product is marketed at 5 to 20 cm (2 to 4 in.). Many of those listed and other species have been transported around the world for research and small-scale growout trials.

Water Quality

Abalone require excellent water quality, which is not surprising given the clean ocean waters in which they evolved. Those coastal waters are saturated with dissolved oxygen and experience fairly stable levels of pH, ammonia, salinity, and temperature. Optimal growth is temperature-dependent and varies between life stages and species. The pH should be around 8.0 and the salinity kept stable between 32 and 35 ppt. Abalone are poor osmoregulators and culture tanks should be shielded from excessive rainfall.

Abalone are very sensitive to hydrogen sulfide, which is produced by the anaerobic breakdown of dead animals, uneaten feed, and feces. Reduced growth has been observed at levels as low as 0.05 ppm H_2S. Ammonia is produced as a metabolite by many aquatic organisms and is toxic to most at levels above 1.0 ppm (un-ionized form). Abalone are especially sensitive to ammonia, showing reduced oxygen consumption at levels as low as 10 µg/L and feeding inhibition at 70 µg/L.

Reproduction and Broodstock

Abalone are dioecious, having separate males and females. The gametes are fertilized externally (Fig. 3). In mature abalone, the sexes are easily distinguished with the male gonads having a cream or pale yellow color, while the mature female gonad has a green coloration. The reproductive cycles of abalone are seasonal and related primarily to water temperature. In temperate species, gonadal development and gamete production increase with temperature; while in tropical species, gonadal development is reduced but not absent at the warmest times of year (1–3). Spawning induction is generally easier in smaller animals, and many hatcheries have also noted that first generation hatchery-reared abalone spawn more readily than wild broodstock. High fertilization rates (above 85%) and larval survival (normally greater than 70%) have resulted in relatively moderate broodstock management requirements.

Abalone are highly fecund molluscs and in temperate species, female abalone measuring 75 to 100 mm (3 to 4 in.) in shell length and weighing 120 to 150 g (4 to 5 oz) routinely release 3 to 6 million eggs per spawn. Large female abalone from temperate waters measuring 20 cm (8 in.) can release over 11 million eggs. Males release

Figure 3. Abalone life history (California Department of Fish and Game).

Table 1. Principal Cultured Abalone (1)

Species	Common Name	Shell Length, [mm (in.)]	Primary Region
H. discus hannai	Ezo awabi	190 (~7.5)	Japan
H. diversicolor supertexta	Tokobushi, small	50 (~2)	China, Taiwan, Japan
H. iris	Paua or black	170 (~7)	New Zealand
H. midae	Perlemoen	90 (~4.5)	South Africa
H. rubra	Black lip	130 (~5)	Australia
H. rufescens	Red	250 (~10)	Mexico, Chile, United States

Total Number of Abalone Induced to Spawn				Percentage of Abalone that Spawned			
Wild		Cultured		Wild		Cultured	
Male	Female	Male	Female	Male	Female	Male	Female
180	450	540	765	51% ±10	27% ±9	43% ±8	38% ±5

[a]All farms had been in production for a minimum of two years (mean ñ s.d., $n = 4$) (8).

copious amounts of sperm, usually more than is required for breeding purposes in cultured populations. Mature temperate species can become gravid in the hatchery in three to four months, while less time is required with tropical species (1,2,4). The size at first sexual maturity is about 35 to 40 mm (1.5 to 4 in.) in shell length for temperate species.

The goal of broodstock management is to provide sexually mature animals in spawning condition throughout the year and not be reliant on wild broodstock; however, many farms still utilize some wild broodstock to maintain production and genetic diversity (Table 2). Currently about one-half of the abalone production broodstock are from wild populations. Maintaining genetic diversity is an important issue as high fecundity allows relatively small numbers of broodstock to meet hatchery needs, and this could result in inbreeding and genetic drift (9–11). The control of abalone reproduction and spawning induction techniques were developed during the 1970s (5,6). Reproductively mature abalone are induced to spawn by using ultraviolet irradiated seawater at low seawater flows, 180 to 200 ml (6 to 7 oz), or by introducing hydrogen peroxide (5 M) to seawater. Other treatments that may be utilized to induce spawning are desiccation or temperature changes (2). Mature eggs are extruded from the gonads and released through the respiratory pores. Extruded eggs are collected and rinsed prior to being resuspended in seawater and the addition of sperm to achieve a concentration between 10^5 and 10^6 sperm/mL.

Broodstock abalone are maintained separately by sex at low density with a continual supply of feed. Many farms also supply broodstock with a diverse algal diet in addition to the kelp provided to production tanks. In Australia, China, Japan, and New Zealand, abalone reared and maintained on prepared diets have been successfully induced to spawn. The control of broodstock conditioning varies among species, but the primary needs are a balanced diet, good quality seawater, and appropriate temperature and photoperiod. In addition, every effort is made to avoid exposure to potential pathogens and reduce stress related to handling and tank maintenance.

In North America, red abalone (*H. rufescens*) broodstock measuring 8 to 12 cm (3 to 5 in.) are held at low density in tanks supplied with seawater at ambient temperature and photoperiod. They are fed a variety of red and brown algae and are able to digest both (2,7). Broodstock are tagged to maintain records of individual spawnings, fecundity, and performance of progeny. Monitoring this early performance is especially important in an animal with a four-year production cycle. Correlating early growth

with overall performance is an important management tool in some shellfish farming enterprises (13). In South Africa, *H. midae* broodstock are conditioned in a similar system but sexually mature individuals become gravid approximately 20 months after spawning, suggesting a two-year reproductive cycle for that species.

In Japan, hatcheries hold *H. discus hannai* in tanks with a controlled photoperiod of 12 hours of light and 12 hours of dark. The water temperature is maintained at 20 °C (68 °F) and seawater flow rate is around 800 L/hr. Japanese hatchery managers routinely hold broodstock at elevated temperatures for maturation and utilize lower temperatures to inhibit spawning in gravid adults until fertilized eggs are required in the hatchery (2).

The difference in the two systems results largely from the natural reproductive cycles of the two species. In wild populations of *H. rufescens*, gravid, sexually mature individuals are found year round, while *H. discus hannai* from Japanese waters exhibit a seasonal reproductive cycle. Gravid *H. discus hannai* are found in summer months, and the elevated broodstock holding temperatures maintain animals in spawning condition throughout the year. As a general rule, broodstock abalone should be maintained in conditions similar to those in the ocean where sexually mature gravid individuals are found. The spawning areas used by northern and southern abalone species are well documented (2).

Larval Rearing and Settlement

Eggs are collected after spawning and fertilization and subsequently held for 24 to 36 hours in a static system. During that time, the microscopic larvae develop to the trochophore stage and hatch out of the egg membrane. The remainder of larval rearing is done by using either flow-through or static systems (Fig. 4). Flow-through systems typically incorporate tanks from 20 to 500 L made of plastic or fiberglass for ease of cleaning. They are supplied with UV-treated 1 μm filtered seawater. Banjo screens of 90 or 100 μm are placed at the seawater outflow to retain the larvae which are generally 220 to 260 μm in diameter (14). The design was first developed in New Zealand and consists of a piece of large diameter plastic pipe attached to the overflow drain (Fig. 4) with 90 to 100 μm screen glued to both ends. The screens provide enough surface area so that the current does not impinge larvae. Flow rates are also low to prevent the weakly swimming larvae from damage in the tanks and on the screens. Gentle aeration is sometimes provided to the larval rearing containers. In static systems, water changes are done one to three
Figure 4. Abalone larval rearing tank with banjo screen.

times per day by flushing the tank or gently collecting the larvae on screens and transferring them to clean rearing containers.

Abalone have swimming planktonic larvae for five to seven days depending on temperature. Temperate and tropical abalone larvae are reared at 13 to 15 °C and 23 to 26 °C, respectively. If excessive bacterial growth develops, larvae are collected on screens and transferred to a clean rearing tank. Healthy larvae swim in a spiraling fashion upward, then drift down, then swim up again. Larval survival is usually around 70% and production ranges from 500,000 to 35 million, depending on the size of the facility.

At the end of the larval rearing period, "competent" planktonic veliger larvae settle on a hard substrate and metamorphose into a crawling benthic juvenile form. Morphological changes include development of the radula, protrusion of the sensory cephalic tentacles, and loss of the swimming organ known as the velum. Behavioral changes signalling the onset of settlement include intermittent swimming and crawling behavior and settlement of some animals at the water line of the rearing container. When these changes are observed, larvae are ready to be placed into the settlement tanks used for their early growth and feeding (2).

Larval Settlement and Nursery Rearing

Indoor and outdoor settlement tanks are used for abalone larvae. Settlement may be enhanced using γ-aminobutyric acid (GABA), diatoms, a diatom/bacterial film or mucous trails of adult abalone (2). When GABA is used, the tanks are cleaned, 1 μm filtered seawater is introduced, and GABA is added to achieve a 10^{-6} M concentration (15). Abalone larvae are then introduced at 2 to 5 larvae/cm^2 of tank surface area. Settlement tanks utilize vertically placed plastic or fiberglass sheeting to increase settlement surface area. Tanks are left static for 12 to 24 hours and then a low flow rate, usually about 1 L/min (0.26 gal/min), is started. The young abalone are very active crawlers

and begin feeding during the first ten days after settlement (16). They require microalgae of 10 μm or less in size for the initial feeding. The radula width of *H. rubra* at six weeks of age is 9 to 11 μm, suggesting that this may be a good indicator of optimum diatom or feed size (17).

Diatom cultures are maintained at some commercial farms, while others use only coarse filtration when filling settlement tanks allowing natural diatom populations to settle and grow on tank walls. A light diatom film is desirable and sunscreen covers are used to manage sunlight intensity as a means of regulating diatom growth rates. The correct species and thickness of the diatom film on the tank walls are critical to early survival and growth (18,19). Newly settled animals can become entangled in heavy diatom films that are conducive to the growth of bacteria and protozoans.

Artificial diets are sometimes used after three months when the abalone are about 2 mm in shell length and have formed their first respiratory pore. A thin bladed red algae, *Palmaria mollis*, is also cultured at some farms for young abalone (20,21).

Nursery tanks are rectangular or round and vary from 180 to 1,000 L (47 to 264 gal). Nursery systems also use vertical substrates similar to those used in settlement tanks, but of different dimensions to accommodate the tank and increased abalone size. In Japan, a series of corrugated fiberglass sheets are held in a plastic-coated rigid metal frame suspended in large tanks (2). Abalone are maintained for approximately four to six months in the nursery area of the farm. Tanks are drained and rinsed every one to three weeks depending on abalone grazing rates and diatom growth. The tanks are gently rinsed with seawater, and dislodged abalone are collected on screens at the outflow.

At the end of the nursery period the 6 to 10 mm abalone have a strong radula capable of scraping large macroalgae or prepared diets. They are transitioned to those diets in the nursery system or in 0.2 m^3 (6.2 ft^3) plastic mesh baskets suspended in large production tanks. Abalone are stocked at high densities of around 2,500 per basket, and the baskets are packed with macroalgae, placing the abalone in close proximity to the new food source.

Production of abalone from nursery systems has greatly increased over the past ten years. Some hatcheries are vertically integrated with growout facilities, while other farms lacking hatcheries purchase larvae for growout. Production of abalone is generally not a constraint to commercial production.

GROWOUT SYSTEMS

Growout systems are located on land with tanks and seawater pumping systems, or they are in-water facilities that use long lines or rafts to support cage structures. Land-based growout facilities utilize concrete or fiberglass tanks. As in the nursery systems, vertical panels placed in the tanks slightly above the tank floor provide additional surface area. Some growout tanks have "V" shaped bottoms or false bottoms to allow rapid removal of feces. In-water cages constructed of heavy extruded plastic mesh and screened plastic barrels are also used and

contain added vertical substrate. A unique abalone farm is located in South Australia, where cages hold abalone on the seafloor and trap the drifting algae transported by currents. Growout systems involve substantial amounts of labor, power, and feed whether they are land-based or in-water facilities (22). Abalone are held one to three years in production systems depending on the species, growth rate, and market size preference. Farmed abalone are usually transported and sold live in the marketplace (23).

In North and South America, the giant kelp *Macrocystis pyrifera* is the main feed used on abalone farms. The northernmost farms use the bull kelp, *Nereocystis luetkeana*. Other kelp and mixed macrophyte species provide most of the feed used in other abalone producing regions throughout the world. Abalone generally prefer red and brown macrophytes, and they have developed enzymes that lyse the cells walls of their preferred algal species (1,26,31–33). Prepared diets are also used in many production systems, most often for small nursery animals.

In Australia, Japan, New Zealand, and South Africa, some producers rely exclusively on prepared feeds, although this generally increases production costs compared with using harvested kelp (7). While prepared feeds are more expensive, there are considerable labor savings because those feeds are consumed at 2 to 7% of body weight compared with 10 to 30% for natural algal diets. Manufactured diets also have a more reliable composition and provide for more consistent growth (1,7).

Abalone are fed kelp once or twice a week based on seawater temperature, season, and consumption rates. Prepared diets are fed in small amounts daily or every few days. As feed quality deteriorates, it is important to replace it with fresh feed. Toxic hydrogen sulfide and ammonia levels can result if kelp is left to decompose in culture tanks, especially at high water temperatures. Growout tanks are drained and rinsed as needed to remove excess fecal material.

Land-based nursery and growout systems use aeration as do some ocean barrel culture operations. Maintaining near saturation levels of dissolved oxygen is essential as abalone will crawl out of tanks with reduced oxygen. Vigorous aeration also serves to distribute feed to all the animals.

NUTRITIONAL REQUIREMENTS OF ABALONE

Abalone require different foods at different life stages for optimal growth and development. Larval abalone do not feed, although they may absorb some nutrients from seawater (25). Rapidly growing young abalone require higher levels of protein and energy than adults (26). Young abalone actively graze surfaces, removing algal and biofilm nutrients from the substrate. Adult wild abalone primarily consume drift kelp, feeding opportunistically as food drifts their way (27–29).

Development of cost-effective artificial diets will foster continued expansion of abalone aquaculture, and researchers have made significant progress in developing diets that are water stable, nutritionally complete,

palatable, and accessible. Knowledge of the specific nutritional requirements of abalone has resulted in diets containing about 30% protein in the form of defatted soybean meal, casein or fish meal. Lipids range from 3 to 5% of prepared diets and the source is usually fish or vegetable oil. Lipids must be stabilized with an antioxidant such as Vitamin E. Abalone require eicosapentanoic (20:5n-3) and docosahexanoic (22:6n-3) fatty acids in their diet. Carbohydrates comprise 30 to 60% of prepared diets and also act as a binder to maintain stability and retard nutrient leaching into the water. Corn and wheat are common sources of carbohydrate. Crude fiber is not readily digested by abalone and generally comprises from 0 to 3% of formulated diets. (7).

Cues that initiate feeding in abalone are not well understood. Abalone feed primarily at night and not all animals will feed on a given night. Because of our poor understanding of feeding behavior and to ensure constant access to food, growers often provide about twice the amount of food the abalone will consume and must be diligent in removing decomposing uneaten feed (30).

Growth

Abalone growth rates are generally slow and variable among individuals and species. From metamorphosis to development of the first respiratory pore at 60 to 90 days, growth is approximately 1 to 1.5 mm/month and the shells are 2 to 2.5 mm long. Growth is rapid for the next 8 to 10 months at 1.5 to 3 mm/month. During this growth phase, the young abalone graze microalgae and mixed biofilms from tank surfaces. Prepared diets with particle sizes between 50 and 300 μm are used during the latter part of that growth phase (1,7,14,34–37).

Some exceptional growth rates have been observed in the tropical species *H. assinina*. Growth of up to 4 to 5 cm the first year are common (2,38). The subtropical abalone, *H. diversicolor supertexta*, average 6–7 cm at two years of age in aquaculture systems in Taiwan. After the first year of accelerated growth, abalone growth rates decrease to 1 to 1.6 mm/month (1,39). Some wild *H. rufescens* populations have shown 5.5 mm/month growth in the summer and 2.5 mm/month in winter, an annual average of 3.5 mm/month for large abalone. *H. discus hannai* reaches 3 cm in 18 months in aquaculture systems and 9 cm in four years in nature.

Variable growth rates are common in abalone but the underlying causes are often unknown (40). There appears to be a genetic component as slow and fast growing abalone maintained their respective growth rates when reared under identical conditions (41). Other factors that influence abalone growth in aquaculture systems are temperature, density, photoperiod, salinity, oxygen, and food intake.

A constant or elevated seawater temperature increases growth in some abalone species (1,42). *H. tuberculata* grew 18 mm/yr when reared in 20 °C (68 °F) seawater (43). *H. fulgens* shows enhanced growth when reared in seawater above 20 °C (68 °F) and *H. discus hannai* will double normal growth rates to reach 6 cm in 2 years when raised at elevated temperatures. Warm water reduces the time for production of 1 to 2 cm *H. rufescens* from one year to

six months when the young abalone are raised in 23 °C (73 °F) compared to 16 °C (61 °F). Low temperature reduces growth by affecting feeding rate and duration as well as food absorption (44,45).

Abalone form localized high density aggregations in culture systems that may affect their growth and nutritional status. High stocking densities reduce abalone growth in aquaculture systems (33,37). *H. diversicolor supertexta* measuring 15 mm exhibited reduced growth at densities greater than 500/m². Other detrimental effects included shell erosion and splits in the shell where the respiratory pores are normally located.

HUSBANDRY AND HEALTH MANAGEMENT

A hard rule in animal husbandry is to minimize stress when it is economically feasible to do so. To accomplish this with abalone means providing clean, well-oxygenated seawater at a stable temperature that is free of ammonia and other contaminants. Larvae and young juvenile abalone in settlement tanks are very sensitive to temperature changes, and as little as a 2 °C (36 °F) temperature change may cause mortality of *H. rufescens* larvae (35).

Good-quality feeds in sufficient quantity should be regularly available and decomposing feed should be removed. Often production and broodstock tanks require cleaning to prevent populations of copepods, nematodes, or harmful bacteria from flourishing. Animals should be kept moist and handled as little as possible during this maintenance. When handling abalone, always lift them from the substrate with a lifter that does not cut the foot as small cuts can result in animals bleeding to death. Lifting abalone from the posterior end of the shell is essential to avoid damage to delicate tissues and organs in the gill and head region (23).

Since abalone are active and feed primarily at night, it is necessary to walk around the growout tanks each morning to check for animals that may have inadvertently crawled out and fallen to the ground. This is also an ideal time to check all tank flows and aeration systems. Cage culture systems have similar husbandry requirements and must also be kept free of excessive fouling organisms that restrict water circulation.

Every effort should be made to prevent the introduction and spread of disease. Broodstock, hatchery, and production growout systems should be isolated from one another. Care should be taken not to mix populations and animals should not be moved between tanks. Similarly, equipment should be disinfected if used in different areas of a farm. If importing broodstock or seed abalone for growout, a shellfish pathologist should examine the population to determine with reasonable certainty that infectious agents or parasites are absent.

FUTURE CONSTRAINTS AND OPPORTUNITIES

The primary constraints to the continued growth and success of the abalone industry are the need for an economical manufactured feed and management of pathogens and parasites. The industry also needs to domesticate broodstock and begin a genetic selection program to enhance growth and other production traits while eliminating the need for wild broodstock.

Recently, prepared diets have been used throughout the entire culture cycle in Australia where restrictions on algal harvest and phenolic compounds unpalatable to abalone prevent the use of brown macroalgae (24). There are a number of companies now producing manufactured feeds, and as more is learned about nutritional requirements and feed formulation, it is hoped these diets will become more cost effective. When this happens, many new production areas distant from major kelp resources will open up. This will include tropical regions that can benefit from the fast growth rates observed in *H. assinina*.

Pathogens such as sabellid worms and rickettsial bacteria are associated with withering syndrome in California black and red abalone and must be managed so they do not significantly impact growers. Proper management and husbandry techniques using specific pathogen-free broodstock and seed abalone should allow the industry to avoid significant losses from these and other potential pathogens.

Genetic improvements achieved by selection, ploidy manipulations, and transgenic technologies have the potential to improve the performance of abalone in culture systems. Some of this work has begun but is not yet near commercial application (12).

The abalone industry will continue to expand as new technologies develop and are incorporated into farming systems. The high demand coupled with stable or declining fisheries ensures that the market will continue to grow and provide opportunities for abalone growers throughout the world.

AERATION SYSTEMS

JOHN COLT
Northwest Fisheries Science Center
Seattle, Washington

OUTLINE

In aquatic culture systems, many of the important water-quality parameters are the levels of dissolved gases, such as oxygen, carbon dioxide, hydrogen sulfide, ammonia, and nitrogen. Aeration, or the addition of dissolved oxygen (DO), is one of the processes most commonly used in aquaculture. The maintenance of environmental quality requires control of levels of dissolved gas. The "best"

aeration system for a given application depends on site conditions, production schedules, the layout of the rearing units, and operational procedures. The design of an aeration system must consider the potential impacts on all the dissolved gases in solution.

TYPES AND CONFIGURATION OF AERATORS

Each aeration device can be classified as either surface, subsurface, or gravity. If the source of oxygen is enriched or pure oxygen gas rather than air, the units are called "pure-oxygen aerators"; these units are covered in a separate entry, pure oxygen systems.

Types of Aerators

Surface aerators spray or splash water into the air and thus transfer oxygen from the air into the water. The major types of surface aerators are shown in Figure 1. Subsurface aerators mix water and air together in an aeration basin and transfer oxygen from air bubbles into the water. The major types of subsurface aerators are shown in Figure 2. Gravity aerators are a special type of surface aerator that use gravity rather than mechanical power to transfer oxygen. This type of aerator is commonly used in flow-through systems where adequate head

Figure 1. Typical surface aerators: (**a**) floating aerator; (**b**) surface aerator with draft tube; (**c**) brush, rotor, or paddlewheel aerator.

is available. The major types of gravity aerator are shown in Figure 3.

Aerator Configuration and Location

Depending on system configuration and on operational limitations, aerators may be placed at different locations (Fig. 4). The aerators may be located in the influent stream (Figs. 4a, 4b, and 4c), the recycle stream (Figs. 4e and 4f), or the rearing unit (Fig. 4d). In the recycle configuration (Figs. 4e and 4f), the recycle flow may be several times larger than the influent flow. In a side-stream system (Figs. 4b and 4c), only part of the water flow passes through the aeration system.

SOLUBILITY OF GASES IN WATER

The solubility of a gas in water depends on its temperature and composition, the salinity of the water, and the total pressure. The air solubility of oxygen at 1 atm (C^*_{760}), as a function of temperature, is listed in standard references (1,2); it may be adjusted to other barometric pressures by the following equation:

$$C^* = C^*_{760} \frac{(\mathrm{BP} - P_w)}{(760 - P_w)} \tag{1}$$

where

$C^* =$ air-solubility of oxygen (mg/L),
$\mathrm{BP} =$ local barometric pressure (mm Hg),
$C^*_{760} =$ air-solubility of oxygen at 760 mm Hg (standard conditions), and
$P_w =$ vapor pressure of water (mm Hg; Reference 1).

Equation 1 is limited to the computation of saturation concentration for air; information for the computation of the saturation concentration of gases other than air can be found in standard references (2). In many aeration systems, hydrostatic head is used to increase the pressure at which gas transfer occurs. A depth of approximately 10 m (30 ft) will double the solubility of a gas.

DISSOLVED-OXYGEN CRITERIA IN INTENSIVE CULTURE

Low-Dissolved-Oxygen Criteria

The growth of fish is not affected until the dissolved oxygen (DO) drops below a critical concentration. This critical concentration is influenced by temperature and by feeding level; it ranges from 5 to 6 mg/L (ppm) for salmon and trout (Salmonidae) and from 3 to 4 mg/L (ppm) for warm-water fish such as channel catfish (*Ictalurus punctatus*) (3,4). The use of oxygen supplementation can also increase survival and improve fish health and quality. Some of the beneficial effects of oxygen supplementation may be due to the stripping of chronic levels of gas supersaturation.
Figure 2. Typical submerged aerators: (**a**) diffused, (**b**) U-tube, (**c**) aerator cone, (**d**) static tube, (**e**) air-lift, (**f**) venturi, (**g**) nozzle.

High-Dissolved-Oxygen Criteria

The maximum allowable DO level depends on several factors, including oxygen toxicity, physiological dysfunctions, and developmental problems. While oxygen is required for the survival of aerobic organisms such as fish, some of the by-products of oxygen metabolism are highly toxic and can overwhelm biochemical defense mechanisms. On the basis of oxygen toxicity considerations, a preliminary maximum oxygen partial pressure of 300 mm Hg has been suggested (5). This corresponds to a dissolved-oxygen concentration equal to 21 mg/L (ppm) at 12 °C (54 °F) and 16 mg/L at 25 °C (77 °F).

The addition of high concentrations of dissolved oxygen can increase the total gas pressure (6). The amount of increase in the total gas pressure depends strongly on the type of aeration unit used and its operating conditions.

Limitations on Maximum Oxygen Consumption

In high-intensity flow-through systems, cumulative oxygen consumption (7) is an important measure of system intensity. The cumulative oxygen consumption (COC) rate for a single rearing unit is equal to the amount of oxygen consumed ($DO_{in} - DO_{out}$). For a serial reuse system, the cumulative oxygen consumption for the overall system is equal to the sum of the oxygen consumed in all of the units.

The utilization of oxygen produces both carbon dioxide and ammonia. The depletion of oxygen may not always be the most severely limiting parameter; when ammonia
Figure 3. Typical gravity aerators: (**a**) corrugated inclined plane, (**b**) lattice, (**c**) cascade, (**d**) packed column, (**e**) spray column, (**f**) tray or screen.

Figure 4. Location of aerators: (**a**) influent; (**b**) influent, side-stream mode with single point of return; (**c**) influent, side-stream mode with multipoint return; (**d**) in-unit; (**e**) recycle, single point of return; (**f**) recycle, multipoint return.

or carbon dioxide is more limiting, aeration will have little effect on carrying capacity (8). Maximum cumulative oxygen consumption (COC), based on limitations due to pH, dissolved oxygen, and un-ionized ammonia, is presented in Figure 5 for water-quality criteria typical in salmon and trout culture.

GAS TRANSFER

The rate at which a slightly soluble gas such as oxygen is transferred into water is proportional to the area of the gas-liquid interface and the difference between the saturation concentration and the existing concentration of
Figure 5. Maximum cumulative oxygen consumption (mg/L) as a function of equilibrium pH_e (pH of a solution in equilibrium with the atmosphere). At low pH_e, COC is limited by the pH criteria; at intermediate pH_e, by the dissolved-oxygen criteria; at high pH_e, by the un-ionized ammonia criteria (8).

the gas in the water (9):

$$\frac{dC}{dt} = K_L \cdot a(C^* - C) \qquad (2)$$

where

$\dfrac{dC}{dt} =$ rate of mass transfer (mass/time),

$K_L =$ overall liquid-phase mass-transfer coefficient (length/time),

$a =$ area of interfacial contact between gas and liquid (length^2/length^3), and

$C^* =$ saturation dissolved-gas concentration at a given temperature, pressure, and mole fraction (mass/volume),

$C =$ current dissolved oxygen concentration (mass/volume).

A positive gradient $(C^* - C)$ transfers oxygen into the liquid phase; conversely, a negative gradient transfers oxygen into the gas phase. The transfer rate can be increased by increasing the value of K_L, a, or C^*. In many systems, it is not possible to determine K_L and a independently, and these two variables are combined to a single term ($K_L a$).

STANDARDIZED AERATOR TESTING UNDER CLEAN WATER CONDITIONS

Standardized testing and rating procedures for in-basin aerators have been developed for wastewater applications. These standards are helpful, but their use in aquaculture systems may not always be the most accurate or valid means of rating aerators.

Unsteady-State Testing

Unsteady-state testing procedures (10) are conducted under standard conditions in an experimental test basin. Some test basins are as large as 3,000 to 6,000 m^3 (4,000 to 8,000 yd^3) and can be used to test aerators as powerful as 50 to 100 kW (70 to 140 hb). Typically, a solution of sodium sulfite and cobalt chloride is used to deoxygenate the water by chemical oxidation. The aerator is then started, and the dissolved-oxygen is measured periodically until the saturation concentration is approached. This testing procedure is termed the unsteady-state test, as the amount of oxygen transferred and the dissolved-oxygen concentration are changing during the test.

Fundamental to the rating of in-basin aerators is the experimental determination of $K_L a$ (Eq. 2) and the computation of the standardized oxygen transfer rate (SOTR). The SOTR is the maximum rate of transfer into water having a dissolved-oxygen concentration of zero mg/L (ppm), at 20 °C (68 °F), 760 mm Hg; it is expressed in kg/hr (lb/hr). In older literature, this parameter is referred to as N_o. The standardized aeration efficiency is expressed as follows:

$$SAE = \frac{SOTR}{P_{in}} \qquad (3)$$

where

$SAE =$ standardized aeration efficiency (kg O$_2$/kW$\cdot$hr, lb O$_2$/hp$\cdot$hr),

$SOTR =$ standardized oxygen transfer rate (kg/hr, lb/hr), and

$P_{in} =$ power input (kw, hp).

The power input should be the measured wire power, that is, the total power actually used by the entire system: (a) motor, drive, and blower; or (b) motor, coupling, and gearbox (11). The standardized oxygen transfer efficiency is equal to the oxygen transferred into the water divided by the mass flow rate of oxygen supplied to the aerator:

$$OTE_o = \frac{SOTR}{\dot{m}} \qquad (4)$$

where

$OTE_o =$ standardized oxygen transfer efficiency (%),

$SOTR =$ standardized oxygen transfer rate (kg/hr, lb/hr), and

$\dot{m} =$ mass flow rate of oxygen (kg/hr, lb/hr).

SOTR, OTE_o, and SAE are reported for aerators and can be used to compare different types or brands of aerators. The standardized procedure for the determination of $K_L a$ reduces the uncertainty in aerator rating and allows more meaningful comparisons between units. Unfortunately, standards for the rating of aerators change from country to country. In Europe, for example, the standard temperature used in the computation of SOTR and SAE is 10 °C, rather than the 20 °C used in the United States.

For design, it is necessary to estimate the performance of a specific aerator under field conditions. The values of SOTR, OTE$_o$, and SAE cannot be used directly for design.

Steady-State Testing

For a number of gravity aerators (such as packed columns), both the input and the effluent oxygen concentrations can be directly measured. For these types of aerators, the field oxygen transfer rate, field aeration efficiency, and field oxygen transfer efficiency can be computed directly from the following three equations. The field oxygen transfer rate is calculated as follows:

$$\text{OTR}_f = 3.6 Q_w\,(\text{DO}_\text{out} - \text{DO}_\text{in}) \tag{5}$$

where

OTR_f = oxygen transfer rate under field conditions (kg/hr),
Q_w = water flow (m^3/s),
DO_out = effluent DO concentration (mg/L), and
DO_in = influent DO concentration (mg/L).

The field aeration efficiency (FAE) is calculated as follows:

$$\text{FAE} = \frac{\text{OTR}_f}{P_\text{in}} \tag{6}$$

where

FAE = field aeration efficiency (kg O$_2$/kW•hr, lb O$_2$/hp•hr),
OTR_f = oxygen transfer rate under field conditions (kg/hr, lb/hr), and
P_in = Power input (kw, hp).

The field oxygen transfer efficiency (OTE$_f$) is calculated as follows:

$$\text{OTE}_f = \frac{\text{OTR}_f}{\dot{\text{m}}} \tag{7}$$

where

OTE$_f$ = oxygen transfer efficiency under field conditions (%),
OTR_f = oxygen transfer rate under field conditions (kg O$_2$/hr, lb O$_2$/hr), and
$\dot{\text{m}}$ = mass flow rate of oxygen (kg/hr, lb/hr).

For some types of atmospheric gravity aerators, $\dot{\text{m}}$ can not be measured, and the aeration effectiveness (12) has been used as a rating parameter, calculated from the following equation:

$$\text{AF} = \left[\frac{C_\text{out} - C_\text{in}}{C^* - C_\text{in}} \right] \times 100 \tag{8}$$

where

AF = aeration effectiveness under field conditions (%),
C_out = effluent dissolved oxygen concentration (mg/L, ppm),
C_in = influent dissolved oxygen concentration (mg/L, ppm), and
C^* = saturation dissolved oxygen concentration (mg/L, ppm).

In the unsteady-state tests, the performance of an aerator was rated under standard conditions. In steady-state tests, unless the actual test conditions are equal to the standard conditions, these test results must reduced to standard conditions for comparison of performance values. The interrelationship of standard and field conditions will be presented in the next section.

PERFORMANCE AND RATING OF AERATION SYSTEMS UNDER FIELD CONDITIONS

Values of SOTR, SAE, and OTE$_o$ are computed for water at 20 °C (68 °F), 760 mm Hg, and having zero dissolved oxygen; therefore, they cannot be used directly for the design of aquatic culture systems. Actual performance under field conditions depends primarily on the required dissolved oxygen concentration (C) and to a lesser extent on temperature, on pressure, and on water characteristics. The rating of aerators under field conditions requires the computation of the oxygen transfer rate under field conditions (OTR$_f$), the field aeration efficiency (FAE), and the oxygen transfer efficiency under field conditions (OTE$_f$). The computation of these parameters assumes that the field installation is identical to the unit tested under standard conditions. The interrelationship between the rating and the field parameters is presented in the following table (10):

Standard Parameter	Field Parameter	Units
$K_L a(20\,°\text{C})$	$K_L a(t)$	1/hr
SOTR	OTR$_f$	kg O$_2$/hr (lb O$_2$/hr)
SAE	FAE	kg O$_2$/kW•hr (lb O$_2$/hp•hr)
OTE$_o$	OTE$_f$	%

Characteristics of Culture Water

Alpha (α). The effects of water characteristics on oxygen transfer are corrected for by the alpha factor, which can be calculated as follows:

$$\alpha = \frac{K_L a — \text{field conditions}}{K_L a — \text{standard conditions}} \tag{9}$$

Here $K_L a$ = volumetric mass transfer coefficient (1/hr).

The value of α depends primarily on the concentration of surfactants in the water. In production catfish ponds, α ranged from 0.66 to 1.07 and averaged 0.94 (12). In recycle systems, α values as low as 0.36 have been measured following feeding (13). The depression of α appears to be

caused by the leaching of soluble compounds from feed or from compounds produced by algae.

Beta (β). The effects of water characteristics on oxygen solubility are corrected for by the beta factor, which is computed as follows:

$$\beta = \frac{C^* - \text{field conditions}}{C^* - \text{standard conditions}} \quad (10)$$

Here C^* = saturation DO concentration.

The beta factor is influenced primarily by dissolved solids and to a lesser extent by dissolved organics and suspended solids. In wastewater, beta values typically range from 0.95 to 1.00 (14,15). Beta values for aquaculture conditions are unavailable.

Theta (Θ). The theta factor is used to correct $K_L a$ for changes in viscosity, surface tension, and diffusion constants all as a function of temperature (15). The temperature variation of $K_L a$ is compensated for as follows:

$$K_l a(t) = K_L a(20\,°\text{C})\Theta^{(t-20\,°\text{C})} \quad (11)$$

where

20 °C (68 °F) is the standard temperature and t is the field temperature (°C)

A value of 1.024 is recommended (15).

Computation of Field Oxygen Transfer Rate (OTR$_f$)

The field oxygen transfer rate (OTR$_f$) is the rate of oxygen transfer under field conditions. It is derived as follows:

$$\text{OTR}_f = \text{SOTR}\left\{\frac{\alpha(1.024^{(t-20)})(\beta C^* - C)}{9.092}\right\} \quad (12)$$

where

OTR$_f$ = field oxygen transfer rate (kg/hr),
   C = minimum dissolved oxygen concentration (mg/L, ppm), and
9.092 = dissolved-oxygen concentration at standard conditions (mg/L, ppm).

The computation of the field oxygen transfer rate (OTR$_f$) requires (*1*) SOTR, (*2*) α and β for the particular water condition, (*3*) local water temperature, and (*4*) C.

Computation of Field Aeration Efficiency (FAE)

The field aeration efficiency (FAE) is the oxygen transfer/unit power input under field conditions. It is derived as follows:

$$\text{FAE} = \text{SAE}\left\{\frac{\alpha(1.024^{(t-20)})(\beta C^* - C)}{9.092}\right\} \quad (13)$$

Here the symbols are as defined for Equations 6, 9, 10, 11, and 12. The impact of hydrostatic pressure on the saturation concentration C^* have been ignored in Equations 12 and 13. These corrections may be significant for aerators submerged in deep aeration basins (10).

PROCESS SELECTION AND DESIGN

A wide range of aeration devices are available for aquaculture. The actual type selected will depend on a variety of factors related to the characteristics of the aerator, the culture system, the site conditions, and system operations. It should be noted that aerator selection may require serious trade-offs between some of these parameters. Many of these tradeoffs may be difficult to quantify, especially if the long-term objectives of the culture system are not well-defined or the oxygen demand of the system changes significantly over the production cycle.

Field Aeration Efficiency

Standardized aeration efficiencies (SAE) for some aerators commonly used in aquatic systems are listed in Table 1.

Table 1. Typical Standardized Aerator Efficiency (SAE) for Aerators Used in Aquaculture (adapted from 16)

Type	SAE (kg O$_2$/kW•hr)[a]
Surface Aerators	
Low-speed surface	1.2–2.4
Low-speed surface with draft tube	1.2–2.4
High-speed surface	1.2–2.4
Paddlewheel	
Triangular blades	2.7–2.9
PVC pipe blades	1.2–1.9
Tractor powered	1.3–2.0
Gravity Aerators	
Cascade weir (45°)	1.5–1.8
Corrugated inclined-plane (20°)	1.0–1.9
Horizontal screens	1.2–2.6
Lattice aerator	1.8–2.6
Packed column	
Zero head	1.2–2.4
0.5–1.0 m head	10–80[b]
Aeration cone	2.5
Submerged Aerators	
Air-lift pump	2.0–2.1
Diffused air	
Fine bubble	1.2–2.0
Medium bubble	1.0–1.6
Coarse bubble	0.6–1.2
Nozzle aerator	1.3–2.6
Propeller aspirator pump	1.7–1.9
Static tube	1.8–2.4
U-tube	
Zero head	0.72–2.3
0.5–1.0 m head	10–40[a]
Venturi aerator	2.0–3.3

[a]lb O$_2$/(hp•hr) = kg O$_2$/(kW•hr × 1.6440).
[b]Does not include pumping power.

The SAE will typically range from 1.0 to 2.6 kg O_2/kW·hr. The SAE of some types of subsurface aerator may range as high as 3.2 to 3.5 kg O_2/kW·hr. If 0.5 to 1.0 m of head is available, the SAE of the U-tube and packed-column aerators can range as high as 40–80 kg O_2/kW·hr. The only power required is for injection of air into the U-tube or for low-pressure fans in the packed columns.

The FAE values for aquaculture systems will be significantly less than the listed SAE values, primarily because of the necessity of maintaining a dissolved oxygen concentration of 5 to 7 mg/L. For example, at 30 °C (86 °F) $\alpha = \beta = 1.0$, and $C = 5$ mg/L (ppm), FAE is equal to only 36% of the SAE value. At high temperatures and C values, the value of FAE is significantly reduced.

Field Aeration Effectiveness

Most gravity aerators can be designed to operate with no power input if 1.0 m or more head is available. Typical values of the aeration effectiveness (AF) are presented in Table 2. Many gravity aerators have very low SAE values; one may, nonetheless, be useful in some applications due to its simplicity of construction and operation. Information on the computation of standard aerator performance under steady-state testing is presented in (16).

Table 2. Aeration Effectiveness (AF) of Typical Gravity Aerators

Type	Height or Head (cm)[a]	AF (%)
Low-Head Types		
Cascade (45°)	25	22–26
	50	36–38
Corrugated inclined-plane (20°)	30	18–29
	60	30–50
Horizontal perforated trays	110	95–100
Lattice aerator	30	29–37
	60	48–61
Simple weir	30	7–10
Splash board	30	23–25
	60	36–41
Packed column	30	94–96
	60	96–98
High-Head Types		
Alfalfa gate	990 to 1,700	61
Ell aspirator	990 to 1,700	83
Gate valve (Half-open)	990 to 1,700	76
Screen	990 to 1,700	59
Screen covered with rocks	990 to 1,700	63
Screen cover	990 to 1,700	52
Screen extension	990 to 1,700	51
Slotted cap	990 to 1,700	65
Splashboard	990 to 1,700	51
Splashboard with holes	990 to 1,700	53
Straight pipe	990 to 1,700	25
Tee aspirator	990 to 1,700	72

[a]Inches = cm/2.54.

Field Oxygen Transfer Rate

In a number of systems, oxygen transfer rate is more important than efficiency. Tractor-powered paddlewheel aerators have been used widely in catfish ponds for emergency aeration (17) and can easily be moved from pond to pond when needed. Diffused aeration with pure oxygen is widely used in transportation systems (18) and in emergency systems for high-intensity systems, because of its ability to transfer large amounts of oxygen without any power input.

Dissolved-Gas Concentrations and Pressures

Dissolved-gas concentrations (or pressures) in the effluent from aeration must be considered in aeration design and operation (6). Lethal dissolved-gas pressures may be produced by some types of submerged aerators (19).

Computation of Oxygen Demand and Supplemental Requirements

The sizing of aeration systems requires estimates of the total oxygen demand by aquatic animals and other organisms, of the available oxygen supplied by water flow (if any), and of the consequent requirement for supplemental oxygen. Because the total oxygen demand of the animals depends on their number, their size, and the water temperature, it is necessary to estimate these parameters over the whole production cycle on a weekly or monthly basis. The temperatures allowed for should include average, extreme maximum, and extreme minimum values.

Average Daily Oxygen Demand

The average daily oxygen demand (20,21) is proportional to the total daily ration:

$$\text{DOD}_{\text{aver}} = (\text{OFR}) \times R \qquad (14)$$

where

DOD_{ave} = average daily oxygen demand (kg/d, lb/d),
OFR = Ratio of average daily oxygen demand to daily feed consumption (kg/kg, lb/lb), and
R = daily feed consumption (kg/d, lb/d).

The oxygen requirement to process a given mass of feed depends on animal size, the feeding rate, the composition of the ration, the digestibility of the feed components, and moisture content; it can be characterized by the oxygen:feed ratio (OFR).

In production salmon and trout systems, OFR ranging from 0.20 to 0.22 kg oxygen/kg wet feed have been reported (22,21). In commercial high-density warm-water fish culture, a value for OFR of 1.00 kg oxygen/kg wet feed is commonly used (Anthonie Schuur, Aquaculture Management Services, personal communication). The higher value of OFR for warm-water fish may be due to higher levels of metabolizable energy in the feed, to lower moisture levels in the feed, to lower re-aeration across the water surface, to higher bacteria oxygen demand (from oxidation of organics and ammonia), or to differences in

activity and feeding behavior. Limited data is available for OFR in recycle systems. The oxygen demand from bacterial oxidation of organic compounds, ammonia, and solids strongly depends on the unit processes and their operation. The upper bound for OFR is the ultimate Biochemical Oxygen Demand of the feed, which for channel-catfish feed is equal to 1.1 kg O_2/kg dry feed (23). Careful feeding, followed by rapid removal of solids from the system, can significantly reduce the OFR. Due to the minor impact of culture animals on a whole pond's respiration, computation of OFR under pond conditions may not be particularly important. Variation of DO and of aeration demand in ponds can be computed by a variety of techniques (24–26).

Maximum Daily Oxygen Demand

On a daily basis, in a flow-through system, the maximum oxygen consumption occurs at about 4 to 6 hours after feeding. A peaking factor of 1.44, to account for the maximum daily oxygen-consumption rate, has been suggested (22):

$$OD_{max} = 1.44(DOD_{aver}) \qquad (15)$$

where

OD_{max} = maximum daily oxygen demand (kg/d, lb/d) and
DOD_{aver} = average daily oxygen demand (kg/d, lb/d).

Supplemental Oxygen Requirement

The amount of available oxygen supplied by the flow (kg/d, lb/d) is calculated as follows:

$$\text{Oxygen supplied by flow} = (A)(Q_w)(DO_{out} - DO_{min}) \qquad (16)$$

where

A = constant (84.4, in kms 5.443×10^{-3} in English units),
Q_w = water flow (m³/s, gpm),
DO_{out} = effluent DO concentration (mg/L, ppm), and
DO_{in} = influent DO concentration (mg/L, ppm).

The amount of supplemental oxygen (kg/d, lb/d) is calculated by combining Equations 14, 16, and 17, as follows:

$$\text{Supplemental oxygen} = 1.44(OFR)(R) - A(Q_w)$$
$$\times (DO_{out} - DO_{min}) \qquad (17)$$

where

OFR = ratio of average daily oxygen demand to daily feed consumption (kg/kg, lb/lb),
R = ration (kg/d, lb/d),
A = constant (84.4, in kms 5.443×10^{-3} in English units), and
Q_w = water flow (m³/s, gpm).

For design purposes, the supplemental oxygen requirement should be based on a weekly (or monthly) biomass and feeding level. Depending on the harvest schedule and temperature, the maximum supplemental oxygen requirement may occur prior to the end of the production cycle. If there is a large variation in biomass between the various rearing units, it may be necessary to compute the supplemental oxygen requirement for each rearing unit.

Number of Units and Power Requirement

The number of units and the power requirement depend on the amount of supplemental oxygen needed (Eq. 17), OTR_f, and FAE.

$$\text{Number of units needed} = \frac{\text{Supplemental oxygen}}{OTR_f} \qquad (18)$$

$$\text{Power requirements (kW)} = \frac{\text{Supplemental oxygen}}{FAE} \qquad (19)$$

System Characteristics

The selection of aerators will also be based on the physical characteristics of (a) the site, (b) the number, size, and configuration of the rearing units, (c) the hydraulics of the rearing units, and (d) the mode of operation. In many cases, the system may be completed before the need for an aeration system is realized. Therefore, it is commonly necessary to design or retrofit an aeration system around a given system, rather than to design a complete culture system from scratch. Some of the most common site considerations are presented in Table 3.

The number, size, and configuration of the rearing units is important in the selection process. In large tanks or ponds, individual mechanical or floating aerators may be used. In the aquarium trade, where a large number of small tanks must be aerated, diffused aeration is commonly used. Although the amount of air available is relatively fixed, the air can be distributed to a large number of individual units inexpensively, and flow to an individual unit can easily be varied.

Aerators that interfere with the normal operations of a culture system or require extensive maintenance will probably not be used long. Operational personnel may lack the time, the knowledge, or the tools to operate and repair some types of aerators. Aerators such as gravity aerators or paddlewheels, which can be constructed and repaired on-site, may be better choices for some operations, even if their overall efficiency is lower than that of other types of aerators. The operational characteristics of different types of aerator systems are presented in Table 3.

Control

The oxygen demand of a production system has a significant diurnal and seasonal variation (Fig. 6). In addition, the oxygen demand from a single raceway or

Table 3. Common Design Considerations

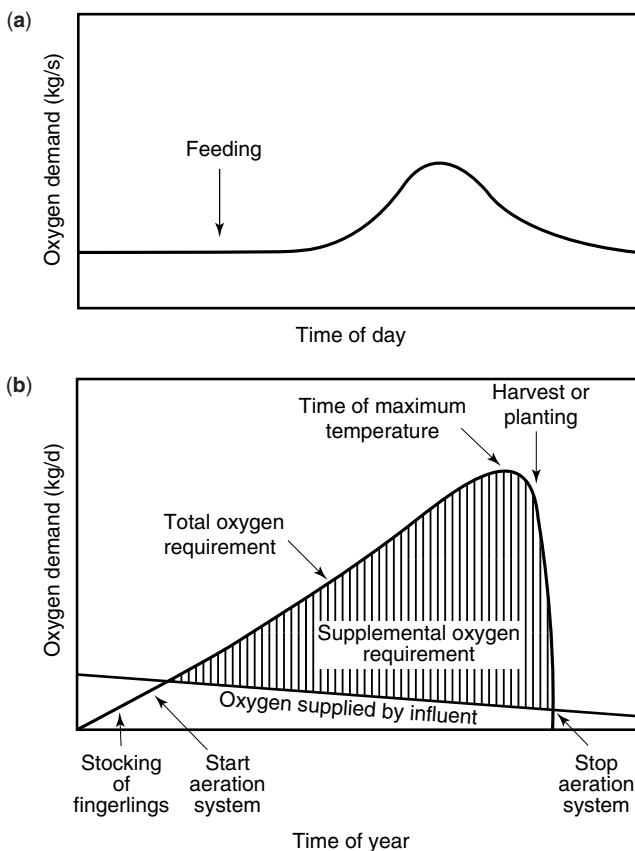
| Item	Considerations
	Site
Head	If enough head is available, operation of a gravity aerator may be possible without the use of external power.
Power	If electrical power is unavailable or unreliable, it may be necessary to use a motor-generator system or an engine-powered aerator.
Location	In remote locations, the lack of spare parts and trained personnel may favor simple systems.
Subsurface	In areas with rocky or unstable soils, excavation may be expensive.
Layout	Retro-fitting existing hatcheries may involve careful consideration of problems associated with installing additional electrical lines, piping, and pumps between or around existing structures and utilities. A side-stream pure oxygen system may be easier to retro-fit at some sites.
	Operational
Fouling of diffusers	Diffusers (airstones) may foul from the growth of algae or bacteria. Fine-bubble diffusers may require special air filters and non-metal air lines to prevent clogging due to rust and scale. Diffusers may foul rapidly if not operated continuously.
Icing	Surface aerators (and some types of gravity aerators) produce enough spray to cause ice on walkways and roads. This situation may present a safety hazard to personnel.
Safety	Electrical lines, fuel tanks, or rotating shafts may present a safety hazard to personnel. Diffused aeration systems may be safer than other systems, because electrical lines are required only for the central blower unit. Electrical safety is a major concern in marine systems, because of the high conductivity of seawater.
Harvesting/feeding	In ponds, static-tube or surface aerators may need to be removed prior to harvesting. Aerators should not interfere with the daily operations of the facility.
Repair	The ease of repair may be an important consideration in remote locations. This consideration includes both the skills and tools required and the local availability of spare parts.
Reliability	A simple and highly reliable aerator is desirable. When adequate head is available, gravity aerators will operate during power failures.


Figure 6. Variation of oxygen demand in a flow-through system with (**a**) time of day (**b**) season of year.

raceway series can change during the transferring or harvesting of fish. The amount of oxygen transfer can be adjusted by turning on another pump or blower. The degree of control depends on the total number of aeration units, the operational characteristics of the aerators, and the layout of the rearing units.

The simplest control strategy for diurnal changes in oxygen demand is to design for the maximum oxygen demand (Fig. 7a). This strategy may result in low FAE values over much of the day.

Step control (Fig. 7b) uses one system to provide base capacity and a second system to provide peak capacity. In raceways, surface aerators are commonly used to provide additional aeration for times at which biomass is high and the output of gravity aerators is insufficient. Surface aerators can also be used to increase the oxygen-transfer rate following feeding, when the oxygen consumption of culture animals increases. In subsurface aerators, oxygen transfer can be changed by changing the air flow to the unit. A system consisting of number of smaller units, each of which can be turned on when needed, may be more efficient than one running a single large blower continuously.

Total required oxygen capacity may be minimized by staggering the feeding times within each raceway series to reduce the peak oxygen demand following feeding (Fig. 7c). This strategy may have the additional benefit of eliminating the need for continuous DO monitoring and for on-line control.

Aerators in ponds are generally run during the nighttime period (Fig. 7d). Because of the high oxygen demand

Figure 7. Control strategies: (**a**) peak demand, (**b**) step control, (**c**) reduced peak demand, (**d**) pond systems.

from algae and bacteria, it is generally impossible to maintain adequate dissolved oxygen concentrations in the entire pond.

ALGAE: TOXIC ALGAE AND ALGAL TOXINS

C.O. PATTERSON
Texas A&M University
College Station, Texas

OUTLINE

Introduction

Increasing Frequency of Harmful Algal Blooms

INTRODUCTION

Although algae form the base of most aquatic food chains and are vital to both freshwater and marine ecosystems, certain species frequently become nuisances. Their presence, especially in high cell concentrations, may discolor water or produce unpleasant odors or flavors. Extremely high cell concentrations may produce episodes of hypoxia or anoxia in water bodies, either because of high respiratory oxygen demand during hours of darkness or because of chemical oxygen demand when the cells die and begin to decay. Algal cells may clog water filtration and purification equipment. Though all these effects cause problems, such problems rarely become life-threatening to humans or domestic animals. More dangerous effects occur when algal species produce chemical compounds which are actively toxic. The terms "red tide" and "brown tide" are increasingly associated in the public mind with outbreaks of toxin-producing algae, but these are misnomers. In many cases, toxin concentrations may reach dangerous levels with no apparent color change in the water, while in other cases discolored water is caused by species that produce no toxins. In this entry, attention focuses on true toxin-producers, ignoring milder nuisances of filter clogging, taste and odor production, and water discoloration. Such toxin-producers are coming to be known as Harmful Algal Blooms (HAB).

INCREASING FREQUENCY OF HARMFUL ALGAL BLOOMS

In recent years, more frequent and more serious outbreaks of toxin-producing algae have generated increasing concern among public health officials and increasing publicity in news media. Funding for the study of toxic algae and algal toxins has increased markedly within the past two decades. As investigators have sought to understand HABs, much literature has been generated, both as journal articles and as monographs (1–10). At least one semipopular book has focused on a specific toxic alga, *Pfiesteria* in the Albemarle–Pamlico–Neuse estuarine system on the Atlantic coast of North Carolina (11). The need for readily available sources of information and rapid dissemination of information

and public health warnings has led to establishment of several Web sites for HABs. These sites should be consulted for the most recent information. Woods Hole Oceanographic Institute maintains the Toxic Marine Algae Web site at *http://www.redtide.whoi.edu/hab/*. The Cyanotox Web site [specializing in blue-green algae (cyanobacteria)] originates from La Trobe University (Victoria, Australia) and can be found at *http://luff.latrobe.edu.au/~botbml/cyanotox.html*. The Canadian Department of Fisheries and Oceans maintains the phycotoxins site at *http://www.maritimes.dfo.ca/science/mesd/he/lists/phycotoxins/index.html*.

It is often asked whether outbreaks of toxic algae are becoming more frequent or whether the increased numbers of reports merely reflect increased scientific and public awareness of these events, improved monitoring and characterization techniques, more detailed observation, and better reporting of episodes. No conclusive answers to this question have been reached, but there is a growing consensus among investigators that the frequency and severity of such outbreaks are increasing and blooms of toxic algae are occurring in locations from which they have been absent in the past (12,13). Kao (14) points out that symptoms of algal toxin poisoning are so distinctive and so startling to observers that it seems unlikely that episodes would have gone unnoticed or unreported if they had occurred in the past. Love and Stephens (15) mention that cases of ciguatera poisoning first began to appear in the islands of Midway, Johnson, Palmyra, Fanning (now Tabuaeran), and Christmas (now Kiritimati) in the early 1940s and were caused by eating fishes that had previously been known to be edible. The World Health Organization recorded approximately 900 cases of human paralytic shellfish poisoning between 1970 and 1983, with many of these cases occurring in regions where paralytic shellfish poisoning had been unknown (16). For example, the readily identified dinoflagellate *Gymnodinium catenatum*, which produces paralytic shellfish poisoning, was reported only twice (in the Gulf of California and off Argentina) between 1940 and 1970. Then, between 1976 and 1994, it was reported 12 times from widely scattered locations around the world, usually in connection with toxic outbreaks (17,18).

ECOLOGICAL FACTORS THAT CONTRIBUTE TO HABS

The causes of increased frequency and severity of toxic outbreaks are still under investigation. A number of possible factors have been identified. Improved transportation methods make it possible for materials, including algal cells, to be moved inadvertently (such as in ballast water) and with unprecedented speed from their ancestral habitats into new locales. Thus seed stocks or inocula transported into new habitats may be released from control by grazers or competing species that had previously held numbers low. In addition, many investigators suspect that ecological factors, such as nutrient availability, water temperatures, water turbidity, and growth-regulator analogs, have been altered in many habitats in ways that stimulate growth of the nuisance species. However, in no case do we

currently have sufficient data or robust enough models to identify specific causes of HAB outbreaks.

Detailed information is now available about the molecular structure and mode of action of most of the algal toxins. We know the cellular-level effects in some detail. Much less is known about the genetic and environmental basis for toxin production. No complete biosynthetic pathway is known for any algal toxin. Similarly, the genetic basis for every algal toxin remains to be elucidated. We cannot yet identify with certainty the strains that produce toxins nor can we define the particular conditions under which toxins are produced. Factors that produce, sustain, and terminate blooms, and that control toxin production during blooms, are not understood. Outbreaks tend to be irregular and unpredictable. Consequently, we have very little predictive capability. Public health officials and agencies are limited almost entirely to reacting after a toxic incident is underway (sometimes even after the incident is essentially finished), rather than having the tools to anticipate incidents. We are even further from being able to manipulate situations to prevent such outbreaks. Disappearance of blooms is often as sudden and mysterious as their appearance. Sexual reproduction and formation of resting cysts seem frequently to be associated with the ending of blooms, especially among dinoflagellates. Sexual mating in some species has been induced under lab conditions by nutrient starvation.

Although every known algal toxin can be produced by more than one species, it is almost always found that any specific harmful bloom is composed of a single species. Factors responsible for bloom formation, and detailed mechanisms of bloom development, remain poorly understood for virtually all species. Investigators have focused on nutrient availability (19–21), effects of vitamins and chelators (22–25), fluctuations of nutrient concentrations produced by upwelling (26,27) or by runoff from land after heavy rains, on the ability of different species to reach nutrient supplies by vertical migration (especially diel migration) (28), on salinity, temperature, light intensity (29–31), competition with other species (32), effects of grazers (33), excystment or resuspension of resting stages or epiphytic forms (34,35), advection or concentration of cells into restricted geographic areas (36,37), and on availability of trace elements (38). Turner et al. (33) noted that "interactions between toxic phytoplankton and their grazers are complex, variable, and situation-specific. An overall synthesis of these interactions is elusive and premature because present results are still too disparate. Accordingly, information from one experimental study or natural bloom should be extrapolated to another with caution." Similar statements might be made with regard to each of the other biotic and abiotic factors influencing blooms of toxic species. Although detailed understanding of the causes and interactions is still in the future, sufficient information has been accumulated to say that each toxic species displays its own pattern of response to physical, chemical, and biological factors in its environment. That is, each toxic species exploits certain environmental parameters more efficiently than any other species. When specific combinations of features come together, a bloom results. Hallegraeff has provided a very useful summary of the "niche-defining factors" for the major marine species of toxin-producers (39). He categorizes such factors as either responses to the physicochemical features of the environment (temperature, salinity, inorganic nutrients, micronutrients, etc.) or as properties of the organisms themselves (mixotrophy/ability to utilize organic nutrients, allelopathy, or grazer avoidance, parameters of life history, ability for vertical migration, or response to turbulence in the water column, etc.). For example, the dinoflagellate *Alexandrium* (a producer of paralytic shellfish poisoning toxins) is sensitive to temperature, responds strikingly to micronutrient availability, and shows vertical migratory behavior. In contrast, most cyanobacteria are strongly sensitive to temperature and to availability of inorganic macronutrients (especially nitrogen and phosphorus). Further investigation will undoubtedly allow us to refine these categories and develop more detailed descriptions of the parameters that define the "toxic bloom niche" of each HAB species.

Prediction and monitoring of HABs assume great importance for public health officials, fisheries managers, academic investigators, and the general population who might encounter these occasionally dangerous organisms. Therefore, a number of studies are underway, seeking to overcome our present frustrating inability to anticipate toxic outbreaks. Some investigators focus on developing predictive models, based on numerical and statistical descriptions of blooms (40). Other groups (41,42) are developing methods to detect HABs by optical methods (using floating buoys, airborne or satellite surveillance, etc.). These techniques emphasize recognition of HAB-forming species from distinctive patterns of light absorbance by chlorophyll and other pigments or by fluorescence emission spectra. Results have been mixed, with no groups yet reporting complete success. Efforts continue in this area, and some optimism seems justified.

TAXONOMY AND IDENTIFICATION OF TOXIC ALGAE

Controversy abounds over the correct identification of virtually all toxin producers. Characteristics that have been used for identification include morphology, isozyme patterns, toxin profiles, life history patterns, sexual mating ability, and nucleic acid sequences. No one of these has proven entirely satisfactory. Additional difficulty results from taxonomic changes; most toxin-producing species are known by several names. Steidinger and Vargo (43) provide a useful list of synonyms for toxic dinoflagellates. The dinoflagellate genus *Alexandrium* is one of the most important producers of potent toxins responsible for paralytic shellfish poisoning. This genus includes about 30 species. Of these, some species produce toxins, while other species have failed to show toxin production. Of the toxin producers, some strains within a single species show toxin production, while others do not. It is clear that danger of toxic outbreaks cannot yet be assessed from taxonomic information alone. In late 1987, a major poisoning event occurred in eastern Canada. Intense efforts by public health authorities established that the toxin-producer was a diatom, initially

identified as *Nitzschia pungens* forma *multiseries*. It required almost 10 years of work before the nomenclature of the organism was resolved; it is now known as *Pseudo-nitzschia multiseries* (44). The situation is further complicated by the growing recognition that different geographic strains (subspecies?) of what seems to be the same species may show sharply different toxin-producing characteristics. For example, the New England strain of the cyanobacterium *Aphanizomenon flos-aquae* is known to produce the paralytic shellfish poisons saxitoxin and neosaxitoxin, while the Oregon strain of the same organism has never shown any sign of toxin production.

Most (perhaps all) toxins are secondary metabolites, with very complex chemical structures. They are the end products of elaborate, multistep biochemical pathways. Very little is known about most of these pathways. Only the biosynthetic pathway for saxitoxins (etiologic agents of Paralytic Shellfish Poisoning) is relatively well understood. However, enough is known about virtually all the pathways to say that it is certain that multiple, probably unique, enzymes are required. The only exception to this general rule appears to be the synthesis of domoic acid by diatoms, where only a few (one to three) unique enzymes may be required (45). Although almost no data are yet available for the enzymes themselves, it can be predicted that the genes encoding these enzymes may occupy large segments of the organisms' DNA, and that collectively, possession of such genetic arrays may serve as a distinctive "signature," which might be used to identify toxin-producers (46).

The taxonomy of all cyanobacteria, including toxin producers, is chaotic and currently undergoing extensive revision. Morphological characters of cyanobacteria are notoriously variable. Many of the features that were thought to distinguish species and even genera are now known to depend on previous growth conditions and are unreliable for accurate identification of field-collected specimens. Consider one extreme example: the cyanobacterium *Spirulina*, which is widely sold commercially as a human nutritional supplement. It has long been thought that *Spirulina* was one of the most easily identified cyanobacterial genera, recognizable by its tightly coiled helical filaments. Patterson and Hearn (unpublished) observed that when *Spirulina* is maintained at high growth rates, it loses its helically coiled growth habit; the filaments straighten and become linear strands, morphologically indistinguishable from strains of *Oscillatoria*. Certain strains of *Oscillatoria* are known to be producers of hepatotoxins and neurotoxins (47,48). Skulberg et al. (49) offered a provisional key for identification of potentially toxigenic cyanobacteria, but it should be used with caution. The presence, position, and form of heterocysts is widely used for identification of filamentous cyanobacteria. Heterocysts, modified cells wherein nitrogen fixation occurs, differentiate only when the organisms are starved of nitrogen. In eutrophic (nitrogen-replete) waters, heterocysts may be completely absent, even from genera capable of forming them. Furthermore, toxic strains of cyanobacteria do not differ morphologically from nontoxic strains, so identification, even to species level, does not reliably predict whether a particular bloom will become toxic.

Analysis of nucleic acid features holds promise for precise identification of toxic species and strains. Scholin (50) provided a useful review of the techniques and difficulties involved. Manhart et al. (51) were able to distinguish Atlantic, Pacific, and Gulf of Mexico isolates of *P. multiseries* from isolates of *P. pungens*, based on distinctive differences in restriction fragment patterns (RFPs) of nuclear DNA. *P. multiseries* is a toxin producer (domoic acid), while *P. pungens* is nontoxic. This technique is not presently suited for field application nor for rapid identification of organisms, but it may provide the basis for development of dependable methods for distinguishing species that are morphologically very similar. Rouhiainen et al. (52) examined 37 strains of toxic and nontoxic cyanobacterial strains from northern Europe. Restriction fragment patterns and Southern blot analyses were shown to distinguish hepatotoxic *Anabaena* isolates from neurotoxic forms and from *Nostoc* strains. Further work is needed to determine whether the distinctive patterns recognized among these isolates from a fairly small geographic area are reliable on a worldwide basis. Successful application of such nucleic acid-based identification techniques will require cultivation of axenic cultures of many species and strains that have not yet been successfully grown in the laboratory. Many toxic strains, especially among marine forms, are notoriously difficult to maintain under laboratory conditions. Culture techniques must improve along with our abilities to carry out analyses of genetic structures.

It is now established that certain nonphotosynthetic bacteria can synthesize saxitoxins and perhaps other toxins as well. It is also known that the presence of certain bacteria enhances production of domoic acid by the diatom *P. multiseries*. Evidence is accumulating that intracellular symbiotic bacteria are present in many strains of toxigenic algae, but it is not yet clear what role these symbionts play in the formation or release of toxins (53,54). Involvement of symbiotic complexes may further complicate the problems of identifying toxic species or strains.

ALGAL TOXINS: THEIR CHEMISTRY AND PHYSIOLOGICAL EFFECTS

Toxins are known to be produced by at least four groups of algae: the Haptophyta (sometimes regarded as Class Prymnesiophyceae within Division Chromophyta), the dinoflagellates (Division Dinophyta or Class Dinophyceae within Division Chromophyta), the diatoms (Class Bacillariophyceae within Division Chromophyta), and the Cyanobacteria ("blue-green algae"). The first three groups show eukaryotic cell structure and hence are true algae. The cyanobacteria possess prokaryotic (bacterial) cell structure, though their old name of "blue-green algae" is still widely used. Dinoflagellates are probably the best known and longest studied of the algal toxin producers. These "red tide" organisms are the most familiar to the general public. Diatoms are the most recent additions to the list of toxin producers, with the first known outbreak of diatom-related poisoning occurring in eastern Canada in 1987 (55,56). Since 1987, toxic diatom blooms have become

familiar to the public as "brown tides." Cyanobacteria are typically the source of toxins in freshwater environments (57,58), while the other groups are almost exclusively found in marine or brackish waters.

Toxicity testing is usually by mouse bioassay. Typically, a sample of the suspected toxin is injected intraperitoneally into the mouse, followed by 24 hours of observation. After 24 hours, any surviving mice are sacrificed for postmortem examination for tissue and cytological injury. This bioassay has formed the basis for the discovery, identification, study, and regulation of all the algal toxins. Like all bioassays, this technique suffers from several drawbacks, including inherent variability in the mice, difficulty of distinguishing effects when several toxins are present in a sample, expense, time delays, and increasing public opposition to testing of this sort. Investigators have developed several alternative assay methods in recent years. Gas chromatography, thin-layer chromatography, high-performance liquid chromatography, radioimmunoassay techniques, and enzyme-linked immunosorbent assay techniques all show promising results. Among the greatest challenges to the use of any of these techniques is the supply of purified toxins to use as standards (59).

Cyanobacterial Toxins

Among the cyanobacteria (blue-green algae), several genera have been shown to be toxin-producers. Cyanobacterial toxins are contained within the living cells and are not released into water until senescence or death of the cells (60). It is still not clear what factors influence or control production of cyanobacterial toxins. Many investigators have suspected that nutrient supplies are critically important, but no agreement has been reached as to which nutrients exert the dominant effect. Most attention has focused on nitrogen, phosphorus, and N:P ratios, since it has long been known that cyanobacteria bloom in waters enriched in N and P. There is still no clear evidence that nutrients influence toxin production other than via their general effect on growth rate. In other words, in nutrient-rich waters, growth rates are high, leading to rapid accumulation of dense populations of toxin-producing cells. But the concentration of toxin/cell appears to change very little.

Among the prokaryotic cyanobacteria (blue-green algae) production of both hepatotoxic and neurotoxic compounds has been extensively studied (61). Additional toxins, producing dermatitis, respiratory distress, and other symptoms have been reported, but are less well characterized. The cyanobacterial toxins include both neurotoxins and hepatotoxins. The most common hepatotoxins seem to be cyclic peptides containing a unique hydrophobic amino acid whose chemical name is usually abbreviated ADDA (3-amino-9-methoxy-2,6,8-trimethyl-10-phenyl-4,6-decadienoic acid). These toxins are called microcystin (seven amino acids in the ring) or nodularin (five amino acids in the ring). These were named for the genera from which they were first isolated (*Microcystis and Nodularia*, respectively), but it is now known that other genera also produce the toxins. The peptides are synthesized nonribosomally, but their

biosynthetic pathways and normal function in the cell are not well understood. Both microcystin and nodularin are rapidly taken into vertebrate liver cells via the bile transport system and are also taken into epithelial cells of the small intestine, using the same bile transport mechanism. Once inside the target cells, the toxins act as potent inhibitors of protein phosphatases (classes 1 and 2A). This produces hyperphosphorylation of cell proteins, with a wide range of effects. One effect, almost immediately observable microscopically, is deformation of liver cells resulting from collapse of the cytoskeleton. Extensive hemorrhage and hepatocyte necrosis follow; the acute cause of death is shock due to blood loss (62). The effect of microcystin and nodularin in inhibiting protein phosphatases is strongly reminiscent of the mode of action of the dinoflagellate toxin, okadaic acid. However, the molecular structure and sites of action of okadaic acid are distinctly different and will be discussed next. Microcystin is degraded slowly (10–30 days) after release, probably by microbial action. Chlorination, flocculation, and filtration do not remove the toxin, although there are indications that ozonation or absorption on activated charcoal effectively remove the toxin.

A wide variety of cellular events and metabolic processes are regulated by the level of phosphorylation of cellular proteins. Proteins are phosphorylated by the action of protein kinases and dephosphorylated by action of phosphatases. Among other processes regulated by the level of phosphorylation is control of cell division and proliferation. Inhibition of phosphatases, leading to hyperphosphorylation, may increase cell proliferation, leading to tumor formation.

In mice, the lethal dose of microcystins via intraperitoneal injection is about 2–3 μg for a 30 g mouse, i.e., about 60–70 μg/kg body weight. Because of widespread consumption of cyanobacterial material as health supplements, concerns have been raised about acceptable levels of toxins in dried cyanobacterial biomass. The Oregon State Health Division has determined that 1 μg/g (1 ppm) is a safe level for microcystins in cyanobacterial material sold for human consumption.

A second type of cyanobacterial hepatotoxin, known as cylindrospermopsin, was originally isolated from *Cylindrospermopsis* in an Australian water supply. The toxin is a novel alkaloid with a cyclic guanidine unit (63). It appears to act by inhibiting protein synthesis. In addition to microcystin, nodularin, and cylindrospermopsin, another group of compounds that act as tumor promoters have also been isolated from cyanobacteria, especially from *Lyngbya*. These toxins, known as aplysiatoxin and lyngbyatoxin, activate protein kinase C, leading to cell proliferation (64).

Dinoflagellate Toxins: Saxitoxins

Paralytic shellfish poisoning (PSP) results from ingestion of any of a family of compounds produced by dinoflagellates. At this time, members of the genera *Alexandrium (Gonyaulax)*, *Pyrodinium*, and *Gymnodinium* have been shown to produce these toxic compounds. In *Alexandrium*, toxin production is enhanced when cells are phosphate limited, but decreases when cells are nitrogen limited (65,66).

The compounds are derivatives of saxitoxin, a tetrahydropurine with a unique 3-carbon ring between C4 and N3 (67,68). The biosynthetic pathway has been extensively studied, and is reasonably well understood (69,70). At least 18 naturally occurring derivatives of saxitoxin have been isolated. All produce their paralytic effect by binding to and blocking the voltage-gated sodium channel of neurons, skeletal muscle cells, and cardiac muscle cells. In normal, unpoisoned cells, the inward flow of sodium ions produces the action potential that is necessary in the transmission of nerve impulses and the contraction of muscle cells. In the presence of saxitoxin and its derivatives, the sodium channel is blocked, no action potential can be generated, and paralysis results.

PSP is potentially life-threatening. Onset of symptoms is rapid, within a few minutes to a few hours after consumption of the toxin. Symptoms include tingling, numbness, or burning of the mouth region, followed by giddiness, drowsiness, and staggering. Severe cases result in respiratory arrest. No antidote is known.

Dinoflagellate Toxins: Brevetoxins

Neurotoxic shellfish poisoning is produced by brevetoxins, products of the dinoflagellate *Ptychodiscus brevis (Gymnodinium breve)*. Brevetoxins are polyethers, with at least nine derivatives now known to be toxic (71). In contrast to the saxitoxins, which act by blocking sodium influx into excitable cells, brevetoxins specifically induce an irreversible channel-mediated sodium ion influx (72). Thus, brevetoxins depolarize both nerve and muscle cells; nerve cells are much more sensitive to these toxins. Depolarization induces neurotransmitter release in neuromuscular preparations, but the essential effect results from the opening of the sodium channels.

Dinoflagellate Toxins: Ciguatoxin and Gambiertoxins

Ciguatera poisoning is probably the most widespread and the least understood of the algal toxin-related syndromes. It is known that several closely related compounds are involved, and that these compounds are produced by several genera and species of dinoflagellates, notably *Gambierdiscus toxicus*, *Coolia monotis*, *Amphidinium carterae*, *Prorocentrum* spp., *Ostreopsis* spp., *Thecadinium* spp., and perhaps others. *G. toxicus* is the causative organism in most cases of ciguatera poisoning. The molecular structures of only a few of the toxins have been determined. Ciguatoxin and gambiertoxin have been shown to be complex cyclic polyethers, structurally reminiscent of brevetoxin and okadaic acid (73). Although some uncertainty remains as to the exact mode of action of ciguatoxins, it appears very likely that they act in much the same way as brevetoxin, that is, by binding to the sodium channel of neuronal membranes and triggering sodium influx (73,74). This irreversibly depolarizes the nerve cell. Effects of ciguatoxin can be blocked by tetrodotoxin, by excess extracellular Ca^{2+}, or by cholinesterase inhibitors.

Maitotoxin coexists with ciguatoxin in ciguateric fish and is one of the most potent marine toxins. It is produced by *G. toxicus* in more abundant quantity than ciguatoxin (75). In smooth muscle and skeletal muscle preparations, maitotoxin causes calcium ion-dependent contraction (76). Maitotoxin may act by changing configuration of a membrane protein, transforming it into a pore that allows Ca^{2+} to flow through (75,77).

Dinoflagellate Toxins: Okadaic Acid

The dinoflagellate genera *Dinophysis* and *Prorocentrum* include species that produce the toxin okadaic acid. This toxin causes diarrhetic shellfish poisoning (DSP), a nonfatal, but temporarily incapacitating illness, involving severe abdominal cramps, vomiting, diarrhea, and chills. Like brevetoxins and ciguatoxins, okadaic acid is a cyclic polyether. However, the mode of action of okadaic acid appears to differ from that of the other polyethers. Okadaic acid is thought to act as an inhibitor of protein phosphatases (78); in this respect, it is similar to microcystin and nodularin, although the molecular structure and the producing organisms are quite different. Okadaic acid apparently produces its effects by inhibiting dephosphorylation of myosin light chains in smooth muscle and thus producing tonic contractions (79). There is uncertainty as to whether okadaic acid is typically released from healthy cells into the water. Carlsson et al. (80), studying a *Dinophysis* bloom, found that it was not.

Diatom Toxins: Domoic Acid

Certain marine diatoms produce the toxin known as domoic acid. Domoic acid poisoning, also becoming known as amnesic shellfish poisoning, produces symptoms of vomiting, diarrhea, abdominal cramps, disorientation, and memory loss. Although the toxin is produced by diatoms (and by certain species of red algae), most cases of poisoning result from consumption of mussels (*Mytilus edulis*) that have accumulated the toxin from the diatoms on which they have fed. The toxin was originally isolated from the diatom genus now known as *Pseudo-nitzschia* and has been subsequently identified in at least seven additional diatom species (81). It has also been found in the red algal genera *Chondria*, *Alsidium*, *Amansia*, Digenea, and *Vidalia*. All reported poisoning incidents appear to have been associated with diatoms, none with reds. Production of domoic acid by *Pseudo-nitzschia* appears to increase when cells are silicate or nitrogen limited (82,83) or with higher levels of temperature and light (84,85).

The molecular structure of domoic acid is a water-soluble tricarboxylic amino acid (82). It appears to act by binding to glutamate receptors of neurons in the central nervous system, especially the hippocampus (86–88). Glutamate (or glutamic acid) is a well-known excitatory neurotransmitter. Domoic acid excites the neuronal membrane, leading to irreversible depolarization, accumulation of intracellular Ca^{2+}, neuronal swelling, and death (89).

Dinoflagellate Toxins: New and Unidentified Forms

The toxic dinoflagellate *Pfiesteria piscicida* and at least two other *Pfiesteria*-like species produce toxins that remain poorly characterized. *Pfiesteria* and the similar species were first discovered in the 1980s and thus far have only been found in the western Atlantic and Gulf regions. These organisms apparently behave as "ambush predators,"

releasing toxins specifically when prey organisms are near (90,91). The toxins narcotize finfish, and cause sloughing of epidermis and formation of open ulcerative lesions in finfish and shellfish. The toxins can be aerosolized and produce muscular pain, abdominal distress, dizziness, disorientation, and memory loss in humans when inhaled (92,93). The chemical structures of these toxins are not yet known. It is known that the toxins include both lipophilic and water-soluble compounds (94,95). Likewise, the mode(s) of action of these toxins have not yet been characterized.

Chrysophyte (Haptophyte) Toxins

The genera *Prymnesium*, *Chrysochromulina*, and *Phaeocystis* include species and strains well known for killing finfish and shellfish, both farmed and free-ranging. Toxin production appears to be promoted by phosphorus deficiency, but expression of the toxin is extremely variable. Dramatic effects seen in nature (massive, wide-ranging fish kills) have been difficult to reproduce under laboratory conditions. Much remains to be learned about the factors that influence or control toxin production and/or release. The toxin is believed to be a glycoside or a family of related glycosides (96). The toxins display a generalized effect on membrane permeability and disturb ionic balances in cells of a wide range of marine organisms by eliciting marked increases in membrane permeability, with resulting leakage of cell contents (97,98). Blood cells are disrupted, so the toxins are often described as hemolytic. These toxins appear to be especially dangerous to gill-breathing animals such as fish, tadpoles, and molluscs.

ALKALINITY

GARY A. WEDEMEYER
Western Fisheries Research Center
Seattle, Washington

OUTLINE

The alkalinity of water is its capacity to chemically neutralize acids. It is commonly expressed as mg/L (or parts per million, ppm) of equivalent calcium carbonate, $CaCO_3$ (1). In water suitable for aquaculture alkalinity is usually due to naturally occurring dissolved-mineral bicarbonates (HCO_3^-), carbonates (CO_3^{-2}), and hydroxides (OH^-), often from limestone deposits; and to a lesser extent, borates, phosphates, and silicates. However, pollution from industrial and municipal effluents or irrigation drain water can also contribute to alkalinity.

Alkalinity is sometimes confused with the related concept, water hardness, which is also expressed in mg/L as $CaCO_3$. Hardness, however, is primarily a measure of the calcium and magnesium concentration, and is independent of alkalinity. Water originating from areas with limestone rock formations may contain both calcium and magnesium carbonates and can therefore reach high levels of both alkalinity and hardness. Waters of high alkalinity usually also have an alkaline pH (pH > 7) and a high concentration of total dissolved solids (TDS). The alkalinity of water supplies used for aquaculture can range from less than 10 mg/L (soft, freshwater ponds, streams) to as high as several hundred mg/L (sea water, hard alkaline fresh water).

ANALYSIS

Alkalinity is most conveniently determined by titrating a water sample with standardized acid (usually 0.1 N HCl) to the methyl orange end point (pH 4.3), using a portable water quality test kit. For highly accurate work, specialized equipment under controlled laboratory conditions should be used (1). In either case, the result is the total alkalinity—commonly expressed in mg/L (or ppm) as $CaCO_3$. In limnology and oceanography research, and in Europe, alkalinity is often expressed in units of milliequivalents per liter (meq/L), where

$$1 \text{ meq/L} = 50 \text{ mg/L as } CaCO_3$$

A total alkalinity determination effectively measures all the bicarbonates, carbonates, and hydroxides present. Many water chemistry test kits used in aquaculture also offer the opportunity to measure the phenolphthalein alkalinity (end point pH 8.3), in addition to the total alkalinity. The phenolphthalein alkalinity measures the total hydroxides (OH^-) and carbonates (CO_3^{-2}) present. If this number is zero or near zero, as it usually will be in ponds with aquatic plants, then the total alkalinity is nearly all due to bicarbonates. Thus, an alkalinity determination can provide useful information on both the total concentration and the identity of the alkaline (basic) substances dissolved in a particular water supply. In addition, the alkalinity, together with the water temperature and pH, can be used to calculate the dissolved CO_2 concentration. Tables or nomographs for this purpose can be found in standard reference works (1).

IMPORTANCE TO AQUACULTURE

Although fish do not have a direct physiological requirement for dissolved carbonates or bicarbonates, the alkalinity of a hatchery water supply can nonetheless strongly influence the health and physiological quality of production fish. Most importantly, the alkalinity provides a buffer against wide fluctuations in water pH that would otherwise occur due to the daily cycle of CO_2 addition and removal by animal and plant respiration and plant photosynthesis. The pH of natural waters is determined by the interactions between the dissolved CO_2 and carbonic acid

produced by plant and animal respiration and the bicarbonate and carbonate minerals from which the alkalinity is derived:

$$CO_2(gas) \rightleftharpoons CO_2\,(aq) + H_2O \rightleftharpoons H_2CO_3$$
$$\rightleftharpoons H^+ + HCO_3^- \rightleftharpoons 2H^+ + CO_3^{-2}$$
Because this system can neutralize added acids or bases, water supplies with a sufficient degree of alkalinity are therefore buffered against the pH increases or decreases that would otherwise occur.

An alkalinity of 10–20 mg/L is usually considered the minimum level needed to stabilize water pH and protect the health and physiological quality of production fish in flow-through raceway culture systems (2). However, pond fish that depend on natural food may grow slowly in waters of such low alkalinity because the production of phytoplankton and zooplankton will be low. Wide fluctuations in pH will also occur. For example, the water available for warmwater pond-fish culture in the southeastern United States is often low in alkalinity and therefore poorly buffered. At night, respiring phytoplankton and fish add CO_2 to the pond water decreasing the pH to as low as 5.5. During daylight hours, rapid algal growth in the intense sunlight can consume dissolved carbon dioxide faster than it can be replaced by fish respiration and diffusion from the atmosphere. The pond pH can increase to 9.5–10 in a matter of hours. Such pH increases, by themselves, can usually be tolerated by warmwater fish if the increases are temporary. However, ammonia is usually also present, and the high pH may increase the proportion of toxic NH_3 to greater than the 0.02 mg/L level generally considered safe (2). Water with an alkalinity of 40 mg/L or more (and a total hardness of 20–200 mg/L) is considered more desirable for both extensive (static ponds) and intensive (flowing water) aquaculture systems (2,3). In addition, pond fertilization is more likely to be successful under such conditions.

Alkalinities in the 100–200 mg/L range offer several additional advantages, including (a) reducing the toxicity of heavy metals, (b) allowing the safe use of copper sulfate as an algicide and fish disease therapeutant, (c) providing adequate buffering capacity against the fluctuations in water pH that would otherwise occur as a result of the natural daily cycles of photosynthesis and respiration, and (d) affording the stable pH and carbon source needed by nitrifying bacteria in the biofilters used in recirculating aquaculture systems (2,3). The latter is especially important in high-density recirculating systems where large amounts of ammonia are produced that must be oxidized to nitrate. The accompanying acid production may be sufficient to consume the carbonates present, and the pH will progressively decrease unless the alkalinity is replenished (4).

In saltwater aquaculture, alkalinity is not normally a consideration. Because of the high concentrations of carbonates, ocean water is strongly buffered at about pH 8.2.

MANAGEMENT RECOMMENDATIONS

Water supplies with a minimum alkalinity of 20–40 mg/L as $CaCO_3$ are considered highly desirable for both cold- and warmwater fish in either intensive or extensive culture systems (2,3). Alkalinities in the 100–200 mg/L range will provide the additional buffering capacity needed to prevent wide pH fluctuations in pond culture systems, prevent leaching of toxic metals bound to soils and sediments, allow the use of copper compounds for fish disease control, and provide the carbon needed to assure biological productivity. In recirculating aquaculture systems, alkalinities in this range will also assure an adequate supply of carbon for the nitrifying bacteria in the biofilters, as well as provide a stable pH.

Low alkalinity is not usually a problem in earthen ponds constructed with soils rich in limestone or in ponds made of concrete. However, many such ponds are lined with plastic or rubber, which effectively cuts off the source of carbonate. If desired, the alkalinity of pond waters can be increased to adequate levels by adding either hydroxides (such as sodium or calcium hydroxide) or carbonate compounds (such as agricultural limestone or sodium bicarbonate). However, only the latter are safe for aquaculture. Sodium bicarbonate is readily soluble in water and will not cause areas of locally high pH. Applied at 10–20 lb per acre-foot of water, it will temporarily correct low alkalinity and mitigate CO_2 and NH_3 problems arising from low or high pH. For longer term alkalinity management, agricultural limestone can be used. However, the amount of lime needed to raise the alkalinity by a particular amount is difficult to calculate directly. As a guideline, Terlizzi (5) has reported that added limestone will increase the alkalinity by about 1 mg/L per 2 kg (4.5 lb) of lime per 1233 m^3 (one acre-foot) of water. In practice, limestone is usually simply applied at 1–2 tons per 1233 m^3 (one acre-foot) at monthly intervals, and the alkalinity monitored until it rises above 20 mg/L. This process is very slow, however, and liming may not succeed at all if pond sediments have been allowed to become strongly acidic (6).

OUTLINE

Alligators and other members of the order Crocodilia (crocodiles and caimans) have long been valued for their hides and meat. The leather from crocodilian hides is used to make attractive luxury apparel items like belts, wallets, purses, briefcases, and shoes. The high value of these leather products led to extensive hunting of these creatures in the wild. By the 1960s, this exploitation, combined with habitat destruction, had depleted many wild populations of crocodilians. Research into the life history, reproduction, nutrition, and environmental requirements of the American alligator (*Alligator mississippiensis*), coupled with rapid recovery of wild populations led to the establishment of commercial farms in the United States in the 1980s. Worldwide, several other species of crocodilians are also cultured using similar methods (1,2).

HISTORICAL PERSPECTIVE

The American alligator was once native to coastal plain and lowland river bottoms from North Carolina to Mexico. Historical records show that the American alligator can grow to 16 feet or more. The only other species of alligator, (*A. sinensis*) is found in China and is endangered.

American alligators were hunted for their hides beginning in the 19th century (3). At the turn of the century, the annual alligator harvest in the US was around 150,000 per year. Overharvesting from the wild, combined with habitat destruction, slowly depleted the wild population. Most states stopped alligator hunting by the 1960s. Under the 1973 Endangered Species Act, the U.S. Fish and Wildlife Service designated alligators as "endangered" or "threatened" species throughout most of their range (with the exception of Louisiana) to protect them from further exploitation (4).

Once protected, alligator populations recovered. Recovery was dramatic in some areas, particularly in Louisiana, which had stopped legal harvesting in 1962. Louisiana reopened limited harvesting of wild alligators based on sustainable yield in 1972. The Louisiana alligator population continued to increase even with sustained harvesting, and by 1984 the Louisiana population was estimated to be near turn-of-the-century numbers (4). Most other southern states also experienced population increases after federal protection.

In 1983, under the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), the U.S. Fish and Wildlife Service changed the classification of the American alligator to what is called "threatened for reasons of similarity in appearance." This classification means that the American alligator is *not* threatened or endangered in its native US range. However, the sale of its products must be strictly regulated so that the products of other crocodilian species are not sold illegally as those of American alligators. Today nuisance control is allowed in several southern states, and limited harvesting from the wild is permitted in Louisiana, Texas, and Florida. In 1996 wild harvest and farm-raised alligators supplied over 240,000 hides to world markets. Approximately 83% of these were from alligator farms (5).

ECOLOGY AND LIFE HISTORY

Alligators inhabit all types of fresh to slightly brackish aquatic habitats. Males grow larger than females, although the growth rate of the sexes is similar up to approximately 1.1 m (3.5 ft) in length (4). Growth and sexual maturity are dependent on climate and the availability of food. Along the Gulf coast, females usually reach sexual maturity at a length of 2 m (6.5 ft) and an age of 9 to 10 years. Sexual maturity is not reached until 18 to 19 years in North Carolina [still 2 m (6.5 ft) in length]. Like other cold-blooded animals, this difference in maturation age is related to temperature. Optimum growth occurs at temperatures between 29 and 33 °C (85–91 °F). No apparent growth takes place below 21 °C (70 °F), while temperatures above 34 °C (93 °F) cause severe metabolic stress and, sometimes, death.

Research has shown that young alligators primarily consume invertebrates like crayfish and insects (6), and as they grow, fish become part of their diet. Mammals such as muskrats and nutria become a substantial portion of the adult diet. Large adult alligators even consume birds and other reptiles, including smaller alligators. Carrion is consumed whenever available (7).

Females do not move or migrate over long distances once they have reached breeding age. They prefer heavily vegetated marsh-type habitat (8). Males move about extensively, but prefer to establish territories in areas of open water (9). Males longer than nine feet are the most successful breeders.

Alligator courtship and breeding are correlated to air temperature and occur between April and July, depending on weather conditions. Courtship and breeding take place in deep (at least 1.8 m or 6 ft), open water. Courtship behavior includes vigorous swimming and bellowing. Both males and females bellow, but the male bellow is much more bass and vocal than that of the female. Most courtship occurs just after sunrise and takes about

45 minutes from precopulatory behavior through the first copulation (10). Repeated copulation is commonly observed.

After courtship and mating, females move to isolated ponds, surrounded by dense vegetation, for nesting, which occurs about two or three weeks after mating. Nest building and egg laying occur at night. Females build nests by raking up surrounding vegetation and soil into a mound. From 20 to 60 eggs are laid from above, into the center of the mound. All the eggs are deposited at one time. When egg laying is completed, the female covers the nest with about 25 cm (1 ft) of vegetation. Nesting occurs only once a year, and not all females nest every year. Females guard their nests against predators.

Warm summertime temperatures, combined with heat generated from the decaying mound of vegetation, maintains temperatures between 24 and 33 °C (75–91 °F) and relative humidities of 94 to 99% in the nest. The eggs hatch in 65 days if the temperature in the nest is consistently above 28 °C (82 °F). The young make grunting or peeping sounds after hatching, and the female often claws open the nest to help release them. Hatching success is generally less than 60% (11). Research done in Louisiana suggests that the survival of young alligators to 1.2 m (4 ft) long averages 17% or less (12). After an alligator reaches this length, it has few enemies other than larger alligators and human beings. A good review of general ecological considerations and information on the natural history of the American alligator is (13).

CONTROLLED BREEDING AND EGG INCUBATION

In Louisiana, Florida, and Texas, eggs and/or hatchlings may be taken from the wild under special permitting regulations. In all other states it is illegal to take eggs or hatchlings from the wild. Therefore, prospective alligator farmers must purchase eggs or hatchlings from existing farms in Louisiana, Florida, or Texas or must produce their own through captive breeding.

Management of Breeding Alligators

Maintaining adult alligators and achieving successful and consistent reproduction has proved difficult and expensive. The exact environmental, social, and dietary needs of adult alligators are poorly understood. Adult alligators that have been reared entirely in captivity behave differently from wild stock (14,15). Farm-raised alligators seem to accept confinement and crowding as adults better than alligators captured from the wild. Also, adult alligators that have been raised together develop a social structure and probably adapt more quickly and breed more consistently than animals from the wild, which lack an established social structure.

Breeding pen design, particularly with respect to the land-to-water ratio and configuration, is very important. The ratio of land area to water area within the pen should be approximately 3 : 1. The shape of ponds needs to maximize the shoreline, utilizing an M, S, W, Z, or similar shape. The reason these shapes work best is that male alligators fight less during the breeding season if they cannot see each other.

A water depth of at least 1.8 m (6 ft) must be maintained during the breeding season. Whenever possible, ponds should also be constructed with drains so that water can be removed if the animals need to be captured. The pond shoreline should be no closer than 23 to 30 m (75–100 ft) from fences. Alligators are good climbers and diggers. Most states that license alligator farming have specific requirements pertaining to fencing in the construction of pens.

Dense vegetation around the pond is needed to provide cover, shade, and nesting material. The natural invasion of wetland plants may be sufficient for cover. Tall, deep grasses can be planted to increase vegetation that can be used for incubation material. Many producers add bales of hay to the breeding pens in June to supplement natural vegetation for nest building.

Shade is important to prevent overheating during the summer. Alligators will burrow into the banks of a pond if adequate shade is not provided. Awnings that provide shade will reduce burrowing activity.

The stocking density of adult alligators is usually between 25 and 50 of the animals per ha (10 to 20 per acre), in pens that are at least 5 ha (2 acres) in area. Adults between 6 and 20 years old are reliable breeders, and females 8 to 10 years old are the most consistent breeders (4,16). The female-to-male ratio should be near 3 to 1, but less than 4 : 1.

Each pen should have several feeding stations to keep the adult alligators spread out. Feeding stations should be established near basking areas or along the shoreline of the pond. Feeding should begin each spring when the temperature rises above 21 °C (70 °F). Alligators should be fed four to six percent of their body weight per week (definitely 6% throughout the summer) (4). Adults should usually be fed only once per week. Early fall feeding appears to be particularly important to enable the females to be in good condition for egg development. Adults do not need to be fed during the late fall and winter when temperatures are below 21 °C (70 °F). It is important that adult alligators not be overfed; they should be trim, not fat, for enhanced reproductive capabilities (16).

Adult breeders should be disturbed as little as possible from February through August, during egg maturation, courting, and nesting. Activities such as moving animals or maintaining ponds should be performed between September and January.

Nesting success in captive alligators has been highly variable. Wild versus farm-raised origin, pen design, density, the development of a social structure within the group, and diet all affect nesting success. Nesting rates for adult females in the wild averages around 60 to 70% where habitat and environmental conditions are excellent (17,18). Nesting rates in captivity are usually much lower, depending on the management skill of the producer.

Clutch size varies with age and condition of the female. Larger and older females generally lay more eggs. Clutch size should average 35 to 40 eggs. Egg fertility can vary from 70 to 95%. Survival of the embryo also varies from 70 to 95%, hatching rate from 50 to 90%. Egg fertility, the survival of the embryo, and the hatching rate of eggs taken from the wild and incubated artificially are 95, 95, and 90%, respectively (19).

Egg Collection

The method and timing of egg collection are very important. Alligator embryos are extremely sensitive to handling from 7 to 28 days after the eggs are laid (20). Many embryos will die if handled during that period. Eggs should be collected within the first week or after the fourth week of natural incubation.

Unlike bird eggs, alligator eggs cannot be turned or repositioned when taken from the nest, except during the first 24 hours after being laid. The top of the eggs should be marked before removing them from the nest, so that they can be maintained in the same position during transport and incubation. Eggs that are laid upright in the nest (with the long axis perpendicular to the ground) will expire unless they are repositioned correctly (with the long axis parallel to the ground) within the first day after nesting.

During collection, the eggs should be supported by 20 to 30 cm (8–12 in.) of moistened nesting material or grass hay, placed in the bottom of the collection container. The marked eggs should be placed in a single layer in the container and in the same position that they were in the nest and should be covered with 5–7.5 cm (2–3 in.) of nesting material (20).

The age of the eggs and their development can be observed by means of changes in the opaque banding that occur during incubation. Figure 1 shows the sequence of banding associated with proper egg development (21).

Incubation and Hatching

Compared with wild nesting, artificial incubation improves hatching rates because of the elimination of predation and weather-related mortality. The best hatching rates for eggs left in the wild are less than 70% (22). Hatching rates for eggs taken from the wild and incubated artificially average 90% or higher.

Eggs should be transferred into incubation baskets and placed in an incubator within three or four hours after collection. Air circulation around the eggs is critical during incubation (19). Egg baskets can be made from plastic-coated 2.5×1.3-cm ($1 \times 1/2$-in.) steel wire mesh or 1.3 cm (1/2 in.) heavy-duty plastic mesh. Dimensions for egg baskets can vary [30×60 cm (1 ft $\times$ 2 ft) and 60×90 cm (2 ft $\times$ 3 ft) are common], but should be 15 cm (6 in.) deep to accommodate both eggs and nesting material. Eggs must be completely surrounded by nesting material, the decomposition of which aids in the breakdown of the eggshell (21). Without this natural decomposition, hatching alligators will have a difficult time breaking

Figure 1. Opaque banding of alligator eggs from day laid through day 52 of incubation. From Ferguson, 1981. T = top view; B = bottom view. Numbers represent days of incubation.

out of the shell and may die. Fresh natural nesting material composed mostly of grasses is best. If natural nest material is not available, grasses which have been soaked in water for about a week prior to incubation can be used.

Hatching baskets should be set about 7.5 cm (3 in.) above heated water in an incubator, in which the temperature, humidity, and water level must be controlled. The relative humidity should be kept above 90% within the chamber, and incubation media should be moistened with warm water as necessary to maintain dampness.

The incubation temperature is critical to the survival and proper development of the hatchlings, even determining their sex (23). Temperatures of 30 °C (86 °F) or below produce all females, while temperatures of 33 °C (91 °F) or above produce all males. Temperatures much above or below these limits cause abnormal development that usually results in high mortality. Both sexes are produced at temperatures between 30 and 33 °C (86−91 °F).

The critical period for sex determination is around 20 to 35 days after the eggs are laid.

Hatchling alligators (Fig. 2) make peeping or chirping sounds after hatching. Unhatched eggs can be carefully opened to release hatchlings. Eggs can be opened at one end, to free the baby alligators without detaching or damaging the umbilical cord. If the umbilical cord is broken the hatchling is likely to bleed to death or develop an infection. Hatchlings should be retained in their hatching baskets for 24 hours to allow the umbilical cord to separate naturally (19). After 24 hours the hatchlings should be removed from the egg baskets, sorted into uniform size groups, and moved into environmentally controlled growout facilities. Size grouping the baby alligators is important. Smaller, weaker individuals will not compete well with their larger siblings.

Hatchlings should be moved into small tanks, 60 × 60 cm (2 × 2 ft) or larger, heated to 30−32 °C (86−89 °F). Maintaining hatchlings at 32 °C (89 °F) for the first week

Figure 2. Newly hatched alligators in hatching tray with natural nesting material, note umbilical cords still attached to egg cases.

aids in increasing their ability to absorb the yolk (4). Usually, hatchlings will start to feed within three days at that temperature. Young that do not start feeding on their own can be force-fed using a large syringe (24). Hatchling tanks should be cleaned daily to prevent outbreaks of disease. Once hatchlings are actively feeding, they are ready to be moved into growout facilities.

GROWOUT

Many different designs of growout facilities have been employed. Growout buildings are basically heavily insulated concrete block, wood, or metal buildings with heated foundations. The concrete slab foundation is laced with hot-water piping or, less commonly, electric heating coils (25). A constant internal temperature is maintained by pumping hot water through the pipes. The slab is insulated to reduce heat loss. Pools, drains, and feeding areas are built into the foundation. Covering about two thirds of each pen is a pool of water, about 30 cm (1 ft) deep at the drain, toward which the bottom of the pool is sloped to facilitate cleaning. The remaining third of each pen, above the water, is used for a feeding and basking deck. Separate pens are constructed within a single building by using concrete block walls at least 90 cm (3 ft) tall.

Pens can be almost any size. In general, smaller pens are used for rearing small alligators, and progressively larger pens are used as the alligators grow. Many producers employ small fiberglass or metal tanks (for small alligators) stacked above the larger floor pens, an approach that maximizes the use of space and heat within the growout houses. Pens and tanks must be "climbproofed" to prevent the nimble young from escaping. Table 1 gives examples of pen size to alligator size and corresponding densities.

Most producers construct only a few sizes of growout pens and simply reduce the density by moving the animals as they grow. Commonly used stocking regimes are as follows:

- 9.2 cm^2 (1 ft^2) per animal until the animal reaches 50 cm (2 ft) in length.
- 27.9 cm^2 (3 ft^2) per animal until the animal reaches 1.2 m (4 ft) in length.
- 55.7 cm^2 (6 ft^2) per animal until the animal reaches 1.8 m (6 ft) in length.

A common construction plan uses an approximately 465-m^2 (5000-ft^2) building (e.g., 10 × 45m or 33 × 150 ft) with an aisle down the middle and pens on either side (25).

A 1.2-m (4-ft) aisle leaves the pens roughly 4.3 m (14 ft) wide. Pens are usually about 4 m (13 ft) long. A 0.9-m (3-ft) high concrete block wall separates individual pens from the aisle.

Within the 4.3 × 4-m (14 × 13-ft) pen is a 1.5-m (5-ft)-wide deck next to the service aisle and a 2.7-m (9-ft)-wide pool. Food is placed on the deck, and the pen is hosed clean from the aisle without entering it. The pool edge slopes rapidly to a depth of 10 in next to the deck, and the pool bottom slopes from there to the drain.

Pens are easily divided by the construction of additional walls down the center. The large pen (4.3 × 4 m) can hold around 160 alligators 60 cm (2 ft) long or 50 alligators 1.2 m (4 ft) long. Some state laws require that alligators less than two feet long be separated from those over 60 cm (2 ft) in length.

Another popular building design is a single "roundhouse" (25), a structure 4.5 to 7.5 m (15−25 ft) in diameter constructed as a single pen. Round houses have also been built from concrete blocks or from a single section, and the roof from a prefabricated metal silo (used for storing grain). The round concrete slab on which the house sits is sloped (at an inclination of about 10 : 1) from the outer edge to a central drain. The roundhouse is filled with water to a depth such that about one-third of the outer floor is left above the water level. Some producers prefer this design because it is a single pen and, therefore, does not disturb alligators in other pens during feeding, cleaning, and handling operations.

Part of any alligator facility is the heating system, which usually consists of water heaters and pumps that circulate warm water through the concrete slab. The warm water is needed to heat the building, fill the pools, and clean the pens. Some heating systems consist of several industrial-sized water heaters. Other systems consist of a flash-type heater to heat water for cleaning and standard water heaters to circulate warm water through the slab. Both systems use thermostats to turn on the heaters and circulation pumps. The temperature in growout buildings must be maintained between 30 and 31 °C (86−88 °F) for optimal growth.

Growout buildings almost never contain any windows, and many producers prefer no skylights. In fact, most animals are kept in near or total darkness, except at feeding and cleaning times.

Feeding and Nutrition

Research reveals that the diet of a wild alligator changes as the animal grows, but, in general, alligators

Table 1. Recommended Pen Sizes for Growout Operations^a

Gator Length [cm (in.)]	Pen Size [m^2 (ft^2)]	Gators per Pen	cm^2 (ft^2) per Gator	m^2 (ft^2) Needed per 350 Gators
18−38 (7−15)	0.8 (9)	20	4.0 (0.45)	14.7 (158)
38−76 (15−30)	11.1 (120)	80	14.0 (1.50)	48.8 (525)
76−122 (30−48)	15.6 (168)	50	32.0 (3.36)	109.3 (1176)
122−152 (48−60)	17.8 (192)	50	36.0 (3.84)	124.9 (1344)
152−183 (60−72)	20.1 (216)	40	50.0 (5.40)	175.6 (1890)

^{a}From Ref. 26.

consume a diet high in protein and low in fat. Early producers fed their animals diets high in fish. Later research showed that wild populations of medium to large alligators eat mostly higher protein prey (i.e., birds and mammals).

Early producers manufactured their own feeds using inexpensive sources of meat, including nutria, beefcattle, horse, chicken, muskrat, fish, beaver, and deer (25). Today, however, artificial diets are available that provide adequate nutrition. These diets have eliminated the need to keep fresh-frozen meat products on hand.

Several feed mills are currently manufacturing pelleted alligator feeds. Commercial feeds, approximately 45% crude protein and 8% fat, are blends of fish meal, meat and bone meal, blood meal, and some vegetable protein, fortified with vitamins and minerals.

At present, most producers feed their animals only commercially available diets, although some continue to feed them a combination of meats and commercial diets.

Feed should be spread out on the deck in small piles to reduce competition and territoriality. Feeding should be done at least 5 days per week; some producers feed their animals 6 or 7 days per week. Alligators are normally fed at rates of 25% of body weight per week the first year; then the rate is gradually reduced to 18% by three years of age or a length of about 1.8 m (6 ft) (25). Feed conversion efficiency decreases as alligators grow larger, but averages about 40% (or between 2:1 and 3:1 when presented as a food conversion ratio), up to a length of 1.8 m (6 ft) (4). Overfeeding wastes money and can lead to gout, which is fairly common in pen-raised alligators, but can be cured by taking the animals off their feed for 7 to 10 days (27). No antibiotics are approved for use on alligators; therefore, any antibiotics that are needed can be obtained only through a prescription from a veterinarian.

Pen cleaning should be coordinated so that the animals are not disturbed just before, during, or soon after feeding. Many producers clean in the morning and feed their animals in the afternoon.

Growth rates of young alligators can be as great as 7.5 cm (3 in.) or more per month when the temperature is held at a constant 30 to 31.5 °C (86 to 89 °F) and the animals are fed a quality diet and protected from stress. Many producers rear alligators from hatchlings to 1.2 m (4 ft) in 14 months, and a few producers have grown alligators to 1.8 m (6 ft) in 24 months. Farm-raised alligators are generally 10% heavier than wild alligators of the same length. Table 2 gives average lengths and weights of wild and farm-raised alligators.

In an effort to reduce costs and still produce a larger (and more valuable) animal, some producers are utilizing outside, or ambient, growout facilities. In this system, alligators are moved into outdoor fenced ponds after the first year of growth in indoor facilities. The alligators are fed a commercial diet during warm weather and are allowed to hibernate during cool seasons. After approximately two years the ponds are drained, usually during the winter to facilitate handling, and the alligators are harvested.

Table 2. Length–Weight Relationships for Wild and Farm-Raised Alligators[a]

Length, (in.)	Weight, Wild, lb (oz)	Weight, Farm Raised, lb (oz)
12	0.15/(2.4)	0.16/(2.6)
18	0.42/(6.7)	0.47/(7.5)
24	0.68/(10.8)	0.75/(12.1)
30	3.5	3.9
36	8.6	9.5
42	13.0	14.7
48	17.7	19.8
54	28.0	31.1
60	39.6	44.0
66	45.4	50.4
72	49.6	55.1

[a] From Ref. 25.

Stress

Alligators are wild creatures that have been thrust into captivity. In the wild, they are relatively shy and reclusive creatures that do not normally aggregate together, except during the breeding season. The artificial conditions that are imposed upon them are unnatural and, therefore, stressful. Stress can lead to slow growth, disease, and aggressive behavior.

Alligators that are crowded into pens appear to be very sensitive to light and sound. Many producers like to keep the animals in the dark or at least in very reduced light. Toward that end, they try to locate and insulate facilities to minimize external noise.

Signs of stress include piling up of the animals, reduced feeding, "stargazing," and fighting (25). Piling up usually occurs in the corners of the pens and can lead to suffocation of those animals on the bottom of the pile. Reduced feeding is a sign of stress. "Stargazing" is a position wherein the alligator rises up on its front feet, arches its back and neck, and points its snout into the air. Fighting among animals that have been penned together, but are not overcrowded, is a definite sign of stress.

Stress often impels the larger animals to fight, causing scarring. A skin condition known as "brown spot" results in cosmetic blemishes to the hide and subsequent scarring. In either case, the quality of the hide is diminished and its value reduced.

Each producer must keep good records on environmental conditions, the animals' consumption of feed, and their general health. When signs of stress appear, the cause must be identified and remedied as soon as possible. Overcrowding, excessive disturbance, and poor feeding practices are common causes of stress.

Harvesting

Written approval and hide tags must be obtained from the appropriate state regulatory agency (e.g., the Department of Conservation and Natural Resources) before any alligators may be harvested. Some states also have a minimum length requirement at harvest (e.g., at least 1.8 m (6 ft), unless the animal has died from natural causes). All alligators must be labeled with tags from

Table 3. Percent Yield of Deboned Alligator Meat on a Live-Weight Basis[a]

Tail	Leg	Torso	Ribs[b]	Jaw
16–17	4–5	6–12	7–10	1

[a]From Ref. 25.
[b]With bones.

the state regulatory agency immediately after slaughter. Alligators may be skinned only at approved sites, using specific skinning instructions issued by the state agency.

Skinning, scraping, and curing must be done carefully to assure quality. Hides that are cut, scratched, or stretched — particularly on the belly — have reduced value.

Hides are scraped carefully to remove all meat and fat and then are washed to eliminate all blood, etc. Fine-grained mixing salt, not rock salt, is used to preserve the hide. Salt is rubbed thoroughly into the skin, with particular attention paid to all creases and flaps, to start the curing process.

Most hides are sold to brokers, who purchase and hold large numbers of hides and then sell them to tanneries for processing. A few farms are large enough to sell directly to the tanneries, the best of which are in Asia and Europe.

Producers who process alligator meat must comply with all sanitation requirements of federal, state, and local authorities. Local health departments can supply guidelines and assistance in complying with sanitation standards. Specific state laws regulate the size of meat cartons, labeling of the cartons (with the names of the seller and buyer), the date of sale, and the tag number that corresponds to the hide. Average deboned dress-out percentages for alligators in the 1.2 to 1.8-m (4 to 6-ft) range are given in Table 3.

It is interesting to note that while the prices of hides fluctuate, meat prices have stayed consistent, and it appears that the supply of alligator meat is well below market demand.

Pharmaceutical Methods of Anesthesia
  Route of Administration
  Anesthetic Agents
Nonpharmaceutical Methods of Anesthesia
Physiological Effects of Fish Restraint
Bibliography

Common aquacultural practices conducted by the private, commercial, and research sectors can be stressful to fish and oftentimes result in immunosuppression or physical injury to handled fish. Both chemical and nonchemical methods of anesthesia are frequently used to minimize stress and facilitate animal restraint during routine husbandry practices and transport, as well as for spawning, surgical, and diagnostic purposes (1–4). The levels of restraint, efficacy, cost, ease of handling, and safety to the animal, handler, and environment must be considered in the selection of the most appropriate anesthetic.

An ideal anesthetic agent should have a wide margin of safety, with rapid induction and recovery periods, while providing consistently effective immobilization or analgesia. Anesthesia involves a combination of narcosis, analgesia, and skeletal muscle relaxation that results from sensory nerve block, motor nerve block, or reduction in reflex activity (4). Since different procedures require different levels of anesthesia, this point should be considered in the selection of the most appropriate anesthetic method. Sedation may be required only for transport or short, simple procedures, such as tagging and injections, while more invasive procedures require full surgical anesthesia. The degree of anesthesia attained is often dictated by either the molecular structure of the anesthetic agent itself, the concentration of anesthetic used, or the duration of exposure to the anesthetic. Other important considerations in selecting an anesthetic include species variation, body mass, health status, age, water chemistry factors, and the withdrawal time of the drug (1,5–7).

The basic stages of anesthesia exhibited by fish are similar to the stages observed in mammalian species (4,8). A hyperexcitable stage occurs during induction and is characterized by erratic swimming, disorientation, increased respiration, and loss of equilibrium. The sedative stage is characterized by loss of reactivity, slow swimming, and decreased respiration. The anesthetic stage is characterized by complete loss of equilibrium and slowing of respiration that progresses to a surgical plane denoted by an inability to swim, shallow respiration, and no response to stimuli. The deepest plane of anesthesia is marked by cessation of opercular movements, which can lead to cardiac failure and death. Since the anesthetic dosage for different preparations will vary with the species, preliminary anesthetic trials with an unfamiliar fish species are recommended prior to enacting the intended use of the anesthetic. For example, metomidate, a commonly used aquatic anesthetic, has been demonstrated to be efficacious in the Atlantic salmon and cod (9,10), but is undesirable for use in red drum and goldfish larvae (6).

PHARMACEUTICAL METHODS OF ANESTHESIA

Route of Administration

Chemically induced methods of immobilization and restraint can be administered by bath immersion, gill perfusion, parenteral injection, or oral administration (1,4,11,12). It is important to remember that both induction and recovery times for some drugs will vary according to the dosage used, the duration of exposure time to the anesthetic agent, and the total body-fat content of the fish (8).

Bath Immersion. For immersion methods, simultaneous preparation of both induction and recovery tanks of water is recommended. Water quality parameters (e.g., pH, temperature, salinity, hardness) in the tanks should closely match those of the natural habitat waters of the fish to be anesthetized. Aeration of these waters is advisable, due to the common development of hypoxia during anesthesia, which occurs secondarily to respiratory depression. Opercular movement is a good indicator of the plane of anesthesia attained and should be monitored throughout any procedure. A fish that enters too deep a plane of anesthesia can be resuscitated by immediate transfer to the recovery water. Oxygen exchange and anesthetic elimination can be enhanced at the gill level by either using open-mouth propulsion of the fish through the water or positioning the fish near an airstone (1,4).

Parenteral Administration. Injection of anesthetics is a possible alternative for larger fish, but this method of anesthesia has been reported to be inconsistent for both maintenance and recovery. Disparities associated with intramuscular administration of anesthetics have often been attributed to the slower uptake or possible leakage of anesthetic agents from injection sites due to anatomical or mechanical factors. The sterile granulomas that may develop at intramuscular injection sites or intraabdominal adhesions from intraperitoneal administration are additional possible sequelae that can occur secondarily to drug-induced tissue irritation or damage. A clinical report regarding intramuscular ketamine administration in various fish species, however, cites no deleterious side effects in the more than 50 trials conducted (1,4,13).

Oral Administration. There have been reports of oral administration of anesthetics in the food fed to fish, by capsule or by using gavage (4). Observations of delayed induction times associated with this method of drug administration have been attributed to probable slow drug absorption by the gastrointestinal tract and the possible difficulties related to incorporation of the drug into the diet. The inability to assess accurately the quantity of drug-treated feed consumed on an individual basis has been another concern.

Anesthetic Agents

The selection of some drugs currently used for anesthetic purposes in aquatic species can be traced to human and veterinary medical literature where the routine use of the drugs developed over the years within the research setting. The approved use of the drugs in commercially important fish species, however, is restricted and varies between countries. For example, Aqui-S is legally approved in New Zealand for use in foodfish with no withdrawal period, but is not approved for this use in the United States. On the other hand, MS-222 is legally approved in Canada and the United States with a 21-day withdrawal period

in foodfish species. Table 1 lists chemical preparations commonly used for fish anesthesia. A short review of the recent literature for these drugs is presented in the paragraphs that follow.

Benzocaine. Benzocaine (ethyl aminobenzene), although not legally approved for use in foodfish in the United States, is a relatively safe, routinely used fish anesthetic. It is supplied as a water-insoluble white crystalline powder that requires reconstitution in ethanol or ether prior to adding it to water. A more water-soluble salt form, benzocaine hydrochloride, is also available, but is more expensive. Stock solutions of this preparation, if made in advance, should be buffered and stored in dark containers to prevent inactivation (4,8). Its solubility and efficacy

in freshwater appear not to be affected by variations in water hardness and pH, but increases in temperature do seem to enhance its solubility (14). Strong aeration of anesthetic waters is important, due to the hypoxic effect of this drug, resulting from reduced gill ventilation subsequent to depression of the medullary respiratory centers. Since this agent is lipophilic, recovery times and residue levels in body tissues will vary according to the amount of stored body fat. The drug withdrawal time in young, nongravid trout (Salmonidae) and largemouth bass (*Micropterus salmoides*), however, has been demonstrated experimentally to be only 24 hr (8).

Tricaine Methane Sulfonate. Tricaine methane sulfonate (3-aminobenzoic acid ethyl ester, or MS-222) is a commonly

Table 1. Commonly Used Fish Anesthetics

Anesthetic	Species	Dosage (ppm)	Water Temperature (°C)	Water Soluble?	Induction Time <5 min?	Recovery Time <10 min?

Aqui-S	Most species (7)	20	—	—	Yes	Yes

used fish anesthetic that is FDA approved in the United States for use in most freshwater and marine species. It is more water soluble than its parent compound, benzocaine, but is also more acidic in nature, requiring its solutions to be buffered with sodium hydroxide or sodium bicarbonate. This agent is eliminated at the level of the gill, kidney, and gall bladder, with no detectable metabolites in the mucus, feces, or gametes (15). It is considered to be a relatively safe drug, but its range of toxicity varies with fish species, fish size, water temperature, and water hardness. Aeration is recommended during induction, as hypoxia is a common sequela, as well as other physiologic effects (see Table 2). Individual variation with regard to dosage of this agent can also be quite broad. One reported human case of retinopathy has been associated with chronic cutaneous exposure to MS-222 (16). Due to this potential occupational hazard, wearing gloves is recommended as a measure to prevent systemic absorption of this compound.

Metomidate. Metomidate (1-(1-phenylethyp)-1H-imidazole-5-carboxylic acid methyl ester) is a rapidly acting, water-soluble, nonbarbiturate, imidazole-based hypnotic that has been found to be effective in various species (1,4,8,9). Due to its lack of analgesic properties in humans, it is recommended only for sedation in fish, and not for use in surgical procedures. Muscle fasciculations can commonly occur with its use, so it is not recommended for detailed procedures as well. It is a potent anesthetic in Atlantic salmon (*Salmo salar*) at low temperatures and induces rapid anesthesia in freshwater salmon parr, but it has been demonstrated to be most efficacious in large

Atlantic salmon that are acclimated to sea water (10). Inhibition of cortisol release has been noted in metomidate-anesthetized fish (4,8), with increases seen in both the hematocrit and blood lactate levels (10). The "chemically induced interrenalectomy" caused by this agent at the interrenal cell level has been suggested to have research potential as a tool to separate catecholamine from the effects of cortisol in stress-related studies (10).

2-Phenoxyethanol. 2-Phenoxyethanol is an inexpensive anesthetic that has been reported to have a narrow margin of safety and to cause hyperactivity during induction or recovery (17). Considerable variation in its activity has been described according to fish species, body size, and density, as well as relative to water quality parameters. It occurs as an oily liquid with both bactericidal and fungicidal properties. In goldfish (*Carassius auratus*), the concentration used has a marked effect on the induction and recovery times. Concentrations of 0.3–0.4 g/L are useful for short procedures, and lower concentrations, of 0.1 and 0.2 g/L, are considered safe for prolonged sedation (18). Its potential use for transport purposes is supported by a study demonstrating its increased effectiveness over other anesthetics in suppressing oxygen consumption in platyfish (*Xiphophorus maculatus*) (19). However, in another transport study, with gilthead sea bream (*Sparus aurata*), a marked stress response was demonstrated subsequent to exposure to the drug, where the return of cortisol and hematologic parameters to normal levels followed metabolic elimination of the drug (20). No detrimental effects on sperm motility

Table 2. Miscellaneous Physiological Side Effects Associated with the Use of Anesthetics

Anesthetic	Effect on Respiration	Effect on Blood Chemistry	Effect on Cortisol	Elimination of Metabolic Wastes	Effect on Heart	Species

were reported with the use of 2-Phenoxyethanol during spawning of grass and silver carp (*Ctenopharyngodon idella* and *Hypopthalmichthys molitrix*, respectively) at a concentration of 0.2 mg/L (21).

Quinaldine Sulfate. Quinaldine sulfate is a water-soluble yellow powder that requires buffering with sodium bicarbonate upon its addition to water. Stock solutions, of 10 g/L, should be protected from exposure to light and air. Its potency is affected by water pH, temperature, and hardness, where it exhibits a decreased toxicity at lower pH and temperature values. It provides rapid induction and recovery rates, but reflex activity is not lost at the time of loss of equilibrium. Disappearance of this touch response generally occurs after approximately 20 seconds of contact, so most procedures can be performed under this anesthetic (1,8). Dosages of 15–70 mg/L have been used for warmwater species (4). The required dosage varies between species, where largemouth bass are most sensitive and carp (Cyprinidae) are relatively resistant. More rapid induction times have been achieved for combinations of quinaldine sulfate and MS-222 than for either drug alone (8,22). Quinaldine sulfate is not metabolized by fish and is excreted mainly at the gill level, but also by way of the kidney and bile, similar to the excretion of MS-222 (15). The parent compound, quinaldine, is not water soluble and requires dissolution in an organic solvent prior to mixing with water. Since it is considered a suspect carcinogen, precautions should be taken during its use (17).

Clove Oil. Although not approved for general use as a fish anesthetic in the United States, clove oil (eugenol derivative) has been demonstrated, both experimentally and clinically, to be as effective as MS-222 in most freshwater and marine species at concentrations of 40–120 ppm (12,23). At 25 ppm, sedation was demonstrated to be adequate in rabbitfish (Siganidae), milkfish (*Chanos chanos*), and striped mullet (*Mugil cephalus*) for conduction of short, simple procedures with induction and recovery times of less than or equal to 2 and 5 minutes, respectively (24); however, there have been reports of prolonged recovery times as well (25,26). The primary constituent of clove oil, eugenol, is similar in structure to MS-222 and 2-phenoxyethanol.

Aqui-S. This particular anesthetic/sedative is approved for use in aquatic species in New Zealand with no withdrawal time and is presently undergoing the New Animal Drug Act (NADA) approval process for use in the United States. The formulation of Aqui-S contains a series of synthetic flavoring ingredients that are individually approved for use in food; one of these ingredients is similar to a major component present in clove oil. Experimentally, induction and recovery times of less than 3 and 10 minutes, respectively, have been demonstrated in most species of adult fish at a dosage of 20 ppm Aqui-S (7).

NONPHARMACEUTICAL METHODS OF ANESTHESIA

Nonpharmaceutical methods of anesthesia are employed in situations where drug withdrawal times may interfere with the impending marketability of some foodfish species, in field studies, and in locations where no approved drugs are commercially available. In the past, carbon dioxide was used in the field setting. Disadvantages of this method are the prolonged induction and recovery periods, shallow anesthesia, and metabolic imbalances associated with the lowered pH (1,17,23). Combined use of sodium bicarbonate and acetic acid in salmon has been suggested as an alternative anesthetic method for laboratory, farm, and field use (27). Electrically induced anesthesia, using alternating, direct, and pulsating currents, is another possibility; however, there is an increased risk to the safety of the operator (28,29). The subsequent rapid immobilization reduces netting stress, but the physiological effects on the hematological parameters are similar to those associated with anesthetic agents (28). Use of AC voltages has resulted in variable and unpredictable levels of narcosis and physical damage (30). Electroanesthesia has been used as a viable anesthetic alternative for tagging and spawning purposes (30,31).

PHYSIOLOGICAL EFFECTS OF FISH RESTRAINT

Reduction of handling stress and physical trauma is a major consideration for fish sedation and anesthesia; however, the physiological and hematological side effects of some anesthetics can closely mimic the effects associated with the stress response. Using different species and varying the duration of exposure to the anesthetic may also cause variation in certain blood parameters. Within the research setting, therefore, any hematological or biochemical measurements obtained from anesthetized fish must be evaluated for potential confounding associated with anesthetic use. Benzocaine, quinaldine, and MS-222 have been reported to affect hepatic enzyme functions; therefore, their use is not recommended prior to hepatic enzyme analytic studies (32,33). Table 2 gives a partial listing of the potential side effects associated with the use of certain anesthetics.

The increasing intensity of fish and shellfish farming, combined with the introduction of new species into culture, was inevitably paralleled by increase in disease. Bacteria represent a large variety and proportion of the pathogenic agents acting as both primary and secondary invaders in intensive culture. Antibiotic therapy for systemic bacterial infections began in the late 1930's, and was shortly followed by the introduction of sulfamerazine into the United States in 1948. As new drugs were introduced in human and veterinary medicine, suitable compounds were investigated for application in fish farming (1). The use of chemotherapy in aquaculture has always been limited by both legal and practical constraints. Considerations such as cost, route of application, labor, drug absorption, toxicity, and environmental impact

have forced many potentially useful drugs to remain unavailable for aquaculture application (2).

Ideally, the selection of a chemotherapeutics against bacterial disease should include the process of isolating and identifying the specific pathogen responsible for the infection, followed by determining of the most efficacious drug. However, this practice is often time consuming, always costly, and mostly overlooked. Selection should also take into account the bioavailability of the drug, the concentrations at which it accumulates in the host tissue, the elimination rate (especially for food fish), and the route of administration. The current method of administering therapy for bacterial infections of food fish is incorporating an approved drug as a premix into feed (3). The treatment of nonfood fish is affected either through the use of medicated feed or, more commonly, by dispensing antibacterial drugs directly into the water as bath treatments. Both of these approaches can be problematic. For example, formulated feeds may not be readily accepted by young stages of fish, particularly larval fish raised on cultured live foods. Drugs may leach out of feed and affect the environment, or they may decompose. However, antibacterial therapy, particularly prophylactic treatment, has lead to unanswered questions concerning the development of antibiotic resistant bacteria, an emerging problem in aquaculture.

DEFINITIONS

Traditionally, the term *antimicrobial drug* was applied only to compounds such as dyes, and synthetic or organic substances used in the treatment of microorganisms. More recently, the term is used synonymously, and has come to overlap in meaning, with the term antibiotic. An *antibiotic* is a natural substance produced by the metabolic processes of microorganisms that can inhibit or kill other microorganisms. Put simply, antibiotics are a kind of chemical warfare used against microorganisms in the same habitat to compete for nutrients and space. Most antibiotics in use today are derived from spore-forming bacteria in the genus *Bacillus* and two actinomycetes *Streptomyces* and *Micromonospora*. Fungi of the genera *Penicillium* and *Cephalosporium* also produce antibiotics. The ability of antibiotics to affect microorganisms differs and is usually related to the mechanism of action and concentration. *Broad-spectrum* antibiotics, such as tetracyclines, inhibit bacterial protein synthesis, a mechanism that affects a variety of bacteria. In contrast, a *narrow-spectrum* antibiotic, such as penicillin acts to inhibit formation of the bacterial cell wall, a process more efficacious against Gram positive bacteria.

An important property of an antimicrobial drug is termed specificity, or *selective toxicity*. Ideally, the antimicrobial agent should act at a target site that is present in the microbe, but absent in the host, resulting in adverse effects on bacterial cells without simultaneously damaging host tissue. Selective toxicity is achieved by exploiting the differences in structure and metabolism of bacteria and host cells. As procaryotes, bacteria are structurally more distinct from eukaryotic host cells than are fungal or protozoan pathogens. Structural differences

between procaryotic and eukaryotic ribosomes and DNA, and the presence and specific chemical composition of bacterial cell walls are likely targets for selective toxicity of many antibacterial drugs (4,5). Depending on concentration a drug may be bacteriostatic or bactericidal. *Bacteriostatic drugs* interfere with the machinery required for cell division, inhibiting reproduction. Their importance is to inhibit the growth of bacteria, thereby preventing the bacterial population from increasing and allowing host defense mechanisms to destroy the static population. *Bactericidal drugs* lyse and kill bacteria by inflicting direct damage on specific cellular targets. The distinction between the two mechanisms has become blurred because some bacteriostatic drugs may be bactericidal at higher concentrations. Conversely, drugs considered bactericidal such as chloramphenicol may be bacteriostatic for *Escherichia coli*, but bactericidal for *Haemophilus influenzae* (4).

MODES OF ACTION

There are four main targets for antibacterial action:

- cell wall synthesis
- protein synthesis
- nucleic acid synthesis
- cell membrane function

Inhibitors of Cell Wall Synthesis

Four classes of antibiotics act as inhibitors of bacterial cell wall synthesis: the beta-lactam family, which includes penicillins, cephalosporins, monobactams, and carbapenems; glycopeptides like vancomycin, cycloserine, and bacitracin. For the most part, these groups are not widely used in aquaculture, probably because their mode of action is more efficacious against Gram positive bacteria. Drugs that inhibit cell wall synthesis act at one of three stages in the process of wall formation. In the typical Gram positive bacterial cell, the cell wall encases the membrane as a continuous, highly cross-linked molecular network that provides structure and keeps the cell from rupturing. This structure, also known as the peptidoglycan, is unique to bacteria and provides an optimum target for selective toxicity. Synthesis of the peptidoglycan invokes three stages: synthesis of the subunits in the bacterial cytoplasm, transport of the subunits outside the cell, and the final cross-linking. Penicillin and cephalosporin act at the final stage by preventing the formation of cross-links between the units of the cell wall, resulting in a weakened network. Strands of peptidoglycan that cannot cross-link have been observed by electron microscopy to accumulate on the cell wall (6). Eventually, the cell membrane extrudes thought the weak points in the cell wall, and the cell ruptures. The bactericidal drugs penicillin and cephalosporin utilize the same mechanisms to cause bacterial cell death.

Glycopeptides, such as vancomycin, act at an earlier stage in cell wall formation than do the penicillin and cephalosporin. During the second stage of peptidoglycan synthesis, the basic repeating units of the cell wall are put together to form a long polymer. Vancomycin

interferes with this mechanism by binding to the end of the pentaglycine polymers that are used to cross-link the growing peptidoglycan structure. This binding prevents new subunits from being incorporated into the growing cell wall.

Bacitracin and cycloserine act at the second and first stages of cell wall synthesis, respectively. Both are of limited clinical use and are not used at all aquaculture.

Penicillin. Penicillin was first isolated by Alexander Fleming in the late 1930s from the fungus *Penicillium notatum*. Now the penicillin family contains almost a dozen drugs all of which contain a beta-lactam ring attached to another five-membered ring containing a sulfur molecule and the side chains attached to those rings. Natural penicillin, chemically known as benzyl penicillin, is administered by injection and cannot be given by mouth. Biochemists have improved upon the original drug by adding chemical side chains to the penicillin core. The addition of side chains affects such chemical properties as solubility and absorption and allows these newer generation or semi-synthetic penicillins to be given orally. The newer also resist acid hydrolysis and counter some mechanisms of bacterial resistance. Some of the newer semi-synthetic penicillin are broad spectrum antibiotics and often are used against Gram negative bacteria, in contrast to the earlier generation of narrow spectrum drugs.

Cephalosporins. The first cephalosporins were isolated in the late 1940s from the fungus *Cephalosporium acremonium*. The family is characterized by a beta-lactam ring attached to another six membered ring. Like penicillin cephalosporin acts at the third stage of bacterial cell wall synthesis. The cephalosporins have a broader spectrum of action and are active against a variety of Gram negative bacteria. Newer generations of cephalosporin have been developed, and these account for the majority of antibiotics administered; however, they are relatively expensive and not readily used in aquaculture.

Vancomycin. Vancomycin is a large molecule that has difficulty penetrating the Gram-negative cell wall. It is a narrow-spectrum drug used mainly for the treatment of Gram-positive cocci and Gram-negative rods that are resistant to beta-lactam drugs.

Inhibitors of Protein Synthesis

Although protein synthesis proceeds in a similar manner in prokaryotic and eukaryotic cells, effective antibiotics can exploit the differences that do exist. Most inhibitors of protein synthesis act at the level of translation by reacting with the ribosome-messenger (mRNA) complex. The size and structure of prokaryotic ribosomes differ from those of eukaryotes affording selective toxicity. Two possible targets of ribosomal inhibition are the 30S and the 50S subunits of prokaryotic ribosomes. Attachment to the 30S subunit by aminoglycoside antibiotics interferes with the binding of transfer RNA (tRNA) to the ribosome, preventing the initiation of protein synthesis. Other animoglycosides like streptomycin also cause misreading of the mRNA. Both mechanisms lead to the formation of abnormal proteins.

Tetracyclines inhibit protein synthesis by binding to the 30S subunit further blocking the binding of tRNA to the mRNA complex. Tetracycline binding inhibits virtually 100% of protein synthesis. Another inhibitor of protein synthesis, chloramphenicol, acts by binding to the 50S ribosomal subunit preventing the formation of peptide bonds. Erythromycin, the best known and most widely used of the macrolide antibiotics, binds to the 50S subunit blocking the translocation step and preventing the release of tRNA after peptide bond formation. Tetracyclines, chloramphenicol, and erythromycin are all bacteriostatic inhibitors of protein synthesis, and all can bind to the ribosomes in eukaryotic mitochondria, causing a variety of toxicities.

Aminoglycosides. Aminoglycosides are derived from different species of the actinomycetes *Streptomyces* and *Micromonospora*. The most frequently used aminoglycosides are neomycin, kanamycin, gentamicin, tobramycin, streptomycin, and amikacin. The original compounds have been chemically altered by the addition of side chains to produce a newer generation of compounds, such as amikacin. The newer compounds are active against organisms that have developed resistance to earlier aminoglycosides. The aminoglycosides have broad spectrum activity and are highly efficacious against most Gram-negative rods. All are bactericidal and therefore rapidly stop protein synthesis. However, they are not readily absorbed from the gut and do not penetrate tissues well. Aminoglycosides are routinely administered by intramuscular injection. Neomycin and kanamycin are more water soluble and are often used as bath treatments in marine aquaria for infections caused by *Vibrio* spp. (7,8). Reports in the literature indicate that neomycin can disrupt nitrifying bacteria leading to an increase in both ammonia and nitrite levels in waters (9). Aminoglycosides generally should not be used sequentially or in combination with tetracycline or each other.

Tetracyclines. Tetracyclines are a large family of cyclic structures that inhibit protein synthesis by preventing animoacyl transfer RNA from entering the acceptor sites on the ribosome. Unfortunately, this action is not selectively toxic for prokaryotes and tetracyclines also will inhibit protein synthesis in eukaryotes. Some selective toxicity is afforded by the greater uptake of tetracyclines by bacterial cells. Tetracyclines are usually administered orally, are well distributed in the tissue, and penetrate host cells to inhibit intracellular bacteria, mycoplasma, rickettsiae, and chlamydiae. Doxycycline and minocycline are absorbed better than tetracycline, oxytetracycline or chlortetracycline. For this reason both doxycycline and minocycline cause less gastrointestinal upset, because there is less inhibition of normal gut flora. Oxytetracycline treatment has been reported to cause immunosuppression in some fish whether the drug is administered by injection, in feed or as a bath. In Rainbow trout (*Oncorhynchus mykiss*), the number of antibody-producing cells was reduced, while both the number of antibody-producing cells and the mitogenic response

were reduced in carp (*Cyprinus*) treated with oxytetracycline (10–12). Tetracycline, minocycline, and doxycycline are suggested treatments against Gram positive infections of mycobacteriosis and streptococcosis (13).

Tetracycline readily binds to calcium and magnesium forming an insoluble chelate, and therefore may not be as effective as a bath treatment in marine waters or fresh waters of higher pH (harder water).

Erythromycin. Erythromycin is a member of a family of large cyclic molecules called macrolides. Members of this family all contain a macro cyclic lactone ring structure to which sugars are attached. Erythromycin specifically binds to the 50S subunit of the ribosome and blocks the translocation step in protein synthesis, thereby preventing the release of transfer RNA after peptide bond formation. Erythromycin is most active against Gram-positive bacterial infections, chlamydiae, rickettsiae, and mycoplasma. For yet unknown reasons, the concentration of erythromycin achieved in Gram-positive bacteria is greater than that in some Gram-negative bacteria (6). It is thought that erythromycin cannot readily penetrate the cell envelope of Gram-negative bacteria.

Erythromycin is readily absorbed at a neutral or a slightly alkaline pH, which makes it particularly useful for the treatment of African Rift Valley lake fish and live bearers. However, bacterial nitrifies will be severely hampered by the use of erythromycin (14).

Chloramphenicol. Chloramphenicol is a broad-spectrum antibiotic with a unique nitrobenzene structure that is responsible for some of the toxic problems associated with its use. Chloramphenicol blocks the action of peptidyl transferase, preventing peptide bond synthesis on the ribosome. It inhibits bacterial protein synthesis selectively, since it has a higher affinity for the transferase of the 50S bacterial subunit than that of the 60S subunit of the eukaryotic ribosome. Because of its unusual stability, chloramphenicol is poorly absorbed through water, and is commonly administered by injection (15). Chloramphenicol is highly illegal to use on foodfish in the United States.

Inhibitors of Nucleic Acid Synthesis

For the most part, inhibitors of nucleic acid synthesis are antimicrobial agents rather than true antibiotics. The exception is rifampin, a chemically altered compound produced by the genus *Streptomyces*. The chemical agents act to inhibit nucleic acid synthesis in one of three main ways: by inhibiting precursor synthesis, by inhibiting DNA replication, or by inhibiting RNA polymerase. The inhibitory effects may be so basic to cell function that protein synthesis and other metabolic pathways appear as targets (4).

Inhibitors of Precursor Synthesis

Sulfonamides. Sulfonamides, also known as sulfa drugs, and trimethoprim are often referred to as antimetabolites, because they interfere with the metabolic synthesis of precursor compounds. The sulfonamides are a group of

molecules produced exclusively by biochemical synthesis; and they act as bacteriostatic inhibitors of bacterial growth. Many sulfonamides have been formulated, but only a few have proved useful in the treatment of bacterial and protozoal infections. The sulfonamides are structural analogs to, and act in competition with, para-aminobenzoic acid (PABA), an essential component in cell synthesis of folic acid (folate). A reduced form of folic acid functions as a coenzyme that transports one-carbon units from molecule to molecule. These one-carbon transfer reactions are required for the synthesis of thymidine, all purines (adenine, guanine), pyrimidines (cytosine, thymine), and several amino acids. Thymidine is necessary for DNA synthesis, and the purines and pyrimidines are necessary for all nucleic acid synthesis in the cell. When folate synthesis is inhibited, cell growth is arrested due to the inability to synthesize these macromolecules. Although the sulfonamides rapidly block folate synthesis, bacteria may continue to grow until their stored pools of folate are depleted.

Folic acid is required for growth by both prokaryotic and eukaryotic cells. Animal cells are unable to synthesize folate, but it enters the cells by active transport from dietary supplementation. Since folate does not readily enter bacterial cells, bacteria must manufacture their own folate intracellularly. The difference in membrane permeability accounts for the selective toxicity of sulfonamides to bacteria. Sulfonamides vary in solubility and are usually administered in feed. Although sulfonamides possess broad-spectrum activity, especially against Gram-negative bacteria, resistance is widespread. Sulfamerazine is approved for use in the United States against furunculosis in salmonids, but the drug was removed from the market by the manufacturer.

Trimethoprim has a pyrimidine-like structure analogous to a moiety of the folic acid molecule. In contrast to the sulfonamides, trimethoprim rapidly inhibits bacterial growth. When trimethoprim is added to a culture of growing bacteria, DNA, RNA, and protein synthesis are all affected. Trimethoprim was initially synthesized to maximize selective toxicity by exploiting the differences between eukaryotic and prokaryotic enzymes (6). The combination of trimethoprim or ormethoprim, a similar compound, with a sulfonamide affords a synergistic effect on cell growth. This effect, known as potentiation, is substantial and is attributed to the fact that the drugs inhibit different enzymes in the same biosynthetic pathway. Romet 30^R (Hoffman-LaRoche), a combination of ormethoprim and sulfadimethoxine is a potentiated sulfonamide drug approved for use in foodfish in the United States to treat *Aeromonas* and *Edwardsiella*. A similar combination of trimethoprim and sulfamethoxazole, while not approved for foodfish in the United states is widely used overseas (16,17).

Inhibitors of DNA and RNA Synthesis

Quinolones. Quinolones form a large family of synthetic agents originating from nalidixic acid, which was discovered as a distillate product of chloroquine synthesis, an antimalarial compound. Nalidixic acid and all newer

quinolone agents are completely synthetic, and structurally related compounds have not been identified as products of living organisms (18). Analogs of nalidixic acid include oxolinic acid and the newer fluoroquinolones, such as sarafloxacin, enrofloxacin, and flumequine. Nalidixic acid and oxolinic acid are active principally against Gram-negative bacteria, while the fluoroquinolones have a broader spectrum that includes some Gram-positive bacteria and intracellular organisms like rickettsiae and chlamydiae. The newer compounds are better absorbed across the intestine. Most quinolones are rapidly bactericidal. All quinolones chelate divalent cations and are inhibited by hard water, and possibly, divalent cations in the diet.

Quinolones inhibit the activity of DNA gyrase, an enzyme involved in the initiation, elongation, and termination phases of DNA replication. Quinolones also inhibit the transcription of certain operons, and aspects of DNA repair, recombination, and transposition (18). Quinolone inhibition is specific to bacterial gyrase and does not affect similar enzymes in eukaryotic cells.

Metronidazole. Metronidazole belongs to a family of compounds called imidazoles, some of which have antifungal and anthelminthic activity. Metronidazole acts against microaerophilic and anaerobic bacteria and some intestinal protozoans by inhibiting hydrogen production. Metronidazole is reduced on entering the susceptible cell, to generate cytotoxic intermediates that cause a loss of the helical structure of DNA, a process that eventually leads to breakage of the cell's DNA (4,19). The selective toxicity of metronidazole is due to the lower redox systems that only anaerobic organisms possess. Metronidazole is bactericidal for anaerobic bacteria and is considered the universal drug of choice for these organisms. The compound is quite insoluble in water and must be thoroughly dissolved before being added to water or feed (20,21).

Rifampin. Rifampin (rifampicin) binds to DNA-dependent RNA polymerase, blocking the synthesis of mRNA and inhibiting cell growth. The selective toxicity of the drug is based on its greater affinity for bacterial polymerases than for equivalent eukaryotic enzymes. Rifampin is a chemical derivative of the fermentation products of the bacterium *Streptomyces mediterranei* and is an effective anti-mycobacterial antibiotic. Although used almost exclusively against mycobacteria, rifampin has activity for other Gram-positive and some Gram-negative bacteria. The efficacy of the drug in treating mycobacteriosis in fish is unproven, but rifampin was shown to be effective in experimental infection (22).

Interference with Enzyme Systems

Nitrofurans. Nitrofurans are synthetic antimicrobial compounds, several of which are commonly used as chemotherapeutants for bacterial fish pathogens. All the derivatives have broad-spectrum activity against Gram-positive and Gram-negative bacteria. Nitrofurans are known to inhibit a variety of enzyme systems in the cell; however, the exact mechanisms are not well understood. Nitrofurantoin generally is more effective at lower pH levels, and other nitrofurans are stable in both fresh and marine waters. Nitrofurans are photosensitive and are inactivated by bright light (8). Nifurpirinol (Furanace) and nitrofurazone (Furacyn^R) are used as single bath treatments or by oral administration. Palatability problems, however, can occur with oral usage of the drug (23). Nitrofurans are strictly illegal for use on foodfish in the United States because they were shown to be carcinogenic and mutagenic. Nitrofurans antagonize the antibacterial action of nalidixic acid and oxolinic acid and should not be used together with these compounds (6). Some scaleless fishes may be sensitive to the nitrofurans (24).

Interference with Mycolic Acid Synthesis

Isoniazid. Isoniazid is an isonicotinic acid hydrazide, a compound that inhibits mycobacteria, but does not affect other types of bacteria or animals to any great degree (4). Isoniazid is bactericidal against many actively growing mycobacteria and is thought to inhibit the synthesis of mycolic acid in the mycobacterial cell wall. Isoniazid prevents the elongation of a 26-carbon fatty acid, inhibiting the synthesis of long-chain fatty acids that are precursors of mycolic acids (6). This primary effect of the drug would explain both its limited spectrum of action and its selective toxicity. The use of isoniazid for mycobacteria in aquaculture remains controversial. Some authors have suggested that there is no suitable treatment for fish infected with mycobacteria, and thus, diseased stocks should be destroyed (25,26).

Inhibitors of Cytoplasmic Membrane Activities

Polymyxins. Polymyxins are true antibiotics synthesized by the bacterium *Bacillus polymyxa*. They are bactericidal, narrow-spectrum polypeptide antibiotics that act primarily against Gram-negative bacteria. The polymyxins exert a cationic detergent-like effect on the lipid bilayers of the cell membranes. Associating with phospholipids, they disrupt the structure of the cell membrane, resulting in leakage of small molecules, such as nucleosides, from the cell. The greater sensitivity of Gram-negative bacteria to polymyxins is most likely explained by the higher phospholipid content present in the cell envelope of these bacteria compared with Gram-positive bacteria.

ANTIMICROBIAL SUSCEPTIBILITY TESTING

Definitions

Following the isolation and identification of a bacterial pathogen, the next standard procedure is the determination of the organism's susceptibility to various antimicrobial drugs. The sensitivity pattern, also referred to as an *antibiogram*, determines which drugs are effective against the bacterium and will likely afford successful treatment.

Antimicrobial susceptibility tests for bacteria can be either quantitative or qualitative. In quantitative tests the minimum amount of drug that inhibits the visible growth of a bacterial isolate is determined. This

lowest concentration termed the *minimum inhibitory concentration* (MIC), is determined by preparing serial dilutions of the test drug in either broth or agar and inoculating with the bacterial isolate. Following incubation, the MIC is recorded as the highest dilution in which there is no macroscopic growth. The MIC is also used as a comparative index for other antimicrobial agents.

Qualitative tests categorize a bacterial isolate as susceptible, intermediate, or resistant to a concentration of a particular antimicrobial agent. The most common qualitative method is the disk diffusion, or Kirby-Bauer, technique. Utilizing this method, fresh (18–24 hours old) bacterial colonies are placed into sterile physiological saline to match a turbidity standard (0.5 McFarland) representing 1.5×10^8 colony forming units/ml (CFU/ml). The suspension is then swabbed onto the surface of a Mueller-Hinton agar plate to create a lawn of bacteria. Antimicrobial-containing disks are then placed on the plate surface. During incubation the drug diffuses thought the agar, establishing a concentration gradient around each disk. Upon observation of the plates, the diameters of *zones of no growth* also known as *zones of inhibition* are measured. The sizes of the zones are compared to standard sizes and interpreted as susceptible, intermediate, or resistant (19). When working with marine bacteria, 1–3% sodium chloride is usually added to the broths or agars, to allow for the growth of halophilic organisms. The addition of salt, may interfere with zone sizes and should be interpreted only on a relative basis. The disk diffusion method should not be performed on selective or differential agars. *In vitro* susceptibility test results do not always correlate with successful treatment of the pathogen. Factors such as host response, drug dynamics, and microbial activity affect the eventual outcome of chemotherapy. Economic factors including cost, ease of handling and delivery, as well as government regulation, impact the availability and subsequent usefulness of drugs in aquaculture.

BACTERIAL RESISTANCE TO ANTIMICROBIAL DRUGS

Bacterial resistance to antimicrobial drugs has become widespread in aquaculture. Cultured fish have been reported to be infected with resistant strains of *Aeromonas hydrophila*, *Aeromonas salmonicida*, *Edwardsiella ictaluri*, *Pasteurella piscicida*, *Vibrio anguillarum*, *Yersinia ruckeri*, and streptococci resistant to many drugs used in aquaculture, including nalidixic acid, oxolinic acid, tetracycline, sulfa drugs, and chloramphenicol (27).

Antimicrobial resistance emerges as a result of a genetic change that is favored in the process of natural selection and may be *intrinsic* or *acquired*. Intrinsic resistance is an inherent physiological, biochemical or morphological feature of the cell that prevents antibiotic action. Intrinsic resistance is present in the cell and not dependent on drug exposure. It results from spontaneous chromosomal mutations that may alter physical or biochemical properties of the bacterial cell. Properties conferring intrinsic resistance include absence or insensitivity of a target site, antibiotic inactivation, and impaired antibiotic uptake.

Acquired resistance implies that an organism has developed resistance to a drug to which it was previously susceptible, following exposure to the drug. Exposure exerts the selective pressure, often resulting in the rapid overgrowth of resistant cells, from which emerges a new population of resistant cells. Acquired resistance confers properties similar to those of intrinsic resistance, as well as, enhancing antibiotic efflux, and causing overproduction of target sites requiring higher drug concentrations to inhibit bacterial growth (28). Acquired resistance can occur as a result of spontaneous chromosomal mutation or by the acquisition of extrachromosomal elements, such as plasmids and transposons. Spontaneous chromosomal mutations occur at a frequency of one gene mutation per 10^5 to 10^7 cells per cell division. These mutations can occur in the presence or absence of the drug, resulting in both intrinsic and acquired resistance.

Antibiotic resistance can be determined by genes that reside in the cell chromosome, on plasmids, or on transposons. Chromosomal mutations include both single and multiple DNA base pair alterations. However, in the vast majority of cases, the precise molecular basis of the mutational events leading to antibiotic resistance is unknown (28). As extrachromosomal genetic elements, plasmids replicate independently of the bacterial chromosome. Plasmid mediated antibiotic resistance is more common than chromosomal resistance in pathogenic bacteria. Genes encoded by plasmids are more mobile than chromosomal genes, because plasmids can be transferred both within and between certain bacteria. Transposons are mobile DNA sequences capable of transferring themselves from one DNA molecule (donor) to another (recipient). Transposons are not able to replicate independently and must be maintained either in the host chromosome or in plasmids. It is believed that transposons account for the emergence of multiple drug resistant bacteria.

Numerous reports in the literature document the emergence of antimicrobial drug resistance in bacterial pathogens of fish and shrimp (29). In the case of quinolone antibacterial drugs resistance is conferred by chromosomal mutation (18). Resistance to older quinolones such as nalidixic and oxolinic acids has been evidenced in such fish pathogens as *A. salmonicida* (30–32), *V. anguillarum* (27,33), and *Y. ruckeri* (34). The newer quinolones such as sarafloxacin and enrofloxacin have shown to be effective against multiple resistant strains of *Aeromonas* spp. (35–37) and *A. salmonicida* (38).

Antibiotic resistance to all other antimicrobial drugs is known to be conferred by chromosomal mutation, but primarily through plasmid acquisition. Plasmids transferring resistance to as many as five antimicrobial drugs have been identified from fish pathogens including *Vibrio salmonicida*, *V. anguillarum*, *A. salmonicida*, *A. hydrophila*, *Edwardsiella tarda*, *Citrobacter freundii*, and *Y. ruckeri* (31,33,39–45). Promising compounds such as florfenicol, a chloramphenicol analog, and a new generation of cephalosporins currently are being evaluated for use against bacterial fish pathogens (35,46,47).

IMMUNOMODULATION BY ANTIMICROBIAL DRUGS

Immunomodulation is a consequence of a change in the number or function of the cells involved in the immune response. Reports have described positive and negative effects, as well as no effect at all, of antimicrobial drugs on the immune response (48). Most studied are the immunomodulating effects of oxytetracycline (OTC), which appears to impair cellular immunity by decreasing mitogen response. Humoral immunity was suppressed in carp evidenced by a significant decrease in antibody producing cells during a primary immune response; however, no effect was observed during the secondary response (49). Some researchers speculate that in cases where the specific response is blocked, the phagocytic defense system becomes more active (49). Pharmacological studies have demonstrated that oxytetracycline (OTC) accumulates in lymphoid tissue which may explain the negative influence of the antibiotic on the immune response of carp. OTC also is known to suppress the antibody response on rainbow trout, while in certain experiments, potentiated sulfonamides did not. Grondel et al. (50) showed that at low concentrations of some chemotherapeutants can stimulate, while higher doses can inhibit, the immune response.

CHEMOTHERAPEUTIC REGULATION

Most of the drugs discussed are NOT approved for use in foodfish by the U.S. Food and Drug Administration and represent experimental or extralabel use. However, oxytetracycline is currently approved for use in certain species for the treatment of some Gram negative bacteria and *Streptococcus iniae*, and Romet[30] is approved for the treatment of *Aeromonas* and *Edwardsiella* infections in foodfish (13). Investigational New Animal Drug protocols (INAD) are being developed, such as erythromycin for use in salmonids to treat infections caused by *Renibacterium salmoninarum*.

Individual fish sensitivity may vary with the drug, treatment time, and dosage. Fish should always be treated in clean water, and water should be changed following the termination of treatment. Aeration and filtration should be maintained during treatment, but activated may have to be removed.

OUTLINE

Plants have developed a number of survival mechanisms to reduce the chances of their seeds being eaten or digested by insects, birds, or other animals. One defense mechanism is the production of compounds called antinutrients or antinutritional factors (ANFs), which are toxic to the animals or inhibit digestion of the seeds. Other compounds, for which the primary purpose in the seeds is not protection, can lower the bioavailability of nutrients to animals or otherwise affect their health. Research with mammalian models in the past 10–15 years has revealed some beneficial effects of certain ANFs, such as the reduction of blood lipids and the reduction in the incidence of cancer (1). Health benefits to fish have not been reported. Therefore, antinutritional factors are an important consideration in animal and fish nutrition because many feed ingredients used in animal and fish feeds are produced from grains, legumes, and oilseeds.

Two main approaches to eliminating ANFs in feed ingredients are the destruction/removal of ANFs during seed processing and changing specific genetic characteristics of the seeds. Some antinutritional factors can be destroyed or removed through certain processing conditions (e.g., high-temperature extrusion processing of soybean or canola meal and solvent extraction of whole oilseeds or their protein-rich by-products following oil extraction). The ANF concentrations in other products have higher lowered to acceptable levels by selective breeding of some oilseeds. Selective breeding has led to the development of new plant cultivars that have higher nutritive value for monogastric finfish species and other animals than the meals derived from their progenitor seeds. More recently, molecular-biology procedures have been employed to develop transgenic seeds with decreased levels of deleterious compounds. Nevertheless, antinutritional factors in feed ingredients of plant origin remain a source of concern, especially in fish feeds, where much less is known about the sensitivity of the fish to these compounds.

GRAINS

Grains are the foundation of most animal and some fish feeds. Ground whole-cereal grains (e.g., corn, wheat, rice, barley, and sorghum) constitute at least 50% of feeds

for channel catfish (*Ictalurus punctatus*), tilapia, carp, and many other omnivorous fishes. Feeds for carnivorous fish, such as salmon, trout, and sea bass, contain ground whole grains at 10–20% of feed formulations and often include products made from grains, such as gluten meals (typically wheat and corn) or milling by-products. The antinutritional factors present in grains are protease inhibitor, hemagglutinins, cyanogen, phytic acid, tannins, estrogenic factors, antivitamin B-1, amylase inhibitor, invertase inhibitor, and dihydroxyphenylalanine (Tables 1 and 2) (2). Of these, phytic acid and hemagglutinin are of principle concern to fish feed producers.

Phytic acid, or phytate, is the hexaphosphate of myoinositol and is the storage form of phosphorus in seeds. In this form, phosphorus is unavailable to monogastric animals, including fish, because these animals lack intestinal phytase. Research with fish has demonstrated that phytic acid can lower the bioavailability of zinc and some other divalent ions, making it necessary to fortify fish diets with supplemental zinc when feeds contain phytic acid. Gatlin and Wilson (3) found that in order to ensure good growth and feed efficiency, the zinc concentration in catfish feeds must be increased five times when phytate-containing ingredients are used. Further, Richardson et al. (4) showed that the addition of

Table 1. Key to Antinutritional Factors in Feed Ingredients[a]

Number	Antinutrient	Heat Sensitive
1	Trypsin inhibitors	Yes
2	Hemagglutinin	Yes
3	Glucosinolates	No
4	Cyanogen	No
5	Phytic acid	Yes/No
6	Saponins	No

[b]See Table 1 for the key to antinutritional compounds.

phytate to chinook salmon feeds, which contained high levels of calcium and phosphorus as well as an adequate dietary zinc level (in the absence of phytate) induced zinc deficiency. The zinc deficiency led to bilateral-lens cataracts, anomalies in the structure of the pyloric-caecal region of the intestine, reduced growth, lowered feed efficiency, and reduced thyroid function. Spinelli et al. (5) reported that adding phytates to rainbow-trout feeds reduced protein bioavailability, presumably through the formation of protein-phytic-acid complexes. However, depressed protein bioavailability has not been observed in trout and salmon which were fed diets containing ingredients inherently rich in phytic acid due to processing (6). While phytate can also chelate other divalent cations (e.g., manganese, copper, magnesium, and iron), there is no evidence that nutritional deficiencies of these elements can occur in fish. Certainly, reduction of the phytate levels in fish feed ingredients is desirable for the reasons mentioned previously and to decrease excretion of unavailable phytate phosphorus into the environment. Phytate phosphorus excretion is of particular concern in freshwater systems where the excess phosphorus can stimulate the growth of phytoplankton and algae.

Recently, plant geneticists have developed varieties of corn and barley that are lower in phytate content than common varieties. These newer varieties contain the typical amount of phosphorus, but much less of the phosphorus is bound to phytic acid. The bioavailability of phosphorus to rainbow trout from low-phytate corn and low-phytate barley was significantly higher than in common corn and barley (7). Similar results will likely be found in other fish species. High-temperature extrusion also appears to be a practical way to reduce the levels of phytate in some plant-protein products before their dietary incorporation, while having beneficial effects on fish performance (8).

Hemagglutinins, also known as lectins, are proteins which cause agglutination of erythrocytes (red blood cells) *in vitro*. Hemagglutinins are destroyed by the acidic conditions in the stomach, suggesting that species of fish possessing acid stomachs will not be affected by them. For carp and other agastric fish species, hemagglutinins could be a problem; however, heat treatment inactivates them. The heat involved in pelletizing fish feeds likely eliminates these compounds as practical problems in fish farming.

Estrogenic factors in plants, also called phytoestrogens, are compounds having weak estrogenic activity which are found in several grains (e.g., barley, oats, rice, and wheat). The compounds having estrogenic activity in grains are isoflavones, coumestans, and resorcyclic acid lactones (9). The amounts of these compounds present in grains are low, and it is unlikely that they have any significant effect in fish at the levels present in fish feeds. However, studies to confirm this have not been done.

Amylase is an intestinal enzyme used to digest carbohydrates. Amylase inhibitors are found in wheat and beans. They have been reported to be heat sensitive [e.g., 95–100 °C (203–212 °F) for 15 min] and digested by pepsin (10). Carnivorous fish (e.g., salmon and trout) have low levels of amylase in their intestine, but herbivorous fish (e.g., carp) have much higher levels, presumably

Table 3. Antinutritional Factors in Oilseeds[a]

Oilseed	Compounds[b]
Soybean	1, 2, 3, 5, 6, 8, 10
Cottonseed	5, 8, 9, 11, 17
Rapeseed/canola	3, 5, 7
Peanut	1, 2, 5, 6, 8
Sunflower	1, 7, 13,
Sesame	5

[b] See Table 1 for the key to antinutritional compounds.

associated with their natural diet (9). In both trout and carp, wheat flour inhibits about 80% of the amylase activity of intestinal fluid. Ground wheat is less inhibitory than wheat flour. The use of wheat flour in fish feeds likely results in reduced amylase activity and thus reduced rates of carbohydrate digestion, especially in fish with little endogenous amylase and in agastric fish lacking pepsin.

OILSEEDS

A number of feed ingredients produced from oilseeds are important in fish feeds, including soybean meal, cottonseed meal, and canola (rapeseed) meal. To a lesser extent, other oilseed meals, including peanut meal, sunflower meal, and sesame seed meal, are included in fish feeds where availability and economics support their use. The antinutritional compounds found in oilseeds are trypsin inhibitors, glucosinolates, phytic acid, saponins, tannins, phytoestrogens, gossypol, antivitamin E, A, D, B-12, arginase inhibitor, and cyclopropenoic acids (Table 3).

SOYBEAN PRODUCTS

Soybean meal contains antinutritional compounds, which must be removed or inactivated by processing before the meal can be used successfully in animal or fish feeds. The principal compounds of concern in soybean meal are trypsin inhibitors, which reduce protein digestibility by binding with the digestive enzyme trypsin in the intestine of the animal. Trypsin inhibitors are sensitive to heat, and once oil is extracted from soybeans, ordinary processing lowers the level of trypsin inhibitors in the dried meal to levels that do not affect the growth of most domestic animals and some species of fish (e.g., catfish). Salmon and trout, however, are more sensitive to the trypsin inhibitor level. Thus, more extensive heat treatment is necessary to reduce residual trypsin inhibitor levels below 5 mg/g, the level above which protein digestibility and growth performance are affected (11). However, overheating the soybean meal may reduce protein quality by fostering reactions between amino acid residues and portions of the carbohydrate fraction in soybeans. Trypsin inhibitor levels were rapidly lowered in unheated soy flakes from 181 trypsin units inhibited (TUI)/mg sample to 1.8 TUI after 20 minutes of heat treatment (120 °C, 25 psi) (12). Protein solubility was reduced from 98 to 70% by this

treatment, but further heating to 40 minutes or more reduced protein solubility to less than 33%, an indication of overheating (13). Protein digestibility, measured in vivo using rainbow trout (*Oncorhynchus mykiss*), was increased from 74 to 91% by 20 minutes of heat treatment. This difference was presumably the result of heat inactivation of trypsin inhibitors. Channel catfish and carp are reported to be less sensitive than salmonids to trypsin inhibitors in soybean meal (14–16).

Regular solvent-extracted soybean meal, the most commonly used soybean product in feeds, is heat-treated to some extent during its manufacture, resulting in values of about 3.0 to 3.5 mg trypsin inhibited/g sample (17). Further heating occurs during feed pelleting, especially during cooking-extrusion pelleting (see the entry "Feed manufacturing technology"). This process presumably lowers trypsin inhibitor activity further. Full-fat soybeans (toasted whole soybeans) containing 46.5 mg TUI had TUI values of 7.6 and 8.5 after being extruded (18), illustrating the effects of cooking-extrusion on trypsin inhibitor levels.

Soy protein concentrates have low levels of trypsin inhibitor (12,19), but contain levels of phytic acid that are at least as high as those in soybean meal (12). The enzyme phytase releases phosphorus from phytic acid, and the addition of phytase to catfish feeds significantly improves the phosphorus availability in soybean-meal-based feeds.

Chemical Tests for Detecting Underheated-Soybean Meal

The various chemical tests used to determine the adequacy of heat treatment of soybean meal can be divided into two groups: those that detect underheated soybean meal and those that detect overheated meal (20). Chemical tests used to detect underheated soybean meal are tests of urease activity, trypsin activity, and protein solubility. Urease is an enzyme naturally-present in soybeans that does not have any substantial nutritional relevance, except that it is heat-sensitive and its activity correlates with residual trypsin activity in dried soybean meal. It is also relatively easy to measure (21). Urease activity in commercial soybean meal ranges from a 0.02 to 0.1 increase in pH (20). Values over a 0.5 increase in pH indicate insufficient heat treatment of the soybean meal. If no increase in pH is detected with the urease test, the soybean meal may have been overheated. Thus, some residual urease activity in the meal is preferred, especially for soybean meal intended for use in poultry feeds. Unheated soybean meal has a >2.25 pH rise in urease activity (22).

Another method for measuring the extent of heat treatment of soybean meal is the water solubility test. This test involves measuring Kjeldahl nitrogen levels in the soybean meal and in a water extract of the soybean meal (20). The method has been slightly modified by extracting the sample in 0.2% KOH (13). Heating decreases the percentage of 0.2% KOH-extractable proteins from about 99% in raw soybean meal to about 72% after 20 minutes of autoclaving. The corresponding decrease in trypsin inhibitor units is from 21.1 to 1.0 (13).

Soy products contain compounds that influence feed intake, gut histology, and immunological function (11). Complete replacement of fish meal with soybean meal in trout feeds lowered growth, primarily by lowering

feed intake, but partial replacement of fish meal with soybean meal (e.g., 29% soybean meal and 42% fish meal in the diet) had no effect on trout feed intake or growth (11). Tolerance of trout to dietary soybean meal appeared to be higher in larger fish and at higher water temperatures. Intestinal mucosa of trout, which were fed soybean-meal-containing diets, were blunted or flattened, thus decreasing the absorptive surface of the proximal and distal intestine. However, it is not known if these intestinal changes are responsible for differences in growth associated with feeding diets containing high levels of soybean meal (11). Antigens present in soybean products stimulate the nonspecific defense mechanisms of trout, but it is unknown if such stimulation of the immune system results in higher resistance to infectious disease (11).

Other Oilseed Products

The other major antinutritional factors associated with other oilseed meals are as follows: glucosinolates and erucic acid in canola/rapeseed meals and gossypol and cyclopropenoic acid in cottonseed meal (Table 3). Glucosinolates interfere with the function of the thyroid gland in fish, posing problems during metamorphosis, smoltification, and maturation (23). Glucosinolates alone are not harmful compounds, but when they are hydrolyzed by the enzyme myrosinase in poorly-processed meals or by intestinal microorganisms, an array of products can result such as thiocyanate ions, isothiocyanates, nitriles and goitrin, depending upon the hydrolysis conditions. Isothiocyanates and nitriles are precursors to thiocyanate, which inhibits uptake of iodide, by the thyroid gland. Extra supplementation of the diet with iodine can overcome this. Goitrin actually inhibits the ability of the thyroid to bind iodide, and providing supplemental iodine cannot overcome this problem. Typically, the major consequences of thyroid function impairment include thyroid hypertrophy and hyperplasia and depressed thyroid hormone synthesis and plasma thyroid hormone titres. These effects lead to reductions in growth, feed intake, and feed utilization. Fortunately, varieties of rapeseed (called canola), which contain very low levels of glucosinolates, have been developed through genetical selection, and residual levels of the glucosinolates can be further decreased by solvent extraction and other means. Hence, the glucosinolates present in some canola protein products (e.g., concentrates and isolates) are very low in concentration and do not pose a problem.

Erucic acid is a 22-carbon monounsaturated fatty acid, and may constitute 20−55% of rapeseed oil (23). This compound causes lipid accumulation and necrosis of the heart tissue (24) and is toxic to coho salmon when fed at 3−6% of the diet (9). However, no erucic acid problems have been reported when rapeseed or canola meals are included in fish feeds, presumably because nearly all of the oil has been removed from these meals. The varieties of canola that have been developed contain lower levels of glucosinolates and erucic acid than in earlier rapeseed varieties. The use of rapeseed/canola-protein products in fish feeds has recently been thoroughly reviewed (6).

The presence of fiber, both independently and perhaps in combination with phytate, in oilseed meals such as

commercial canola meal, appears to have the greatest adverse effects on feed digestibility in salmonids like the rainbow trout (25). Indeed, the insoluble fibers in the meal may depress the gut transit time and the absorption of amino acids and peptides, whereas the soluble fibers could inhibit digestive enzymes and restrict the diffusion of hydrolysis products (26).

Gossypol causes a number of problems in fish, including anorexia and increased lipid deposition in the liver. Gossypol is contained in the pigment glands of cotton, therefore, glandless cotton is free of gossypol. Fish species differ in their sensitivity to gossypol, with trout being sensitive, channel catfish more sensitive, and blue tilapia the most sensitive of the species for which information is available (23). Growth depression occurred in trout, which were fed more than 290 mg gossypol/kg diet, with more than 900 mg/kg for channel catfish and 1800 mg/kg for tilapia needed to lower growth. Solvent-extracted cottonseed meal samples from the United States contained between 400 and 800 mg gossypol/kg (27). Thus, catfish feeds containing no more than 20% cottonseed meal would not deliver enough gossypol to affect the fish. The use of cottonseed meal in fish feeds has recently been thoroughly reviewed (27). Cottonseed meal also contains cyclopropenoic fatty acids (sterculic and malvalic acids). These fatty acids are quite toxic in their own right and powerful carcinogens when fed to rainbow trout or salmon in combination with aflatoxins, fairly common toxins produced by *Aspergillis flavis*, a common mold found on grains (9). Cottonseed meal contains residual levels of cyclopropenoic fatty acids, even after oil extraction. Thus, it should not be used in feeds for trout or salmon.

LEGUMES

Legumes include peas, beans, alfalfa and ipil-ipil. Many contain trypsin inhibitors, hemagglutinin, cyanogens, phytic acid, saponin, antivitamin factors, and mimosins (Table 4). Most of these antinutritional factors have been discussed previously, with the exception of saponin and mimosin. Saponin is a nonprotein constituent of soybeans, which makes up about 0.5% of the weight of the soybean and is extractable from soybean globulins with alcohol. Isolated saponins do not harm chicks, rats, or mice when fed up to three times the amount found in soybean meal, but a crude saponin extract of soybean meal is reported to lower the feed intake of chinook salmon fingerlings and to

reduce the growth of rainbow trout (28). Mimosin is found in ipil-ipil, and its effects on fish are unknown.

TUBERS

Tubers are potatoes, sweet potatoes, and cassava. The most important antinutritional factors in tubers are trypsin inhibitors, although potatoes also contain hemagglutinin, cyanogen, phytoestrogens, amylase inhibitor, invertase inhibitor, and cholinesterase inhibitor (Table 5). Cooking tubers before including them in feeds reduces the levels of these antinutritional factors to insignificant levels, especially considering the small amount of tuber products used in fish feeds.

OTHER ANTINUTRITIONAL FACTORS FOUND IN FEED INGREDIENTS

Thiaminase

Many species of fish, mainly freshwater species, contain thiaminase, an enzyme that hydrolyzes thiamin in feed preparations (23). Thiaminase is destroyed by heat treatment and also by the acidification used to produce fish silage. Thiaminase is a relatively slow-acting enzyme, therefore, feeding raw fish combined with dry mash within hours of preparation is not a high risk. An alternative strategy is to feed raw fish and dry mash containing thiamin separately.

Histamine and Gizzerosine

Histamine, 4-(2-aminoethyl)imidazol, is a primary amine arising from the decarboxylation of the amino acid, L-histidine. The toxic effects of histamine in the food supply of humans has been positively associated with scombroid-fish poisoning (29), an allergic reaction resulting from the ingestion of spoiled fish, usually of the families Scombridae and Scomberesocidae. The U.S. Food and Drug Administration has established a hazard-action level of 50 mg histamine/100 g canned tuna (30), and for fresh and frozen fish, the level is 20 mg histamine/100 g fish (31).

Histamine production in fish muscle can be controlled by low storage temperatures, which often help to reduce enzymatic and most microbial activities. However, if onboard refrigeration is inadequate, many of the fish captured could undergo significant deterioration prior to processing into fish meal. During the processing of fish meal (capture, transport, and storage), microbial and enzymatic degradation can take place rapidly at warm temperatures to produce high concentrations of histamine. If a significant portion of the catch is delivered to processing plants in a partially-decomposed state, then further degradation can occur after the fish have been unloaded, especially if the raw material is stored in nonrefrigerated concrete pits prior to processing (32).

Gizzard erosion and the resultant black vomit disease of chickens has long been associated with feeding thermally-abused fish meal, but it was not until 1983 that an active substance from fish meal was isolated (33). The active compound named gizzerosine was presumably formed through the condensation of histamine with the epsilon amino group of lysine during high-temperature processing of raw fish into fish meal. Mori et al. (34,35) synthesized several forms of the compound and established the L-form as a potent inducer of gizzard erosion in chickens. In one study, Mori et al. (34) observed severe gizzard erosion in chickens fed less than 50 µg gizzerosine/day (about 2.2 mg/kg diet) for one week. Considerable experimental evidence indicates that gizzerosine induces gizzard erosion in chickens by hyperstimulating the gastric-acid-secreting cells of the proventriculus.

Putrescine and cadaverine, as well as tyramine, β-phenylethylamine, and tryptamine, have been shown to potentiate histamine toxicity in vivo by inhibition of the histamine-metabolizing enzymes, diamine oxidase and histamine-N-methyltransferase (36). These data strongly suggest that fish meal toxicity to chickens is most likely related to the complex interactions among many chemical compounds found in degraded fish products.

In a study by Fairgrieve et al. (37), growth, feed intake, and the development of gastric abnormalities were assessed in juvenile rainbow trout. The fish were fed diets containing fish meal, which was acutely toxic to chickens, or they were fed casein or fish meal diets supplemented with histamine and two suspected potentiators of histamine toxicity (putrescine and cadaverine) and abusively heated. Rainbow trout were less sensitive than chickens to gastric erosion (GE)-positive fish meal, and there was no correlation between the GE score and the nutritional value of the fish meal for rainbow trout. Fish, which were fed diets containing GE-positive fish meal, had distended stomachs but no gastric lesions or cellular abnormalities. Similar effects were obtained by feeding diets containing casein or GE-negative fish meal supplemented with histamine (2,000 mg/kg dry diet). The addition of putrescine and cadaverine (500 mg/kg dry diet each) to the histamine-supplemented diets had no further effect. Feed consumption, feed efficiency, and growth were similar among dietary treatments, indicating that stomach distension did not reduce feed intake or impair gastric function. This study also showed that stomach distension resulting from feeding diets containing GE-positive fish meal could be duplicated by feeding diets supplemented with 2,000 mg histamine/kg diet.

Phytotoxins (Toxins of Algal Origin)

Many species of marine algae are capable of producing toxins, including paralytic shellfish toxin (PSP), diarrheic shellfish toxin (DSP) and domoic acid, which causes amnesic shellfish poisoning (ASP) (38). Shellfish, specifically bivalve mollusks, concentrate these toxins and

are the principal vector through which the toxins are transferred to humans and possibly to farmed fish. Very little is known about the direct effects of these toxins on farmed fish or on the accumulation and/or biotransformations that may occur if farmed fish are fed diets containing contaminated shellfish or other marine product containing toxins. However, the potential human health risk is serious (38).

Sardines, and presumably other fish utilizing algae as food, consume algae containing domoic acid without apparent signs of toxicity (39). If these fish are harvested and used to produce fish meal, domoic acid, which is heat stable, can be concentrated in the fish meal by a factor of at least three, reaching 130 µg domoic acid per g fish meal (40). Rainbow trout, which were fed diets containing contaminated fish meal, did not exhibit any signs of toxicity or growth retardation, even though they consumed 50 µg domoic acid per kg body weight, much more than is required to cause illness in humans. Domoic acid was present in the GI tract of the trout, but not in the edible tissues (40).

MICROBIAL TOXINS

Molds that grow on feed ingredients and on prepared feeds are an important group of toxins affecting fish (9). In particular, aflatoxins, which are produced by the mold *Aspergillis flavis*, cause serious health problems in fish at much lower intake levels than in terrestrial animals. Cottonseed meal, peanut meal, and corn products are the most problematic feed ingredients with respect to aflatoxins, and grains including wheat, rice, barley, and oats are the next most problematic feed ingredients (9). Prolonged intake of very low levels of aflatoxin (<1 ppb) causes liver cancer after one year in rainbow trout, the most sensitive vertebrate to aflatoxin intake. Acute toxicity in rainbow trout is observed when fish are fed diets containing between 0.8 µg and 1.9 µg aflatoxin per g feed, depending upon the type of aflatoxin. Differences in sensitivity exist among strains of rainbow trout, among trout species, among other salmonids, and among other species of fish. Coho salmon and channel catfish, for example, are much more resistant to aflatoxin exposure than are rainbow trout (9). Other mold toxins of concern in fish feeding include ochratoxin, sometimes found as a contaminant of corn and wheat, vomitoxin, found in cereal grains, and T-2 toxin, also found in cereal grains. Of these, only vomitoxin has been evaluated in fish, with dietary levels of 20 µg toxin/g feed or higher causing feed refusal in trout (41). Obviously, fish should never be fed moldy feed.

SUMMARY

The biological significance of antinutritional factors in feed ingredients varies among factors and within factors among fish species. Research to document the relative importance of antinutritional factors in fish is extensive for some (e.g., glucosinolates), less extensive for others (e.g., phytic acid, trypsin inhibitors, gossypol), and nearly absent for others. If compounds that lower feed palatability

are included in the antinutritional factor category, the practical significance of antinutritional factors increases. As use of feed ingredients from grains and oilseeds in fish feeds increases, the importance of understanding the biological effects of antinutritional factors on farmed fish and of developing methods for inactivating the antinutritional factors or overcoming their effects will become a critical element in the expansion of aquaculture production.

AQUATIC VEGETATION CONTROL

MICHAEL P. MASSER
Texas A&M University
College Station, Texas

OUTLINE

Aquatic vegetation control can be one of the most perplexing problems facing any pond manager. Aquatic vegetation, particularly rooted and floating vegetation, may limit production and complicate feeding, harvesting, and predator control (1). Many water quality problems such as low dissolved oxygen, high carbon dioxide, and toxic nitrogenous compounds are driven by aquatic vegetation (2). Water-level manipulation (through clogging drains and intakes) in ponds and raceways can also be complicated by aquatic vegetation. Most water quality concerns in heavily fed and fertilized aquaculture ponds are driven by planktonic algae. Certain algae produce off-flavor compounds that result in unmarketable products and disrupt cash flow, production sequencing, and marketing strategies.

CLASSIFICATION OF AQUATIC VEGETATION

Aquatic vegetation is generally classified as either (*1*) algae, (*2*) floating, (*3*) submerged, or (*4*) emergent. These classification groups are somewhat arbitrary, and a few species appear to overlap more than a single group.

Some aquatic plants now common to many countries are not native (nonindigenous) to that continent. These include water hyacinth, hydrilla, Eurasian watermilfoil, giant water fern, and water lettuce. Aquarium and water garden enthusiasts have spread many of these species because of their attractiveness or because of accidental inclusion in shipments of other ornamental plants. However, in aquaculture even native species can become nuisances, because their rapid growth is stimulated by the high nutrient content common to culture ponds (2). For purposes of this discussion, forms or species will be limited to those that are most commonly problematic in aquaculture. Identification is the first key step in developing a management strategy for aquatic vegetation. Many publications, web sites, and computer software packages are available to assist in identifying aquatic vegetation (3–6).

Algae

Algae are the most common type of aquatic vegetation in aquaculture ponds (7). There are thousands of species of algae. Various algal species inhabit all known ranges of temperature and salinity in aquatic environments. Algae vary greatly in size and body form, ranging from microscopic single-celled species to groups of cells called colonies, or chains of cells called filaments (Fig. 1). Based on size and shape, algae are usually subdivided
Figure 1. Structures of three types of algae common to aquaculture ponds. (Used by permission from IFAS, Center for Aquatic Plants, University of Florida, Gainesville, 1990.)

into three groups: (*1*) planktonic, (*2*) filamentous, and (*3*) macroalgae. The largest multicellular or macroalgae species are the marine kelps.

Algae do not flower or bear seeds, unlike most other aquatic plants. Algal reproduction, depending on the species, can be by asexual division, by resting cell or "cyst" formation, or by a simple form of sexual reproduction that results in spore formation. In some species spores and cysts can resist desiccation and can be borne by winds or birds to colonize other bodies of water (8). The production of new plants or colonies by fragmentation of multicellular forms is also common.

In pond aquaculture, some of the most problematic algae are single-celled and small multicellular species that proliferate in vast numbers [*Anabaena*, *Anacystis* (formerly *Microcystis*), *Cosmarium*, *Coelastrum*, etc.]. These dense algal or phytoplankton populations are referred to as "blooms." While the blooms produce most of the dissolved oxygen in ponds, they also can cause wide fluctuations in dissolved oxygen, carbon dioxide, nitrogen, and phosphorus levels in ponds, as their populations rapidly expand and die (2). Some species of algae can be toxic to other aquatic organisms and even man; these include *Anacystis*, *Anabaena*, *Gonyaulax*, *Gymnodinium*, and *Pfiesteria* (9).

Filamentous algae (*Spirogyra*, *Lyngbya*, *Pithophora*, *Oedogonium*, etc.) are often problems in pond, cage (or net pen), and raceway culture. Filamentous algae usually start growing along the pond bottom or become attached to structures in the water (e.g., cage mesh, raceway walls, etc.) wherever sunlight penetrates. Filamentous algae

often form thick mats along the pond bottom that, as they grow, trap gasses among the filaments. This trapped gas eventually causes the mats to peel off the bottom and float to the surface. The floating mats of filamentous algae are often referred to as "pond scum or pond moss." Filamentous mats can entrap and kill larval fish, trap feed and make it unavailable to culture organisms, reduce culture chamber volume, complicate seining (or make it impossible), and if they cover most of the surface they can cause oxygen depletions (10).

In freshwater, there a few macroalgaes that resemble rooted, submerged aquatic macrophytes. These include members of the stonewort family. Common among these are *Chara* (Fig. 2) and *Nitella* species. These macroalgae do not have true roots and are attached to the pond bottom with rhizoids. Kelp, planktonic algae, and floating filamentous algae get their nutrients directly from the water column.

Marine macroalgaes (i.e., kelps) are an integral part of certain marine ecosystems. Some varieties of kelp are cultured, or harvested from the wild, as food or food supplements for humans and animals. Marine kelps can foul net pens, causing water circulation problems and reducing functional culture volume (11).

In aquaculture, algae growth is sometimes promoted through fertilization to stimulate the natural food chain for the species being cultured. Elaborate steps are taken, and selected fertilizers applied, to produce algal blooms or mats

Chara spp. Muskgrass

Figure 2. *Chara* spp., muskgrass, is a member of the stonewort family of macroalgaes. (Used by permission from IFAS, Center for Aquatic Plants, University of Florida, Gainesville, 1990.)

for particular culture situations (12). Pond production of many species of fish and shellfish larvae and fry depend on fertilization to stimulate phytoplankton and zooplankton blooms for the cultured species to feed on (see the entry "Fertilization of fish ponds").

Floating Plants

Free-floating plants include such groups as the duckweeds (*Lemna* and *Spirodela*; Fig. 3), water hyacinth (*Eichhornia crassipes*; Fig. 4), water lettuce (*Pistia stratiotes*), some forms of bladderwort (*Utricularia* spp.), and water

Water hyacinth

Figure 4. The water hyacinth is considered one of the most noxious aquatic weeds in the world. (Used by permission from IFAS, Center for Aquatic Plants, University of Florida, Gainesville, 1990.)

ferns (*Azolla* and *Salvinia* spp.) (13,14). Water hyacinth, water lettuce, and giant salvinia are examples of aquatic plants that have been carried by man into nonindigenous environments. The water hyacinth is considered one of the most noxious aquatic weeds in the world. Floating plants like water hyacinth, water lettuce, and bladderwort are not usually a problem in aquaculture situations and can be removed by physical means (i.e., seining). The duckweeds (Family Lemnaceae), and particularly watermeal (*Wolffia columbiana*), are the smallest flowering plants (angiosperms) in the world. Duckweeds, watermeal, and water ferns can be problematic in aquaculture where they can rapidly cover the water surface, thus reducing oxygen production and transfer (15). Duckweeds are occasionally cultured to feed the young of species like tilapia and grass carp (16).

Submerged Plants

Submerged, or submersed, aquatic vegetation refers to those plants that grow underwater and, in some species, up to the water surface. Some submerged plants have small vegetative structures and/or flowers, as well as seed heads that extend above the surface; these plants can be confused with emergent plants. Submerged plants are usually flaccid and dependent on the water for support. They generally do not have rigid stems like emergent aquatic plants.

Hydrilla (*Hydrilla verticillata*), egeria (*Egeria densa*), and Eurasian watermilfoil (*Myriophyllum spicatum*; see Fig. 5) are examples of submerged aquatic plants that have been spread to nonindigenous environments, where they have caused severe problems in many parts of the world (Fig. 6) (17). These species typically spread rapidly by fragmentation, outcompete native species, and form dense stands that limit access and impact many water use activities.

In aquaculture, submerged aquatic vegetation can cause problems by reducing the effective culture volume of the production system, by entanglement of larvae, by trapping feed, by restricting the dispersal of feed, and

Myriophyllum spicatum

Figure 6. These species spread rapidly by fragmentation and form dense stands. (Used by permission from IFAS, Center for Aquatic Plants, University of Florida, Gainesville, 1990.)

by restricting or halting seining activities. Submerged aquatic vegetation can cause oxygen depletions due to nighttime respiration and die-offs. Submerged macrophytes that often cause problems in aquaculture include naiads (*Najas* spp.; Fig. 7), pond weeds (*Potamogeton* spp.; Fig. 8), coontail (*Ceratophyllum demersum*), and widgeongrass (*Ruppia maritima*). These macrophytes compete with planktonic algae for nutrients and light (10). Usually the most critical factor regulating submerged aquatic vegetation growth is turbidity.

Emergent Plants

Emergent, or emersed, plants are rooted aquatic plants that have stems or leaves that are rigid enough to rise above the surface of the water (13). Emergent aquatic plants are usually shallow water (<3 m) or shoreline inhabitants. Water lilies and lotus belong in this group, but are seldom a problem in aquaculture. Species that often cause problems in ponds include cattails (*Typha* spp.), rushes (*Juncus* spp.; Fig. 9), sedges (*Cyperus* spp.), spikerushes (*Eleocharis* spp.), water primrose (*Ludwigia*

spp.; Fig. 10), and water pennywort (*Hydrocotyle ranunculoides*; Fig. 11).

Like most other aquatic vegetation, emergent plants can restrict access, reduce the effective culture volume, interfere with feeding and seining, and the quality the quality of the water.

MANAGEMENT METHODS

There is no single way to manage or control the wide range of aquatic plants. Effective management efforts begin with prevention. Once aquatic vegetation is established then management measures can include mechanical or physical, biological, and/or chemical control. Generally, an integrated pest management (IPM) approach is the best way to develop a sustainable, long-term aquatic strategy for management of vegetation. IPM involves combining or integrating several management methods to achieve effective, long-lasting control. Obviously, all methods of management must be compatible with the culture system and species in production.

Juncus effusus
Soft rush

Figure 9. Emergent species such as soft rush can interfere with water access, feeding and seining. (Used by permission from IFAS, Center for Aquatic Plants, University of Florida, Gainesville, 1990.)

Prevention

In pond culture, prevention includes proper pond location, design, construction, and possibly, fertilization, stocking of aquatic herbivores, and drawdowns.

Ponds should not be located where they will get heavy runoff of organic matter. The enrichment of organic matter from excessive livestock, fertilized fields, septic tanks, or other sources tends to promote the growth of aquatic vegetation. Filling ponds from surface-water sources that have existing aquatic vegetation or receive heavy organic enrichment can also cause problems.

Aquatic vegetation can be discouraged if ponds are constructed with banks that slope quickly to a depth of 75 cm or more. This depth, coupled with a good fertilization program, can effectively shade most of the pond bottom and minimize the area where rooted aquatic vegetation can establish (10).

Shading by, and competition from, planktonic algae for nutrients is possibly the best overall management strategy for preventing rooted aquatic vegetation from becoming established. While planktonic algal blooms may not discourage all forms of emergent shoreline
Ludwigia repens
Red ludwigia

vegetation, they will prevent submerged types and those emergent weeds that establish themselves in deeper water (19). Organic and inorganic fertilizers can be used in pond environments to produce plankton blooms (12). Fertilization techniques will vary depending on the species cultured, chemical composition of the fertilizer, and characteristics of the pond to be fertilized. However, the initiation of a fertilization program after noxious vegetation is established may increase the rapid growth and spread of the problem species. Nontoxic chemical dyes have also been developed that can be added to pond water to reduce the penetration of light and suppress the growth of aquatic plants.

Another common method to prevent some forms of aquatic vegetation from establishing themselves is the stocking of herbivorous fish. Grass carp (*Ctenopharyngodon idella*) are probably the most commonly stocked herbivorous fish, but tilapia (e.g., *Tilapia zillii*), common carp (*Cyprinus carpio*), and other less known species have been utilized in the control of aquatic vegetation. (See the section "Biological control.")

Drawdowns are another method to control or prevent certain aquatic vegetation problems. Winter drawdowns, which expose shallow pond bottom areas to freezing and desiccation can successfully prevent the establishment and spread of many species of submerged vegetation (20). Drawdowns are most effective if repeated for three to five consecutive years.

Mechanical or Physical Control

Mechanical or physical control methods include the simple removal of aquatic vegetation by hand (pulling, raking, and seining), the use of mechanical cutters or harvesters, and the use of physical barriers along the pond bottom (21).
Pulling, raking, and seining usually work in aquaculture ponds when aquatic vegetation is confined to a small area. Mechanical cutters and harvesters are utilized in some public waters, but are seldom used in aquaculture because of the costs of these systems. Pond liners and bottom barriers made from plastic sheets or woven fiberglass cloth can be effective in eliminating rooted vegetation (22). Liners and barriers are seldom used in aquaculture because of the expense and incompatibility with some species or culture techniques.

Biological Control

Biological control is usually desirable in aquaculture because of the relatively low costs and the opportunity to control vegetation without the use of chemicals. Chemicals can in some cases stress the cultured organism, contaminate its flesh, cause a deterioration in the quality of water, or be directly toxic. While host-specific insects (e.g., hydrilla fly and alligatorweed flea beetle) have

been used to control some types of aquatic vegetation in public waters, these methods are not generally utilized in aquaculture. Biological control utilizing a desirable food species is the most commonly practiced method of control of aquatic vegetation in aquaculture. Using a desirable food species also has the added benefit of producing another saleable crop. However, consumption of feed, competition, predation, or some other adverse effect of biocontrol agents must be considered.

Crayfish (*Procambarus*, *Orconectes*, and *Cherax* spp.) will control some types of submerged and emergent aquatic vegetation if stocked singularly in ponds or with species with which they are compatible (23). Stocking rates for crayfish are usually between 28 to 84 kg/ha (25 to 75 lb/ac).

Fish species generally chosen for biological control are the grass carp, tilapia, common carp, and a few other native species used in specific regions like India (e.g., rohu, *Labeo rohita*) or South America (e.g., pacu, *Piaractus* sp.) that are not generally available in other regions.

The grass carp is a native of eastern China and Siberia (24). It is a highly adaptable species that has been introduced into many countries for the control of aquatic vegetation. Grass carp tolerate a wide range of environmental extremes in temperature, pH, dissolved oxygen, and salinity (up to 7.5–8 ppt). They prefer soft submerged vegetation, including filamentous algae, but also control duckweeds (25). Grass carp will not reproduce in ponds (i.e., stagnant water), so they must be stocked at a density that will be sufficient to control the problem vegetation. Stocking densities of grass carp for the control of aquatic vegetation vary widely with the type of vegetation, water temperature, weight of fish stocked, and legal restrictions. Grass carp are generally stocked between 12 to 100/ha (5 to 40/ac) to control aquatic vegetation. In ponds containing predatory fish species, grass carp should be large enough at stocking to preclude predation.

Tilapia (*Sarotherodon*, *Oreochromis*, and *Tilapia* spp.) have been used successfully in the control of some types of aquatic vegetation. Tilapia are known to control filamentous algae, duckweeds, watermeal, and most submersed macrophytes if they are stocked or reproduce in sufficient numbers. Stocking rates are usually around 200 mixed-sex adults/ha (80/ac) (26). One drawback, or attribute of tilapias (depending on your long-term goals), is their inability to survive water temperatures below 55 °F (13 °C), necessitating annually restocking them in temperate climates. Tilapia culture ponds seldom have aquatic vegetation problems. Mixed-sex tilapia are not usually stocked in aquaculture situations with other species because of their tendency to overpopulate and compete with more desirable species. In a few cases tilapia have been stocked for vegetation control along with predaceous fish species that control the tilapia population.

Common carp, including Koi (*C. carpio*), will consume filamentous algae and some types of soft, submerged aquatic vegetation and duckweeds. Their benthic foraging habit also uproots vegetation and increases turbidity in ponds, effectively shading out submerged vegetation. Common carp are usually stocked at 125 to 250/ha (50 to 100/ac). Common carp, like tilapias, can overpopulate a pond quickly and are not generally used in aquaculture for control of aquatic vegetation. Carp production ponds seldom have submerged weed problems.

Ducks, geese, and swans will eat many types of aquatic vegetation and will help reduce or control some aquatic weeds (23). However, they are rarely desirable around aquaculture facilities at the population levels that would be required to control vegetation.

Many mammals, including cattle, water buffalo, goats, swine, moose, nutria, muskrats, capybara, and manatee eat aquatic plants. Cattle, water buffalo, swine, and goats can be grazed on emergent and marginal plants around ponds. Unlike cattle, water buffalo, and swine, goats are particularly effective in controlling many emergent and brush species without damaging dams and levees. The burrowing habits of nutria and muskrats are problematic around aquaculture facilities, and therefore, those mammals are usually discouraged from inhabiting areas near such facilities.

In many countries, the introduction of species like the grass carp, tilapia, and other nonindigenous fishes is regulated. Development of techniques to produce sterile individuals of these species (e.g., triploid grass carp) have led to the legalization of these sterile fishes in many countries (or states) where normal representatives of the species are illegal. Before stocking these species the aquaculturist should check local regulations.

Chemical Control

Most countries have an approval process for all pesticides, including aquatic herbicides. In some cases, registered herbicides differ from country to country. For purposes of this discussion, aquatic herbicides registered by the U.S. Environmental Protection Agency are presented. In general, herbicides should be considered a temporary solution. Many weed species will return, unless an integrated management approach is used. In most cases in aquaculture, herbicides are used as a temporary control measure while preventive, mechanical, or biological methods for long-term solutions are sought.

Herbicides are usually classified on the basis of their properties, including absorption, selectivity, and plant processes affected (27). Absorption properties are characterized as either contact or systemic herbicides. Contact herbicides (copper, diquat, and endothall) act quickly and generally kill all plants that they come in contact with. Contact herbicides are most effective on annual plants, but often multiple treatments are necessary to control perennial vegetation. Systemic herbicides (2,4-D, fluridone, and glyphosate) are absorbed and move within the plant to a site at which they go into action. Systemic herbicides tend to act more slowly, but are generally more effective against perennial and woody vegetation.

Selectivity refers to whether a herbicide affects certain plant species more than others. Physical factors, application methods, formulations, and morphological characteristics of the target plant can influence selectivity. Herbicides that are toxic to any plant are nonselective and often referred to as "broad spectrum." Broad spectrum herbicides include copper, diquat, endothall, and

glyphosate. The truly selective herbicides are fluridone and 2,4-D.

Plant processes affected by herbicides include tissue development, respiration, photosynthesis, and enzyme activity. Herbicides that disrupt tissue development (2,4-D) are also called plant growth regulators and cause abnormal tissue development. Plant respiration is disrupted by endothall herbicides. Photosynthesis is disrupted by copper compounds, diquat, and fluridone. Glyphosate disrupts the enzymes involved in nitrogen metabolism.

Herbicide formulations can be liquid, powder, or granular. All herbicides carry warnings regarding drinking water, livestock watering, swimming, fish consumption, and irrigation (14). Local, state, or national laws may also require special certification or notification requirements when utilizing certain herbicides. Label directions and precautions must be followed completely.

Factors that can affect herbicidal control include temperature, light intensity, water quality variables (e.g., pH, alkalinity, hardness, and turbidity), and seasonal timing. Herbicide labels contain important information regarding interactions with water quality and treatment timing. Generally herbicides are most effective if applied while plants are actively growing, under sunny conditions, and when water temperatures are above $16\,°C$ ($60\,°F$). Some species are best controlled before they seed (e.g., alligatorweed) while others are best controlled late in the growing season when they are actively storing food reserves in their roots (e.g., cattails and willows).

Probably the most common problem in chemical control is failure to accurately calculate the area or volume to be treated (28,29). This results in either limited or no control due to inadequate or excessive concentration. Overdosing can cause rapid vegetation die-off, leading to oxygen depletion and stress or mortality of the cultured organisms. An overdose may also be directly toxic to the cultured species.

Most of the herbicides discussed here (except for possibly copper and some endothalls) are not themselves toxic to fish if used according to label directions. However, the danger of treating with any herbicide is that the decomposing vegetation will cause a reduction in dissolved oxygen. Bacterial and fungal respiration during decomposition can reduce dissolved oxygen to critical or lethal levels for cultured species (30). The risk of depletion of oxygen can be reduced by treating only a portion of the pond at a time (usually less than 25%) and then allowing the treated vegetation to decompose before continuing the treatment. Usually 10 to 14 days are sufficient to allow for decomposition. In many cases the lowest dissolved oxygen levels will occur 7 to 10 days after treatment. Providing mechanical aeration during and after herbicide treatments can be critical.

The first step in chemical control is the accurate identification of the aquatic weed or weeds to be controlled. Herbicides that work on one species often will not be effective on other similar species. The second most important step in chemical control of vegetation is to carefully follow all directions on the herbicide label. Table 1 gives specific recommendations on the effectiveness of selected aquatic herbicide formulations on specific types of aquatic vegetation.

Copper Compounds

Copper sulfate, or "blue stone," is a commonly available inorganic copper compound. Complexed copper compounds bind copper sulfate to carrier molecules that keep the active copper in solution longer. Chelated copper compounds contain copper, but are organic compounds. Copper compounds are contact herbicides that interfere with photosynthesis and are generally effective on algae and a few submerged weeds but have few water use restrictions.

Copper sulfate is very corrosive to metals (e.g., steel) and can irritate eyes and nasal passages. The effectiveness of copper sulfate depends on the alkalinity of the water. In waters of less than 50 ppm total alkalinity as $CaCO_3$, the amount that will kill algae may also kill fish. Some species, like rainbow trout (*Oncorhynchus mykiss*), are very sensitive to copper and are easily killed. At high alkalinity (>200 ppm) copper sulfate is often not effective because it precipitates too quickly.

Chelated copper compounds are somewhat less toxic to fish and less corrosive. Chelated copper compounds are available in liquid and granular formulations but are more expensive than copper sulfate. However, chelated copper compounds are more stable in water and generally are active longer in water than inorganic copper. Check the product label for water use restrictions and other precautions.

2,4-D Compounds

Many different herbicides contain 2,4-D, but only a few are approved and labeled for aquatic use. 2,4-D is a selective, systemic herbicide that is effective on some aquatic broadleaf vegetation. It is available in granular and liquid formulations. Granular formulations are relatively nontoxic to fish and will control many submerged and some emergent (e.g., watershield and waterlilies) types of vegetation. Liquid formulations are generally used to control emergent vegetation. The liquid ester formulations are often more toxic to fish than the other forms. Check the product label for water use restrictions and other precautions.

Diquat Compounds

Diquat compounds are contact herbicides that interfere with photosynthesis and are only available in liquid formulations. Diquat is effective in controlling most filamentous algae and many submerged plants if injected uniformly into the water column. It is also effective on duckweed and other floating plants if sprayed directly on the plant with the addition of a registered aquatic surfactant.

Diquat is rapidly tied up or neutralized by clay particles or organic matter in the water. Therefore, diquat is only used in clear and nonmuddy waters. Diquat is often mixed with chelated copper compounds or endothall to broaden the variety of aquatic vegetation controlled. Diquat can cause severe eye damage and must be used with caution.

Table 1. Treatment Response of Common Aquatic Plants to Registered Herbicides and Grass Carp[a]

Aquatic Group and Vegetation	Aquatic Herbicide[b]						Grass Carp

[c] Hydrothol formulations.

[d] Aquathol formulations.

[e] Granular 2,4-D formulations.

[f] Liquid 2,4-D formulations.

Check the product label for water use restrictions and other precautions.

Endothall Compounds

Endothall compounds are contact herbicides that interfere with plant respiration. They are available in liquid and granular formulations. These herbicides are effective in controlling many types of submerged aquatic vegetation. Endothalls are applied over the surface or injected uniformly below the water surface. Endothalls generally work best in the spring when vegetation is actively growing and water temperatures are around 18 °C (65 °F). The Aquathol formulations work best on submerged aquatic vegetation, while the Hydrothol formulations are most effective for algae control. Hydrothol can be toxic to fish and is seldom used in culture situations. Check the product label for water use restrictions.

Glyphosate Compounds

Glyphosate is a liquid systemic herbicide that disrupts enzymes important in nitrogen metabolism. Glyphosate must be applied directly to the dry foliage of vegetation. It will control many floating and emergent types of aquatic vegetation. A registered aquatic nonionic surfactant must be added to glyphosate for it to be effective in aquatic situations. Rate and time of application of glyphosate depends on the targeted species. Check the product label for water use restrictions.

Fluridone Compounds

Fluridone is a systemic herbicide that controls most submerged and many emergent species of aquatic vegetation. It comes in granular and liquid formulations that can be sprayed, broadcast, or injected into the water.

Fluridone is slow acting and should not be applied in flowing water. It can injure desired shoreline vegetation if their roots extend into the water. Check the product label for water use restrictions.

CONCLUSIONS

Noxious aquatic vegetation is usually a reccurring problem in aquaculture. It is difficult to find any control that has no ecological, sociological, or economic drawbacks. For this reason an integrated approach is best, but most integrated approaches are site specific and must be developed individually by each aquaculturist.

The main reasons aquatic vegetation control fails are (1) misidentification of the problem species, (2) misapplication of the control technique (e.g., chemical), and (3) miscalculation of the area or volume of the treatment site. Pond managers that correctly address these three tenets should substantially improve their aquatic vegetation control success.

Bibliography

With the exception of North America, Australia has the largest and most diverse freshwater crayfish fauna

in the world. Over 100 species of crayfish live in Australian rivers, lakes, and swamps. All Australian crayfish belong to the family Parastacidae. Aquaculture interest has been directed toward three species, *Cherax tenuimanus*, or marron, *C. albidus-destructor*, or yabbie, and *C. quadricarinatus*, or red claw (1). Of these three species, the red claw is considered to have the best traits for commercial aquaculture and has been the primary species cultured outside of Australia on a commercial scale (2). Scientists did not become aware of the red claw's potential for culture until the mid-1980s. Since then, the red claw has been introduced to many countries in the Americas and Southeast Asia.

Red claw crayfish are native to northern Australia. They are reported to reach a maximum size of 400 to 600 g (0.9 to 1.3 lb) and attain sizes of 50 to 100 g (1.8 to 3.5 oz) in six months (2–5). Red claws reach sexual maturity at about six to eight months of age and are considered to be multiple spawners, spawning three to five times a year (4,6). Reproduction is easily obtained in tanks and ponds under culture conditions. Red claw crayfish are tolerant of a wide range of water quality conditions commonly occurring in culture operations. They survive water temperatures between 12 and 34 °C (54 and 93 °F), but grow best within a range of 22 to 30 °C (71.6 to 86 °F) (2). Red claws are reported to be nonburrowers; however, some have been reported to make shallow burrows (3,7).

INDOOR HATCHERIES FOR RED CLAW CRAYFISH

Spawning

Red claw crayfish will not survive winter conditions in cool, temperate climates, so indoor spawning techniques are needed in such areas. The photoperiod and temperature have a significant influence on spawning rates (8). Spawning activity begins at about 20 °C (68 °F) and increases until about 30 °C (86 °F). Average monthly spawning rates at 28 °C (83 °F) may range from 15% with less than 12 hours of light to over 35% with more than 12 hours of light. Peak spawning occurs with day lengths of 14 hours, but high spawning rates can be maintained only for about three months (9).

Evaluation of the effects of stocking density and sex ratios on red claw reproduction in indoor tanks indicates no suppression of spawning at densities from 20 to 32 red claw brooders/m² (10.8/brooders/ft²) (8,10). Male-to-female sex ratios from 1 : 1 to 1 : 5 have been used successfully (8). The size of the males does not appear to affect spawning success when the males are within 28 g (1 oz) of each other, but mixed sizes (small, medium, and large, together) results in as much as a 49% reduction in spawning success. The size of the females does not appear to affect spawning activity, as long as mature females are used (10).

Mature red claw crayfish accept a wide variety of feeds, from fresh vegetable matter to chopped meats and manufactured diets. They are slow feeders, usually foraging for food throughout the afternoon and early evening. Varying dietary protein levels, from 30 to 45% and the addition of supplements such as beef liver or soybeans were found to have no effect on the number of eggs per spawn, but did decrease mortality rates, because of cannibalism among broodstock (10).

After spawning, females carry their eggs attached to their pleopods until the eggs hatch. At 28 °C (83 °F), incubation requires as few as 30 days (11), but has lasted 40 to 70 days under different environmental conditions (4,10,12). During incubation, changes in egg color appear to be consistent and predictable (4,11): Eggs are cream colored when first spawned, khaki or olive green after one weeks, dark brown after two weeks, reddish after three weeks, and hatch after four weeks. After hatching, juveniles cling to the female's pleopods for 7 to 10 days before dispersing.

Fecundity is an important part of the measurement of the reproductive potential of a culture animal. Fecundity in crayfish is usually defined as the number of eggs produced per spawn. Female red claw crayfish with newly spawned eggs bear an average of 10 eggs/g (284 eggs/oz) of the female's body weight (11). About 30% of the eggs are lost during incubation, resulting in an average of 7 eggs/g (200 eggs/oz) of the female's body weight at hatching (11). Broodstock held under stressful conditions and first-time spawners usually have fewer eggs.

Juvenile Rearing

Spawning in indoor tanks has been relatively successful, but rearing juveniles at high densities has been more difficult. Stocking densities from 50 to 1,250 juveniles/m² (10.8 juveniles/ft²) have been reported (13). With good rearing conditions, survival rates range from 84 to 95% at densities up to 250 juveniles/m² (10.8 juveniles/ft²), but decreased rapidly at higher densities. Final juvenile weights were significantly higher at densities of 100 juveniles/m² (10.8 juveniles/ft²) and lower. No difference in final juvenile weights at densities of 250 juveniles/m² (10.8 juveniles/ft²) and greater have been found (13). The use of additional substrate such as window screen or netting, and size grading after four weeks has been used to increase the survival rate (13). Commercially available diets for juveniles have been evaluated, and the best results (80% survival after 28 days) have been obtained by feeding the juveniles commercial shrimp pellets, supplemented during the first week with *Artemia* nauplii (14). Dietary levels of 33% protein appear to be adequate for juveniles in indoor systems (15,16).

Red claw crayfish juveniles have the ability to regulate their oxygen consumption rate over a wide range of environmental conditions, yet do not utilize anaerobic pathways to withstand hypoxic or anoxic conditions (17). Weight gain and survival have occurred over a temperature range from 16 to 32 °C (61–90 °F), but maximum weight gain and survival have been observed at 28 °C (82 °F) (17). Weight gain and survival have also been observed over a salinity range from 0 to 20 ppt, but are reduced at a salinity of 5 ppt and above (17,18).

Juvenile red claw's tolerances of ammonia, nitrite, and nitrate are similar to those reported for other crayfish species. The 96-hour LC_{50} value for nitrite toxicity for hatchlings is 1.03 ppm and for older juveniles is

4.7 ppm (19,20). Growth in juveniles is reduced at 0.4 ppm nitrite and 1.7 ppm total ammonia (19,20).

OUTDOOR CULTURE IN TEMPERATE CLIMATES

A water temperature of about 20 °C (68 °F) is considered safe for moving red claw crayfish to outdoor ponds. Culture ponds generally range from small ponds of 0.1 ha (0.25 acre) up to larger ponds of 1 ha (2.5 acre). Pond depths generally range from 0.7 to 1.0 m (2.3 to 3.3 ft). The red claws, like most crayfish, are detritivores and opportunistic carnivores and feed on most types of organic matter (4). Feeding strategies have combined forage-based systems typical of those used for North-American red swamp crayfish with pelleted rations commonly used for other crustaceans. Dry grasses added at amounts up to 500 kg/ha (445 lb/acre) per month, divided into several applications, have been used effectively. Pelleted shrimp or crayfish rations fed at 2–3% of the estimated red claw biomass per day are usually added to culture ponds, in addition to the forage material (5,21).

Different stocking densities for use in a five-month growing season have been evaluated. When stocked at 10,000 juveniles/ha (4,050 juveniles/acre), red claws averaged 67 g (2.4 oz), with a total yield of 475 kg/ha (423 lb/acre) at harvest. As densities increase, yields increase and average size decreases. At 50,000 juveniles/ha (20,250 juveniles/acre), the average weight of a juvenile was 38 g (1.3 oz), with a yield of 1,422 kg/ha (1,266 lb/acre) at harvest (5). An economic evaluation of these results indicated that the commercial potential for red claw culture is most sensitive to the cost of juveniles, the percentage of harvestable biomass in the large-size classes, the price that the large-size classes receive, and the length of the growing season (22). Typical stocking densities have been about 30,000 juveniles/ha (12,150 juveniles/acre) (23).

To increase yields and profits, red claw polyculture has been evaluated (24–26). Red claw polyculture experiments have been conducted with tilapia, *Oreochromis* species. Early experiences have suggested that a red claw/tilapia polyculture may not be beneficial. Competition between the two species for food and space, and the negative impact of reduced water quality, appear to be the primary factors affecting red claw growth in polyculture (26).

RED CLAW CULTURE IN TROPICAL COUNTRIES

Red claw crayfish farming began in tropical regions around 1993. Farms now exist in Central and South America and Southeast Asia, ranging in size from about 2 ha (5 acres) to 50 ha (120 acres). Most farms use pond spawning techniques similar to those developed in Australia, combined with large-scale growout (23).

Spawning and nursery operations are performed in small ponds [0.1 to 0.25 ha (0.25 to 0.6 acre)]. Spawning ponds are stocked with mature red claws at densities of about 2 crayfish/m² (10.8 crayfish/ft²). Spawning usually begins within a few months after stocking. Bag material like that used for holding vegetables and citrus fruit is gathered into bundles of about four bags each. Each bundle is then weighted on one corner with a rock and placed in 0.5 m (1.5 ft) of water, with 3 m (10 ft) separating each bundle, around the edge of the pond. Juveniles are harvested by gently lifting the folded bags until a fine-mesh dip net can be slipped under the bundle, at which point the juveniles are shaken off. Estimates vary widely, but juvenile collections may run between 500,000 and 1,000,000 juveniles/ha (200,000 to 420,000 juveniles/acre) every four to five months (23).

Some farm managers stock 2.5- to 5-cm (1 to 2-in.) juveniles directly into 0.5- to 1.0-ha (1.2 to 2.5 acre) growout ponds at densities of 30,000 to 70,000 juveniles/ha (12,150 to 28,350 juveniles/acre), while others stock slightly higher densities into medium-sized ponds for about three months before harvesting and then restock at about 30,000 juveniles/ha (12,150 juveniles/acre) for another three to four months (23). Feeding strategies are similar to those used in temperate climates. Locally available forage materials, such as dry grasses, are provided at rates of 100 to 200 kg/ha (90 to 180 lb/acre) monthly. Daily applications of pelleted crustacean rations are added at 2–3% of the estimated red claw biomass. Water exchange is usually held to a minimum, with only enough water added to replace that lost from evaporation and seepage. Some farms have begun to use mechanical aeration to maintain satisfactory levels of dissolved oxygen and to increase water circulation (23).

Harvesting is accomplished with flow traps. Ponds are drained until only 10–20% of the water remains. Fresh water is pumped from a nearby supply canal or pond into a box, which overflows through an enclosed ramp positioned between the top of the box and the pond bottom. Red claw crayfish following the flow move up the ramp and fall into the box, from which they cannot escape. Some producers have reported that 90% of the crop can be harvested from a production pond during a single night (23).

Most producers expect to harvest about 1,500 to 2,000 kg/ha (1,300 to 1,800 lb/acre) per crop with two crops a year when 70- to 100-g (2.5 to 3.5-oz) red claws are produced. Yields can be increased with higher densities, but harvest size usually decreases as density increases (23).

ECOLOGICAL IMPACTS AND DISEASES

Potential ecological impacts from the introduction of red claw crayfish have been considered, and experiments have been conducted in year-round culture conditions to determine possible interactions between red claw crayfish and North American red swamp crayfish (7). The general health of red claw and red swamp crayfish was monitored throughout the year as the two species were cultured together and separately, respectively. No significant disease outbreaks occurred. Australian red claw crayfish grew well from May through October, but did not survive the winter. Red swamp crayfish, on the other hand, survived and grew well only during the cooler months. No negative effects on red swamp crawfish were observed (7).

No disease outbreaks have been reported from red claw farms. A number of bacteria and ectocommencals have

been identified on farmed red claws, but have thus far been similar to those reported from other crayfish (7,27–29). Of major concern have been the potential effects of the fungus *Aphanomyces astaci*, known to cause significant mortalities in crayfish from most regions of the world, except North America. Challenge studies with *A. astaci* revealed the fungus to be pathogenic to red claws at 14 °C (57 °F) (30). No mortalities occurred at 20 °C (68 °F). Furthermore, no detrimental effects from *A. astaci* were observed when red claw crayfish were challenged at 20 °C (68 °F), nor could the fungus be isolated from the host red claw (30).

MARKETING

Red claw crayfish markets have developed in two directions. In temperate climates for which outdoor growing seasons are limited, producers have begun to develop markets in the ornamental pet trade. Indoor recirculating systems are used for spawning and juvenile rearing. Juveniles raised in indoor tanks and fed commercial shrimp diets usually have an attractive blue appearance. Small blue red claw crayfish are sold after about three months, when they are between 38 mm (1.5 in.) and 76 mm (3 in.) long.

Most producers culture red claw crayfish as a food animal. Farms are usually located in subtropical and tropical zones. Target market sizes are 70 g (2.5 oz) and above, so that they are larger than North American crawfish and fall into what might be considered a small-lobster-size category. A highly desirable aspect of the red claw, from a marketing point of view, is the large dressout percentage (30 to 35%), which more closely approximates that of lobster than it does North American crawfish (20 to 25%). Red claw crayfish can be marketed either as whole (live or frozen) animals, frozen processed (shell-on) tails, or processed tail meat. Tails from larger animals may be considered as a substitute for 54- to 84-g (2- to 3-oz) spiny lobster tails (e.g., *Panulirus* spp.) and small clawed lobsters, such as the Norway lobster, *Nephrops norvegicus.* Whether the red claw can command similar market prices as lobsters remains to be seen, since market research is limited (31).

AYU CULTURE

HEISUKE NAKAGAWA
Hiroshima University
Higashi-hiroshima
Japan

OUTLINE

The ayu, *Plecoglossus altivelis* well known in Japan, is also called the "pond smelt" or "sweet fish." It is an anadromous member of the Plecoglossidae (Fig. 1). The ayu is native to east Asia, family is taxonomically close to salmonids, and has a life span of only one year. Ayu is one of the most popular and economically important freshwater fish in Japan, because of its favored taste and odor. Japan widely produces ayu for traditional culinary use. Taiwan produces ayu mainly for restaurant consumption. The cultural production of ayu in east Asian countries such as Korea, China, and Taiwan, is capable of further growth.

D.S. Jordan, an ichthyologist, said, "the one fish of all its fishes is the ayu its flesh is white and tender, and so very delicate in taste and odor that one who tastes it crisply fried or boiled feels that he has never tasted real fish before." A subspecies of this fish, Ryukyu ayu (*P. altivelis ryukyuensis*), distributed in the Okinawa islands

Figure 1. Wild ayu in Japan.
Figure 2. Annual production of wild-caught and cultured ayu.

in southwest Japan, is now on the brink of extinction in that area, because of environmental deterioration.

The merits of culturing ayu come from its high market value and growth rate. In the past, the ayu was a luxury fish in Japan, but it is now inexpensive, due to increasing production in aquaculture [Fig. 2(1)]. The amount of aquacultural production of ayu has been close to that of capture fisheries in rivers.

Natural History of Ayu

The downstream movement of mature ayu for spawning begins in early autumn. Following the completion of spawning, spent males and females die. The eggs are adhesive and are laid on sand in the lower reaches of rivers, from September to November. The eggs can hatch after about two weeks. The newly hatched larvae, which are 7 mm (0.28 in.) in length, are carried downstream to the sea, where they remain during winter. Larval-stage ayu are planktonivorous. In the following spring, the young individuals, which are 6–8 cm (2.4–3.1 in.) in total length and 3–5 g (0.10–0.17 oz) in weight, start the anadromous migration back to the rivers. After upstream movement, the fish change their feeding habitats to an herbivorous diet. The main sources of food in rivers are adherent blue-green algae, and diatoms, which contain 45–48% crude protein. Detailed embryological and physiological descriptions of ayu have been provided by Iwai (2).

Construction of artificial dams to meet industrial and agricultural demands has led to serious problems in the upstream movement of anadromous fishes. Therefore, young individuals [5–6 cm (2.01–2.4 in.) in total length] are released into the upper reaches of rivers, to enhance the natural supply of ayu, by Fisherman's Cooperative Associations in Japan. For example, in the Ohta-gawa river in Hiroshima prefecture, more than 70% of released ayu can be recovered annually by fishing. Almost all of the ayu caught in rivers by commercial and sport fishermen are used for food in restaurants and homes.

SEEDLING ACQUISITION AND PRODUCTION

About 80–90% of the fry for culture and stock enhancement are landlocked ayu, which are captured mainly in Lake Biwa, in Shiga prefecture. The remainder (10–20%)

are artificially produced. In addition, a small amount of wild fry caught along the seashore are used.

Seashore Fry

Wild fry 3.5–8.0 cm (1.38–3.15 in.) in total length and weighing 0.1–5.0 g (0.04–0.18 oz) caught along the seashore by seine nets during December and April are acclimated to freshwater. The fry can be reared with formulated feed.

Landlocked Fry

Landlocked fry, which weigh 0.3–5 g (0.01–0.18 oz) can be caught in Lake Biwa from February to June by using pound nets or scoop nets. These fry do not vary much in size. They are transported in tanks filled with sea water and can be fed with formulated feeds.

Artificially Produced Fry

In hatcheries, artificial fertilization is carried out by the same method used for trout. Laid eggs, which usually number from 20,000 to 50,000 (the maximum is 100,000) per female, adhere to hatchery nets. The suitable water temperature range for hatching is 12–20 °C (54–68 °F). The eggs hatch after 16 to 17 days at 15 °C (59 °F). It is necessary to acclimate the artificially produced fry larvae to sea water before feeding them live organisms. First foods include rotifers (*Brachionus plicatilis*) for fry of 7–35 mm (0.28–1.38 in.) in total length and brine shrimp (*Artemia salina*) for fry of 13–35 mm (0.51–1.38 in.). Fry larger than 10 mm (0.39 in.) are gradually adjusted to formulated feed. Rearing density is about 10 kg (22 lb) of fish per metric ton. The mortality rate is less than 2% from hatching to a size of 4–6 g (0.14–0.21 oz).

INTENSIVE CULTURE

Production techniques for ayu in Japan are well established. Production is about 20–70 kg/m^2 (4.09–14.31 lb/ft^2), with a depth of 1 m (3 ft). Mortality over 90 days may be only 10% during the period that ayu grow from 4–6 g (0.14–0.21 oz) to a market weight of 50–80 g (1.34–2.82 oz), in the absence of disease.

Culture System

A water supply system and a sufficient volume of water are essential for ayu culture. Ayu are reared in specially built concrete ponds, usually measuring 100–400 m^2 (1076–4304 ft^2) and averaging 150 m^2 (1615 ft^2), that are supplied with running water. Both river and well water are used for finishing production and cultivation. Octangular and round ponds are popular for cultivation (Fig. 3). The optimum water flow rate is at least 10 l/sec in 100-m^2 ponds with a depth of 1 m (3.28 ft). Round tanks are beneficial for producing water currents in rearing ponds and for discharging solid waste from a center outlet. Most ayu culture is carried out in outdoor tanks, but is also done in indoor tanks, because of the facility of water temperature control.

Figure 3. Typical ayu culture farm with outdoor ponds.

Environmental Factors

The empirically determined optimum rearing density is 150–200 fish/m^2 (13.94–18.59 fish/ft^2), but the culture density in farms is actually 500–600 fish/m^2 (46.47–55.76 fish/ft^2). Young individuals weighing 2–4 g (0.07–0.14 oz) reach 10 g (0.35 oz) in one month, 25–40 g (0.88–1.41 oz) in two months, 50–60 g (1.76–2.12 oz) in three months, and 70–100 g (2.47–3.53 oz) in four months.

The dissolved-oxygen requirement of ayu is higher than that of warmwater fish. Dissolved-oxygen levels should be higher than 5 mg/L (ppm). Ammonium and nitrate levels should be maintained at less than 2–3 mg/L and 0.2 mg/L (ppm), respectively. Ayu farmers use air pumps to aerate the water, although this process is expensive.

Sudden temperature changes in rearing ponds render ayu more susceptible to disease. The thermal tolerance range of ayu is from 13 to 30 °C (55 to 86 °F) and the optimum range is 15 to 25 °C (59 to 77 °F). The growth rate at 18 to 20 °C (64 to 68 °F), is twice as high as that at 13 to 16 °C (55 to 61 °F), indicating a high dependence on rearing temperature for optimum growth.

The fact that wild ayu live in waters with strong currents implies a need for water current in rearing tanks. A strong water current elevates body-weight gain and feed efficiency, but lightly suppresses lipid reserves. Body-weight loss during starvation before marketing is suppressed by rearing ayu in stronger water currents (35–45 cm/s) (1.15–1.48 ft/s). Thus, a strong water currents improve lipid metabolism, by mobilizing lipid reserves for various energy demands. Therefore, rearing tanks should have controlled water currents of about 45 cm/s (1.48 ft/s) (3). Under such conditions, the fish face the current and disperse throughout the rearing ponds. However, some expenses, such as electricity for controlling water current, are restricting factors.

Photoperiod affects hormonal regulation and influences reproductive cycles in ayu. Farmers use their knowledge of these relationships to control maturation in male fish. Roe-containing females are sold commercially. However, as gonadal maturation of males toward autumn is accompanied by darkening of the skin, male fish have a depressed market value. Maturation of male fish can be

suppressed by maintaining light at greater than 50 lux for more than 16 hours daily.

Nutritional Requirements

After the fry stage, granular and crumble-type formulated feeds [ϕ 0.07–2.4 mm (0.003–0.094 in.)] are used throughout the rearing period. Extruded-type feeds have been recently employed as well. Formulated feeds for fry typically contain the following ingredients as protein and lipid sources: salmon egg and milt powder, krill meal, clam powder, casein and its hydrolyzed products, yeast, squid soluble, zein, fish meal, scallop powder, shrimp meal, gluten, amino acids, *Streptomyces* fermentation product, hen's egg powder, soybean lecithin, starch, and squid oil.

The proximate composition of commercial feeds is shown in Table 1. Ingredients in commercial feeds for growout are brown fish meal, krill meal, corn, wheat, soybean meal, peas, cotton seed meal, and kelp meal, as well as minerals and vitamins. Values of the proximate composition of commercial feeds for juveniles larger than 10 g (0.35 oz) are officially standardized as follows: crude protein $\geq$45.0%, crude fat $\geq$3.0%, crude fiber $\leq$4.0, and crude ash $\leq$15.0%. Ayu of more than 5–6 cm (1.97–2.36 in.) are herbivorous, feeding on algae, diatoms, and blue-green algae in the freshwater habitat. Nevertheless, commercial feeds that contain plants as the only protein source have not been fully used by ayu farmers.

The protein requirement of ayu is relatively high. Crude protein levels of 45–48% in the feed appear to satisfy the requirement. To improve growth and feed efficiency, oil, which is usually obtained from Alaskan pollack liver, has occasionally been supplemented, at about 2% of the diet. However, supplementation with oil leads to increased lipid reserves in muscle and viscera (4) and may deteriorate carcass quality. Essential fatty acids are n-3 fatty acids, such as C18:3n3 and C20:5n3, and should be provided at 1% of dietary lipids (5). In addition, phospholipids (e.g., phosphatidyl choline) are indispensable for growth and survival in the larval stage (6). Medium-chain triglycerides or plant oils are occasionally employed in formulated feeds. Medium-chain triglycerides can be consumed as an energy source without deposition in the body (7).

The vitamin and mineral requirements of ayu are not well established. Supplementation of vitamin C to commercial feed increases the aggression of ayu, a trait that is characteristic of wild ayu (8).

Various feed supplements have recently been used as trace nutrients in order to improve carcass quality.

Table 1. Composition of Commercial Ayu Feeds

	Starter	Juvenile	Adult
Fish size (cm)	<3.5	4.3–12	>9
Type of feed	Granule	Crumble	Crumble
Feed size (mm)	0.07–0.45	0.3–1.5	0.9–2.4
Crude protein (%)	50.0–60.0	47.0–55.0	45.0–50.0
Crude fat (%)	3.0–10.0	3.0–10.0	5.0–8.0
Crude fiber (%)	1.0–1.4	1.0–3.0	3.0–4.0
Crude ash (%)	14.0–17.0	15.0–17.5	15.0–19.0

Supplementation of *Chlorella* extract and *Spirulina* to formulated feed improves physiological condition, stress response, and resistance to disease (9–11). Wild ayu are tinged with a yellowish-orange color and a characteristic light yellow spot near the pectoral fin. They exhibit an orange band below the lateral line when mature. Surface color can be improved by dietary *Spirulina*, which contains β-carotene and zeaxanthin. Products such as marigolds and krill meal have been used as other sources of carotenoids.

Feeding Regimes

The most serious problem in maintaining quality ayu is excessive lipid accumulation in muscle and viscera. This leads to a loss of appetite and to the deterioration of carcass quality. High feeding frequency seems to result in greater overall food intake. However, feeding to apparent satiation does not always improve growth. A proper feeding regime depresses lipogenesis and activates lipolysis (12), allowing dietary protein to be spared, resulting in an improvement of carcass quality, and better growth performance. Feeding frequency is controlled with the use of automatic feeders: Fish less than 1 g (0.04 oz) are fed four or five times per day, fish 1–10 g (0.04–0.35 oz) three or four times, fish 10–80 g (0.35–2.82 oz) three times; and fish 180 g (6.35 oz) or larger two times.

Diseases

Overfeeding and a high rearing density, which are generally unavoidable in the culture of commercial fish, can lead to a variety of diseases. *Cytophaga psychrophila* infection, known in salmonid culture, has recently been widespread and caused considerable damage to ayu production. The extent of damage caused by *C. psychrophila* occasionally accounts for more than 50% of total disease outbreaks.

Ayu infected with *Vibrio anguillarum* show the following symptoms: tumescence of the body surface, dermal ulcers, and hemorrhaging of the base of pectoral fins. Vaccination is effective for preventing the disease.

Aeromonas hydrophila characteristically infects young ayu weighing less than 50 g (1.76 oz) at water temperatures greater than 20 °C (68 °F). Bacterial gill disease, associated with *Flavobacterium* sp., can be prevented by avoiding high-density rearing and overfeeding and can be cured by bathing fish in a 0.7 to 1% NaCl solution for one to two hours.

Streptococcus sp. infection is characterized by hemorrhages on the body surface, ocular disease, abdominal dropsy, etc.

Other problems include stomach mycosis, mycotic granulomatosis from *Aphanomyces piscicida*, ichthyophoniasis from *Ichthyophonus hoferi*, and phoma infection from *Phoma* sp. Phoma infection occurs in young ayu, and no method for curing the disease has been found yet.

Parasitic diseases include *Glugea plecoglossi* infection, which occurs at water temperatures greater than 18 °C (64 °F). Gyrodactylosis is associated with high-density rearing. The symptoms of fish attacked by the flukes *Gyrodactylus japonicus*, *G. tominagai*, and *G. plecoglossi*

are poor appetite and hemorrhages on the skin. The flukes are found on the skin, fins, and gills of infected fish. A gill disease caused by *Pseudergasilus zucconis* is not lethal.

A typical disease of ayu is the so-called "chochin disease," which morphologically resembles ulcerative dermal necrosis in salmonids. The disease is caused by overcrowded rearing conditions and inadequate feeding regimes. It is not lethal, however, and reduction of stocking density can allow recovery to take place.

MARKETING AND QUALITY CONTROL

The market value of cultured ayu is distinctly different from that of ayu captured in rivers. The general market size of ayu is 50–150 g (1.76–5.29 oz); fish of this size can be obtained between June and October. Smaller fish [20–60 g (0.71–2.12 oz)] can be sold by May, which is before the opening of the capture fisheries in rivers. The market prices of cultured ayu ranged from ¥1200 to ¥2800/kg in 1995–1996. The price fluctuates with the season, and peak prices are to be found between April and September. Most cultured ayu are sold live, chilled, or frozen. Fry and feed costs make up the largest production costs at 17–22% and 22–24%, respectively. Blowers and water pumping can account for as much as 25% of the total production cost.

Cultured ayu are considerably different from wild ayu in appearance, especially skin color and shape. The odor, muscle, taste muscle hardness, and lipid content also clearly distinguish between wild and cultured ayu. The wild ayu have proven to be most highly favored, for their nonoily, plain taste.

"Semiwild ayu" have been produced under special rearing techniques. Although the quality of semiwild ayu is not yet officially standardized, the higher quality products are differentiated by skin color and odor from regularly cultured ayu. Special techniques to produce semiwild ayu are supplementation of carotenoids, plant oil, medium-chain triglycerides, or any combination thereof, in formulated feeds; starvation for several days before marketing; rearing in strong water current; reduction of rearing density, etc. Trace nutrients, such as *Chlorella* extract, garlic extract, *Spirulina*, and Chinese drugs, are sometimes used as well.

Wild ayu have a sweet smell, like the aroma of watermelon and cucumber. The characteristic odor is caused by the sessile algae growing on stones in the rivers where ayu dwell. The algae are the main food source for ayu. The main chemical components associated with the odor are 2-trans-6-cis-nonadienal and cis-3-hexenol (13). Cultured ayu are not as palatable as wild ayu, because they lack this specific odor. Supplementation of the odor-causing chemicals in formulated feed has not been successful in giving this special odor to cultured ayu. A bitter taste in wild ayu is attributable to anserin (14).

Ayu accumulate energy as adipose tissues in the peritoneal cavity and along the dorsal neural spine. A comparison of lipid content of cultured ayu (from 12 hatcheries) and wild ayu (from nine rivers) showed that the lipid level in the muscle of the cultured fish (8.2 ± 2.5%) was much higher than that of wild fish (3.4 ± 1.7%) (15). Research is needed to find a way to suppress lipid accumulation without sacrifice of growth.

OUTLINE

Gram-Negative Agents
Gram-Positive Agents
Bibliography

Bacterial diseases have historically been among the most significant problems facing aquaculturists worldwide. The oldest record of bacterial disease in aquaculture names "redpest" in eels in the Mediterranean as early as 1718 (1), and the causative agent *Vibrio anguillarum* was first cultured in 1883 (2). It has been estimated that 10% of fish loss in aquaculture is due to disease and that, of this portion, more than half is due to bacterial disease (3,4). Economic losses resulting from bacterial disease are difficult to assess, because many cases go unreported; however, a single bacterial disease, Enteric Septicemia of Catfish (ESC), is believed to cost the U.S. catfish industry US$19 million in direct fish losses annually (5,6). Bacterial pathogens are, in some cases, highly host-specific, infecting and causing disease in only one genus or even one species of fish. Others have a broad host range. Some are obligate pathogens, not normal free-living components of the aquatic ecosystem but ones requiring a fish host to survive. Others are facultative pathogens that are normal inhabitants of the aquatic environment and require stress to assist in initiating disease in a fish population. Despite our current knowledge of approximately 70 species of bacterial agents having the capability of causing disease in aquaculture (7), new diseases caused by previously undocumented bacterial fish pathogens continue to surface almost yearly. The aquaculture industry has experienced tremendous growth in recent years, and, as culture practices have become more intensive in order to increase profitability and as new species of fish are cultured, new, highly virulent bacterial pathogens have emerged. Currently, bacterial taxonomy is in transition, due to the utilization of more precise molecular methods of classification, and the names of many previously recognized pathogens have changed. This entry addresses only those bacteria that are established as pathogens in aquaculture. The most currently approved names, as well as the older names with which readers may be more familiar, are included. Older names or taxonomically invalid names are highlighted by quotation marks, (i.e., "*Haemophilus piscium*"). Despite the importance of bacterial disease in aquaculture, only one book is available that covers management techniques (7), and only two books are available that deal specifically with description of bacterial

pathogens and of the diseases that they cause (8,9). Review articles that deal with various mechanisms of bacterial pathogenesis, have been written and several books are available that contain chapters devoted to methods of diagnosis of bacterial diseases and of identification of bacterial pathogens (10–13).

GRAM-NEGATIVE AGENTS

A. *Enterobacteriaceae*. Facultatively anaerobic, oxidase negative, gram-negative rods.

I. *Edwardsiella tarda*. Causative agent of *Edwardsiella* Septicemia. Synonyms: Emphysematous putrefactive disease of catfish; red disease of eels; edwardsiellosis of salmon, of tilapia, and of striped bass.

a. History — The bacterium was originally described in 1962, from 256 isolates obtained from various sources in Japan; however most of the isolates were from snakes. Five isolates from human gastrointestinal infections were referred to as the "Asakusa group" (14). In the same year, a new disease of eels, "red disease," was described, and the causative agent was named "*Paracolobactrum anguillimortiferum*" by Hoshina (15). A new genus, *Edwardsiella*, including a new species, *E. tarda*, was described from 37 human isolates in the U.S. by Ewing, in 1965 (16). In 1973, *E. tarda* was almost simultaneously recognized as the cause of "red disease" of eels in Japan and Taiwan (17) and of "emphysematous putrefactive disease of catfish" in the U.S. (18). Cultures of "*P. anguillimortiferum*" were no longer available for comparison, so *E. tarda* became the valid scientific name.

b. Culture — Primary isolation of the bacterium from diseased fish is achieved on standard media, such as brain heart infusion agar (BHIA) or tryptic soy agar (TSA) with 5% sheep blood and incubation at 25–37 °C. Growth is rapid, with 1–2 mm colonies present in 24 hours. On EIM-selective medium (19), *E. tarda* forms a small green colony with a black center.

c. Description — Short-gram negative rod, $0.6 \times 2.0\,\mu m$, motile by peritrichous flagella at 25 and 37 °C, oxidase-negative, indole-positive, fermentative in semisolid glucose motility deeps (GMD), K/A with hydrogen sulfide production and gas in triple sugar iron (TSI) agar slants. The bacterium is differentiated from closely related organisms in Table 1.

d. Epizootiology — *Edwardsiella* septicemia appears to be favored by high water temperatures [28 °C (82 °F) and above] and by the presence of high levels of organic matter in catfish ponds. Infections in eels in Taiwan occur when water temperatures are fluctuating between 10 and 18 °C (50–64 °F). The incidence of *E. tarda* infections is relatively rare in channel catfish (*Ictalurus punctatus*) ponds and, mortality rates are usually low (~5%), but, when infected fish are moved into confined areas such as holding tanks, mortalities can reach levels as high as 50%.

Table 1. Biochemical and Biophysical Characteristics Important in Differentiating Three Fish Pathogens Belonging to the Family *Enterobacteriaceae*

Characteristic	*E. ictaluri*	*E. tarda*	*Y. ruckeri*
Motility at 25 °C	+	+	+
Motility at 35 °C	−	+	−
Indole	−	+	−
Citrate (simmons)	−	−	+
Trehalose	−	−	+
Gelatin (22 °C)	−	−	+
Gas from glucose (25 °C)	+	+	−
H$_2$S	−	+	−

The reservoir of infection is unclear, but the bacterium has been associated with a variety of aquatic invertebrates and of aquatic and terrestrial vertebrates. Fecal contamination of water from human or animal sources, may be a source of the bacterium. There is also some speculation that *E. tarda* may comprose a part of the normal microflora of the surfaces of certain fishes or snakes. In the U.S., *E. tarda* was isolated from as many as 88% of domestic dressed channel catfish (20) and was found in 30% of imported dressed fish. The bacterium was also found in 75% of catfish pond water samples, in 64% of pond mud samples, and in 100% of frogs, turtles, and crayfish from catfish ponds.

e. Geographic range and host susceptibility — *E. tarda* is found in both freshwater and brackish-water environments. It has been reported from 25 countries in North and Central America, Europe, Asia, Australia, Africa, and the Middle East. The bacterium has been isolated from over 20 species of freshwater and marine fish; it occurs most commonly in the following: the channel catfish, *I. punctatus*; the common carp, *Cyprinus carpio*; the largemouth bass, *Micropterus salmoides*; the striped bass, *Morone saxatilis*; the red sea bream, *Chrysophrys major*; the Japanese flounder, *Paralichthys olivaceus*; tilapia, *Oreochromis* sp.; yellowtail, *Seriola quinqueradiata*; and rarely in salmonids. The bacterium also causes disease in snakes, alligators, and sea lions and in various birds, cattle, and swine (8).

f. Clinical signs of disease and treatment — *Edwardsiella* septicemia in eels is characterized by hemorrhagic fins, by petechiae on the belly, by a swollen protruding anus, and by necrotic foci in the internal organs. Gas filled pockets may form between the skin and muscle. In channel catfish with emphesematous putrefactive disease, 3–5 mm (0.12–0.20 in.) cutaneous ulcers form in the skin. These lesions progress into larger abcesses deep in the tissues and emit a foul odor when ruptured. Eye disease is common in tilapia and striped bass, and infected fish exhibit exophthalmia and corneal opacity. Treatment in catfish is best achieved with medicated feeds: Romet 50 mg/kg/day (23.0 mg/lb/day) for 5 days and Terramycin 23.0–34.0 mg/lb/day for 10–14 days, both of which are approved for use in catfish by the United States Food and Drug Administration (USFDA). Japanese strains of *E. tarda* are resistant to many antibiotics; however, nalidixic acid has been used with success (7). *E. tarda* is serologically heterogeneous, with 49 O antigens and 37 H antigens; therefore, production of effective vaccines has met with difficulty (55).

II. Edwardsiella ictaluri. Causative agent of Enteric Septicemia of Catfish

a. History — The disease was first documented from cases involving diseased channel catfish submitted to the Southeastern Cooperative Fish Disease Laboratory at Auburn University in 1976. The laboratory, under the direction of Drs. W.A. Rogers and J.A. Plumb, recorded 26 cases of this new disease syndrome, from ponds primarily in Alabama and Georgia, between January 1976 and October 1979. The disease was described by Hawke in a published account in 1979 (21), and the causative organism was described as a new species, *E. ictaluri*, in 1981 (22). Records from fish disease diagnostic laboratories indicate that the disease was not prevalent in the industry immediately following its discovery. Enteric septicemia of catfish (ESC) occurred in only 8% of the total cases reported by the Mississippi Cooperative Extension Service in 1980 and 1981. Between 1982 and 1986, however, the increase in ESC incidence was explosive, and the economic impact on the catfish industry was significant (3). Enteric septicemia of catfish is believed to have been present in cultured catfish prior to its description, because archived tissues from the Fish Farming Experiment Station at Stuttgart, Arkansas reacted with a monoclonal antibody specific for *E. ictaluri* (23). Currently, ESC is the most important disease of farm raised catfish, accounting for approximately 30% of all disease cases submitted to fish diagnostic laboratories in the Southeastern United States. In Mississippi, where catfish make up the majority of case submissions, it has been reported at frequencies as high as 47% of the yearly total (3). It is estimated that ESC costs the catfish industry $19 million yearly in direct fish losses (6) and ESC is considered a disease of current or potential international significance by the OIE (65).

b. Culture — Primary isolation from the kidney, liver, spleen, or brain of diseased fish is achieved on standard media such as BHIA or TSA with 5% sheep blood. The bacterium has a narrow temperature range for optimum growth (25–28 °C), and primary isolation plates should be incubated within this range. Growth is slow even at these temperatures, with 1–2 mm colonies present in 48 hours. *E. ictaluri* forms a small pale green colony on EIM-selective medium (19).

c. Description — The bacterium is a short Gram-negative rod, 0.75 × 1.25 μm, motile by peritrichous flagella at 25–30 °C but not at 35 °C, oxidase-negative, fermentative in GMD, indole-negative, K/A with H$_2$S negative in TSI slant, and citrate-negative. The bacterium is differentiated from closely related fish pathogens in Table 1. The species is antigenically and physiologically homogeneous, regardless of the geographic source of the isolate. Confirmatory identification can be made with serological tests, among them the slide agglutination test, the indirect florescent antibody test (IFAT), the enzyme immunoassay (EIA), and the enzyme linked immunosorbent assay (ELISA). *E. ictaluri* may be identified with the API 20E

system (BioMerieux Vitek Inc.) by generation of the code number 4004000.

d. Epizootiology — Outbreaks of ESC are strongly correlated with pond water temperature, with high stocking densities, and with stress resulting from poor water quality. The so-called "ESC window" occurs in the spring and in the fall, when water temperatures are in the range 22–28 °C (72–82 °F). When initially described, *E. ictaluri* was thought to be an obligate pathogen, because its survival was limited to approximately 8 days in sterile pond water (21); however, it was later found to survive for 95 days in pond mud at 25 °C (77 °F) (24). *E. ictaluri* infections are very common in commercial catfish ponds in the southeastern U.S. but are rarely found as the cause of natural fish kills. Mortality rates in cultured fish may vary from less than 10% to 50% or more of the population. The disease is most common, and causes the highest mortalities, in fingerling channel catfish, but production-size catfish with no previous exposure are also highly susceptible. Survivors of outbreaks are believed to become asymptomatic carriers that can transmit the disease if stocked into a pond containing a population of naive fish.

e. Geographic range and host susceptibility — *E. ictaluri* is known to occur primarily in the southeastern U.S. Isolated instances of disease have been reported from Thailand and Australia, in atypical species. The bacterium is specific for channel catfish, with other species of catfish apparently being less susceptible. Rare outbreaks have been documented in the blue catfish (*Ictalurus furcatus*), in the white catfish (*Ictalurus melas*), and in the brown bullhead (*Ictalurus nebulosus*). Natural infections have been found in the walking catfish (*Clarias batrachus*) in Thailand, and in two aquarium species, the Bengal danio (*Danio devario*) and the glass knife fish (*Eigemannia virescens*). Experimental infection and disease have been induced in chinook salmon (*Oncorhynchus tshawytscha*) and in rainbow trout (*Oncorhynchus mykiss*), but many species of warm and coldwater fish are refractory (7,25).

f. Clinical signs of disease and treatment — ESC occurs in acute, subacute, and chronic forms in channel catfish. The acute form is characterized by only a few clinical signs; clear or straw colored fluid in the body cavity, exophthalmia, petechial hemorrhage around the head and operculum, and enlargement of the kidney and spleen. The subacute form is characterized by more obvious external signs; small 2–3 mm (0.2–0.25 in.) ulcerative lesions (red or white spots) in the skin, hemorrhage and necrotic foci in the liver, hemorrhage in the intestine, and bloody ascites. The chronic form is characterized by an ulcer in the top of the head in the area of the sutura fontanelle between the two frontal bones of the skull (a phenomenon resulting in the name "hole in the head disease"). This lesion develops from inflammatory accumulations in the brain cavity, as a result of meningoencephalitis. The meningoencephalitis results in such behavioral signs as spinning or spiraling, prior to death. Treatment of channel catfish with ESC is best achieved orally with medicated feeds (Romet for 5 days with 3 days of withdrawal or Terramycin for 10–14 days with 21 days of withdrawal). The emergence of resistant strains in the late 1980s prompted investigations

into alternative antimicrobials (sarafloxacin, amoxicillin, florfenicol); however, none has achieved USFDA clearance. Currently, experimental live attenuated vaccines show promise, but an effective commercial vaccine is not available.

III. Yersinia ruckeri. Causative agent of Enteric Redmouth Disease. Synonyms: "Hagerman redmouth," "salmonid blood spot."

a. History — The disease was first observed in rainbow trout aquaculture in the Hagerman Valley, Idaho, in the 1950s and was described by Rucker in 1966 (26). A description of the causative bacterium was first published by Ross et al. in 1966 (27), and the pathogen was named *Y. ruckeri* by Ewing et al., in 1978 (28). The common name, enteric redmouth disease (ERM), was adopted by the Fish Health Section of the American Fisheries Society in 1975 (29). Enteric redmouth disease has historically been one of the most significant diseases in salmonid aquaculture, with the potential for cumulative losses of 70% of some populations. The economic impact on the trout industry in the late 1970s was significant, with over US$2 million in losses annually; however, the current practice of vaccinating trout fingerlings with commercially available vaccines has reduced the impact on the industry.

b. Culture — Primary isolation of *Y. ruckeri* is achieved on general purpose bacteriological media (BHI or TSA w/5% sheep blood) and incubation in a normal atmosphere at 22–25 °C. Colonies (1–2 mm) are visible in 24–48 hours. The bacterium is capable of growth over a wide temperature range (9–37 °C); however, the strains that grow at 37 °C are avirulent for trout. *Y. ruckeri* forms a green colony surrounded by a zone of hydrolysis on Shotts and Waltman (SW) selective medium (30), and it produces a yellow colony on the selective medium of Rodgers (31). These media, although useful in selective isolation of the organism from exposed surfaces or intestinal cultures, are not specific enough for confirmatory identification.

c. Description — The bacterium is gram-negative and oxidase-negative. Cells of *Y. ruckeri* are rod shaped (1.0 × 1.0–3.0 μm), becoming filamentous in older cultures. The bacterium is motile by peritrichous flagella in the optimum temperature range, but non-motile strains occasionally occur (27). With the exception of sorbitol fermentation (approximately 32% of strains are positive), the strains are fairly homogeneous in biochemical phenotype. Most strains are positive in the following reactions: glucose fermentation in GMD; ONPG; lysine and ornithine decarboxylase; citrate utilization; Jordans tartrate; and gelatin liquefaction. The bacterium gives a negative reaction for H_2S, indole, and Voges–Proskauer. Features useful in differentiating *Y. ruckeri* from related fish pathogens are given in Table 1. Genetically, *Y. ruckeri* is distantly related to other members of the genus, being only 38% homologous by DNA–DNA hybridization (28). Five different serovars of *Y. ruckeri* are recognized, on the basis of formalin-killed whole-cell serology, and their occurrence seems to be correlated with the geographic region from which they are isolated. The serovars are described as follows: Serovar I (Idaho strains), Serovar II (Oregon

strains), Serovar III (Australian strains), Serovar IV (excluded), Serovar V (Colorado strains), and Serovar VI (Ontario strains).

d. Epizootiology — Although *Y. ruckeri* is thought to be an obligate pathogen of salmonids, the role of stress is very important in the initiation of outbreaks (27). The bacterium has also been shown to survive up to two months in mud. Experimentally, the efficiency of transmission of ERM from carriers to susceptible fish and subsequent disease is greatly enhanced by the addition of stress. Reservoirs, other than survivors of outbreaks, have not been identified. Survivors carry the bacterium in their intestine and shed organisms into the water on a cyclical basis every 35–40 days; shedding precedes recurrent outbreaks of the disease by several days. Vertical transmission of *Y. ruckeri* has not been demonstrated. Fingerlings are the most susceptible to infection, and mortality in acute outbreaks may range from 30–70%. Enteric redmouth commonly occurs as a chronic disease, particularly in older fish >12 cm (4.75 in.), with cumulative mortality being approximately 30%. Most outbreaks occur when water temperatures are in the range 11–18 °C (52–64 °F), with the greatest severity occurring between 15 and 18 °C (59–64 °F).

e. Geographic range and host susceptibility — Since its initial isolation in the Hagerman Valley of Idaho, the disease has been found throughout U.S. trout-growing areas. Fish disease caused by *Y. ruckeri* has been confirmed in many regions throughout the world, including North America, Europe, Australia, Finland, Norway, and South Africa. The rainbow trout is the species most susceptible; however, all salmonids can be infected. Some nonsalmonid species, such as the fathead minnow, *Pimephales promelas*, the cisco, *Coregonus artedii*, the whitefish, *Coregonus clupesformis*, the sturgeon, *Acipenser* spp., and the turbot, *Scophthalmus maximus*, are susceptible. The bacterium has also been isolated from invertebrates, sea gulls, and muskrats, from sewage, and from river water. One human clinical isolate was reported (7,8).

f. Clinical signs of disease and treatment — As the common name of the disease suggests, reddening around the mouth and operculum (due to subcutaneous hemorrhage) is the most obvious of the gross external clinical signs. Other external signs that are commonly reported are exophthalmia and a general darkening of body pigmentation. Internal clinical signs are indistinguishable from other gram-negative bacterial septicemias. Treatment of ERM is best accomplished by feeding Romet or Terramycin medicated feeds at 50 mg/kg (23 mg/lb/day) body weight/day for 5 or 14 days respectively. ERM is successfully managed by vaccination of fingerlings with commercial bath vaccines.

IV. Other Enterobacteriaceae. Other members of the *Enterobacteriaceae* have, rarely, been implicated as the cause of disease in fish. Bacteria of the genera *Proteus*, *Serratia*, *Citrobacter*, *Enterobacter*, and *Hafnia* have been implicated as causative agents of fish disease; however, these diseases have not appeared with any consistency in aquaculture settings (9).

B. *Aeromonadaceae.* Facultatively anaerobic, oxidase-positive, 0/129-resistant, Gram-negative rods.

I. Aeromonas hydrophila ("A. punctata, A. liquefaciens"), A. sobria, A. caviae. Causative agents of Motile Aeromonad Septicemia. Synonyms: hemorrhagic septicemia, infectious dropsy, infectious abdominal dropsy, red sore. The motile aeromonads are treated here as a group, because the number of species involved is in question and because the taxonomy is in a state of transition.

a. History — Although reference is made as early as 1891 to fish with hemorrhagic septicemia (32), the description of a bacterial disease in cultured carp with infectious dropsy caused by "*Pseudomonas punctata*" (*A. punctata*), by Schaperclaus in 1930, is believed to be the first documented case of motile aeromonad septicemia (MAS) (33). Ewing et al., in 1961 (34), proposed that *A. punctata*, *A. hydrophila*, and *A. liquefaciens* were all variants of the same species and included them all in a single species, *A. hydrophila*. The name of the disease syndrome was changed to "motile aeromonad septicemia" in 1975, to reflect the multispecies etiology of the disease. Seven species of motile aeromonads were recognized by Carnahan et al., in 1991; however, only *A. hydrophila*, *A. sobria*, and *A. caviae* are currently recognized as representative of the motile aeromonad fish pathogens.

b. Culture — Primary isolation is achieved by streaking on standard media such as BHIA or TSA and incubation at 30–37 °C. Growth is rapid at these temperatures, with 2–3 mm, cream-colored colonies visible in 18–24 hrs. Most strains are beta–hemolytic on blood agar. Motile *Aeromonas* spp., form yellow–orange colonies on Rimler–Shotts selective medium when incubated at 35 °C (36).

c. Description — Short, gram-negative rods, 0.8 × 1.0 μm, motile by a single polar flagellum, oxidase-positive, fermentative in glucose motility deeps. Aeromonads also uniformly reduce nitrate to nitrite. Motile aeromonads are easily differentiated from the motile vibrios and *Photobacterium* by resistance to vibriostatic agent, 0/129 (2,4-diaminop-6,7-diisopropyl pteridine phosphate). The motile aeromonad fish pathogens are differentiated from related fish pathogens in Table 2.

d. Epizootiology — Motile aeromonad septicemia is considered one of the most common diseases of cultured warm-water fish in freshwater environments. The bacterium is also known to cause disease in brackish-water fish culture at salinities up to 15 ppt. Aeromonads are common members of the microflora of natural waters, are ubiquitous in a variety of environments, and are commonly found as part of the normal microflora of the intestine and skin of fish. Motile aeromonad septicemia occurs most frequently in the spring of the year but can occur year round (7). Natural fish kills on lakes and reservoirs in the spring are often a result of MAS epizootics acting either alone or in concert with parasitic infestation (37). The motile aeromonads are considered opportunistic pathogens, and MAS is usually considered a stress related disease. Such stress factors as rising water temperatures, handling, transport, poor water quality, and parasitic load may contribute to outbreaks. Those outbreaks are chronic

Table 2. Biochemical and Biophysical Characteristics Important in Differentiating Some Fish Pathogens in the Family *Aeromonadaceae*

Characteristic	A. hydrophila	A. sobria	A. caviae	A. salmonicida subsp. salmonicida	acromogenes
Motility at 25 °C	+	+	+	−	−
Gas in GMD[a]	+	+	−	+	−
Esculin hydrolysis	+	−	+	+	−
Brown pigment	−	−	−	+	−
Voges–Proskauer	+	+	−	−	−
Growth at 37 °C	+	+	+	−	−
Acid from arabinose	+	−	+	+	−

[a]GMD = glucose motility deep, incubated at optimum growth temperature of bacterium tested.

in nature, with low mortality rates. "Poststocking syndrome" is a disease that is characterized by a peak in mortality approximately three days following the transport and stocking of fish in a new pond or unit. Infection, disease, and mortality may continue for a few days; then the losses diminish and stop. Motile aeromonads are often a major component in "winter mortality syndrome" or "winterkill," a disease in catfish ponds related to rapid temperature drops in the winter months, to fungal disease, and to secondary bacterial infection. The exception to this may be certain strains of *A. sobria* and *A. hydrophila* that possess a surface protein layer (S-layer) that serves as a virulence factor (38). Highly virulent strains may cause a typical hemorrhagic septicemia, with rapid progress and high mortality rates.

e. Geographic range and species susceptibility — Motile aeromonads are found in warm-water freshwater and brackish-water environments throughout the world. This group of bacteria shows little or no host specificity; it infects a variety of freshwater and brackish-water fish hosts. Aquatic animals other than fish are susceptible to motile aeromonad infections; Compare redleg disease of frogs and fatal disease of reptiles (39). Although not considered a serious health concern, *A. hydrophila* has occasionally been responsible for wound infections and even fatal septicemia in humans (7).

f. Clinical signs of disease and treatment — MAS occurs in acute and chronic forms. The acute form is a typical bacterial septicemia characterized by exophthalmia, abdominal distension due to ascites, petechial hemorrhage in the skin, and diffuse necrosis in the internal organs. The progress of infection may be so rapid that few clinical signs are evident (38). The chronic form is characterized by the formation of deep muscular ulcerations, with associated hemorrhage and inflammation. Treatment for acute disease is with medicated feeds (Romet® or Terramycin®) at 50 mg/kg/day. The chronic form of the disease usually responds to improvement of water quality and to removal of stress. Vaccination is not considered feasible, because of the multiplicity of strains and serotypes encountered.

II. Aeromonas salmonicida. Nonmotile Aeromonads.

Three subspecies or groups of *A. salmonicida* have been proposed by McCarthy and Roberts (40), and supported by various taxonomists (41) on the basis of epizootiology and phenotype, even though DNA homology studies do not support the necessity for subspecies.

Group 1. *A. salmonicida* subsp. *salmonicida*
Causative agent of furunculosis in salmonids.

Group 2. *A. salmonicida* subsp. acromogenes ("*Haemophilus piscium*")
Causative agent of ulcer disease in salmonids and bacterial septicemia of salmonids (phenotypically atypical strains).

Group 3. *A. salmonicida* subsp. *nova*
Causative agent of carp erythrodermatitis and goldfish ulcer disease (phenotypically atypical strains).

a. History — The first report of furunculosis is from 1894, by Emmerich and Weibel, from a trout hatchery in Germany (42). The bacterium was referred to as *Bacillus der Forellenseuche* in Germany and *Bacillus salmonicida* in England in the early 1900s and was reclassified as *A. salmonicida* by Griffin in 1953 (43). The name furunculosis is somewhat of a misnomer and was given to describe the "boil-like" lesions of the original form of the disease in trout; however, from a pathologic standpoint, there is little similarity to the pus-filled boils that occur in humans (44). Judging from clinical signs, one can speculate that ulcer disease of trout was probably first seen in 1899 by Calkins (45). Ulcer disease of trout (UD) was described by Snieszko (46), and the causative bacterium was named *H. piscium* (from diseased brook trout) in 1980 (47). The relationship between *A. salmonicida* and *H. piscium* was investigated by Paterson (48) and by McCarthy and Roberts (40), and it was concluded that *H. piscium* was simply an atypical, achromogenic strain of *A. salmonicida*. Carp erythrodermatitis (CE) was described in 1972 by Fijan (49) from common carp, and goldfish ulcer disease (GUD) was described in 1980 by Elliott and Shotts (50).

b. Culture — Primary isolation of typical strains is achieved on BHI agar, TSA agar, or TSA agar with 5% sheep blood and incubation at 20–25 °C. Growth is fairly rapid even at these temperatures, with 2-mm cream-colored colonies visible in 48 hours. Some atypical strains from ulcer disease may be somewhat fastidious, and growth may be enhanced by the addition of fish peptone to the primary isolation medium (45).

c. Description — *A. salmonicida* is a gram-negative, facultatively anaerobic, nonmotile rod, 0.8–1.3 ×

1.3–2.0 μm. Typical strains, when grown on media containing tyrosine, produce a brown, water-soluble pigment. Atypical strains do not produce this pigment; they also vary on a few tests involving enzyme production and carbohydrate fermentation. Fresh isolates from fish are virulent, produce "rough" colonies (because of the presence of a surface protein "A-layer"), and autoagglutinate in broth culture. Colonies that have been subcultured, particularly at higher temperatures 25 °C (77 °F), are nonvirulent, become "smooth," are A-layer negative, and do not autoagglutinate (51). Once the bacterium has lost the A-layer via high-temperature incubation, it cannot be induced to revert to being A-layer positive. The nonmotile subspecies of *A. salmonicida* are differentiated from related fish pathogens in Table 2.

d. Epizootiology—*A. salmonicida* is considered an obligate pathogen, even though recent studies have shown it can survive for months in fresh water and in muds. The current belief is that furunculosis and other related diseases caused by the subspecies of *A. salmonicida* are transmitted horizontally from fish to fish by close contact through the skin or by ingestion of water containing high numbers of the organism (40). Skin damage due to abrasion or to external parasites (such as salmon lice) may open portals of entry for the bacterium. Asymptomatic infected carriers are vehicles for persistence within a population. Vertical transmission is not believed to be important in the spread of furunculosis. The disease has always been an important economic problem in salmonid aquaculture, and it has recently been cited as a problem in such new aquaculture venues as the sea-ranching of salmon in Scotland and Norway, where losses as high as 20% have been reported (8).

e. Geographic range and host susceptibility—Furunculosis of salmonids is found in almost every region of the world in which trout are grown, most notably in North America, Great Britain, Europe, Asia, and South Africa (7). All salmonids are susceptible to the disease. Atypical strains produce carp erythrodermatitis in common carp (*C. carpio*) in Europe and Great Britain but not in North America or Asia. Goldfish ulcer disease has been diagnosed from the goldfish, (*Carassius auratus*), in the U.S., Italy, Great Britain, Japan, and Australia (7).

f. Clinical signs of disease and treatment—Gross external clinical signs in salmonids with furunculosis vary depending on the time course of the disease process. In acute disease, fish show very few clinical signs, and mortality is high. In chronic disease, the following signs become apparent: darkening, lethargy, anorexia, petechial hemorrhage, swellings in the skin/muscle containing necrotic debris (furuncles), and hemorrhage in the gill filaments. In nonsalmonids infected with atypical strains, the disease begins with small localized skin infections that progress into larger ulcerations, which may be secondarily infected by motile aeromonads or pseudomonads. The disease ultimately becomes a septicemia, if the fish does not die first from a secondary infection. Medicated feeds with Terramycin® or Romet® administered at 50 mg/kg/day (23 mg/lb/day) have traditionally been the treatment of choice in the U.S. During the 1980s, drug-resistant strains of *A. salmonicida* began to appear in

Europe and Norway, and additional antimicrobials had to be explored. In Scotland, there are currently four antibacterial agents licenced for control of furunculosis: oxytetracycline, oxolinic acid, trimethoprim-sulfadiazine, and amoxicillin. Multiple resistance to these drugs is common now, with the exception of amoxicillin (52); however, some isolates of *A. salmonicida* subsp. acromogenes have recently been reported to be resistant to amoxicillin (53). Florphenicol has been reported to be a very effective chemotherapeutic in experimental trials (54). *A. salmonicida* is an antigenically homogeneous species, with variability only in the presence or absence of A-layer; however, there have over the last 50 years been many failed attempts at producing successful commercial vaccines (55). The use of oil-adjuvanted vaccines has given the first encouraging results (56).

C. Vibrionaceae. Facultatively anaerobic, oxidase positive, 0/129 sensitive, gram-negative curved rods. All but two species are halophilic and thus are known primarily as pathogens of marine fish.

I. Vibrio anguillarum, Listonella anguillarum and Vibrio ordalii. Causative agents of vibriosis. Synonyms: salt water furunculosis, boil disease, ulcer disease, red pest of eels.

a. History—As stated in the introduction to this chapter, vibriosis may well be the longest known bacterial disease in aquaculture. The clinical signs of a disease in eels cultured in the Mediterreanean as early as 1718 are consistent with vibriosis (1). The causative agent was first cultured from diseased eels with "red pest" in 1883 (2) and named *V. anguillarum* in 1909 by Bergeman (57). Two distinct biochemical phenotypes of *V. anguillarum* were recognized by Nybelin in 1935; that work led to the designation of *V. anguillarum biovar I* and biovar II (9). The more fastidious and nonreactive strains composing biotype II received their own species status in 1981, after the work of Schiewe (58). Today, the taxonomy of this group of organisms is in a confused state, after the suggestion of MacDonell and Colwell in 1985 that *V. anguillarum* and *V. ordalii* be reclassified in the genus *Listonella* (59). Currently references to both names are found in the literature.

b. Culture—*V. anguillarum* may be cultured from diseased fish tissues on standard culture media such as TSA with or without 5% sheep blood or BHIA and incubation at 25–30 °C. The organism grows rapidly and 2-mm colonies are visible within 24 hours. *V. anguillarum* and *V. ordalii* are halophilic and grow on culture media with a final salt concentration of 1–3%. Primary isolation of *V. ordalii* is improved by using seawater agar with 3% salt and incubation at 15–25 °C. Growth is slow, and up to seven days may be required for typical colonies to develop (7). *V. anguillarum*, but not *V. ordalii*, can be isolated on thiosulfate citrate bile sucrose (TCBS) selective medium, on which it produces a yellow colony. This medium is not differential, so additional testing is required to speciate the organisms forming yellow colonies. A new selective and differential medium, *V. anguillarum* medium (VAM), used alone or in combination with dot-blot hybridization,

Table 3. Biochemical and Biophysical Characteristics Important in Differentiating Some Fish Pathogens of the Family Vibrionaceae

has been employed for environmental enumeration of *V. anguillarum* (60).

c. Description — Short, gram-negative, slightly curved rods, 0.5×1.4–$2.6\ \mu m$, motile by monotrichous or multitrichous sheathed polar flagella at 25–$30\,^{\circ}C$, oxidase-positive, fermentative in glucose deeps, and sensitive to vibriostat 0/129. *V. anguillarum* is more reactive in biochemical tests than *V. ordalii*, being positive for arginine dihydrolase, Voges–Proskauer, beta–galactosidase, indole, citrate, arabinose, and sorbitol. The vibrionaceae pathogenic to fish are differentiated in Table 3.

d. Epizootiology — *V. anguillarum* is regarded as the marine counterpart to *A. hydrophila*, being a part of the normal microflora of the marine aquatic environment and marine fish (61). The bacterium exhibits long-term survival in aquatic environments, and virulent and nonvirulent strains may occur. Transmission is horizontal, via the water column, and infection is a result either of direct invasion of the skin or intestine by virulent strains, or of colonization of skin abrasions by less virulent strains, or of both. Perhaps the best-characterized virulence mechanism in a fish pathogen is the siderophore-mediated, plasmid-encoded, high-affinity iron-transport system in *V. anguillarum* strain 775 (62). The expression of this system requires a stretch of about 25 kilobases (kb) of a 65-kb plasmid, pJM1, and curing *V. anguillarum* strain 775 of pJM1 results in loss of virulence (63). *V. anguillarum* is a serious problem in marine aquaculture, particularly in stressed populations, and it is therefore considered an opportunistic pathogen. Temperature also plays a role, with mortalities in salmonids being highest (60%) at 18–$20\,^{\circ}C$ (64–$68\,^{\circ}F$) and lowest (4%) at $6\,^{\circ}C$ ($43\,^{\circ}F$) (64).

e. Geographic range and host susceptibility — *V. anguillarum* is found worldwide in a variety of marine fish species, and on rare occasions in freshwater species. It is a significant fish pathogen in all coastal areas of North America, the North Sea, the Atlantic and Mediterreanean coasts of Europe and North Africa, and Asia. *V. ordalii* outbreaks are confined to the Northwest Pacific Coast of North America and Japan (7). Approximately 50 species of marine fish have been listed as being susceptible to vibriosis, but salmonids, eels (*Anguilla* spp.), hybrid striped bass (*Morone* sp.), milkfish (*Chanos chanos*), and ayu (*Plecoglossus altivelis*) are the most important aquaculture species. *V. ordalii* occurs most commonly in salmon and trout.

f. Clinical signs of disease and treatment — Clinical signs of vibriosis are similar to motile aeromonad septicemia. Acute disease is accompanied by few clinical signs other than erratic swimming behavior and lethargy. The spleen may be enlarged, and the liver, kidney, and spleen may contain necrotic foci. In chronically infected fish, skin/muscle ulcerations become prominent, as does anemia. In *V. ordalii*-infected fish, the bacteria are less dispersed in the tissue, and microcolonies can be observed in sections of heart and skeletal muscle. Control of vibriosis is best achieved by maintaining good husbandry practices and by using commercially available multivalent vaccines. Treatment of the disease in salmonids is by medicated feed (Romet® 50 mg/kg/day (23 mg/lb/day) for 5 days or Terramycin® 50–75 mg/kg/day (23–34 mg/lb/day) for 10–14 days). Clearance for Romet® in salmonids is 42 days that for Terramycin® is 21 days.

II. Vibrio salmonicida. Causative agent of coldwater vibriosis. Synonyms: Hitra disease, hemorrhagic syndrome.

a. History — Coldwater vibriosis (CV) is a disease that affects primarily the Atlantic-salmon industry in Norway. The disease was first described as a multifactorial malady by Poppe in 1977 (66), from Atlantic salmon cultured on the island of Hitra off the coast of Norway. Egidius (67)

suggested a bacterial etiology for the condition and, along with work by Holm (68), provided a description of the etiologic agent of CV. The bacterium was fully described, and named *V. salmonicida*, by Egidius et al., in 1986 (69). Monoclonal antibodies to a major surface antigen, VS-P1, were used to confirm the identity of *V. salmonicida* (by immunohistochemistry) in archived tissues from original outbreaks of "Hitra disease" in 1977 (70).

b.   Culture — Primary isolation of *V. salmonicida* is difficult, but it can be accomplished on TSA with 5% sheep blood or BHIA, provided 1.5–2% salt is added to the medium. Optimum temperature for incubation of primary isolation plates is 15–17 °C, and growth is slow, requiring 72 hrs to form 1–2 mm, smooth, grey colonies.

c.   Description — The bacterium is a gram-negative, slightly curved or pleomorphic, motile rod 0.5–2.0 μm long. *V. salmonicida* is psychrophilic, and fails to grow above 25 °C. It is oxidase-positive, motile, and sensitive to vibriostat 0/129. The bacterium is generally non-reactive on many biochemical tests; it is differentiated in Table 3 from related organisms. Strains of *V. salmonicida* are serologically and biochemically homogeneous (68) and are distinct from *V. anguillarum*, *V. ordalii*, and other vibrios. Rare isolates from Atlantic cod belong to a different serotype.

d.   Epizootiology — Coldwater vibriosis is transmitted via the water from carrier fish (71), and infection is primarily through the gills. The organism is capable of survival in seawater and sediments for over one year. Mortalities in natural CV outbreaks are high, losses of 5% per day being common. Mortality in experimentally infected Atlantic salmon was 90% at 45 days postinfection. Most natural infections on fish farms occur in the autumn and winter, when water temperatures are between 4 and 9 °C. All ages and size classes of salmonids are susceptible.

e.   Geographic range and host susceptibility — CV has been reported from the coast of Norway, the Shetland Islands of northern Scotland, the Faroe Islands, eastern Canada, and the northeastern U.S. (7). Atlantic salmon grown in salt water or brackish-water net-pens are most susceptible. An outbreak of CV has been reported from a highly stressed, net-pen cultured population of juvenile Atlantic cod (*Gadus morhua*) (72).

f.   Clinical signs of disease and treatment — Acutely infected fish come to the surface of net-pens, swim erratically, and exhibit few (if any) external clinical signs. In subacute to chronic stages of the disease, pale gills, hemorrhage at the base of the fins and in the muscle, reddish and prolapsed anus, bloody ascetic fluid in the peritoneal cavity, and hemorrhage and watery contents in the posterior intestine are all notable clinical signs. Histopathologically, CV is similar to vibriosis caused by *V. anguillarum*, except with more pronounced heart and muscle damage (13). CV is believed to be a multifactorial disease, so reducing stress on the population is a primary management strategy. Effective commercial vaccines have had a positive impact on the Norwegian Atlantic salmon aquaculture industry. In one field trial, mortalities were reduced from 24.9% to 1.87% (73). Feeds medicated with Tribrissen, Terramycin®, or furazolidone were used, initially at 75–100 mg/kg (34–45 mg/lb/day) body weight/day for 10 days, with positive results. Recent development of resistant strains, however, has led to the evaluation of new drugs, such as Florfenicol (54).

III. Vibrio vulnificus Biogroup 2. Causative agent of *V. vulnificus* infection of eel.

a.   History — *V. vulnificus* biogroup 2 was originally documented as the cause of serious outbreaks of bacterial disease in eel populations in Japan between 1975 and 1977 (74). The disease is now known from Europe, where it has caused similar outbreaks in Spain (75), the Netherlands, and England (9). The bacterium was properly classified as *V. vulnificus*, and a new biotype (biogroup 2) was established by Tison et al. in 1982 (76).

b.   Culture — Primary isolation is accomplished on seawater agar or TSA with an additional 2% NaCl. Growth is slow, requiring 4–7 days at 20–25 °C.

c.   Description — Short gram-negative rods 0.5–2.0 μm long, oxidase-positive, sensitive to vibriostat 0/129, motile by a single polar flagellum, with growth between 20 and 37 °C. *V. vulnificus* biogroup 2 differs from typical *V. vulnificus* by negative results in tests for indole, for ornithine decarboxylase, and for acid from mannitol or sorbitol and by growth at 42 °C (9). Characteristics that differentiate *V. vulnificus* are found in Table 3.

d.   Epizootiology — Little has been reported on the epizootiology of this disease, but it is believed to be an opportunistic infection, because the organism has low virulence in experimental infections and is ubiquitous in the marine environment.

e.   Geographic range and host susceptibility — The disease is currently known to be a problem in eel mariculture in Japan, England, the Netherlands, and Spain. Thus far, only Japanese eels (*Anguilla japonica*) and European eels (*Anguilla anguilla*) are known to be susceptible. All strains pathogenic to fish form a homogeneous group in terms of serology and of biochemical phenotype.

f.   Clinical signs of disease and treatment — The disease is characterized by hemorrhage in the gills and along the flank or tail. Internally necrotic lesions may be found in the liver, the spleen, the heart, and the intestine; they bear close resemblance to lesions seen with classical vibriosis in eel.

IV. Other Vibrio spp. Several additional species of vibrios have been found on various occasions to be pathogenic for fish and shellfish (7,9,13). Uncertainty about their overall impact on aquaculture has led to listing these additional species here as potential pathogens, without going into detail. With time, some of these bacteria may emerge as significant pathogens in aquaculture:

- *V. alginolyticus* — gilthead seabream, mullet, penaed shrimp.
- *V. vulnificus* biogroup 1 or typical strains — hybrid striped bass, red drum, tilapia, prawns.
- *V. carchariae* — sharks.
- *V. cholerae*, *V. mimicus* — ayu, channel catfish, red drum, crayfish.

V. fischeri — turbot, penaed shrimp.

V. harveyi — snook.

V. *Photobacterium damselae* subsp. *damselae* ("*Vibrio damsela*," "*Listonella damsela*"). Causative agent of ulcerative disease of damselfish and of hemorrhagic septicemia of various other species. Synonym: Vibriosis

a. History — *P. damselae* subsp. *damselae* ("*Vibrio damsela*") was initially discovered as the causative agent of an ulcerative disease in damselfish (*Chromis punctipinnis*) inhabiting the coastal waters of southern California (77). Additional work by Grimes in 1984, on isolates from captive sharks, confirmed the new species (78). The organism has also been isolated from human wound infections (77). The taxonomy of the organism has changed since its initial description, having been moved to *Listonella* in 1985 (59) and later to *Photobacterium* in 1991 (79).

b. Culture — Primary isolation is accomplished on BHIA or TSA with 5% sheep blood and incubation at 25 °C for 48 hours. Addition of 2% NaCl to primary isolation medium is suggested. Growth is rapid, with typical 2-mm colonies visible after 48 hours incubation at 25 °C. TCBS agar may be used for selective isolation; however, additional testing is required for speciation.

c. Description — Short (0.5–2.0 μm), gram-negative, slightly curved or pleomorphic rods weakly motile by one or more sheathed, polar flagella. *P. damselae* subsp. *damselae* is positive for oxidase, urease, and arginine dihydrolase and negative for acid from sucrose. Additional characteristics that differentiate it from related organisms are found in Table 4.

d. Epizootiology — *P. damselae* subsp. *damselae* is a normal inhabitant of marine waters; it may invade highly susceptible fish directly, and less susceptible fish secondarily to injury. Host specificity was investigated

in laboratory experiments by scarifying the dermis of a variety of fish species and swabbing the area with a solution containing 10^8 viable cells of *P. damselae*. Only damselfish succumbed to the disease by this method.

e. Geographic range and host susceptibility — *P. damselae* subsp. *damselae* has been documented as a pathogen of natural populations of damselfish in coastal southern California (77), in sharks and dolphins held in captivity (78), in cultured turbot and sea bream in Europe (80,81), in yellowtail (*S. quinqueradiata*) in Japan (82), in rainbow trout in Denmark (83), and in barramundi (*Lates calcarifer*) in Australia (84). Stress associated with temperatures higher than normal is a common theme in aquaculture outbreaks.

f. Clinical signs of disease and treatment — *P. damselae* subsp. *damselae* causes ulcerative lesions in the skin of affected damselfish, usually near the pectoral fin and caudal peduncle. Ulcers sometimes increase in size to ~20 mm (1.75 in.), prior to death of the fish. In turbot and seabream, ulcers are not noticed, but hemorrhages in the eyes, at the base of the fins, and around the anus, as well as abdominal distension are typical clinical signs. Treatment of *P. damselae* infections in Europe and Japan is done with oxytetracycline, oxolinic acid, and trimethoprim−sulfamethoxazole.

VI. *Photobacterium damselae* subsp. *piscicida* ("*Pasteurella piscicida*"). Causative agent of photobacteriosis. Synonyms: Pasteurellosis, pseudotuberculosis.

a. History — Photobacteriosis was first described by Snieszko et al., in 1964 (85), from a massive natural fish kill involving white perch (*Morone americana*) and striped bass (*M. saxatilis*) in the upper Chesapeake Bay, U.S. The authors placed the causative organism in the genus *Pasteurella*, on the basis of physiological, morphological, and staining characteristics. The bacterium was

Table 4. Biochemical and Biophysical Characteristics Important in Differentiating Among Gram-Positive Cocci and Cocco Bacilli which have been Isolated from Fish

studied morphologically, physiologically, and serologically in 1968 by Janssen and Surgalla (86), who concluded that it represented a new species and proposed the name "*P. piscicida*." Outbreaks of "pseudotuberculosis" in cultured yellowtail in the late 1960s in Japan were attributed to this bacterium (87). Photobacteriosis remains one of the most serious diseases affecting Japanese mariculture; losses of yellowtail in excess of 2000 tons were reported in 1989 (88). Prior to 1990, there were no reports of photobacteriosis from Europe. After an account by Toranzo et al., in 1991 (89) of the disease in gilthead seabream (*Sparus aurata*) cultured in Spain, the disease seemed to spread throughout the region. Currently, photobacteriosis represents a significant economic problem in European and Meditereanean mariculture. The first report of photobacteriosis from cultured fish in the U.S. was from striped bass cultured in brackish water ponds on the Alabama Gulf Coast by Hawke et al., in 1987 (90). In 1990, the disease recurred on the U.S. Gulf Coast, in Louisiana, and yearly outbreaks have severely damaged an emerging hybrid striped bass mariculture industry (91). "*P. piscicida*" was never accepted as a valid name by bacterial taxonomists, and ultimately the bacterium was renamed *P. damselae* subsp. *piscicida* in 1995, on the basis of 16 sRNA sequencing (92); the name was later corrected to *P. damselae* subsp. *piscicida*.

b. Culture — Primary isolation is accomplished on TSA with 5% sheep blood or BHIA with 1–2.5% NaCl and incubation at 25–28 °C. Typical 1–2 mm, grey, nonhemolytic colonies appear after 48 hours of incubation. A selective medium is not available.

c. Description — *P. damselae* subsp. *piscicida* is a gram-negative, slightly curved or pleomorphic, nonflagellated, nonmotile rod (0.7 × 0.7–2.6 μm), often exhibiting bipolar staining. Coccoid forms predominate in older cultures. It is positive in tests for oxidase, catalase, Voges–Proskauer, and arginine dihydrolase, and it ferments glucose, mannose, galactose, and fructose. It is halophilic, requiring 0.5% salt to grow, and it is sensitive to vibriostatic agent 0/129. Strains of *P. damselae* subsp. *damselae* are serologically and phenotypically homogeneous regardless of the geographic source (93) and are easily differentiated from *P. damselae* subsp. *damselae* and other Vibrionaceae (Table 3).

d. Epizootiology — *P. damselae* subsp. *piscicida* was initially considered an obligate pathogen, because it fails to survive in brackish water for more than five days (94); however, Magarinos et al., demonstrated long term survival in seawater and in sediment, in a viable but nonculturable form that retains virulence (95). A carrier or latent state has not been demonstrated in susceptible hosts, but it has been theorized that other species of fish in the vicinity of fish farms, or perhaps an invertebrate, may harbor the pathogen (96). Most susceptible hosts can be infected via the water, so horizontal transmission from fish to fish within a culture unit is the most likely method of spread during epizootics. Outbreaks on fish farms are explosive and are characterized by sudden reduction in feeding response and rapid onset of mortality. Cumulative mortalities in striped bass (80%),

gilthead seabream (40%), and striped jack (34%) have all been documented as occurring over a four week period. Outbreaks of photobacteriosis are correlated with water temperatures of 18–25 °C (64–77 °F) and salinities of 5–25 ppt.

e. Geographic range and host susceptibility — Since its initial description from white perch in Chesapeake Bay, reports of new hosts and of an extented range have continued to increase. At present, the disease is known from Japan, the Atlantic and Gulf Coasts of the U.S., Europe, the Mediterranean, and Israel. The list of susceptible hosts of aquaculture importance includes the yellowtail, the striped jack (*Pseudocaranx dentex*), the ayu, the black seabream (*Mylio macrocephalus*), the red seabream (*Pagrus major*), striped bass (and hybrids), the gilthead seabream (*S. aurata*), and the sea bass (*Dicentrarchus labrax*) (7).

f. Clinical signs of disease and treatment — Photobacteriosis is an acute bacterial septicemia with a striking lack of gross clinical signs in most susceptible hosts. In hybrid striped bass and striped bass, redness in the operculum, enlargement of the spleen, and pallor of the gills are the only consistent signs. Necrotic foci are seen microscopically in the spleen and kidney, but an inflammatory response is lacking. In yellowtail, the disease progresses slightly more slowly, and white miliary lesions of about 1–2 mm (0.1–0.2 in.) become visible in the spleen and kidney. Necrotic foci containing bacterial colonies in the splenic parenchyma, and an associated chronic inflammatory response, has led to the use of the misleading pathological term "pseudotuberculosis" (13). Because of the rapid onset of disease, medicated feeds are usually not offered early enough in the infection to be effective. If timely application is achieved, the pathogen responds well to treatment with oxytetracycline, Romet, oxolinic acid, ampicillin, amoxicillin, and florfenicol medicated feeds. Currently, there are no drugs approved for treatment of photobacteriosis in hybrid striped bass in the U.S. With the widespread use of antibiotics on Japanese fish farms, resistant strains of the pathogen, carrying R-plasmids marking multiple drug resistance, have been isolated. Because of the general ineffectiveness of medicated feeds in combating the disease, vaccination is a logical approach for future management. Commercial vaccines are currently in the developmental stage.

VII. Plesiomonas shigelloides and
VIII. Shewanella putrefaciens (Pseudomonas putrefaciens, Alteromonas putrefaciens). *P. shigelloides* and *S. putrefaciens* are bacteria of only questionable importance as pathogens in aquaculture. Only one published report lists *P. shigelloides* as a fish pathogen. The bacterium was isolated from diseased, farmed rainbow trout in Portugal (98). *S. putrefaciens* has also been reported on only one occasion, from rabbitfish grown in sea cages in the Red Sea (99). There are other anecdotal accounts of *P. shigelloides* and *S. putrefaciens* as suspected pathogens in a variety of fresh and marine fish species (9). Both species are commonly isolated as post-mortem contaminants from decomposing fish tissue and from the intestines of healthy fish. With this in mind, further description of

the organisms is not given, other than to include data on identification of *P. shigelloides* to allow comparison with closely related organisms with which it might be confused (Table 3). The bacteria are presently classified in the Vibrionaceae but may be subject to a reclassification, one pending acceptance of the recommendations of MacDonell and Colwell (59).

D. *Pseudomonadaceae*

I. *Pseudomonas anguilliseptica*. Causative agent of red spot disease of eels, hemorrhagic septicemia of marine fish. Synonym for Japanese eel disease, Sekiten-byo.

a. History — *P. anguilliseptica* was first described in 1972, as the causative agent of red spot disease of cultured eels (*A. japonica*) in Japan, by Wakabayashi and Egusa (100). The disease has become one of the most significant problems in eel culture in Japan and recently has been reported from European eels (*A. anguilla*) cultured in Scotland (101). The disease seems to be increasing in importance in eel growing areas throughout many parts of the world (9). Recent outbreaks of disease on mariculture farms in Finland (102), in Malaysia (103), in Japan (104,105), and along the Mediterranean and Atlantic Coasts of France in a variety of fish species (106) are referred to as "hemorrhagic septicemia," and *P. anguilliseptica* is the causative agent. The lack of host specificity represents a potential hazard for many farmed species in the future.

b. Culture — Primary isolation can be made on nutrient agar with 10% horse blood or nutrient agar containing 0.5% (w/v) NaCl adjusted to pH 7.4. Incubation should be between 20–25 °C, and the resulting growth is slow, requiring 72 hours for small (∼1 mm), shiny, pale-grey colonies to form.

c. Description — *P. anguilliseptica* is a Gram-negative rod (5.0–10.0 × 0.8 μm), motile by a single polar flagellum at 15 °C but not at 25 °C. The bacterium is oxidase and catalase-positive, does not produce acid from glucose or any of a number of other carbohydrates oxidatively or fermentatively, and is resistant to vibriostatic agent (0/129). Growth occurs between 5 and 30 °C at 0–4% NaCl. The occurrence of pleomorphic, filamentous rods 5–10 μm in length makes this bacterium unique in appearance.

d. Epizootiology — In Japan, the disease occurs in eels during April and May, when temperatures are between 15 and 20 °C (59–68 °F). Mortalities decline in the summer months, when water temperatures are between 20 and 25 °C (68–77 °F); however, outbreaks may recur in the fall, when temperatures decrease. Because of the salt tolerance of the organism, disease outbreaks are prevalent in brackish-water ponds (107). In experimental infections, Japanese eels are most susceptible to infection and disease at around 19–20 °C (66–68 °F), and very little mortality occurs above 25 °C (77 °F). Juvenile European eels (elvers) are much more susceptible to infection than adults (96% mortality vs 3.9% mortality) (101), and applications of copper sulfate at 25 to 100 μg/L increase the susceptibility of eels to infection and disease.

e. Geographic range and host susceptibility — Red spot disease primarily affects the Japanese eel in Japan and the European eel in Scotland (100,101). The Japanese eel has been shown to be the more susceptible of the two species. *P. anguilliseptica* has also been reported from eels in Taiwan (7). Recently, outbreaks of the disease have occurred in farmed black sea bream and ayu in Japan (104,105), in salmonids in Finland (102), and in sea bass, sea bream, and turbot cultured on the French Mediterreanean and Atlantic coasts (106). Heavy mortalities were reported in 1987 during infections of the giant sea perch (*L. calcarifer*) and in grouper cultured in offshore sea cages in Malaysia (103). *P. anguilliseptica* has also been isolated from wild Baltic herring on the southwest coast of Finland (108). Wild fish were suspected to serving as a vector to transmit the disease to farmed salmonids. Experimental infections have been achieved in ayu, bluegill, carp, goldfish, and loach (109).

f. Clinical signs of disease and treatment — Japanese eels exhibit extensive petechial hemorrhage in the subepidermal layer of the jaws, on the underside of the head, and along the ventral body surface. Internally, there are petechiae in the peritoneum, enlargement of the liver, and atrophy of the kidney and spleen. Pericarditis is also commonly observed. Clinical signs in other fish species are typical of hemorrhagic septicemia. Treatment of the disease in eels is achieved in a variety of ways, including the following: administering feed medicated with Romet® [50 mg/kg/day (23 mg/lb/day) for five days] or oxolinic acid [5–20 mg/kg/day (0.9–9.0 mg/lb) for three days]; antibiotic baths with oxolinic acid [2–10 mg/L (ppm)]; or raising the water temperature to >27 °C (80.6 °F). Formalin-killed bacterins are effective vaccines against red spot when administered by injection, but not when delivered by immersion (110).

II. *Pseudomonas fluorescens*. Causative agent of Pseudomoniasis. Synonyms: bacterial tail rot, fin rot, hemorrhagic septicemia.

a. History — *P. fluorescens* was described originally (as *Bacillus fluorescens*) by Trevisan in 1889 (111). The bacterium is a normal inhabitant of soil and water and has been associated with the spoilage of such foods as eggs, fish, and milk (111). Early accounts of hemorrhagic septicemia in cultured carp by Otte in 1963 included *P. fluorescens* along with the motile aeromonads as potential causative agents (9). The importance of *P. fluorescens* in aquaculture is not clear, and its occurrence over the years has been sporadic.

b. Culture — Primary isolation is achieved on nutrient agar, TSA with 5% sheep blood, or BHIA and incubation at 22–25 °C. Cetrimide agar (Difco) or Pseudosel (BBL) are selective media used to isolate pseudomonads from mixed populations of gram negative rods (112). Growth on standard isolation media is rapid, with 1–2 mm, cream-colored colonies visible in 24 hours at 25 °C.

c. Description — *P. fluorescens* is a gram-negative rod (0.5 × 1.5–4.0 μm) that is motile by 1–3 polar flagella and is positive in tests for oxidase, catalase and arginine dihydrolase. *P. fluorescens* produces acid from glucose

aerobically, but is not fermentative (giving a +/no change reaction in GMD). Colonies on TSA, Cetrimide agar, or Mueller Hinton agar plates produce a diffusible yellow–green pigment (pyoverdin) that is fluorescent under short wavelength (ca. 254 nm) ultraviolet light (112). Growth occurs in the range of 4–37 °C but not at 42 °C. Five biovars are reported in Bergey's Manual of Systematic Bacteriology (111), but strains pathogenic to fish have not been classified by this method.

d. Epizootiology — *P. fluorescens* is an opportunistic pathogen that usually invades the host secondarily to stress or injury. Ghittino, in 1966, stated that degraded environmental conditions were vital to initiation of outbreaks of hemorrhagic septicemia caused by *P. fluorescens* and that often the infection was secondary to viral infection (45). *P. fluorescens* is most often seen causing fin rot and skin lesions in a variety of fish species reared under stressful conditions (45). Pseudomonad infections display many similarities to motile aeromonad septicemia. One exception is that *P. fluorescens* infections can also occur at low temperatures. For instance, 100% mortality was observed in tench fry over a 10-day period at 10 °C (50 °F) (113). Winter mortality in silver and bighead carp at temperatures near freezing has also been reported by Csaba (114).

e. Geographic range and host susceptibility — *P. fluorescens* is ubiquitous in aquatic environments world wide. Published accounts of pseudomoniasis have listed a wide range of susceptible fish species, including silver and bighead carp, goldfish, koi, tench, grass carp, black carp, white catfish, rainbow trout, and freshwater tropical aquarium species (12).

f. Clinical signs of disease and treatment — The most common clinical sign in pseudomoniasis is fin or tail rot, in which large portions of the fins are lost due to necrosis. In carp, the disease is usually indistinguishable from motile aeromonad septicemia, displaying hemorrhages in the skin and ascetic fluid accumulations in the body cavity. In rainbow trout and koi, the presence of skin lesions similar to those seen in ulcer disease are common. Treatment of pseudomonas septicemia is best achieved by improvement of water quality conditions and by elimination of environmental stress. On nonfood fish, bath treatments with benzalkonium chloride [1–2 mg/L (ppm) for 1 hour] and furnace [0.1 mg/L (ppm) for 24 hours] may be effective (9). Pseudomonads are notorious for multiple drug resistance; therefore, isolation of the pathogen and determination of antimicrobial susceptibility is essential before a recommendation can be made. Vaccines are currently not in use, presumably because of the relationship of stress to disease outbreaks.

***III. Other Pseudomonas* spp.** A variety of pseudomonads have been implicated as fish pathogens (9), but, because of a lack of consistency in their occurrence, they are simply listed here, along with their susceptible host(s) and geographic location:

P. chlororaphis — amago trout (*Oncorhynchus rhodurus*); Japan (9).

P. pseudoalcaligenes — rainbow trout; England (9).

P. sp. ("hemorrhagic ascites") — ayu; Japan (115).

GRAM-POSITIVE AGENTS

A. *Streptococcaceae.* Small cocci, usually in chains, facultatively anaerobic, catalase negative.

Recent changes in the classification of the streptococci, stemming from molecular taxonomic studies, from the taxonomic reassignment of previously known fish pathogens, and from the recent discovery of several new fish pathogens, have led to a great many changes in this group, and, hopefully, to elimination of some of the confusion. Streptococci have been recognized as fish pathogens since 1958 (116); they have traditionally been grouped on the basis of a few phenotypic characteristics (biochemical test reactions), of hemolytic reactions, and of Lancefield serology. This system breaks down because some streptococci do not possess a known Lancefield antigen, because members of different species may belong to the same Lancefield group, and because strains within a species may have heterogeneous Lancefield antigens. Also, hemolysis patterns may be interpreted differently in different laboratories. In spite of these problems, these methods are still useful as initial steps in the identification process (117). Because the older references use this system, many of the early descriptions of streptococci pathogenic to fish are incomplete. This defect has resulted in a multitude of published reports of streptococcal disease in a variety of fish species, giving the impression that many different species are the etiologic agents of disease. Some reviewers, out of frustration, simply lump them all together as causative agents of a single disease: "streptococcosis." In cases where strains were archived, these agents have been renamed and (often) reclassified; however, information on other unavailable strains is too sketchy for them to be classified properly. Discussed under this heading are diseases caused by members of the genera *Streptococcus*, *Enterococcus* (previously group D streptococci), *Lactococcus* (formerly group N streptococci), and *Vagococcus* (formerly motile group N streptococci).

I. Streptococcus iniae ("Streptococcus shiloi"). Causative agent of streptococcosis. Synonyms: -hemolytic streptococcal disease, bacterial meningoencephalitis, mad fish disease, golf ball disease of freshwater dolphin.

a. History — *S. iniae* was first described from diseased Amazon freshwater dolphin (*Inia geoffrensis*) housed at a public aquarium in San Francisco, California (118). The dolphin (an aquatic mammal) had numerous subcutaneous abcesses (a condition called "golf ball disease") from which β-hemolytic streptococci were isolated. The disease was reported from the same species at another aquarium in New York two years later (119). There were no further reports of this organism causing disease in the U.S. until 1994, when Perera et al. (120) described *S. iniae* as the causative agent of an epizootic in hybrid tilapia (*Oreochromis niloticus* × *O. aureus*) cultured in Texas. Eldar et al. (121), described a new species in 1994, *S. shiloi*, as the causative agent of "bacterial meningoencephalitis" in cultured tilapia and trout in

Israel; however, *S. shiloi* was later shown to be a junior synonym of *S. iniae* (122). Epizootics caused by β-hemolytic streptococci occurred on Japanese fish farms between 1979 and 1986 in a variety of species. Although the descriptions are difficult to compare, because of the different methods used, all appear consistent with *S. iniae*, and one archived strain has been identified by serology as *S. iniae* (8). The first report of *S. iniae* infection in commercially reared hybrid striped bass in the U.S. was by Stoffregen et al., in 1996, from fish cultured in closed recirculating systems (123). With the development of closed-recirculating-system technology, *S. iniae* has also emerged as the first significant disease of cultured tilapia in the U.S., having been identified in 14 states (124). In Israel and Japan, it has become an even more significant problem, causing losses in the millions of dollars yearly (125).

b. Culture — Primary isolation is on TSA with 5% sheep blood. Incubation should be between 30–35 °C in a normal atmosphere. Growth is slow, requiring 48 hours for typical opaque-white colonies to develop on blood agar. Selective isolation is best achieved on Columbia CNA agar with 5% sheep blood. The bacterium fails to grow on enterococcal-selective media containing sodium aside.

c. Description — *S. iniae* is a gram-positive coccus (0.6–0.8 μm) in pairs or chains. Typical colonies on TSA blood agar are surrounded by a very narrow zone of β-hemolysis and a broader zone of α-hemolysis, although more strongly β-hemolytic strains can occur. Hemolysis is best demonstrated by stabbing the blood agar with the inoculating loop. Growth is between 10, 40 and 50 °C, and optimum growth is at 37 °C. The bacterium is nonmotile, fermentative in GMD, negative for catalase and bile esculin, and positive for esculin, leucine arylamidase (LAP), pyrrolidonyl-arylamidase (PYR), and the CAMP test. *S. iniae* does not react with any of the available Lancefield typing antisera. Biochemical tests useful in differentiating *S. iniae* from other gram-positive cocci are found in Table 4.

d. Epizootiology — Opinions vary as to the source of *S. iniae* in the aquatic environment and its degree of pathogenicity. One school of thought is that the organism is widespread in the environment, possibly disseminated by homoiothermic animals, and that it causes disease in fish only under conditions of stress. Others feel that the bacterium is well adapted as a fish pathogen with limited host specificity and that it must be transmitted horizontally from sick or carrier fish to susceptible hosts. Currently this question is unresolved. What is known is that disease outbreaks are more common in high-density aquaculture environments and that epizootics are often preceded by degraded water quality conditions or by injury resulting from handling. Tilapia appear to become more susceptible when they are subjected to temperature extremes or rapid temperature shifts. Experimental infections were achieved in tilapia by injection, by oral intubation, and by immersion at 15 °C (59 °F) to 35 °C (95 °F), with the highest rate of mortality at 20 °C (68 °F) (126). The bacterium survives for only two days in sterile saline (0.85% NaCl), although

it is able to survive in muds around sea farms in Japan from year to year (127). The zoonotic potential of *S. iniae* was realized in the winter of 1995–96 in Toronto, Canada, when eight cases of invasive disease were reported in people who sustained minor injuries (cuts or scratches) while preparing fresh whole tilapia purchased in local markets but originating from fish farms in the U.S. A single clone (determined by genetic analysis) is believed to be responsible for the human disease (128).

e. Geographic range and host susceptibility — *S. iniae* is currently known in the U.S. and Canada as a pathogen of tilapia and of hybrid striped bass, in Japan as a pathogen of yellowtail, ayu, tilapia, and flounder (8), and in Israel as a pathogen of tilapia and trout. The host specificity has not been well defined, but red drum (*Sciaenops ocellatus*), channel catfish, carp, and black seabream are refractory to experimental infection (126,129). The *Streptococcus* sp., described by Al-Harbi from hybrid tilapia in Saudi Arabia (130) and the *Streptococcus* sp., described from spinefoot (*Siganus canaliculatus*) cultured in Singapore (131) are believed to be biotypes of *S. iniae* (Al-Harbi, personal communication) (8).

f. Clinical signs of disease and treatment — Tilapia and hybrid striped bass infected with *S. iniae* circle listlessly at the surface, spiral, spin, or swim erratically. The disease is a typical bacterial septicemia in the acute phase. Infected fish often have petechiae around the anus and mouth, have congestion in the fins, and may exhibit bilateral or unilateral exophthalmia accompanied by corneal opacity. The liver, kidney, and spleen are pale and enlarged, and ascites can cause abdominal swelling. The chronic stages of the disease are characterized by infection of the brain, the optic nerve, and the eye, by subcutaneous abcesses, by fibrin deposits in the peritoneal cavity, and by pericarditis. Clinical signs in other species are very similar to those described above. Although the bacterium is sensitive to ampicillin, amoxicillin, oxytetracycline, and erythromycin, feeds medicated with these antimicrobic agents have met with only limited success, with recurrence of disease several weeks following treatment. Enrofloxacin in feed at 5 or 10 mg/kg/day (2.3–4.5 mg/lb) was an effective chemotherapeutic (123) when used to treat cultured hybrid striped bass. There are currently no USFDA-approved antimicrobic agents for treatment of streptoccocal disease in hybrid striped bass or tilapia in U.S. aquaculture. In Japan, erythromycin at 50 mg/kg/day (23 mg per lb) for four to seven days has been effective in cultured yellowtail. Formalin-killed injectable vaccines have been investigated by Eldar and have induced protection lasting four months in rainbow trout (132).

II. *Streptococcus difficilis* ("*Streptococcus difficile*") — Group B, Type Ib *Streptococcus* sp. Causative agent of group B Streptococcosis. Synonyms: nonhemolytic streptococcal disease, bacterial meningoencephalitis.

a. History — Nonhemolytic group B, type Ib streptococci were first described as fish pathogens by Robinson and Meyer in 1966 (133) from diseased golden shiners (*Notemigonus crysoleucas*) cultured in farm ponds in

Arkansas, U.S. Koch's postulates were fulfilled in shiners, and several other species of fish were found to be susceptible to experimental infection with the streptococci. Unspeciated group B, type Ib nonhemolytic *Streptococcus* sp., were documented as causative agents of large fish kills in estuarine bays along the Florida and Alabama U.S. Gulf Coast in the fall of 1972 by Plumb et al., (134), in Lake Pontchartrain, Louisiana, U.S. in the fall of 1978 (135), and in the Chesapeake Bay, Maryland, U.S. in the fall of 1988 by Baya et al. (136). A variety of marine and estuarine species were affected during these outbreaks. A group B, type Ib *Streptococcus* has been responsible for mortality in bull minnows (*Fundulus grandis*) and in hybrid striped bass at mariculture facilities on the Alabama and Louisiana Gulf Coast from 1984 to the present (124,137). In 1994 Eldar et al., described a new species, *S. difficile*, as the causative agent of bacterial meningoencephalitis in cultured tilapia in Israel (121). *S. difficile* was later shown to be a group B, type Ib nonhemolytic *Streptococcus* that by whole cell protein electrophoretic analysis was identical to *S. agalactiae* (138). Biochemically, the bacterium was more similar to other group B, type Ib streptococci isolated from fish. In a study conducted in 1990, Elliott demonstrated the similarity in whole cell protein electrophoretic profiles of group B streptococci from humans, mice, cattle, frogs and fish (139). The group B streptococci isolated from shiners, tilapia, and estuarine fish are probably biotypes of the same species, although this has yet to be demonstrated by genetic analysis. The name was corrected to *S. difficilis* in 1998 (140).

b.   Culture — Primary isolation is on TSA with 5% sheep blood or BHIA. Incubation is between 25–30 °C in a normal atmosphere; however, growth may be enhanced in an atmosphere of 5% O_2, 10% CO_2, and 85% N_2. Growth is slow, requiring 48 hours for typical opaque–white colonies to develop on blood agar. Selective isolation is best achieved on Columbia CNA agar with 5% sheep blood, and the bacterium fails to grow on enterococcal selective media containing sodium aside.

c.   Description — *S. difficilis* is a gram-positive coccus (0.6–0.8 μm) in pairs or chains. The bacterium is nonmotile, and colonies on blood agar are (non) γ-hemolytic. Growth occurs between 20–30 °C, and the organism fails to grow above 35 °C or below 15 °C in a normal atmosphere. Growth occurs in BHI broth with 0.5–4.0% salt, but not in 6.5% salt. The bacterium is fermentative in GMD, negative for catalase and esculin hydrolysis, and positive for Voges–Proskauer, hippurate, alkaline phosphatase (PAL), leucine arylamidase (LAP), arginine dihydrolase (ADH), and acid from ribose. The CAMP reaction is variable. Biochemical tests useful in differentiating *S. difficilis* from other gram-positive cocci are found in Table 4.

d.   Epizootiology — In natural fish kills caused by group B type Ib streptococci, high water temperatures, combined with poor tidal flushing in tributaries leading into estuaries, were speculated to be the stressors that initiated infections. In Alabama and Florida, the infections seemed to begin in menhaden (*Brevoortia* sp.), a schooling planktivorous fish, and spread to carnivores and scavengers that fed on the moribund and dead menhaden. Outbreaks on mariculture farms in Louisiana and Alabama were strongly correlated with high water temperatures in late summer and early fall and with bouts of low dissolved oxygen. Experimental infections have been conducted with tilapia (125) and bullminnows (137). The LD_{50} of *S. difficilis* in tilapia by IP injection, recorded over a 6-week period, was 10^7–10^8 colony-forming units (CFU) for cultures that had been passed repeatedly on culture plates and 10^2 CFU for cultures that had been passed $3\times$ in fish. Rasheed and Plumb found the 96-hour LD_{50} for group B type Ib streptococci to be 1.4×10^4 CFU and the 7-day LD_{50} to be 7.5×10 CFU by IP injection, in bullminnows, but could not establish experimental infections by oral intubation with 10^6 cells or bath immersion in 10^{10} CFU/mL (137). When fish were injured by scratching the skin with a scalpel blade prior to immersion, mortality rates of 75–100% resulted after 7 days.

e.   Geographic range and host susceptibility — *S. difficilis* and other group B type Ib streptococci are known in Israel as pathogens of tilapia and mullet, in Japan as pathogens of yellowtail, and in the U.S. as pathogens of the following wild marine and estuarine species: menhaden (*Brevoortia patronus*), sea catfish (*Arius felis*), striped mullet (*Mugil cephalus*), pinfish (*Lagodon rhomboides*), Atlantic croaker (*Micropogonias undulatus*), spot (*Leiostomus xanthurus*), stingray (*Dasyatis* sp.), silver sea trout (*Cynoscion nothus*), spotted sea trout (*Cynoscion nebulosus*), bluefish (*Pomatomus saltatrix*), red snapper (*Lutjanus campechanus*), striped bass (*M. saxatilis*), and weakfish (*Cynoscion regalis*) (7). Susceptible species in U.S. aquaculture/mariculture are tilapia, hybrid striped bass, bullminnows, and golden shiners. Freshwater species that have been experimentally infected are bluegill (*Lepomis macrochirus*), green sunfish (*Lepomis cyanellus*), buffalo (*Ictiobus cyprinellus*), goldfish (*C. auratus*), black crappie (*Pomoxis nigromaculatus*), and largemouth bass (*M. salmoides*). Channel catfish are refractory to experimental infection (133). American toads (*Bufo americanus*) were susceptible to experimental infection, and 80% mortality was reported in bullfrogs (*Rana catesbeiana*) cultured in Brazil (141).

f.   Clinical signs of disease and treatment — The clinical signs of streptococcal disease in tilapia and hybrid striped bass are similar to those of *S. iniae* infection. Bacterial septicemia in the acute phase and meningoencephalitis in the chronic phase are the most common pathological conditions. Eye disease characterized by exophthalmia, corneal opacity, hemorrhage, and rupture of the globe are commonly observed in chronic infections. Death does not always result following infection, and a certain percentage of fish become blind as a result of infections of the eye or of the optic nerve. Enlargement of the spleen, exophthalmia, and focal necrosis of the liver are characteristic of the disease in bullminnows. Group B streptococci have been shown to be sensitive to terramycin, erythromycin, ampicillin, and amoxicillin, but difficulties with recurrent infections, similar to those encountered with *S. iniae* following antibiotic treatment,

are common. Erythromycin-medicated feed, 25–50 mg/kg (11–23 mg/lb/day) of body weight per day for four to seven days, was effective in controlling *Streptococcus* in yellowtail in Japan. Vaccines have been used experimentally to control the disease in tilapia, yellowtail, and hybrid striped bass.

III. Other *Streptococcus* sp. Other species of *Streptococcus* have been implicated as fish pathogens, but information about these infections is limited; therefore, they will only be listed, along with their hosts and geographic locations:

Streptococcus dysgalactiae — tilapia; U.S.
S. sp. *similar to dysgalactiae* — ayu (*P. altivelis*); Japan.
S. parauberis — turbot (*S. maximus*); Spain.

B. *Streptococcus* — Like Bacteria

I. *Lactococcus garvieae* ("*Enterococcus seriolicida*"). Causative agent of *Lactococcus* septicemia. Synonyms: streptococcosis, enterococcosis, enterococcal infection.

a. History — Gram-positive cocci, producing -hemolysis on blood agar plates, have been implicated as causative agents of fish disease since the first description from rainbow trout in Japan by Hoshina in 1958 (116). The streptococcus of Hoshina has never been classified properly, on account of the lack of complete phenotypic data; however, it shares many characteristics with the streptococcus strains isolated from yellowtail mariculture farms near Shikoku Island, Japan by Kusuda in 1974 and from eels in Japan in 1977 (142,143). Since 1974, the disease has spread throughout Japan and has become the most economically important disease in Japanese mariculture (88). In 1989, the reported losses were 8,240 tons of yellowtail and 180.8 tons of other maricultured species such as sea bream, saurel (*Trachurus japonicus*), and flounder. The classification of the bacterium has gone through several changes in recent years. Initially it was referred to as *Streptococcus* sp., in the Japanese literature, because it did not conform to any of the described species as determined by biochemical and cultural characteristics or by Lancefield serotyping (144). In 1991, the organism was described by Kusuda as a new species, *E. seriolicida*, on the basis of DNA–DNA hybridization, despite its lack of a Lancefield group D antigen (145). In 1996, during studies of the DNA relatedness between strains of enterococci from various sources and lactococci isolated from water buffalos with mastitis, *L. garvieae* and *E. seriolicida* were found to be related at the species level. Because *L. garvieae* was the senior synonym of *E. seriolicida*, the name was retained (146).

b. Culture — Primary isolation is on TSA with 5% sheep blood, or BHIA, and incubation is at 30–35 °C in a normal atmosphere. Growth is rapid, but 48 hours may be required for full visualization of the small (1.0 mm diameter) white colonies. Selective isolation is achieved on phenyl ethyl alcohol (PEA) blood agar or on blood agar containing .01% sodium aside.

c. Description — *L. garvieae* is a Gram-positive ovoid coccus (1.4 × 0.7 μm) forming short chains. The bacterium is nonmotile, and colonies on blood agar are α-hemolytic. Growth occurs between 10 and 45 °C, between 0 and 6.5% NaCl, and between pH of 4.5 and 9.6. Optimum growth is at 37 °C, 0% NaCl, and pH 7.5. The bacterium is fermentative in GMD, negative for catalase and hippurate hydrolysis, and positive for Voges–Proskauer, arginine dihydrolase, tetrazolium reduction, and bile-esculin hydrolysis. Biochemical tests useful in differentiating *L. garvieae* from other gram positive cocci are found in Table 4.

d. Epizootiology — *L. garvieae* may be detected in the aquatic environment year-round in Japan, but the highest counts are detected in sea water in the summer months in the vicinity of sea cages. Transmission of *L. garvieae* is horizontal, from one infected fish to another, in high-density aquaculture; however, the feeding of contaminated raw fish was determined to be a common source of infection (147). The bacterium was shown to survive for up to six months in frozen sandlance, a food commonly used in yellowtail culture. The bacterium has also been isolated from muds in the vicinity of sea cages during the cooler months of the year; these muds serve as a reservoir for infection (148). Wild fish such as sardine, anchovy and round herring are known to harbor the bacterium, and asymptomatic yellowtail can serve as carriers (147).

e. Geographic range and host susceptibility — *L. garvieae* is primarily a disease that affects cultured yellowtail and eel in Japan. Although the history is difficult to trace, because of problems with the taxonomy of streptococci pathogenic to fish, the initial outbreaks are believed to have been in the populations of yellowtail cultured near Shikoku Island from July to September of 1974 (88). Since 1974, the disease has occurred with increasing frequency and has become a disease of great economic importance in Japanese aquaculture. In cultured eels, the disease was first reported (by Kusuda) in 1978 (143).

f. Clinical signs of disease and treatment — Clinical signs of *L. garvieae* infections are similar to those due to other streptococcal infections in fish. The typical gross external clinical signs are exophthalmia, petechiae on the inside walls of the operculum, and congestion and hemorrhage in the intestine. Necrotic areas may be noted in the enlarged spleen and kidney. The first effective chemotherapeutant for the treatment of *L. garvieae* infections was erythromycin [25 mg/kg (11 mg/lb) fish/day for four to seven days in medicated feed], and, since 1984, erythromycin and spiramycin have been used to control the disease in Japan. Resistant strains have emerged in recent years; to combat infections due to them, josamycin has been used effectively at 30 mg/kg/day (13.6 mg/lb) for three days (149). Experimental vaccines have been effective at inducing protection, by immersion or by injection, but an effective vaccine has not been produced on a commercial scale. Nonspecific immunostimulants, such as the β-1,3 glucans, have produced increased resistance to infection by lactococci when injected at 2–10 mg/kg fish (150).

II. *Lactococcus piscium, Carnobacterium piscicola* ("*Lactobacillus piscicola*") and *Vagococcus salmoninarum.* Causative agents of pseudokidney disease in salmonids and of bacteremia in striped bass and channel catfish.

a. History — These three species are placed together on account of the similarity of the disease condition that they produce in salmonid fishes. Pseudokidney disease was named for the propensity to misdiagnose it as kidney disease, a condition in salmonids caused by the gram-positive bacterium *R. salmoninarum*, when only gram-stained tissue smears are examined. The latter is a common method of diagnosis, because *Renibacterium* is fastidious, and so special media and prolonged incubation times are required for isolation. Pseudokidney disease was described by Ross and Toth in 1974 (151) as a disease of adult salmonid broodfish that had undergone stress associated with handling or/or spawning. The causative organism was originally isolated and identified as *L. piscicola* by Hui, 1984 (152), but other unidentified coccobacilli were also isolated from certain fish. *L. piscicola* was renamed *C. piscicola* by Collins et al., in 1990 (153), who used molecular taxonomic methods. A new species, *V. salmoninarum*, was described in 1990 by Wallbanks et al. (154), from two cultures originally considered atypical lactobacilli isolated from diseased trout in Oregon and Idaho 1968 and 1981. *V. salmoninarum* infections were not again reported until yearly outbreaks of disease were recorded on a trout farm in the southwest of France from 1993–1997 (155). Another bacterium associated with pseudokidney disease of salmonids, *L. piscium*, was described as a new species by Williams et al., in 1990 (156), but very little information concerning pathogenesis or range of occurrence is available. Isolates of *Carnobacterium* spp., were reported by Baya et al., in 1991 (157), from cultured populations of striped bass and channel catfish and from wild populations of brown bullheads.

b. Culture — *Carnobacterium*, *Vagococcus*, and *Lactococcus* are not fastidious and are easily isolated on standard media such as TSA, TSA with 5% sheep blood, or BHIA. Incubation is between 20–25 °C, and small, white, round, entire, 1-mm colonies appear within 48 hours.

c. Description — 1. *V. salmoninarum* is a short, ovoid, nonmotile, gram-positive coccobacillus ($0.5 \times 2 \, \mu m$) occurring singly, in pairs, or in short chains. The bacterium is facultatively anaerobic; it grows between 5 and 37 °C but fails to grow at 40 °C. Tests for esculin hydrolysis, hippurate, and H_2S are positive; tests for arginine dihydrolase (ADH), catalase, oxidase, and urease are negative. Positive results are obtained in tests for the enzymes alkaline phosphatase (PAL), leucine arylamidase (LAP), pyrrolidonyl–arylamidase (PYR), and para–nitrophenyl–galactosidase (PNPG). Most strains are weakly α-hemolytic after two to three days of incubation. Growth occurs at pH 9.6 and in the presence of 40% bile, but not in 6.5% NaCl.

2. *C. piscicola* is a short, nonmotile, gram-positive rod ($0.5 \times 1.5 \, \mu m$) occurring singly, in pairs or in short chains. The bacterium is facultatively anaerobic; it grows between 10 and 37 °C but fails to grow at 42 °C. Tests for esculin hydrolysis, ADH, and PYR are positive; tests for hippurate, urease, and H_2S are negative. Most strains are α-hemolytic and grow at pH 9.6 and in 6.5% salt but not in the presence of 40% bile. Results of PAL and LAP enzyme tests are not available.

3. *L. piscium* is a nonmotile, gram-positive coccus ($0.5 \times 1.0 \, \mu m$) occurring singly, in pairs or short chains. The bacterium is nonhemolytic and facultatively anaerobic; it grows between 5 and 30 °C but fails to grow at 40 °C or at pH 9.6. Tests for esculin hydrolysis and starch hydrolysis are positive; tests for ADH, urease, H_2S, hippurate, and PYR are negative. Test results for growth in 40% bile are not available. Biochemical tests useful in differentiating this group of gram-positive organisms are included in Table 4.

d. Epizootiology — Pseudokidney disease is normally a chronic condition in salmonids, one resulting in low mortality rates and generally regarded as an opportunistic infection caused by one or more of the gram-positive organisms listed in this section. The bacteria have traditionally been considered to be normal components of the aquatic microflora and to gain entrance into the fish following trauma associated with spawning. Losses can be substantial, however, as is evidenced by mortality rates as high as 50% on trout farms in France caused by *V. salmoninarum* infections. The affected fish were adult trout weighing 600–4000 g (1.3 lb to 8.8 lb), and peak mortality followed the handling associated with the sorting and stripping of fish for spawning (155). Water temperatures during the outbreaks were lower than in other cases of pseudokidney disease, with peak mortality at around 9–10 °C (48–50 °F). A report by Michel in 1986 (158) indicated that young salmonids and carp reared in western Europe were susceptible to infection with *C. piscicola* and *L. piscicola*, although they noted that adult fish were the ones most commonly affected.

e. Geographic range and host susceptibility — *C. piscicola* is most commonly associated with adult salmonids with pseudokidney disease from the Pacific Northwest region of North America (152,159) and from Newfoundland, Canada (160); it has also been reported from brown trout (*Salmo trutta*), rainbow trout (*O. mykiss*), and common carp (*C. carpio*) cultured in France and Belgium (158). Isolates of *V. salmoninarum* have been obtained (*1*) from salmonids from the Pacific Northwest of the U.S. (154) and (*2*) from the southwest of France from diseased rainbow trout (155). The *L. piscium* type culture, HR1A-68, was isolated by R.A. Holt from rainbow trout at the Hood River Hatchery, Oregon (156). *Carnobacterium* spp., similar to *C. piscicola* were isolated from cultured striped bass and channel catfish and from wild populations of brown bullheads from Chesapeake Bay, Maryland (157). Attempts to confirm Koch's postulates with Maryland strains were successful in trout, but striped bass and catfish seemed to enter into a carrier state after being injected with the bacterium. Difficulty in recreating pseudokidney disease by experimental infection has been noted by several authors;

it is probably due to the low virulence of the bacterial strains (158,159).

f. Clinical signs of disease and treatment — *Carnobacterium* infections in salmonids are systemic and usually chronic in nature, with one or more of the following pathological signs: abdominal distension due to ascites, splenomegaly, muscle granulomata, internal hemorrhages, subcutaneous sanguineous vesciculation, and renal granulomata (152,158). In trout infected with *V. salmoninarum*, the prominent pathological manifestations were septicemia (with epicarditis) and meningitis (155). Treatment of pseudokidney disease is not well documented; however, strains of *Carnobacterium* have been shown to be susceptible to tetracycline, ampicillin, and erythromycin. Treatment of *V. salmoninarum* infections in France with ampicillin, amoxicillin, or erythromycin failed to prevent or decrease trout mortality. Vaccines for pseudokidney disease have not been considered, because of the opportunistic nature of the disease and the variety of causative bacteria.

III. Enterococcus faecium, E. faecalis and Enterococcus spp. Causative agents of enterococcosis of rainbow trout and other species.

a. History — Enterococcus-like bacteria were recorded as fish pathogens as early as 1974 by Boomker et al., in 1979 (161) from rainbow trout cultured in South Africa; additional reports from this same geographic area were published in 1986 by Bragg and Broere (162). Carson and Munday described a disease in farmed rainbow trout in Australia caused by a similar organism, from outbreaks between 1982 and 1990 (163). Today, the disease is considered one of the major diseases of farmed fish in Australia and South Africa. Other published accounts of organisms presumptively identified as *Enterococcus* sp., or *E. faecalis* have been described from farmed rainbow trout in Italy by Ceschia (164) and Ghittino (cited in 164). In an unpublished case report, *E. faecium* was determined to be the causative agent of enterococcosis in hybrid striped bass cultured in semiclosed intensive culture systems in the U.S. (7), and unidentified enterococci have been isolated from diseased channel catfish (165). An organism presumptively identified as *Enterococcus* sp., has been described from diseased turbot cultured in Galicia, northwest Spain (166).

b. Culture — Primary isolation is on TSA with 5% sheep blood or BHIA and incubation at 30–35 °C in a normal atmosphere. Growth is relatively fast, but 48 hours may be required for formation of typical 1 mm, smooth, white colonies. Selective isolation is achieved on aside blood agar (0.2 g/L sodium aside) (Difco Laboratories, Detroit, Michigan) or by using a selective isolation procedure outlined by Bragg (167): In this method, tissue samples are placed in nutrient broth containing 100 μg/mL nalidixic acid and 160 μg/mL oxolinic acid or 200 μg/mL of sodium aside, and they are incubated for three days at room temperature; samples from the broth are then plated on tetrazolium agar plates, and small red colonies appearing on this medium are presumptively enterococci. Cephalexin–Aztreonam–Arabinose Agar (CAA) has also been used for the selective isolation and differentiation of *E. faecium* (168).

c. Description — The genus *Enterococcus* was created in 1984 to include the enteric streptococci *Streptococcus faecalis* and *S. faecium*, and, since that time, 17 additional species have been proposed for inclusion in the genus. The enterococci are gram-positive cocci occurring singly, in pairs, or short chains. The organisms are facultatively anaerobic and catalase-negative, and optimum growth occurs at 35 °C, however, most strains grow at 10 and 45 °C. The bacteria also grow in 6.5% NaCl and at pH 9.6 and hydrolyze esculin in the presence of 40% bile salts. Most hydrolyze pyrrolidonyl–naphthylamide (PYR), produce leucine arylamidase (LAP), and possess the Lancefield group D antigen. Biochemical tests useful in differentiating *Enterococcus* spp., from other gram-positive cocci are included in Table 4. Recent isolates from Italy (164), Spain (166), Australia, and South Africa (169) may ultimately be identified as biotypes or serotypes of *L. garvieae*, because they fail to grow at 45 °C, do not possess the group D antigen, and are otherwise biochemically identical to *L. garvieae*. This problem cannot be solved until genetic analysis is done on the strains in question. Strains from Spanish turbot differ serologically from the Italian trout strains as visualized by immunoblots and ELISA, and trout strains are not immunogenic in turbot (170).

d. Epizootiology — Temperatures were in the range of 19 °C (66 °F) on South African farms where outbreaks first occurred, and temperatures did not fluctuate due to the groundwater source; however, in subsequent cases reported in 1986 by Bragg and Broere, temperatures ranged from 18 to 25 °C (64–77 °F) and were believed to be a stress factor. Other factors such as water quality, feed, and feeding practices were found to be acceptable, but temporary overcrowding during periods of new pond construction did seem to be a predisposing factor to disease. On Italian farms, poor water quality was implicated as a factor leading to increased susceptibility to infection. The source or reservoir of the pathogen has not been determined, but, once it is established in a fish population, horizontal transmission can occur through damaged skin or by the fecal-oral route. Infectivity studies with turbot (mean weight 10 g) produced an LD_{50} in the range of 10^4 cells by intraperitoneal injection. Chronic disease in hybrid striped bass occurred at temperatures between 26 and 28 °C (79–82 °F) in fish stocked at high densities; this case was complicated by a parasitic infection with *Epistylis* sp.

e. Geographic range and host susceptibility — Thus far, enterococci have been implicated as causative agents of disease for rainbow trout in Australia, South Africa, and Italy, for turbot in Spain, and for hybrid striped bass and channel catfish in the U.S. Outbreaks in South Africa have occurred in cultured populations of rainbow trout in the Eastern Transvaal area; however, an extensive survey of fish populations in eight river systems in Natal yielded no isolations of enterococci or streptococci (171).

f. Clinical signs of disease and treatment — In trout, turbot, and hybrid striped bass, the clinical signs are reminiscent of other streptococcal diseases in fish.

Bilateral exophthalmia, corneal opacity, subcutaneous abcesses in periorbital spaces and at the base of fins, and caudal peduncle are common external signs. Internal clinical signs include pale liver, dark red enlarged spleen, hemorrhage in the intestine, and ascites in the peritoneal cavity. Treatment depends on the sensitivity of the individual strain isolated, because enterococci are often resistant to many of the common antibiotics used in aquaculture. Antibiotics that have been used in various cases include oxytetracycline, erythromycin, ampicillin, and enrofloxacin; however, the disease is chronic in nature, and short term medicated feed treatments are rarely effective. Vaccines are not yet available for enterococcal infections in fish.

C. Other Aerobic and Facultatively Anaerobic Gram-Positive Cocci. Organisms in this group have uncertain status as fish pathogens and will therefore just be listed with their hosts:

Micrococcus luteus — rainbow trout; UK.

Aerococcus viridans — lobsters.

Planococcus sp. — Atlantic salmon rainbow trout; UK.

Staphylococcus aureus — silver carp; India.

S. epidermidis — yellowtail, red sea bream; Japan.

D. Aerobic Gram-Positive Rods

I. *Renibacterium salmoninarum*. Causative agent of bacterial kidney disease. Synonyms: Dee disease, corynebacterial kidney disease, salmonid kidney disease.

a. History — Bacterial kidney disease (BKD) was first described in the early 1930s in wild populations of Atlantic salmon from the Dee river in Scotland and was thus named "Dee disease" (172). It was subsequently found in rainbow trout, brook trout (*Salvelinus fontinalis*), and brown trout (*Salmo trutta*) in the U.S.: in Massachusetts by Belding and Merrill, and in California by Wales (as cited by Earp (173)). The first isolations from Canada were in 1937, in cutthroat trout (*Salmo clarki*), by Duff (as cited by Evelyn et al., in 1986 (174)). Now BKD is known from hatchery and farmed salmonid populations in many parts of the world, from both fresh and marine waters, but only rarely has it been observed causing mortality in wild fish stocks. The causative agent of BKD was originally classified as a *Corynebacterium* (175), on the basis of morphology and staining. As additional information was gathered following the first successful culturing of the organism, investigators realized that it belonged in a new, previously undescribed genus. The new genus and species was described, and it was named *R. salmoninarum* by Sanders and Fryer in 1980 (176).

b. Culture — Culture of the fastidious causative agent of bacterial kidney disease was not achieved until Earp used a specially formulated nutrient-rich medium. Growth on this medium was poor, requiring more than 14 days to obtain small colonies. Continued improvements were made on the isolation medium, but most significant was the discovery by Ordal and Earp in 1956 (175) that L-cysteine added to nutrient-rich blood agar provided a significant boost in growth. This medium (cysteine blood agar) was used until the development of KDM2 medium by Evelyn in 1977 (177), which utilized the addition of fetal calf serum and replaced blood and many of the other nutrients with peptone, cysteine, and yeast extract. KDM2 and a selective medium, SKDM, derived from it by Austin et al., in 1983 (178) are currently in use for the primary isolation of *R. salmoninarum*. At 15 °C incubation, the organism requires 20 days for the appearance of smooth, white, creamy, 2-mm colonies. Because the organism grows slowly, plates must be kept moist during the incubation process. Research on improved culture techniques is ongoing, and rich, serum-free, semidefined media have been developed by Embley (179) and Sheih (9).

c. Description — *R. salmoninarum* is a gram-positive rod (0.5 × 1.0 μm) occurring singly or in pairs. The bacterium is a nonmotile, not spore-forming, not acid-fast, fastidious bacterium that grows best at 15–18 °C. The bacterium fails to grow at temperatures above 25 or below 5 °C. *R. salmoninarum* strains from different geographic locations are homogeneous, typically being positive in tests for catalase, litmus milk, alkaline phosphatase, caprylate esterase, glucosidase, leucine arylamidase, α-mannosidase, and trypsinase. The organism fails to liquefy gelatin and does not grow in 1% sodium chloride. Serologically, isolates appear to be homogeneous when tested using polyclonal antisera, however, differences among strains can be detected with monoclonal antibodies (180). All strains apparently possess a heat-stable 57-kd surface protein. Antibodies to this antigen have been useful for detecting *Renibacterium* by ELISA, and it has been determined that the observed strain differences result from the recognition by monoclonal antibodies of different epitopes on the 57 kd surface protein (181).

d. Epizootiology — It is generally felt that *R. salmoninarum* is an obligate pathogen of salmonids and that its reservoir of infection is other infected salmonids. Outbreaks of BKD have not been reported from nonsalmonids. Survival of the pathogen can occur outside the host, but it is short-lived in water and mud. Bacterial kidney disease can be present as an overt infection, or it can exist in a carrier-only state. Water quality seems to influence cumulative mortality and severity of disease; BKD is more common at soft-water hatcheries than at those with high total hardness. A serious problem is the effect of BKD on the survival of salmon smolts as they are moved from freshwater to seawater. Mortality rates as high as 17% have occurred in smolts moved to saltwater, as against 4% in those kept in freshwater (182). BKD can occur over a wide range of temperatures, but most epizootics occur in the fall between 12 and 18 °C (54–64 °F) and in the winter between 8 and 11 °C (46–52 °F). Water temperature influences the time between experimental exposure and death. Mortality occurs at 30–35 days postexposure at 11 °C (52 °F) at 60 to 90 days postexposure at 7–10 °C (45–50 °F). Bullock, in 1978 (183), was able to demonstrate vertical transmission of BKD and theorized that the bacterium was carried within the egg, because surface disinfection of the egg

had no effect on transmission efficiency. This hypothesis was later proven to be true by Evelyn et al. (174), who demonstrated that *Renibacterium*-infected coelomic fluid is the source of infection for the egg. Several studies have shown that the dietary composition of feed influences the susceptibility of fish to *Renibacterium* infections (8).

e. Geographic range and host susceptibility — BKD has been reported from most areas of the world where salmonids occur, with the exception of Australia, New Zealand, and the Soviet Union. The disease has been reported from the United Kingdom, Europe, Japan, North America, and South America (Chile). All salmonids are considered susceptible, but brook trout and chinook salmon are the most susceptible. Natural outbreaks have been documented only in salmonids; however, a few fish species, such as the sable fish, the Pacific herring, the shiner perch, the common shiner, and the fathead minnow, have been infected experimentally.

f. Clinical signs of disease and treatment — External clinical signs of BKD are uncommon, except in the terminal stages of disease. The most common early signs of infection are dark pigmentation, exophthalmia, hemorrhages at the base of fins, and abdominal distension associated with a widely disseminated bacteremia. As the disease progresses, pale gills, exophthalmia, cutaneous blisters, and ulcerative abcesses may be seen externally; internally, cavitations in the musculature, bloody/turbid fluid, and creamy white granulomatous lesions are common in the kidney. Treatment of BKD by chemotherapy is not particularly effective, presumably because of the intracellular nature of the pathogen. Erythromycin is the antimicrobial of choice for treatment and prophylaxis against BKD. Treatment recommendations vary from oral administration in medicated feed at 100 mg/kg (45 mg/lb/day) of fish/day for 21 days for fingerlings [Wolf and Dunbar 1959 (184)] to injection of prespawn female salmon with 10−20 mg/kg (4.5−9.0 mg/lb) body weight and 1−2 mg/L (ppm) for 30 min as an additive during water-hardening of eggs. Disinfection of egg surfaces using iodophors at 25−100 mg/L (ppm) for 5 minutes has proven beneficial in reducing transmission of the disease. Although research on vaccination of salmonids for BKD has been ongoing since 1971 (185), there has been only limited success, and a commercial vaccine is currently not available.

II. Other Aerobic Gram-Positive Rods. Several other species of aerobic gram-positive, rod-shaped bacteria have been implicated as pathogens of fish, but because of uncertainty as to their significance, they are only mentioned here along with their hosts:

Corynebacterium sp. — rainbow trout (186).
Corynebacterium aquaticum — striped bass (187).
Rhodococcus sp. — chinook salmon (188).

E. Gram-Positive, Acid-Fast Rods

I. Mycobacterium marinum ("Mycobacterium piscium, M. platypoecilus, M. anabanti"), M. fortuitum, M. chelonei ("M. chelonei subsp. piscarium, M. salmoniphilum"). Causative agent of mycobacteriosis of fish. Synonym: fish tuberculosis.

Three species of mycobacteria are recognized as fish pathogens; they are discussed together here because of the similarities in the pathologic condition they produce in fish.

a. History — Acid-fast staining bacteria were first described as fish pathogens of common carp in 1987 in Europe by Bataillon (189); this is one of the oldest known fish diseases. The name "fish tuberculosis" was coined to reflect the similarity to human tuberculosis: the acid-fast staining reaction, and the granulomatous lesions commonly seen in infections. This old name has given way over the years to the less threatening name "mycobacteriosis." The first isolation of an organism in this group was reported by Bataillon in 1902 (190), but the cultures of that organism, named *Mycobacterium piscium*, have been lost, and the name lacks validity. *Mycobacterium marinum* was described by Aronson in 1926 (191) from a tropical coral fish kept at the Philadelphia Aquarium. *M. marinum* was originally thought to cause disease only in marine fish; however, it has subsequently been reported from many freshwater species as well, and the original isolates of *M. piscium* are believed to have been a strain of *M. marinum*. *Mycobacterium fortuitum* was isolated from diseased neon fish in 1953 (192) and continues to occur commonly in tropical aquarium species. Mycobacteriosis of Pacific salmon was originally described by Earp et al., in 1953 (173), and the causative organism, *Mycobacterium salmoniphilum*, was cultured, described, and named by Ross in 1960 (193). *M. salmoniphilum* was later shown to be a strain of *M. chelonei* (194), with the species name being corrected to *M. chelonei* (195).

b. Culture — Isolation and culture of the mycobacteria is difficult due to their fastidious nature and slow growth rate. Primary isolation is best achieved on Dorsett egg, Lowenstein−Jensen, Petragnani, or Middlebrook 7H10, with subcultures maintained in capped tubes. If the cell number per gram of tissue is high and contamination is low, general-purpose media such as TSA with 5% sheep blood may be used for primary isolation. Incubation should be at 20−30 °C for 2−30 days. *Mycobacterium fortuitum* is classified as a rapid grower, and colonies should appear in less than seven days on culture media. *M. chelonei* is also classified as a fast grower on subculture, but primary isolation may take several weeks. *M. marinum* is a slow grower, requiring 7−10 days for visible growth and several weeks for typical colonies to develop at 25 °C. Of the three species, only *M. fortuitum* is capable of growth at 37 °C. Selective isolation from contaminated sites on or in the fish may be enhanced by homogenizing the tissue in a grinder and treating it with 0.3% solution of the disinfectant Zepheran® (benzalkonium chloride 17%) for 20 minutes, prior to the adding of several drops of the homogenate to culture media (196). Because of the extended incubation times, care must be taken to keep plated media moist, by incubating in a humid atmosphere.

c. Description — Representatives of all the species of mycobacteria pathogenic to fish are Gram-positive, acid-alcohol-fast, non-motile, non-sporing, pleomorphic rods (1.0−4.0 × 0.2−0.6 μm), with occasional filamentous or

coccoid forms. Colonies of *M. marinum* may vary in their appearance, depending on the culture medium and incubation time. *M. marinum* is said to be photochromogenic, because cultures incubated in the dark will produce white colonies, whereas cultures exposed to light will form yellow to yellow/orange colonies. Other mycobacteria can be photochromogenic, so this characteristic alone cannot be used for identification; however, *M. marinum* does not reduce nitrate and cannot grow at 37 °C, to separate it from similar organisms. Both *M. fortuitum* and *M. chelonei* are nonchromogenic and grow more rapidly than *M. marinum*, producing smoother, white- to buff-colored colonies, and are differentiated from other mycobacteria by their ability to grow on MacConkey agar. *M. fortuitum* is positive on iron-uptake, sucrose-utilization, and nitrate-reduction tests; they separate it from *M. chelonei*, which is negative on these tests. In addition to pigment and growth at 37 °C, *M. marinum* may be differentiated from *M. fortuitum* and *M. chelonei* by positive results for production of nicotinamidase and pyrazinamidase.

d. Epizootiology — Little is known about the epizootiology of mycobacterial infections in fish. The organisms mentioned in this section are all common in the soil and in freshwater and marine environments, and the factors that lead to the development and spread of disease are unknown. Mycobacterial infections are more common in aquarium fish and in food fish cultured in closed or semiclosed recirculating tank systems (197); they are very rare in pond fish. Stress due to overcrowding, to poor water quality, and to ingestion of contaminated food or aquatic detritus have all been mentioned as factors leading to mycobacterial infections. Feeding infected trash fish to cultured Pacific salmon (192) and snakehead (*Channa* sp.) (198) resulted in mycobacteriosis. Vertical transmission has been confirmed in the Mexican platyfish (*Xiphophorus maculatus*), but it has not been confirmed in salmonids (199). Historically, mycobacteriosis has not been the cause of disease in natural fish populations, and it has only rarely been seen as subclinical infections in feral fish (200). In 1997 and 1998, outbreaks of mycobacteriosis in wild populations of striped bass in Chesapeake Bay were documented by Vogelbein (201), with as many as 30 to 50% of the striped bass in certain tributaries reported as having skin lesions. As many as five different species of mycobacteria, including *M. marinum* were isolated from fish in this study, and the underlying cause of the epizootic is under investigation.

e. Geographic range and host susceptibility — Nigrelli and Vogel (202) published a list of 151 species of freshwater and marine fish that were susceptible to mycobacteriosis. That list has continued to grow, and the opinion is generally held that most, if not all fish species are susceptible to the disease. The occurrence of mycobacteriosis is worldwide in both marine and freshwater locations. *Mycobacterium marinum* and *M. fortuitum* are pathogenic to humans, and *M. marinum* causes the condition known as "fish handler's disease" or "swimming pool granuloma." The names result from the tendency for cutaneous granulomas to develop in the skin at the extremities of the body, such as the fingers, the toes, and the outsides of the elbows and the knees. Human infections are confined to the extremities by the optimum temperature range of the bacterium, which is normally 30–33 °C (86–91 °F).

f. Clinical signs of disease and treatment — Mycobacteriosis is a chronic, systemic, progressive, wasting disease that often goes unnoticed in a fish population until a high percentage of fish have become infected. Gross clinical signs include anorexia, emaciation, shallow hemorrhagic skin lesions, ulcers, and fin erosion. Cold-water salmonids may not exhibit all of these signs. Internally, greyish-white miliary granulomas are seen primarily in the spleen and the head kidney, but they may be found in most of the tissues of the fish. Organs such as the spleen and the kidney may be greatly enlarged and have a granular appearance. Treatment of mycobacterial infections, even when an early diagnosis is made, is not economically feasible for food fish. Infected stocks are best destroyed, and the systems disinfected, before new fish are brought in. Cleaning and disinfection of fish systems with HTH, chlorox solution, or chlorine dioxide-based sterilants is best. Care should be taken by fish culturists when handling infected fish, to avoid spine wounds, skin abrasions, and prolonged contact with water containing mycobacteria. More valuable ornamental fish may be treated in accordance with the antimicrobic susceptibility of the strain isolated.

II. *Nocardia asteroides, N. seriolae ("N. kampachi")*. Causative agents of nocardiosis.

The species are discussed together because of the similarity in the disease condition they cause in fish.

a. History — Nocardiosis was first described (from the neon tetra, a tropical freshwater fish), in 1963, by Valdez and Conroy (203). Snieszko et al., described the disease in rainbow trout in 1964 (204) and Campbell and MacKelvie found the disease in brook trout in 1968 (205). The species responsible for these early cases was identified as *Nocardia asteroides*. A second species, *N. kampachi*, was described by Kariya (206) in 1968 as the causative agent of disease in cultured yellowtail in Japan. The name *N. kampachi* was never fully accepted by taxonomists, and in 1988 Kudo et al. (207), proposed the name *N. seriolae* for the causative agent of nocardiosis of Japanese yellowtail. Nocardiosis has become one of the more important diseases in Japanese mariculture, with 262 tons of yellowtail reported lost to the disease in 1989 (88).

b. Culture — Nocardiae are typically less fastidious than the mycobacteria, and they can be cultured on standard media such as TSA with 5% blood and BHIA, although they also grow on Lowenstein–Jensen and Ogawa egg media. Incubation should be between 20 and 30 °C. Colonies of *Nocardia asteroides* appear in 4–5 days; 10 days may be required for *N. seriolae* colonies to appear. Colonies of *N. asteroides* are ridged and folded, are pigmented pinkish-white to yellow-orange, and produce aerial hyphae along the colony margin. *N. seriolae* produces flat and wrinkled colonies.

c. Description — *Nocardia* sp., are gram-positive, weakly acid-fast, nonmotile, long-branching bacilli that, in tissue imprints, resemble mycobacteria. Identification of isolates as *N. asteroides* is based on the physiological and

biochemical description of Gordon and Mihm in 1962 (208). Acid is produced from glucose and glycerol but not from adonitol, arabinose, erythritol, inositol, lactose, maltose, mannitol, raffinose, sorbitol, or xylose. A characteristic of *N. asteroides* is the ability to grow at 37 °C; however, not all isolates of this species from fish are capable of growing at this temperature, and *N. seriolae* does not grow at 37 °C. *N. seriolae* is biochemically very similar to *N. asteroides*, but differs in the sugar fermentation pattern and organic acid utilization patterns reported by Kusuda (209).

d. Epizootiology — Norcardiosis is a slowly developing chronic infection, with accompanying low mortality. It is known to be a normal inhabitant of soil and water, and carrier fish may serve as a reservoir of infection. On rare occasions, mortality rates can be as high as 20% over a two week period, as was reported from cultured Formosan snakehead in ponds on Taiwan (210). Snieszko et al. (204), were unable to transmit *N. asteroides* to rainbow trout by feeding, but injection reproduced the disease in one to three months. Kusuda (209) also succeeded in transmitting the disease in yellowtail by injection or by smearing surface wounds with *N. seriolae*, results indicating a preference for this route of infection.

e. Geographic range and host susceptibility — Nocardiosis has been reported from the United States, Argentina, Germany, Japan, and Taiwan, and the potential exists for its occcurrence on a world wide basis. Thus far, infections with *N. asteroides* have been reported in rainbow trout, brook trout, neon tetra, snakehead, and giant gourami, and *N. seriolae* ("*N. kampachi*") has been reported in the yellowtail.

f. Clinical signs of disease and treatment — Norcardiosis shares many characteristics with mycobacteriosis, and the two diseases are often confused, particularly when histopathology is the only tool used for diagnosis. Young fish are the most vulnerable, but all ages may be affected, particularly in the late summer and early fall. In early stages of the disease in yellowtail, the clinical signs are emaciation, inactivity, and discoloration of the skin. Subcutaneous abcesses appear, later in the infection, in the skin and gill; they are white and about 5 mm (0.44 in.) in diameter. These lesions become histologically tuberculoid, with a fibrous capsule and bacterial filaments located in the center of the lesion. Abdominal distension resulting from internal granulomata may occur. Diffuse granulomatous lesions may be found in the skeletal muscle, in all of the visceral organs (particularly the spleen), and in the mesentery. Little is known concerning the treatment of norcardiosis. Food fish such as the yellowtail have been treated with 4–100 mg (1.8–45.4 mg/lb/day) of sulfamonomethoxine/kg/day for five to seven days, and mortality has been slowed; but a cure has not been reported. In most cases, removal and disposal of infected fish is the proper course of action followed by disinfection of facilities.

F. Gram-Positive Anaerobic Rods

I. Eubacterium tarantellus. Causative agent of eubacterial meningitis of marine and estuarine fish.

a. History — An anaerobic gram-positive rod was determined to be the causative agent of a large fish kill on Biscayne Bay, Florida in 1976 (211). The striped mullet (*M. cephalus*) was the species primarily affected; it exhibited a neurological condition resulting from a bacterial meningitis. In 1977, Udey et al. (212), described the bacterium as a new species, *Eubacterium tarantellus*. The *Catenabacterium* described from epizootics in red drum and grey mullet along the Texas coast is most likely the same organism (9,213).

b. Culture — The organism is readily cultured from the brain and liver on standard media, such as TSA with 5% sheep blood or BHIA plates with anaerobic incubation in a gas pack or other suitable anaerobic chamber at 20 °C for three to five days. Culture plates should be prereduced prior to primary isolation. Tissues from fish, including brain tissue, may be inoculated directly into fluid thioglycollate medium with 1% NaCl and 100 mcg/mL gentamycin incubated at 30 °C.

c. Description — *Eubacterium tarantellus* is a long, unbranched, filamentous, gram-positive, asporogenous rod that can fragment into shorter bacilli of 1.3–1.6 × 1.0–17.0 μm. Good growth occurs between 20 and 37 °C under anaerobic conditions, and colonies on agar media are flat, translucent, approximately 2–5 mm in diameter, colorless, rhizoid, and slightly mucoid. Colonies on blood agar are surrounded by a zone of β-hemolysis.

d. Epizootiology — Under laboratory conditions, the disease cannot be transmitted by direct fish-to-fish contact but can be reproduced by intraperitoneal injection of susceptible hosts, such as the mullet, with the bacterium. This fact had led some investigators to suspect that transmission occurs via external parasites. The organism has an affinity for the brain, the spinal cord, and the liver, regardless of the mode of infection. The salinity tolerance of the organism is 2 ppt, so it would be restricted to low-salinity environments. The bacterium has been found in several species of marine and estuarine fish showing no signs of disease, so some species may serve as carriers of the organism.

e. Geographic range and host susceptibility — The bacterium has been found in a variety of estuarine fishes, including the striped mullet, the snook (*Centropomus undecimalis*), the red drum, and the Gulf flounder (*Paralichthys albigutta*) (213). The range is not well known, but outbreaks of the disease have been restricted to estuaries of the Gulf of Mexico along the coasts of Florida and Texas.

f. Clinical signs of disease and treatment — Eubacterial meningitis is characterized by a neurological impairment that causes erratic swimming behavior of fish near death. Following experimental infection, the progress of the disease is slow, with clinical signs not appearing until 14 to 30 days postinoculation. Affected fish show darkened pigmentation, uncoordinated swimming movements, and inability to maintain proper orientation in the water column. Moribund fish may hang vertically, lie still on the bottom of the tank, swim slowly while rotating about their long axis, or whirl. Little is available in the literature concerning treatment of this disease; however, suggestions include the controlling of ectoparasites and

the use of erythromycin- and oxytetracycline-medicated feed at 100 mg/kg/day (45.4 mg/lb/day) for 5 days.

II. *Clostridium botulinum, Clostridium* spp. *Clostridium botulinum* and other *Clostridium* species have been isolated from diseased cultured fish on several occasions, but their significance in aquaculture is uncertain and therefore is not covered in detail. Isolation of strictly anaerobic, gram-positive rods with subterminal or terminal ovoid endospores would indicate the possibility of *Clostridium* spp.

G. Miscellaneous Bacterial Agents: Gliding, Flexing, and Yellow-Pigmented Gram-Negative Bacteria

I. *Flavobacterium columnare* ("*Bacillus columnaris, Chondrococcus columnaris, Cytophaga columnaris, Flexibacter columnaris"*). Causative agent of columnaris disease.

a. History — Columnaris disease was first described by Davis in 1922 (214) in warm-water fish from the Mississippi River, but it was not until the work of Ordal and Rucker in 1944 (215) that the organism was isolated, characterized, and named *Chondrococcus columnaris*. Davis originally named the organism *Bacillus columnaris*, inspired by the formation of columnar masses of cells that were visible microscopically on wet mounts of infected fish tissue. A year following the work of Ordal and Rucker, Garnjobst published an account of isolation of the bacterium and assigned it to the genus *Cytophaga* (216). The bacterium has been renamed and reclassified several times over the years on the basis of morphological and biochemical features, having been referred to at various times as *Chondrococcus columnaris*, *Cytophaga columnaris*, and *Flexibacter columnaris* (9). The currently accepted name for the organism, *Flavobacterium columnare*, was adopted in 1996, as suggested by Bernardet (217); however, total agreement has not been achieved, as evidenced by the opinion of Bader and Shotts, following their work on sequence analysis of the 16s ribosomal-RNA genes of *F. columnare* and other closely related organisms in this group (218), that the genus *Flexibacter* should be retained.

b. Culture — Culture of *F. columnare* may be accomplished on a variety of low-nutrient, low-agar-content media. The commonly used medium is the cytophaga agar (CA) of Anacker and Ordals (219); however, shorter incubation times and higher yields may be obtained in media containing salts, such as Shieh medium (220). Selective isolation of columnaris can be achieved from contaminated external sites such as the skin and gills on selective cytophaga agar (SCA) (221) or on Hsu-Shotts (HS) medium (222). *Flavobacterium columnare* may be incubated at 10−33 °C, but primary isolation plates are typically incubated at 28−30 °C. Pale yellow rhizoid colonies are present after 48 hours of incubation. A dilute form of Mueller−Hinton medium must be used for antimicrobic susceptibility testing (with disc diffusion methods) or for determination of minimal inhibitory concentration (MIC) in broth (221).

c. Description — Long, slender, gram-negative rods (0.3−0.5 × 3−10 μm), motile by gliding on surfaces, nonmotile in suspension except for flexing movement, with formation of columnar aggregates of cells on infected tissue (often referred to as "haystacks"). The physiological characteristics of *F. columnare*, as described by Bernardet and Grimont (223), are the following: strict aerobic growth; no acid produced from carbohydrates; positive for cytochrome oxidase and catalase; nitrate reduced to nitrite; positive for hydrogen sulfide; cellulose, chitin, starch, esculin, and agar not hydrolyzed; gelatin, casein, and tyrosine hydrolyzed; arginine, lysine, and ornithine not decarboxylated; flexirubin pigments produced. The NaCl tolerance is reported as 0.5%, but this may be variable. Griffin (224) devised a simple method of identifying *F. columnare*, using five characteristics that separate it from other yellow-pigment-producing aquatic bacteria:

1. Ability to grow in the presence of neomycin sulfate and polymyxin B
2. Colonies on CA plates typically rhizoid and pigmented pale yellow
3. Production of gelatin-degrading enzymes
4. Binding of congo red dye to the colony
5. Production of a chondroitin sulfate-degrading enzyme.

d. Epizootiology — Columnaris disease is one of the most common diseases in freshwater aquaculture worldwide, affecting a wide variety of species. It may occur as a secondary infection following stress or injury or as a primary infection. Columnaris disease most often occurs as an external infection of the skin, the fins, or the gills, but it has been isolated systemically from fish showing no external clinical signs. These internal isolates may indicate a systemic form of the disease; however, histopathological lesions are often lacking. Mixed infections involving other bacterial pathogens are also common. Hawke and Thune (221) found from 99 different cases of bacterial disease in catfish ponds in Louisiana,U.S.A. that columnaris disease was diagnosed in 53.5% of the submissions. In this study, *F. columnare* was the sole etiological agent in 7.0% of the cases; it was present in mixed infections with other pathogens (i.e., *Aeromonas* spp., *E. ictaluri*, and *E. tarda*) in 46.5% of the cases. Transmission of columnaris disease is typically from fish to fish via the water, but stress resulting from handling and poor water quality exacerbates the disease. Survival of *F. columnare* is poor in water with pH less than 7.0, with hardness less than 50 mg/L (ppm), or with low organic matter. Only 35% of inoculated cells survive for one week in sterile pond water at 20 °C (68 °F); this result indicates a need for carrier fish to maintain the organism in the aquatic environment (225).

e. Geographic range and host susceptibility — Columnaris exists worldwide in a variety of freshwater habitats. The channel catfish is the most severely affected aquaculture species in the U.S.; however, golden shiners, fathead minnows, hybrid striped bass, and goldfish are susceptible. In Europe and Asia, columnaris is a problem in cultured eels and in common carp. Salmonids and cultured

centrarchids are also susceptible under permissive water temperatures. Anderson and Conroy (226) listed 36 species of fish from which columnaris disease had been described, and most species of fish are considered susceptible to infection.

f. Clinical signs of disease and treatment — Columnaris disease is characterized by shallow, white-to-yellowish focal patches of necrosis in the skin, often extending around the dorsal fin (hence, the term "saddleback"). Necrotic foci in the gills may also be observed, and lesions often appear brown or muddy, a coloration due to clay particles or detritus trapped in the slime secreted by the bacteria. Secondary infection of skin lesions by *Aeromonas* spp., is common and results in deeper, liquefactive lesions in the muscle. On catfish, the infected skin loses its natural sheen, and a grey-to-white margin surrounds the lesion. The mouth and inner walls of the oral cavity may be covered with a yellowish mucoid material. Scraping those areas and observing wet mounts of the tissue microscopically at 400× allows the investigator to observe the typical thin, filamentous, flexing rods and "haystack" formation described previously. This method of diagnosis is commonly used, although it is advisable to isolate the bacterium in pure culture and to run confirmatory biochemical tests or serology, for reliable identification. Improved husbandry and water quality conditions can help prevent columnaris disease, but, once an outbreak has occurred, only two basic methods of treatment are available. External columnaris may be treated by adding potassium permanganate to the water at 2 ppm over the permanganate demand. Potassium permanganate imparts a red color to the water and this color should persist for four to five hours for an effective treatment. Potassium permanganate is on deferred status by the USFDA: though currently permitted for use on food fish, it is not yet fully approved, and it may be made illegal in the future if new evidence finds it to be unsafe. Feeds medicated with Romet® or Terramycin® are effective for controlling columnaris disease, although they are not labeled specifically for treatment of this disease in the United States (227). Maintaining a salinity of 5 ppt is inhibitory to the development of columnaris disease.

II. Flavobacterium branchiophilum ("F. branchiophila"). Causative agent of bacterial gill disease.

a. History — Bacterial gill disease (BGD) of salmonids was originally described by Davis in 1926, from a salmonid fish hatchery (228). The primary etiological agent of BGD, *Flavobacterium branchiophila*, was described in 1989 by Wakabayashi (229), and the name of the bacterium was revised in 1990 to *F. branchiophilum* (230). *Cytophaga aquatilis* was also described as a causative agent of BGD by Strohl and Tait (231); this bacterium has been renamed *Flavobacterium hydatis* (217). It is suspected that other related *Flavobacterium* spp., *Cytophaga* spp., and *Flexibacter* spp., play an opportunistic role in BGD (7). The disease is now known to be multifactorial; degraded environmental conditions work in concert with bacteria to produce the classic lesions of BGD.

b. Culture — Primary isolation of *Flavobacterium branchiophilum* and related organisms associated with

BGD is on cytophaga agar (CA). *Flavobacterium branchiophilum* is somewhat fastidious and grows slowly, producing 0.1–1.0 mm yellow, round, transparent, colonies on CA after two to five days of incubation at 25 °C. The organism grows between 10 and 30 °C, but not at 37 °C.

c. Description — Long, thin, gram-negative rods (0.5 × 5 to 8 μm); nonmotile by any mechanism; oxidase-positive; gelatin, casein, and starch hydrolyzed, but not chitin or esculin; acid produced from glucose, fructose, sucrose, maltose, and trehalose.

d. Epizootiology — The epizootiology of BGD is confusing, because many different etiologic agents have been implicated, and attempts to fulfill Koch's postulates with various isolates have failed. *Flavobacterium branchiophilum* has been successfully transmitted, and BGD was experimentally induced in the laboratory, but extreme environmental stress was required to initiate infection. It is now accepted that BGD is initiated following injury to the gills by chemical or physical irritants (7). If excess feed or detritus is present in the water column, these particles may become impinged in the hyperplastic and mucus-slime-covered gills and cause asphyxiation. Salmonid fry and fingerlings less than 5 cm (2 in.) in length are most susceptible to BGD, and mortality rates in affected populations can be as high as 80% over a one-week period. The survivability of *F. branchiophilum* in water is unknown, but infection is believed to be transmitted from fish to fish. Disease outbreaks commonly occur between 12 and 19 °C.

e. Geographic range and host susceptibility — Bacterial gill disease has been found in most parts of the world where fish are cultured in intensive freshwater systems. *Flavobacterium branchiophilum* has been reported from Japan, the United States, Hungary, the Netherlands, and Canada. Many species of fish are susceptible to BGD; however, the cultured species most affected are all of the salmonids, the common carp, goldfish, channel catfish, eels, and fathead minnows (232).

f. Clinical signs of disease and treatment — Bacterial gill disease is diagnosed by microscopic examination of diseased gill tissue. The presence of tufts of filamentous bacteria between hyperplastic secondary lamellae are indicative of the disease. Culture on CA is recommended for isolation and identification of *F. branchiophilum* and other related organisms. Bacterial colonization and fusion of the gill lamellae begins on the distal end of filaments and results in "clubbing" of the gills. Maintenance of good water quality and reduction of stress is the best method for controlling BGD. Disinfectants such as benzalkonium chloride have been used successfully at 1–2 mg/L (ppm) for one hour for treating infected salmonids in raceways, but the margin of safety is small. Chloramine-T at 8–10 mg/L (ppm) for one hour is the most effective treatment for BGD; however, neither of these compounds is currently approved by the USFDA for treatment of food fish (7,8).

III. Flavobacterium psychrophilum ("Cytophaga psychrophila, Flexibacter psychrophilus"). Causative agent of bacterial cold-water disease. Synonym: peduncle disease.

a. History — A disease of salmonids originally referred to as "peduncle disease" was described by Davis in 1946

from the eastern United States (233). This observation of a characteristic open lesion on or near the caudal peduncle led to the common name first used for the disease. The causative bacterium was isolated, was described, and was named *Cytophaga psychrophila* by Borg in 1960 (234); however, Bernardet and Grimont, using DNA relatedness techniques, renamed the organism *Flexibacter psychrophilus* (223). The bacterium has recently received additional reclassification; it is currently named *Flavobacterium psychrophilum* (217).

b. Culture — Primary isolation is on cytophaga agar (CA) incubated at 15–20 °C. After 48–96 hours incubation, 1–5 mm, bright yellow, raised, convex colonies with a thin spreading irregular edge are visible. Improved growth is reported for this organism in Shieh broth and Shieh agar media (220) and in tryptone-yeast extract (TYE) (8). Generally, growth is limited on standard media such as TSA. The organism grows at temperatures between 4 and 25 °C. No growth is detectable at 30 °C.

c. Description — Long, slender, Gram-negative rods, (0.3–0.75 × 2–7 μm), but filamentous forms 10–40 μm in length are occasionally observed. The bacterium is motile by gliding on solid surfaces, nonmotile in suspension. The physiological characteristics of *F. psychrophilum*, as described by Bernardet and Grimont, are: strict aerobic growth; no acid produced from carbohydrates; oxidase-negative; catalase-positive; negative for hydrogen sulfide; hydrolysis of casein, gelatin, albumin, elastin, tyrosine, and collagen; no hydrolysis of agar, cellulose, starch, or chitin; flexirubin pigments are produced. The NaCl tolerance is 0.5 to 1.0%.

d. Epizootiology — Bacterial cold-water disease (BCWD) appears in the early spring at hatcheries, when water temperatures are between 4 and 10 °C (39–50 °F), and the severity of the disease depends on the age and development of the affected fry. In sac fry, the mortality rate may be as high as 50%, but, when the disease occurs in fingerlings in rearing units, losses are usually less than 20%. Experimental infection was induced by Holt (235) in coho and chinook salmon and in rainbow trout at temperatures of 3 to 15 °C (37–59 °F), but, above 15 °C, the severity of the disease was greatly reduced. The natural reservoir of the bacterium is not understood, but it is generally believed that transmission is from fish that serve as carriers of the organism.

e. Geographic range and host susceptibility — Bacterial cold-water disease occurs throughout the trout- and salmon-growing regions of North America, Europe, and Japan. It is a serious problem in the northwestern United States and western Canada. All salmonid species are believed to be affected, but coho salmon are particularly susceptible (8). The nonsalmonids affected include European eels, carp, tench (*Tinca tinca*), and crucian carp (*Carassius carassius*).

f. Clinical signs of disease and treatment — The clinical signs of BCWD vary with the size and the age of affected fish. When the disease occurs in sac fry, the primary sign is erosion of the skin covering the yolk sac. Older fish exhibit lethargy, spiral swimming behavior, and the classic shallow peduncle lesion. The caudal peduncle of affected fingerlings first turns white; the skin then becomes necrotic and is sloughed off, leaving exposed underlying muscle tissue. Lesions can also occur laterally, dorsally, or on the isthmus. Internally, petechiae may be observed in the liver, pyloric cecae, adipose tissue, heart, swim bladder, and peritoneal lining. Outbreaks of BCWD are difficult to treat, because the infection is systemic and because affected fry do not feed. Bath treatments with water-soluble Terramycin® at 10–50 mg/L (ppm) and with quaternary ammonium compounds at 2 mg/L (ppm) are effective when infections are confined to the skin. For systemic infections, oxytetracycline in the diet at 50–75 mg/kg of fish/day (23–34 mg/lb) for 10 days has been found to be effective (7,8).

IV. Flexibacter maritimus ("Cytophaga marina"). Causative agent of salt water columnaris. Synonym: black patch necrosis of Dover sole (*Solea solea*).

a. History — A marine form of columnaris disease was described as early as 1960 by Borg (234), and a detailed account of a columnaris-like disease in juvenile red sea bream in Japan was given by Masumura and Wakabayashi (236). *Flexibacter maritimus* was first described in 1986 from a variety of marine fish species in Japanese aquaculture by Wakabayashi (237). An organism described as the causative agent of "black patch necrosis" of cultured Dover sole in Scotland (238) was later determined to be *F. maritimus*. Recently, *F. maritimus* has been found to be the cause of mortality in farm-reared sea bass in France (239) and in turbot, Atlantic salmon, and coho salmon cultured in Spain (240). Chinook salmon reared in sea cages in southern California, as well as white sea bass (*Atractoscion nobilis*), northern anchovy (*Engraulis mordax*), and Pacific sardine (*Sardinops sagax*), have been diagnosed with *F. maritimus* infections (241).

b. Culture — This bacterium must be cultured on cytophaga agar (CA) prepared with at least 30% sea water. Addition of sodium chloride to CA is not sufficient to culture the organism. Incubation is at 25–30 °C; however, growth can occur between 15 and 34 °C (8). A selective medium for the isolation of *F. maritimus* from external lesions has been developed in Spain (240).

c. Description — Long, slender, gram-negative rods, 0.5 × 2.0–10.0 μm, with occasional filamentous forms 30 μm in length; motile by gliding on solid surfaces, nonmotile in suspension except for flexing; and formation of columnar aggregates of cells on infected tissue. *Flexibacter maritimus* produces catalase and cytochrome oxidase and hydrolyses casein, gelatin, tributyrin, and tyrosin. Hydrogen sulfide is not produced; acid is not produced from carbohydrates and agar; cellulose, chitin, starch, and esculin are not degraded. Nitrate is reduced to nitrite. Flexirubin pigments are not produced.

d. Epizootiology — Saltwater columnaris of red sea bream occurs in the spring after transfer of juveniles from the hatchery to inshore net cages. The disease rarely affects sea bream greater than 60 mm (2.3 in.) in length. Stress occurring during the transfer period is believed to be responsible for initiation of infection. Black patch necrosis occurs in juvenile Dover sole between 60 and 100 days of age and occurs more frequently in the summer.

e. Geographic range and host susceptibility—*Flexibacter maritimus* is confirmed from red sea bream, black sea bream, and flounder in Japan and from the Dover sole in Scotland; however, it is speculated that many species of marine fish are susceptible to the disease. Sea-cage reared salmonids are also susceptible on the Pacific coast of the United States (241) and off the coast of Spain (239).

f. Clinical signs of disease and treatment—The clinical signs of saltwater columnaris and of black patch necrosis are similar to those of columnaris disease in fresh water species. (See sections G, I, and F of this entry). Avoiding overcrowding, overfeeding, and stress is the best means of managing the disease; antibiotic feeds have met with little success. Addition of a sand substrate to tanks containing juvenile Dover sole greatly reduced the incidence of black patch necrosis (238).

H. Obligate Intracellular Bacteria

I. Piscirickettsia salmonis. Causative agent of salmonid rickettsial septicemia. Synonyms: coho salmon syndrome, Huito disease.

a. History—Salmonid rickettsial septicemia (SRS) of coho salmon was first noticed in Chile as early as 1981, but it was not until 1991, in the published account of Cvitanich (242), that a formal description of the disease was given and the disease was formally named. The incidence of the disease has increased over the years; currently, it is the major problem affecting salmonid aquaculture in Chile. The organism was formally recognized as belonging to a new taxon, and the name *Piscirickettsia salmonis* was proposed by Fryer (243). This name currently has valid standing. Since 1988, the disease has been recognized as a problem on 51 farms on the west coast of Norway in cage-reared Atlantic salmon (244).

b. Culture—Attempts to culture *P. salmonis* on artificial media have been unsuccessful. The organism must be grown in cell culture, on cell lines of salmonid and non-salmonid origin; chinook salmon embryo CHSE-214 is the cell line of choice for isolation from infected kidney tissue. Incubation is at 15–18 °C, and cytopathic effect is witnessed within five to six days.

c. Description—*Piscirickettsia salmonis* is an obligate intracellular pathogen. The cells are pleomorphic but are predominantly gram-negative cocci ($0.5 \times 1.5–2.0$ μm) that are nonmotile.

d. Epizootiology—Salmonid rickettsial septicemia was first reported from the southern coast of Chile in salmonids reared in sea cages. There are no indigenous salmonids on the Pacific coast of South America; it is theorized that *P. salmonis* originated from local marine fish species and infected the introduced salmon. Samples of various ectoparasites of Chilean salmon revealed positive identification of *P. salmonis* from *Cerathothoa gaudichaudii*, a hematophagous external parasite now believed to be a vector for the disease (245).

e. Geographic range and host susceptibility—Once thought to be restricted to salmonids in Chile, the disease has now been reported from Atlantic salmon in Norway (244). Experimental infections have been achieved in coho salmon and rainbow trout (246).

f. Clinical signs of disease and treatment—Infected fish gather at the surface of cages and exhibit lethargy and inappetence. External signs include darker-than-normal coloration, pale gills, and hemorrhagic skin lesions. Internally, the fish exhibit ascites, peritonitis, and pale discoloration of swollen organs. The gastrointestinal tract, swim bladder, and fat deposits may have petechial hemorrhages. The disease is not apparent in the freshwater stage of culture; it does not appear until 6–12 weeks after transfer to seawater. The organism is sensitive to some antibiotics, among them clarithromycin, chloramphenicol, erythromycin, gentamycin, oxytetracycline, sarafloxacin, and streptomycin, but it is not sensitive to penicillin (8,9).

BAITFISH CULTURE

NATHAN STONE
University of Arkansas at Pine Bluff
Pine Bluff, Arkansas

OUTLINE

Baitfish is a general term used to describe live fish sold for fishing bait or as "feeders," fish fed to ornamental fish and to invertebrates with piscivorous food habits. Over 20 species of fish are caught from the wild and used for bait, while relatively few, ubiquitous species are raised on farms. Major farm-raised species are the golden shiner (*Notemigonus crysoleucas*), the fathead minnow (*Pimephales promelas*) and the goldfish (*Carassius auratus*). Retail sales of baitfish for recreational fishing in North America have been estimated at $1 billion annually (1). Unique aspects of baitfish farming, as compared to food fish culture, include the vast numbers of individual fish produced, the variety of sizes required by the market, and the relatively greater importance of market forces. Arkansas farmers alone sell over six billion baitfish annually, so it is easy to see why fish propagation and early rearing of fry are critical aspects of baitfish culture. To produce a variety of fish sizes, farmers manipulate stocking and feeding rates to control growth while maintaining fish health. Fish are judged on appearance and must remain vigorous through the often-complex marketing process. Demand for bait is highly volatile, seasonal, and sensitive to weather conditions. Customer preferences vary widely in different regions. There is fierce competition in marketing baitfish.

DEVELOPMENT OF BAITFISH FARMING

Use of natural fish foods as bait is an ancient and common practice and over 75% of freshwater game fish caught are captured using some form of live bait (2). As an aquacultural product, baitfish rank third or fourth in value in the United States, and estimates based on industry surveys are thought to be of low accuracy, (3) due to under-reporting by farmers and wholesalers (4). In addition to recreational fishing and feeder fish markets, baitfish are also used in certain commercial saltwater fishing operations (5,6).

Sources of baitfish include wild capture, extensive culture, and intensive culture. Statistics are limited, but perhaps only half of all baitfish are farm raised. In the past, virtually all baitfish were captured from the wild. The Great Lakes supported a large fishery for emerald (*Notropis atherinoides*) and spottail (*Notropis hudsonius*) shiners (7) and schools of minnows were said to be so dense that upwards of 100,000 could be captured in one scoop of a large dipnet (8). In many areas, collecting small fish for bait from the wild is still legal and commercial fishermen use seines or traps to remove fish (3,9,10). Research by Brandt and Schreck (11) evaluated the effects of baitfish harvesting and found no significant impact on the densities of bait or game fishes in the study stream. However, wild-caught bait is often a mix of fish species, and its use can potentially affect recipient water bodies (1). Introduction of nonindigenous species by bait bucket transfer was judged to be almost a certainty by Ludwig and Leitch (12). Concerns regarding undesirable fish introductions from wild-caught bait were expressed as early as 1952 by Miller (13), who developed a key to 32 species of fish sold as bait along the lower Colorado River.

Extensive culture refers to the practice, in northern states, of raising seasonal crops of fathead minnows or white suckers in shallow (pothole) lakes. Adult fathead minnows or white sucker fry are stocked in the spring, allowed to grow (and spawn, in the case of fatheads), and then harvested before the next winter. These "winter-kill" lakes are so-named because they usually freeze solid during the winter, and remaining fish are killed. Yields are relatively low, as fish are raised on natural foods alone, but costs are also minimal.

Intensive baitfish farming was initially promoted as a solution to the shortages of minnows experienced in the 1930s and 1940s in Michigan and other north central states. As early as 1934, the Michigan Department of Conservation conducted research on the propagation of minnows (14). The first baitfish farms in Arkansas began in the late 1940s. Baitfish are raised in many states, but production is concentrated in Arkansas. Arkansas had an estimated 11,251 hectares (27,800 acres) of ponds that produced fish in 1997, with a farm-gate value of $51.6 million (15).

Relatively little research has been conducted on baitfish culture, perhaps due to the highly insular and competitive nature of the baitfish industry. Davis (16) and Brown and Gratzek (17) conducted comprehensive reviews of baitfish culture and marketing. Extension manuals on baitfish farming published over the past 60 years have served as the primary sources of industry information (18).

CULTURE METHODS

A wide variety of culture techniques are used for producing baitfish. Methods vary with species and from farm to farm. Marketing and distribution networks and market volatility exert such a powerful influence on the feasibility of the baitfish business that efficiency in production is of secondary importance. Individual farms may specialize in one species or raise a variety of baitfish species. Fish species raised for bait are easily propagated, hardy, fast growing, widely distributed, and attractive to game fish. Most baitfish are minnows, members of the family Cyprinidae. In a food selectivity study, northern pike were found to prefer soft-rayed fish (e.g., minnows) to spiny-rayed fish (e.g., perch or bluegill) of similar size (19). Golden shiners are the primary bait species, and goldfish the primary feeder fish species. Fathead minnows are sold mainly as bait, although limited quantities of small "rosy-red" fathead minnows are also marketed as feeders. A color variant of the normal fathead minnow, rosy red fatheads sell for more than twice the price of normal-colored fish, but commercial production in outdoor ponds is problematic due to poor survival (20,21). A limited number of larger goldfish are sold as trotline bait (also "trot-line" or "trout-line," a method of fishing where unattended lines are attached to limbs or floats) or as ornamental fish for garden pools.

Facilities

Most baitfish are raised in earthen ponds similar to those used for channel catfish culture. Typical pond size varies

with the species being raised. Ponds used for golden shiners are often 2 to 8 hectares (5 to 20 acres) in size, while ponds up to 4 hectares (10 acres) are used for fathead minnows. Feeder goldfish are best raised in smaller ponds (0.8 hectares or 2 acres), as fish density must be carefully controlled to keep fish small. The trend is toward smaller ponds, as farmers increase stocking and feeding rates. Water depth is kept shallow (0.8 to 1.8 m; $2\frac{1}{2}$ to 6 ft) so that farm crews can harvest fish without draining. Pond levees are normally a minimum of 3.7 m (12 ft) wide to permit passage of farm trucks, and at least one levee of each pond should have a good gravel surface for all-weather access to fish, for the purposes of feeding and harvest.

Groundwater (well water) is used almost exclusively in baitfish culture. Surface water often contains wild fish, which, if introduced into production ponds, would compete with, or prey upon, the small baitfish. Wild fish would also require manual removal from bait species before shipment, a difficult and costly procedure. Fine mesh, self-cleaning mechanical filters are used to screen surface water, when it is used.

Estimates of water requirements for baitfish farming vary but at least 190 to 470 L/min/ha (20 to 50 gal/min/acre) is desirable. To prevent aquatic weeds from becoming established, enough water should be available to fill a pond within 7 to 10 days. Baitfish farmers routinely capture and reuse pond water in order to reduce groundwater consumption. As ponds are drained, water is relifted (using pumps) into other ponds. Farmers also fill ponds to less than the maximum capacity, leaving room for the capture of rainwater.

Harvested baitfish are held in vats, in a minnow shed, before shipment to market. Vats are shallow tanks, usually constructed of cement-covered blocks or concrete. Minnow sheds vary in size from small, open-sided shelters covering a dozen or so vats to fully enclosed buildings with dozens of vats. Larger sheds may have offices and break rooms as well as drive-through doors that allow workers to load hauling trucks indoors.

Propagation

Spawning techniques are similar for golden shiners and goldfish. Both species reproduce by scattering adhesive eggs over vegetation, and no parental care is given to the eggs. Both species will spawn multiple times during the spawning season. Goldfish begin spawning when the water temperature exceeds 16 to 18 °C (60 to 64 °F), while golden shiners start spawning at 20 to 21 °C (68 to 70 °F).

Traditionally, golden shiners and goldfish have been propagated using either the wild-spawn or egg-transfer method. In the wild-spawn method, broodfish are stocked into newly flooded ponds, which have margins or strips of standing vegetation. Fish spawn freely on the vegetation, and the resulting young may be raised with the parent fish or juveniles may be transferred to separate ponds. Reproductive success using this method is unpredictable. After the initial spawning, subsequent generations of eggs and fry are subject to intense predation by their older siblings. Young fish are often attacked by parasites spread

from the broodfish (22). To increase fry production, most baitfish farmers use the egg-transfer method.

In the egg-transfer method, 3.8-cm (1.5 in.) thick spawning mats are used to collect eggs. Spanish moss was once commonly used, but producers have switched to a mat material made of latex-coated coconut fibers on a polyester mesh backing. This material was originally designed for (and is still used) as a heating and air-conditioning filter. Typically, 46 × 76 centimeter (18 × 30 in.) sections of mat material are sandwiched within a supporting wire mesh. Mats are placed level with the pond surface along the edges of brood ponds, at a depth of 2 to 5 centimeters (1 to 2 in.) (Fig. 1). Wooden stakes are used to hold the mats in place, or mats may be placed on floating racks. Alternatively, eggs are collected on weighted 3- to 4-m (10 to 12 ft) lengths of mat material placed in shallow water. After 24 hours, mats with eggs are transferred into a rearing pond containing a shallow layer of fresh well water, for incubation and hatching. Eggs hatch in 3 to 7 days, with warmer temperatures promoting faster development.

Stocking rates for eggs vary widely. Ponds are stocked lightly if rapid growth is desired, while other ponds may be stocked heavily with the aim of spreading out fish later. A single mat may contain from 5,000 to 250,000 eggs, and farmers transfer from 125 to 500 mats per hectare (50 to 200 mats per acre). As a result, ponds may be stocked with

Figure 1. Spawning mats staked along the edge of a golden-shiner brood pond.

upwards of 5 to 10 million eggs per hectare (2 to 4 million eggs per acre) for golden shiners, resulting in 1 to 4 million fry per hectare (0.5 to 1.5 million per acre). Feeder goldfish eggs are stocked at up to 25 million per hectare (10 million eggs per acre).

Incubating eggs are attacked by fungus, and eggs within the mats may be subjected to low dissolved-oxygen levels, even when pond levels are adequate (23). Fungus is thought to be the major cause of egg loss, and hatching rates were found to be less than 32% (average of 22.5%) even when mats were held in aerated tanks (24). Hatching eggs in indoor tanks was proposed by Morrison and Burtle (25) as a way to increase hatching rates and to allow stocking known numbers of fry into rearing ponds. Additional research has been conducted over the past decade, and within the last two years, a number of major Arkansas baitfish producers have adopted tank hatching methods. Egg survival is greatly improved, as eggs can be treated for fungus, and thus fewer brooders are needed. In commercial hatcheries, eggs are generally left attached to spawning material for incubation. Alternatively, sodium sulfite has been shown to be effective in removing golden shiner eggs from spawning mats (26), and detached eggs can be incubated in hatching jars (27).

In the tank hatching method, eggs are treated daily for fungus until eggs are eyed (the eye of the developing larvae becomes dark with pigment). Water is sprayed into tanks for aeration and to flush ammonia. Once fry hatch, they are held in tanks a day or two until the majority are able to swim freely. A 100- to 150-micron particle size feed (28) is offered to sustain older fry, but the efficacy of this practice is questionable, as newly hatched cyprinid fry are apparently unable to utilize prepared feeds fully (29). Fry are then harvested from hatching tanks, numbers are estimated, and fry are placed in plastic bags for transport to rearing ponds.

Newly hatched goldfish fry are approximately 4.5 to 5 mm (0.2 in.) in length (30,31), larval golden shiners range in length from 3 to 6 mm (0.1 to 0.2 in.) (32,33), and fathead minnows, 4 to 6 mm (0.2 in.) (32). These tiny fish are subject to predation by aquatic insects, especially backswimmers (34) and predaceous copepods (35). If necessary, baitfish farmers prepare fry ponds using the insecticide Baytex, for controlling predaceous insects, or Dylox, for copepod control (36).

A recent trend is to spawn broodfish in shallow tanks instead of ponds. This practice helps farmers extend the natural spawning season and keep mats free of debris that would interfere with tank hatching. Fish can be spawned indoors in the spring before they normally can be spawned in ponds, or fish can be spawned throughout the summer months, when reproduction does not occur naturally (37,38). Feeder goldfish producers developed the first commercial systems, which have since been used for golden shiners as well.

Fathead minnows reproduce by laying adhesive eggs on the undersides of floating and submerged objects. Eggs are small, slightly over 1 millimeter (0.04 in.) in diameter (39,40). Fathead minnows start spawning at 15 to 18°C (59 to 64°F), and will continue to spawn until the water temperature exceeds 29°C (85°F) (41).

Gale and Buynak (42) determined fecundity and spawning frequency for five pairs of fathead minnows. On average, females spawned every 4 days (range, 2 to 16 days) during the spawning season. Total number of clutches per female over the 3-month study was 16 to 26, and total egg production per female for that period was 6,803 to 10,164 (mean = 8,604). Fathead males have been shown to release chemical compounds that are attractive to females (43).

Typically, fathead minnow producers use the wild-spawn method of reproduction (41,18). Broodfish are stocked into ponds and allowed to spawn. The optimum sex ratio for broodfish in ponds is 5 females:1 male (44,45). Male fatheads are generally larger than the females, and a #15 or #16 grader (slot width of 0.60 to 0.64 cm, 15/64 to 16/64 in.) is used to separate broodstock by sex. Farmers use plastic tarps, plastic irrigation tubing, wooden pallets, plywood, or even cardboard as spawning substrate. Young fish are left in the same pond with the adults, and fish for sale are periodically harvested. Yields are low (on average, 392 kilograms per hectare; 350 pounds per acre) (15), probably because older siblings or other predators eat many new fry. Producers may also move the spawning substrate with the eggs or transfer juvenile fish to new ponds at rates of 124,000 to 740,000 per hectare (50,000 to 300,000 per acre). Feeder fish are stocked at higher rates.

Fry Transfer Method

Although commonly listed as a method of propagation, "fry transfer" is simply stocking of ponds through transfer of juvenile fish. Once a new crop of fish reaches about 2 to 3 cm (0.8 to 1.2 in.) in length, the juvenile fish are hardy enough to withstand being harvested and transferred to other ponds. Golden shiners are stocked at 124,000 to 500,000 per hectare (50,000 to 200,000 per acre), while goldfish are stocked at 1 to 4 million per hectare (0.5 to 1.5 million per acre).

Fertilization

Rearing ponds are fertilized after the transferred eggs hatch or in preparation for stocking fry to promote the development of natural foods. A combination of organic and inorganic fertilizer is applied to fry ponds, while inorganic fertilizer alone is applied to maintain algae blooms in ponds with older fish. In the past, baitfish farmers used fertilizers extensively throughout the growing season, but usage has decreased, as feeding rates have increased.

Natural Foods, Nutrition, Feeds, and Feeding

Golden shiners are sight feeders adapted to feeding on zooplanktons, but they also eat a wide variety of other animal and plant materials (46–48). Young goldfish feed heavily on zooplankton, then become more omnivorous with age, feeding on algae and detritus as well as small invertebrates (49,50). The goldfish has a long digestive tract, twice that of its body length (51). Fathead minnows are primarily algae eaters, but animal foods such as

zooplankton and insect larvae are also consumed (52,53). All three species readily accept prepared feeds.

Nutritional requirements for baitfish species are poorly understood and what knowledge exists usually is not reflected in commercial diets. Lochmann and Phillips (54) summarized current baitfish nutrition and feeding practices. Commercially-available baitfish feeds are similar, if not identical, to those used for channel catfish, yet high-fat diets may be beneficial for baitfish, to improve fish vigor and stress resistance (55). Amino acid requirements for baitfish are similar to those of common carp and channel catfish (56). In the absence of natural foods, optimal protein level for golden shiners and goldfish was found to be 29% (57). Formulation of practical diets for baitfish is complicated by the presence of natural foods, which form an important part of the diet of cultured fish even when complete feeds are provided (58,59). In a pond study, Lochmann and Phillips (60) found that growth, yield, and survival of golden shiners was unaffected by the presence or absence of a vitamin and mineral supplement in the prepared feed.

Feeding is now a standard practice in baitfish culture, as it can double or triple yields over those produced from natural foods alone. In raising baitfish, as compared to catfish production, feed is a relatively small proportion of total costs (61). Farmers feed newly hatched fish finely ground powdered feed called meal several times a day at rates of 2 to 11 kg/ha (2–10 lb/acre) per day. As fish size increases, farmers switch to crumbles (crumbled extruded pellets), and then to pelleted feeds. Feeding rates increase with fish size up to 22 to 28 kg/ha (20 to 25 lb/acre) per day for golden shiners and 45 to 56 kg/ha (40 to 50 lb/acre) per day for goldfish. Over the winter, fish are fed on warmer days, and feeding at 2% body weight per day is recommended for high fish production (21). Feeding rates for fish vary widely depending on the intended market.

In an aquarium study that measured weight gain of golden shiners, pelleted feeds were found to be superior to meal, but that difference was not seen in a corresponding pond trial (62). Floating feed offers farmers the advantage of being able to see their fish, and feeding response is used to estimate pond inventories. Increasing the daily feeding rate generally increases the size of baitfish, but not always the yield (21,63,64). In ponds that are fed and managed identically, differences in water quality, natural foods, and fish survival result in wide variations in fish sizes and yields.

Water Quality

During the production season, farmers monitor water quality in production ponds. Baitfish farmers have increased their use of aeration as stocking and feeding rates have increased. Many farms have permanent electric aerators in at least some ponds, and most baitfish farmers utilize portable tractor-driven aerators or pumps to provide emergency aeration.

In production ponds golden shiners can withstand dissolved-oxygen levels as low as 1.0 to 1.5 mg/liter (ppm) for short periods. They are apparently very tolerant of the low oxygen levels found under the ice during northern winters and have high survival rates even when dissolved-oxygen levels reach 0.2 or 0.3 ppm (65). Fish farmers report that adult-fathead minnows have similar tolerance levels to golden shiners; however, the fry are quite sensitive to low oxygen, and survival is reduced at levels below 4 ppm (66). Goldfish are more resistant to low-oxygen levels than the other two species, and can withstand levels of 0.5 ppm for several hours.

In addition to low oxygen, farmers occasionally encounter high-ammonia levels, especially after algal blooms crash. In these cases, feeding rates are reduced and new water may be added to create a zone of improved quality water. Circulating water within baitfish ponds was proposed as a method of improving water quality and fish production, but has been shown ineffective in increasing yields (67,68).

Murai and Andrews (69) examined the salinity tolerance of golden shiner and goldfish eggs and fry. Eggs were only slightly affected by salinity levels as high as 8 parts per thousand (ppt). However, levels as low as 2 ppt reduced survival of fry.

Diseases

Baitfish are susceptible to a wide variety of parasites and other diseases. Crowded conditions and restricted feed promote disease. Farmers carefully check ponds for signs of sick fish and routinely submit fish samples to diagnostic laboratories for fish health checks. Common parasites are single-celled protozoans and monogenic trematodes (flukes) (18,70,71). Fathead minnows are particularly susceptible to infestation by digenic trematodes (grubs). The crustacean parasites *Lernaea*, *Argulus*, and *Ergasilus* are also found on occasion, and two species of tapeworms can also occur in baitfish. One baitfish virus (Golden shiner virus) (72) has been described. Incidence of virus infection was found to increase with fish density (73). Golden shiners are also afflicted by a microsporidian parasite, *Pleistophora ovariae*, that grows in the ovaries and progressively destroys them (74,75). The progressive impact of this disease on older fish has prompted farmers to use one-year-old broodstock. Bacterial infections by *Aeromonas* sp. or *Flavobacterium columnare* (columnaris) can also cause fish losses, especially after fish have been subjected to suboptimal environmental conditions (77). Rarer diseases include myxosporidians (78).

Other Pond Management Problems

Fish-eating birds are a major problem for baitfish farmers. Despite expensive and time-consuming scare programs, birds consume hundreds of thousands of dollars worth of baitfish each year. Wading birds can also infect ponds with parasitic grubs. Snakes also feed on minnows, especially when fish are spawning and insensitive to danger.

Annual Production Cycle in Arkansas

The annual production cycle on baitfish (golden shiner and goldfish) farms starts with the spring spawning season (April and May), a period of intense activity. Ponds are drained to make room for the new crop. Spawning mats are placed in brood ponds daily for egg deposition and then

moved the next morning to rearing ponds or a hatchery. As eggs hatch, the new fry must be fed several times a day. Meanwhile, ponds with fish from the previous year are harvested to meet spring markets, especially for crappie (*Pomoxis* spp.) bait. In June, warm weather brings a close to spawning, but farmers remain busy harvesting, as the market shifts toward a larger (bass) minnow, demand for which peaks around the July 4th holiday. Farmers spread out the new crop of juvenile fish, harvesting small, stunted fish from overcrowded ponds and moving them to other ponds with light loads of fish. Fish are fed daily, and ponds are monitored to detect disease or water quality problems. The demand for bait slows in August with the heat of summer, then picks back up again with cooler fall temperatures. Larger minnows for bass bait are removed from ponds with the new crop of fish by seining and pond grading (capturing fish with a net and running them through a floating grader to retain the large fish). Ponds may be fertilized in the fall, if necessary, to ensure a phytoplankton bloom that will last the winter. Winter markets require large minnows used in ice fishing. Although prolonged ice cover is rare in Arkansas, farmers will harvest by seining under the ice, if necessary, to meet market demands. Fish are fed on warmer winter days, and preparations are made for the next year's production cycle.

Harvesting

Golden-shiner and fathead-minnow producers usually harvest only a portion of the fish in a pond at a time (partial harvest) to obtain needed fish. Feeder-goldfish producers will usually completely harvest a pond within a week after harvesting commences, since the remaining fish will quickly grow too large for the feeder market if left at low densities. Fish are baited into corners using a sinking feed, then captured using knotless nylon seines (Fig. 2). The fish are transferred from the harvest seine to hauling tanks in buckets, each containing about 11 kilograms (25 lb) of minnows. Oxygen-equipped transport trucks carry the fish to the minnow shed, where they are unloaded into vats through a plastic pipe.

Holding, Grading, and Transport

Baitfish are held in shallow vats (0.5 m or 20 in. deep) before shipment to market. Typical vats contain 5,700 to 7,600 L of water (1,500 to 2,000 gal), and can hold 160 to 180 kg (350 to 400 lb) of fish. Fish are left untouched for the first 24 hours to allow them time to adjust to vat conditions and to empty their digestive tracts (purge), a process referred to as "hardening." Salt is often added at a rate of 0.5%. Vats are flushed initially to remove residual pond water, then at daily or twice daily intervals, and a light flow of water is left to prevent the buildup of ammonia. Groundwater is used in vats because it is clean and cool, but it may contain excess dissolved gases and high concentrations of iron. Spray towers or packed columns are used to aerate the water and, if necessary, pressurized sand filters are used to remove flocculated iron.

Most farmers use low-pressure blowers and 5 to 7 airstones per vat to maintain adequate dissolved-oxygen levels. A few operations still use 110-volt hanging agitators for vat aeration. A new procedure found on several farms equips each vat with an oxygen saturator (where water is pumped downwards through pipes of increasing diameter, as oxygen bubbles upwards, providing for a long contact time for gas transfer). Use of oxygen saturators at least doubles the weight of fish that can be held in a vat. Costs of operating saturator units are reduced because farms keep storage tanks of liquid oxygen for refilling cylinders on fish hauling trucks, and the units use oxygen gas that would otherwise be lost due to venting from storage tanks.

Fish are graded (separated into size categories) the second day in the vats. Farmers typically use drag graders, panels of evenly spaced aluminum bars that are pulled through the tanks (Fig. 3). Large fish are removed first, and then fish are separated by using progressively smaller graders. Graders are numbered by the width of the grader bar, spacing in units of 0.4 centimeter (1/64 in.), the industry standard.

Fish are graded into several size categories, depending on species. Golden shiners are usually separated into jumbos, mediums, and crappie bait. Tables of average

Figure 2. Harvesting golden shiners with a seine.

Figure 3. Holding vats for baitfish. The men are crowding golden shiners with a grader, in preparation for loading a hauling truck.

golden shiner lengths and weights for different graders have been developed (79). Feeder fish are classified by the weight of 1,000 fish; the standard category that makes up 90% of sales is 1.4 kilograms (3 lb) per 1,000 (18). Fish that are unsold several days after grading are returned to ponds. However, returned fish, or "turn backs," generally do not remain healthy and fish losses may be high.

Most baitfish are transported to market by hauling trucks equipped with insulated tanks and liquid-oxygen aeration systems. Feeder fish may be sent by truckload or in insulated shipping boxes. Fish sent by box are placed in a small amount of chilled water inside a double layer of plastic bags. The inner bag is then filled with oxygen and the bags are sealed. Ice is added to keep fish cool. Customers may pick up boxed fish at the closest airport or an overnight deliver company will transport the boxes directly to the retail shop.

MARKETING

Marketing is the most difficult aspect of baitfish farming. Live fish are a highly perishable product. Demand for bait varies widely with the weather, and farmers must monitor weekend weather forecasts for regions where their fish are sold in order to decide how many fish to harvest, grade, and harden in vats in anticipation of sales orders. In addition, live haulers (people who drive tractor-trailer loads of fish) face complex regulations governing transport and sales that vary widely from state to state (10). Baitfish farmers must also adjust quickly to varying demands for different sizes of baitfish, and small, isolated farms may have difficulty meeting these changing market requirements. Despite the highly competitive nature of the business, fish are routinely bought and sold among farms so that for individual farms can meet marketing obligations without losing customers.

Fish farms may sell to distributors, wholesalers, or directly to the public. Distributors (jobbers) haul fish to major wholesale outlet centers around the country. These distribution centers have their own holding facilities and retail networks. Fish are then delivered to retail outlets on a weekly or twice weekly schedule or are sold to other wholesalers. Fish losses are absorbed by the farmer and are usually made up in the next shipment.

ECONOMICS

Few economic analyses of baitfish farming have been conducted. Pounds et al. (61) examined economic effects of intensifying golden shiner production. Fixed costs in baitfish farming (costs incurred whether fish are grown or not, such as payments on land, facilities, ponds and equipment) are relatively high when contrasted to catfish production, so there are strong economic incentives to increase yield. Returns to investment in baitfish farming were found to be relatively low. Established farmers with high levels of equity capital (debt-free land and ponds) were able to produce fish at a profit (80).

Confounding factors affecting economic analyses of baitfish farming include diverse culture methods, multiple species and market sizes, variable demand, and market restrictions and barriers. Yields from individual ponds can exceed 1,100 kilograms per hectare (1,000 pounds per acre) for golden shiners and 1,700 kilograms per hectare (1,500 pounds per acre) for goldfish. A common mistake of novices is to develop budgets that assume high yields and that all the fish will be sold. In fact, average yields are considerably lower and market constraints can leave farmers with unsold fish. Baitfish farming is a challenging business.

BARRAMUNDI CULTURE

GEOFF ALLAN
Port Stephens Research Centre
Taylors Beach, Australia

ROBERT R. STICKNEY
Texas Sea Grant College Program
Bryan, Texas

A relative newcomer on the aquaculture scene, the barramundi, or Asian sea bass (*Lates calcarifer*), is being farmed in southeast Asia and Australia. Production was estimated at nearly 20,000 tons in 1997 and included about 500 tons from Australia (1). Barramundi is a member of the family Latidae and is renowned as an excellent sportfish, especially in the rivers of northern Australia. It has fine eating qualities and is prized on the live-fish market in several southeast Asian cities and in Asian communities within Australia.

CULTURE OF BARRAMUNDI

Barramundi are protandrous hermaphrodites; that is, they first develop as males, but later change into females with functional ovaries. In the wild, males mature at about four years of age and convert to females at between six and eight years old. In culture, precocious development occurs and males and females mature as early as one or two years, respectively. Year-round hatchery production in possible through the manipulation of temperature (2), but hatchery production is limited by the inability of culturists to maintain functional males in the breeding population (3).

When barramundi culture was initiated in the mid-1980s, it was common practice to collect fry from nature for stocking into culture systems. This was followed by collecting gametes from wild adults, although that practice was unreliable, so the current emphasis is on establishing and maintaining captive broodstock.

Barramundi broodstock can be kept in reproductive condition year-round through environmental manipulation. Spawning usually requires administration of reproductive hormones. Hatching takes about 14 to 17 hours and larvae commence feeding one to two days after hatching (4). Larvae can be reared intensively in hatchery tanks, or extensively, in fertilized marine ponds. Larval barramundi feed on zooplankton. Copepods and rotifers are among their prey, although brine shrimp (*Artemia* sp.) can be successfully used as well, particularly if they are enhanced with *n*-3 fatty acids.

Fingerlings are typically maintained in nursery tanks or cages until they are about 80 mm (3.1 in.) total length, at which time they are introduced to formulated diets (4). Regular grading during the fingerling and early juvenile stages is essential to reduce cannibalism.

Growout facilities include tanks, cages, and ponds where water temperatures exceed 20 °C (68 °F), and preferably, are about 25 °C (77 °F). There are several intensive, indoor, environment-controlled recirculating systems producing barramundi in Australia. In addition, some fish are produced in earthen ponds. However, the majority of production occurs in cages located in estuaries or rivers, or within ponds (4). The largest farmer of barramundi in Australia produces approximately 140 tons/year, mainly in 5 m × 5 m (14 ft × 14 ft) cages within large freshwater ponds. In southeast Asia, most fish are produced in cages located in rivers, estuaries, or protected marine areas.

Barramundi are subject to various bacterial, fungal, and viral diseases, usually following stress such as sub-optimal water quality, poor nutrition, or harvesting (4). Columnaris is a particularly common bacterial disease, frequently associated with reduced temperature. Similarly, fungal outbreaks occur most often in cold water and appear as white blotches. Viral diseases have been reported, and one, the picornalike virus, can cause devastating hatchery losses. Concerns that this virus can be transferred to other native fish has led to the imposition of stringent controls on barramundi farming outside its natural range in some parts of Australia (e.g., New South Wales).

Nutritional research on barramundi is not extensive. The fish are carnivorous, and recent research has indicated that nutrient-dense formulated diets with about 20 mJ/kg OE and greater than 45% protein outperformed lower protein energy and diets that formed the basis of early commercial diets (5,6). Field-based research clearly indicated that barramundi grew equally well on diets where either meat meal or fish meal supplied the majority of the protein.

BIOCHEMICAL OXYGEN DEMAND

DAVID E. OWSLEY
Dworshak Fisheries Complex
Ahsahka, Idaho

OUTLINE

Definition
Discussion
Pollution Abatement
Conclusion
Bibliography

DEFINITION

Biochemical oxygen demand (BOD) is defined as the amount of oxygen required by bacteria to stabilize organic matter under aerobic conditions. BOD is the major criterion used in monitoring and controlling the pollution of natural waters. It is a limiting factor when organic matter must be restricted to maintain desired levels of dissolved oxygen. It is used by engineers to design treatment systems for sewage and industrial wastes, by regulatory agencies to control pollution of receiving waters, and by aquaculturists to maintain fish rearing environments and effluent control from hatcheries.

DISCUSSION

The term "biochemical oxygen demand" means the same thing to everyone who is involved in monitoring or controlling waste discharges. It is a regulatory parameter, no matter whether you work at a hatchery or at a sewage treatment facility. It is often referred to as "biological oxygen demand's" as well, and it is closely related to chemical oxygen demand (COD), which is the amount of oxygen required to chemically oxidize all of the organic matter in a water sample.

The BOD test is a wet oxidation procedure wherein living organisms serve as the medium for oxidation of the organic matter to carbon dioxide and water. The organic matter serves as "food" for the organisms, and energy is derived from its oxidation. The primary organisms are soil bacteria. The BOD test is essentially a bioassay procedure in which the oxygen consumed by bacteria is measured while the bacteria oxidize the organic matter under a controlled environment during a 5-day incubation period at $20\,^{\circ}C$ ($68\,^{\circ}F$). This temperature is considered to be a median value for natural bodies of water. Most of the BOD is everted after 5 days, although it takes 20 days for complete oxidation. The BOD everted throughout the first 5 days is approximately 70 to 80% of the total BOD. The BOD test procedures can be found in (1).

The levels of pollutant in a flow-through hatchery effluent can be determined with the following general equation (2):

$$\text{Average ppm pollutant} = \frac{\text{Pollutant factor} \times \text{amt of food fed (lb)}}{\text{Water flow (gpm)}}.$$

The following pollutant factors should be used in the equation:

Total ammonia	2.67
Nitrate	7.25
Phosphate	0.417
Settleable solids	25.0
Biochemical oxygen demand	28.3

Liao (3) has reported on the extent of pollution problems occurring at fish hatcheries in the United States. Principal parameters measured included BOD, ammonia, nitrate, suspended solids, and phosphates. Attempts were made to correlate the values encountered with fish loadings, water supply rates, and fish feeding rates. Liao's observations are summarized in Table 1.

Later, studies were carried out by Brisbin (4), who measured the wastewater discharge from the Summerland Hatchery and gave the following ranges for polluting substances:

Table 1. Polluting Characteristics of Hatchery Wastewater

Flow rates	0.52–26.0 lb of fish per gal per min
Fish loadings	0.069–1.14 lb of fish per ft^3 of holding capacity
Feeding rates[a]	1.14–7.15 lb per 100 fish per day
BOD	0.645–2.496 lb per 100 lb of fish per day
Suspended solids	0.5–3.0 lb per 100 lb of fish per day
Ammonia	0.031–0.404 lb of nitrogen per 100 lb of fish per day
Nitrate	0.006–1.501 lb of nitrogen per 100 lb of fish per day
Phosphate	0.004–0.094 lb of phosphate per 100 lb of fish per day

[a]Nine of the 15 hatcheries studied used feeding rates exceeding 3.7 lb of food per 100 lb of fish per day.

Table 2. Wastewater Discharge Parameters

Pollutant	Concentration (mg/L)	Concentration (lb/100 lb of fish)
BOD	3.5	0.47–0.99
Suspended solids	4.3–8.1	0.29–2.61
Volatile suspended solids	4.1–6.5	0.27–2.56
Ammonia	0.26–0.7	0.05–0.18
Nitrates	0.05–0.26	0.01–0.11
Nitrates	0.04–1.1	0.18–0.24
Phosphates	0.11–0.14	0.02–0.027

POLLUTION ABATEMENT

Liao et al. (5) reported that for pollution abatement, the systems were evaluated by comparing the amounts of pollutants discharged (10% bypass) to waste by the reuse systems to the amounts of pollutants discharged from a control single-pass rearing unit.

The percentages of pollutants reduced are calculated based on the number of pounds of pollutants reduced per 100 lbs of fish per day, as indicated in Table 3. The control single-pass rearing tank, installed at the Bozeman Station, was loaded and operated in the same manner as the fish tanks connected to the treatment systems. Therefore, the percentage calculated for pollutant discharge, based on the discharge from the control single-pass unit, should be reasonable. However, for comparison, the pollutants discharged from various single-pass and reuse systems are listed in Table 4. Also, it must be pointed out that the

Table 3. Average Reduction of Pollutant Discharge by the Bozeman Pilot Plant Reuse Systems[a]

	Activated Sludge	Extended Aeration	Upflow Filter	New Upflow Filter	Trickling Filter
BOD	97	93	89	91	86
Suspended solids	88	95	79	—	91
NH_4-N	23	10	49	49	69
PO_4-P Orthophosphate	24	25	$+25^b$	$+33^b$	$+33^b$

Total ammonia	11.2
Nitrate	4.3

[a] After Boyd (7).

phosphate indicated in Tables 3 and 4 is orthophosphate, rather than total phosphate.

Boyd (6 and 7) reported the following BOD levels for warmwater rearing ponds in Tables 5 and 6.

CONCLUSION

The biochemical oxygen demand is an important parameter for aquaculturists. It is an indicator of levels of pollution for receiving streams and rearing ponds. BOD levels are easy to determine, understand, and apply to studies of the environment.

Bibliography

Largemouth bass (*Micropterus salmoides*) are the most sought-after freshwater sportfish in the United States. This species was originally found only in North America and has been cultured in the United States since the late 1800s (1). Currently, it is cultured both for stocking as a sportfish and for use as a foodfish. A survey of state and federal agencies on production of largemouth bass was conducted in 1997. The data were obtained from either 1995 or 1996. State and federal hatcheries produced approximately 21 million largemouth bass (LMB) for sportfish stocking. Most (89%) of the bass were stocked as fingerlings. States do not keep records on the exact number of bass produced each year in private commercial hatcheries. However, I estimate that at least as many bass are raised by commercial hatcheries as by state and federal hatcheries. The 1998 *Aquaculture Magazine Buyer's Guide* lists 103 hatcheries that produce LMB. Twenty of the hatcheries indicate that they sell "market-size" fish. Most commercial producers of LMB also produce other species, such as sunfish and channel catfish; only a few units produce LMB exclusively.

Some states require an aquaculture license to rear and sell fish, but others do not. In a few states, it is not legal to rear largemouth bass for stocking. Also, there are a few states in which it is not legal to sell LMB as foodfish. Since regulations are continuously changing, one should check with the appropriate state regulatory agency before culturing LMB or for further information.

The current wholesale value of LMB depends on the geographic location of the hatchery, the size of the fish,

and the number of fish in the sale. As a rough guide, 3.8- to 5.1-cm (1.5- to 2.0-in.) bass are sold for $0.12 each, 10.2- to 15.2-cm (4- to 6-in.) fish for $0.55 each, 15.2- to 20.3-cm (6- to 8-in.) fish for $1.05 each, and larger (live) fish for $7.70/kg ($3.50/lb).

BIOLOGY

The basic biology of the largemouth bass has been reviewed by Heidinger (2). Additional information can be found in a symposium on black bass edited by Clepper (3). There are two recognized subspecies of largemouth bass: the northern largemouth bass, *M. salmoides salmoides*, and the southern Florida largemouth bass, *M. salmoides floridanus*. Contrary to popular belief, these two subspecies cannot be visually distinguished from one another; genetic tests are required to tell the two subspecies apart. Knowing which subspecies one is working with is important, because the southern subspecies cannot tolerate as cold a temperature as can the northern subspecies. In 2-m-deep (6-ft-deep) culture ponds located at the latitude of southern Illinois, young-of-the-year largemouth bass of the Florida subspecies die during normal winters. During winter, the ponds reach 4 °C (39 °F) for several months. Some researchers believe that even the northern subspecies is stressed at temperatures of 2 to 3 °C (36 to 37 °F). Such low temperatures occur at northern latitudes when winds keep shallow ponds from freezing.

LMB, like most fish, have to swallow their prey whole. In nature, the diet of LMB changes as they grow, but all sizes feed on live organisms. As bass increase in size, they eat larger organisms, which they forage for. Initially, fry eat primarily zooplankton. Then they eat insects and zooplankton until they reach 25 to 51 mm (1 to 2 in.) in total length. Bass over 51 mm tend to eat small fish. Adults feed heavily on fish and crayfish. Their large mouth, unwillingness to accept a prepared diet unless trained, and highly cannibalistic nature make them more difficult to culture than rainbow trout or channel catfish. Approximately 5 kg (11 lb) of prey fish, such as golden shiners, are required to produce 1 kg (2.2 lb) of LMB. Additionally, LMB do not eat plants, as they do not have the enzymes necessary to break down the cellulose in the walls of plants. Plant material is seldom found in the stomachs of bass. However, their elastic stomachs may contain prey organisms that weigh up to 10% of the weight of the bass. In nature, bass do not feed continuously, which is why it is not uncommon to find that 50% of a population at any given time have empty stomachs.

LMB spawn at 24 to 30 °C (75 to 86 °F). Male LMB usually build their nests at depths of 0.33 to 1.33 m (1 to 4 ft) on any firm substrate. The male bass places his head in the center of the nest and sweeps debris out in front of him. He then returns and, with his head in the middle of the nest, pivots around in a circle (4). Thus, the diameter of the nest approximates twice the length of the bass. Males are solitary nesters, and they chase other males out of their nesting territory. Unless some line-of-sight obstruction exists, nests are usually at least 2 m (6.5 ft) apart (4). Male LMB guard their nest and over a period of several days may entice more than one female

to lay eggs in it. After the enticement period is over, the male defends the nest area against almost all other fish, including female LMB.

Not all of the eggs that a female LMB lays in a season mature in her ovary at the same time. Thus, she may lay her eggs in more than one nest (5). This nesting behavior has led to the recommendation that to best use the eggs present in females, two to three males should be stocked into a brood pond for each female stocked. This technique probably also shortens the duration of spawning. Successful bass nests have been reported to contain 5,000 to 43,000 eggs (6,7). Fertilized eggs are yellow to orange (they may be creamy white in pellet-fed females), spherical [1.4−1.8 mm (0.05−0.07 in.) in diameter], semiopaque, contain one large oil globule [0.5−0.7 mm (0.02−0.03 in.) in diameter], and are adhesive and demersal (4,8,9). The diameter of the egg increases with the size of the female (10). The eggs water harden within 15 minutes after fertilization, and at 10, 18, and 28 °C (50, 64, and 82 °F), the eggs hatch in 317, 55, and 49 hours, respectively (11,12). Upon hatching, the prelarvae are 3 to 5.5 mm (0.12 to 0.22 in.) in total length. They do not have mouths, gills, paired fins, or inflated gas bladders (4,8,10). Prior to inflating their gas bladder, larvae are found in debris at the bottom of the nest. At 22 °C (71 °F), it takes approximately five days for the gas bladder to inflate (9). Even though a connection between the gas bladder and the foregut, called the pneumatic duct, exists in 3- to 8-mm (0.12- to 0.31-in.) larvae, the larvae do not have to gulp air to fill their gas bladders (12). Fry must eat within six days after becoming free swimming, or else they will die (13). Fry do not feed at night, and they pass food through their stomachs much faster (3 hours) than adults (18 hours).

Male LMB guard their brood of fingerlings for 14 to 28 days, after which the young disperse. Female bass grow larger and live longer than male bass. Bass tend to live longer in the northern portion of their range than they do in the southern portion. A 24-year-old female bass from New York is the oldest bass on record (14).

CULTURE

LMB culture has been reviewed by Clepper (3), Heidinger (2), and Stickney (15). There is no single best method to produce LMB; almost all producers have developed some procedures that are unique to their operation. The procedures described later are composites from many agencies and private growers, and only a few of the variations are presented. Most adult LMB are placed in ponds to spawn, but to gain more control, there is a movement toward raceway spawning. The fry are either left in the spawning ponds or, more commonly, moved to rearing ponds. In either case, they initially feed on zooplankton and then zooplankton and aquatic insects until they are 25 to 51 mm (1 to 2 in.) long. Fingerlings 7.6 to 10.2 cm (3 to 4 in.) long can be raised at a low density on insects. If larger fish are desired, 25- to 51-mm (1 to 2 in.) fingerlings are trained in tanks to take a prepared diet, and then the trained bass are reared in ponds, net pens, or raceways to the appropriate size.

BROODSTOCK

Broodstock LMB are normally maintained in the hatchery. The genetic makeup of broodstock should be considered. Most fish geneticists recommend that the initial broodstock come from local sources, especially if the offspring are going to be used for stocking in the region. If the bass are going to be used only as foodfish, then the development of genetic stocks (strains) for this use would make sense. However, at this time, such stocks have not been developed. In order to prevent inbreeding, it is necessary to maintain a fairly large number of broodfish that are not closely related (16). Most mathematical calculations indicate that it is desirable to have 1,000 or more broodfish if one is going to introduce the offspring into natural populations. In a small hatchery, this is not economically feasible; however, one should try to maintain 300 to 400 broodfish of an equal sex ratio.

The sexual maturity of LMB depends more on size than age (17). Female bass reach maturity when approximately 25 cm (10 in.) in total length, while males may be mature at 22 cm (9 in.) (17–19). Thus, in the southern portion of their range, LMB mature in one year, whereas slower growing bass in the northern portion of their range may take three to four years to reach sexual maturity. Normally, larger 0.7- to 1.8-kg (1.5- to 4-lb) bass are kept as broodfish in a hatchery. Externally, bass greater than 35 cm (14 in.) in total length have been sexed correctly 92% of the time by looking at the scaleless area surrounding and immediately adjacent to the urogenital opening (20). However, Manns and Whiteside (21) were able to sex bass only 67% correctly using Parker's characteristics. In the male, the aforementioned area is nearly circular in shape, while in the female it is elliptical or pear shaped. One must hold the fish carefully in order not to change the shape of the scaleless area. Prior to spring spawning, the females that are heavy with eggs, which may weigh up to 10% of the female's body weight, are easy to separate from the thinner males. Just prior to spawning, ripe females have a swollen, red, and protruding vent. Semen may be expressed from the males by placing pressure on the abdomen.

Most producers replace their broodfish when they reach four to five years of age, when they weight 1.8 to 2.3 kg (4 to 5 lb). Larger fish are more difficult to handle. Also, some producers seem to have significant mortality in their older broodfish. The cause of this mortality is not well understood. However, at the San Marcos, Texas, National Fish Hatchery and Technology Center, eight-year-old LMB broodfish have been successfully used to produce offspring (15). It is desirable to keep genetically selected broodfish for as long as possible.

Broodfish are held throughout much of the year in ponds at rates of 336 to 448 kg/ha (300 to 400 lb/acre) (22). To maintain the fish in good physical condition, it is extremely important to feed them adequately. Live prey fish are frequently used; however, pelleted rations or combinations of prey fish and pellets are also used. Three kg of prey fish/kg (3 lb/lb) of LMB are required for maintenance, and 5 kg of preyfish/kg (11 lb/lb) of LMB are required for growth (22).

Rosenblum et al. (23) and Snow and Maxwell (24) found no difference in gonad development and fecundity between pellet- and prey-fed LMB. Pellet feed usually contains less than 10% water, whereas fish contain 80% water. Thus, per unit weight of food, there is much more caloric energy in pelleted food than in fish. For this reason, in terms of weight, less pelleted food needs to be fed than prey fish. Pelleted food is also desirable because it is relatively easy to store, and the amount fed daily can be adjusted to the feeding response of the bass. As the water cools, metabolism decreases, and food consumption also decreases. One good rule of thumb is to feed bass what they will consume once a day in 10 or 15 minutes, or 3% of their body weight daily. Feeding should be continued throughout the ice-free portion of the winter, especially during warm periods, but at a reduced rate of 1% of their body weight daily. Many aquaculturists prefer to have prey fish in the ponds during the winter, especially if long periods of ice cover persist. However, one potential problem of introducing prey fish is that they may carry parasites to the brood bass.

Commercially available fish feed comes in a variety of sizes. As the size of the bass increases from fingerling to adult, the size of the pellet should also increase (Table 1). Adult bass should be fed pellets that are 6 to 19 mm (0.25 to 0.75 in.) in diameter. Minimum protein requirements ($\approx$40%) for 1-year-old and younger largemouth bass (25) are probably closer to those of salmon than those of channel catfish, in terms of their nutrient energy and protein requirement. Thus, a fairly high-quality fish food needs to be used for bass.

Large numbers of eggs may be lost in the spring, due to unstable temperatures. LMB spawn during the first warm spell. If water temperatures subsequently drop due to a cold spell, the LMB will leave the nest, and the eggs will be lost. Renesting will usually occur, but fewer progeny are produced. Spawning can be delayed until the weather stabilizes by holding broodstock in cages, holding sexes in separate ponds, or flushing ponds or raceways with enough cool water to hold the water temperatures below spawning temperatures.

Table 1. Pellet Sizes and Approximate Percentage of Body Weight for Feeding Largemouth Bass Fingerlings Under Summer Condition[a]

Fish Length		Pellet Diameter		Body Weight
(cm)	(in.)	(mm)	(in.)	(%)

[a]This practical feeding guideline was developed from (15) and data collected at the San Marcos National Fish Hatchery, using Biodiet®.

FINGERLING PRODUCTION

Spawning–Rearing Pond Method

The simplest method of producing fingerlings is to stock broodfish at a relatively low density, 25 to 100 per hectare (10 to 40 per acre). The pond should be fertilized with an organic fertilizer, such as manure, cottonseed meal, or alfalfa meal, to produce zooplankton (26). The adult fish spawn, and either both the young and adults are left in the ponds or as many adults as is practical are removed by angling after the bass stop spawning. When these fingerlings reach 25 to 51 mm (1 to 2 in.) in length, which takes 40 to 70 days, they are usually harvested by seining.

Production will vary considerably, from a few hundred fish to 123,500 per ha (50,000 per acre). Not all of the bass will spawn at the same time, and the older, slightly larger fingerlings may prey on the younger, slightly smaller ones. Adult bass left in the pond will also prey on the fingerlings. Once the zooplankton and insects are eaten, the fingerling LMB will turn cannibalistic. Although this technique is the simplest way to produce small fingerlings, the number of fry produced is unpredictable, since there are very few controls. Usually, less than a thousand larger sized fingerling can be produced per ha (2.5 acres), unless some type of prey fish is stocked into the juvenile-rearing pond. Unless prey fish are available at a very cheap price, this procedure is not economical.

Fry-Transfer Method

Before the mid-1900s culturists began to remove fry from the spawning pond at some stage and place them into a fertilized rearing pond. Spawning ponds that are free of other fish and predacious insects are usually stocked with 99 to 247 brood bass per ha (40 to 100 per acre) when water temperatures reach 17 to 20 °C (63 to 68 °F). Much higher stocking densities have also been used (3). Since a female may spawn from one to five times over the two- to eight-week spawning season, a male-to-female sex ratio of 2 : 1 or 3 : 1 is recommended (27). On average, with broodfish in good condition, 247,000 to 494,000 fry per ha (100,000 to 200,000 per acre) can be removed from a spawning pond (3). If the pond has a mud bottom, it may be necessary to place 2- to 5-cm (0.75- to 2-in.) gravel at 2- to 3-m (7- to 10-ft) intervals. Light-colored gravel allows the culturist to observe the spawning bass more easily than dark-colored gravel. The patches of gravel should be about 0.9 m (3 ft) in diameter and placed at a water depth of 0.6 to 1.2 m (2 to 4 ft). To keep the gravel from scattering, it is sometimes confined in boxes or old tires.

Depending on the water temperature, eggs take 48 to 96 hours to hatch. By day five to seven, fry inflate their gas bladder and rise from the nest. LMB fry aggregate in a rather compact school for two to three weeks, until they are 12 to 25 mm (0.5 to 1.0 in.) in total length. Schooling fry are captured either with fry traps, a lift net, or by short seine hauls along the shoreline with a small, fine-mesh seine. Fewer fry can be recovered from a spawning pond that is turbid or contains abundant vegetation. It may be necessary to treat the pond with organic material and lime to reduce turbidity or with an herbicide to reduce algae. To produce 38- to 51-mm (1.5- to 2.0-in.) fingerlings, prepared rearing ponds are stocked with 99,000 to 198,000 fry/ha (40,000 to 80,000 fry/acre). Several methods can be used to estimate the number of fry being moved from the spawning pond to the rearing pond. For example, a sample of fry can be counted into a container. Fry are then added to a similar container until the numbers in the containers visually appear to be equal. This procedure is then repeated until the desired number of fish have been stocked. Also, a known number of fish can be weighed or volumetrically measured. For example, a 500-mL (17-oz) beaker is filled with 250 mL (8.5 oz) of water, followed by 250 mL (8.5 oz) of fry. Five ml of fry are counted (28). The number–weight or number–volume relationship can then be used to calculate the number of fish for stocking. These techniques should estimate within ±10% the actual number stocked. The visual technique is probably the least stressful for small fish (3). If the culturist has an excess of fry and is, therefore, more interested in maximizing the yield of fingerlings rather than the survival rate, it is not necessary to stock as accurate numbers of fry.

The rearing ponds are filled with water 10 to 20 days before the 10- to 18-mm (0.5- to 0.75-in.) fry are stocked. This technique allows time for the zooplankton population to build up, but does not usually allow time for predacious insects, such as notonectids (back swimmers), which feed on small bass, to reach large numbers in the pond. Ponds should also be fertilized to produce a heavy crop of zooplankton. Snow (3) has recommended planting ryegrass in drained rearing ponds in the fall, to produce 2,240 to 2,688 kg per ha (2,000 to 2,500 lb per acre) of green organic material before the pond is flooded in the spring. Too much organic material that decays rapidly can cause an oxygen depletion. Snow also recommended one to three applications of inorganic 8-8-0 fertilizer at a rate of 112 kg per ha (100 lb per acre) per application, to supplement the ryegrass. In actuality, culturists have to experiment with what works best at their hatcheries. For additional information on fertilizing and reducing turbidity in ponds, see Boyd (26).

Harvesting should start when bass reach 38 mm (1.5 in.) in length, which occurs 2 to 4 weeks after stocking. With good management, it should be possible to recover 75 to 80% of the small bass stocked. Fish are usually harvested by trapping, seining, or draining the pond. Failure to harvest when the fish reach 38 to 50 mm (1.5 to 2 in.) in length will lead to cannibalism and low survival rates; however, cannibalism can happen at any time. Cannibalism is aggrevated by stocking fry at different ages, and hence different sizes, and by a lack of food. Ponds should be checked frequently for appropriate invertebrates. If the invertebrates are gone, then the bass need to be harvested, regardless of their size. Heavy filamentous algae or attached vegetation can make harvesting very difficult and should be controlled with an approved herbicide. Grass carp cannot be used for vegetation control during this phase, because they will damage the fingerling bass when they are confined with them in the seine. Many types of aquatic vegetation start to grow from the bottom of ponds. Properly constructed ponds that have a water depth primarily greater than

Table 2. Requirements for the Production of Various Numbers of Florida Bass Fingerlings, Using the Fry Transfer Method[a]

[b] Based on fry production of 250,000 fry per hectare (100,000 per ac).

0.9 m (3 ft) also help to reduce vegetation, as light on the bottom is required for vegetation to start to grow.

White (22) has estimated the size of the fish production unit and the weight of broodfish needed to produce 2.5- to 10.2-cm (1- to 4-in.) fingerlings on natural food (Table 2). As the size of the bass increases, the number of fingerlings produced decreases and the amount of resources greatly increases. The number of bass per kg (0.45 lb) also decreases rapidly as the size of the bass increases (Table 3).

Intensive Method

A significant commercial market exists for 15- to 20-cm (6- to 8-in.) LMB for stocking into private lakes that have established fish communities. Advanced fingerling or yearling LMB are usually raised on pelleted food. The intensive method normally involves seining 25- to 51-mm (1- to 2-in.) fingerlings from their rearing pond, concentrating them in tanks, training them to accept a prepared diet, transferring the trained fish into a rearing pond or raceway, and feeding them a prepared diet until they reach the desired size. LMB have been trained to eat ground fish, fish eggs, krill, beef heart, etc. (29–31). Snow (32) has trained LMB to accept Oregon Moist Pellet. Other, similar diets are now on the market. Such diets are relatively expensive, contain approximately 10% water, and are best stored under refrigeration. To feed the trained fingerlings in rearing ponds, most growers switch to a less expensive diet that contains less water.

Fingerlings measuring 25 to 55 mm (1 to 2 in.) in length are moved from rearing ponds into training tanks. Circular and rectangular tanks of 845 to 1,691 L (200 to 400 gal) are often used. Although training facilities and procedures vary, successful ones all tend to have common characteristics. The fingerlings need to be concentrated in 21 to 30 °C (75 to 86 °F) water devoid of natural food. Frequently, initial training densities range from 3 to 12 fingerlings per liter (10 to 40 fingerlings per gal). To account for variation in the size of the bass trained, some culturists base their training densities on weight. Ranges of 5 to 7 g/L (0.04 to 0.06 lb/gal) are often used. The key to avoiding cannibalism is to stock and maintain the fingerlings at a uniform size and offer them food

Table 3. Number of Largemouth Bass per Unit of Weight at Various Lengths

Total Length[a]		Fish per Unit of Weight

frequently. Grading with a bar grader may be necessary two or three times during the 7- to 10-day training period.

Culturists feed at different frequencies. Belt feeders are used to continuously offer the commercial diet (Fig. 1), but some training diets tend to clog the belt. Many culturists hand-feed fingerlings every 5 to 10 minutes throughout
Figure 1. Belt-type automatic feeder on a circular training tank.

Figure 2. Battery-operated pelleted food feeder anchored in the middle of an advanced-fingerling production pond.

Figure 3. Paddlewheel aerator powered by the PTO of a tractor.

Figure 4. Jar-type egg-incubation system.

at least part of the day, while others feed the fingerlings five times a day if they are using a training sequence involving ground fish or krill as a starter diet. Some culturists continuously illuminate the training facilities, while others do not. One can expect in excess of 60% of the fingerlings to learn to accept the prepared diet. Fingerlings that have been produced from first- or second-generation hatchery-reared broodfish tend to have training rates in excess of 90%. Oxygen levels should be maintained above 5 ppm in the training facilities. Complete flush rates (turnover rates) of one to four times per hour help maintain suitable oxygen levels without excessive current and unionized ammonia below 0.025 ppm (15). Aeration using gaseous oxygen or liquid oxygen can be used to supplement the oxygen added from the flush water. U-tube technology can be used to enhance diffusion efficiency of the oxygen into the water (33). Packed columns are also used by some culturalists.

After learning to accept the pelleted food, the trained fingerlings are graded to remove nonbreeders and cannibals and then moved into growout ponds at a stocking rate of 37,000 to 49,000 fingerlings per ha (15,000 to 20,000 fingerlings per acre). One can expect 40 to 50% of the bass to continue to accept the pelleted feed in the pond. Many of the smaller fish that decline pellets will survive. This percentage can be increased to 90 to 95% if the trained fingerlings are confined by a net or screen in a portion of the pond or in cages for 7 to 10 days. Some culturists use small ponds of 0.2 ha (0.5 acre). If placed in the middle of the pond, battery-operated mechanical feeders can be used to offer pelleted feed essentially over the entire pond at hourly intervals (Fig. 2). Ponds are frequently or continuously aerated with a paddlewheel aerator or blower, to maintain oxygen levels at higher feeding rates that are needed to produce higher standing stocks of bass (Fig. 3).

Other variations of intensive fry production involve removing the fry before they leave the nest site (3) or removing the fertilized eggs from the nest and incubating them in jars (Fig. 4) or in Heath Vertical Incubators (Fig. 5). In either case, the bass are encouraged to spawn in nest boxes provided by the culturist. Nest boxes have been used in ponds lined with plastic (15), in earthen ponds, and in raceways. In general, spawning boxes placed 1.8
to 3.7 m (6 to 12 ft) apart are used to collect either fry or eggs. A spawning box for the collection of pre-swim-up fry is actually a box within a box, where each box has a wire-mesh bottom. The smaller, interior box contains spawning gravel [pebbles from 2 to 5 cm (0.75 to 2 in.) in diameter] and has a wire-mesh bottom large enough [10 to 20 mm (0.39 to 0.79 in.)] for sac fry to wiggle through

Figure 5. Heath Vertical egg-incubation system.

easily following hatching. The outside box has a wire-mesh bottom that is too small for fry to move through (15). Fry are collected from the outer box by removing the inner box. For more details on spawning boxes see Huston (34). To collect bass eggs, some culturists use a spawning box that has a 46 × 46-cm (18 × 18-in.) bottom and is 9 cm (3.5 in.) deep. The box is filled with 1.3- to 2.5-cm (0.5- to 1-in.) gravel (see Fig. 6) and has a coarse screen on the bottom and 7.6-cm (3-in.) legs. A 0.1-mm (24-mesh-per-in.) fine mesh saran screen attached to a 1.3 m × 1.3-m (0.5 × 0.5-in.) plastic pipe frame is placed on top of the gravel inside the box. Bass lay their adhesive eggs on the saran screen (35). The eggs are removed from the screen by a slight rolling action into a pan containing water and then are poured into a Heath Vertical Incubator tray or into jars.

Spawning mats of similar size, weighted indoor–outdoor carpet, or nylon felt have also been used to collect eggs (36,37). Mats can be dipped in a 1.5% buffered sodium sulfite solution for two to three minutes to remove the eggs (3).

LMB tend to spawn within a week if male and female broodfish have been separated in the spring before spawning if they are placed together after spawning

Figure 6. Spawning nest box used to transfer eggs, half-filled with gravel.

temperatures have been reached, and if there are more mats or nest boxes than males. An advantage of using nest boxes and mats is that fry of the same age, and thus the same size, can be stocked, a practice that reduces cannibalism. Separating the sexes also has the advantage of delaying spawning until the water temperature has stabilized. Male bass will desert their nest, and the eggs will die, if a severe cold front sufficiently reduces the water temperature. This problem is particularly prevalent at northern latitudes. Taking the eggs from spawning structures is another way to alleviates the problem.

FOOD-SIZE BASS

Certain ethnic groups have created a primary demand for adult bass as foodfish. The customers for this market are centered in large cities, such as San Francisco, Chicago, and New York, and demand live fish. It takes two to three years, depending upon latitude, to raise fish of an adequate size for these markets. Basically, trained advanced fingerling or yearling largemouth bass are stocked into rearing ponds at rates of 3,700 per hectare (1,500 per acre) and raised to 0.7 kg (1.5 lb) or larger.

The food supply initially limits the amount of LMB one can raise per unit area. This limit is overcome by feeding the fish. The second limit is the pond's ability to process the waste materials of the LMB without depleting all of the dissolved oxygen. This limit is increased by mechanically aerating the pond. Without feeding, one might expect a pond to produce 112 kg of LMB per hectare (100 lb per acre). With feeding, 1,684 to 2,245 kg of LMB per hectare (1,500 to 2,000 lb per acre) or more might be raised before the amount of oxygen becomes a limiting factor. Without aeration or flushing, oxygen depletion frequently occurs when feeding rates reach 20 kg per ha (17.8 lb per acre) per day. By aerating or flushing, a production of 3,368 kg of LMB per hectare (3,000 lb per acre) can be reached.

HANDLING AND TRANSPORT

Healthy LMB are not particularly difficult to handle, but any severe stress, including a heavy parasite load, should be avoided. In general, LMB's tolerance of handling and physical and chemical conditions is intermediate between that of salmon/shad and minnows/catfish (2). Within 72 hours, 50% of the bass die when the unionized ammonia-N level is 0.82 mg/L, the alkalinity is 232 mg/L, and the hardness is 272 ppm (15). With in 96 hours, 50% of the bass die when the nitrite-N level is 140 ppm (38). Ideally, LMB should be seined and transported when water temperatures are cool. LMB can withstand a wide range of temperatures if acclimated, but handling below 4.5 °C (40 °F) makes it more difficult to avoid stressing the fish (39).

Williamson et al. (15) gave a more detailed review of stress in LMB. Carmichael et al. (40) presented a complex procedure for safely hauling 200-g (0.44-lb) LMB at a density of 180 g/L (1.5 lb/gal) for up to 30 hours, that virtually eliminated mortality due to hauling stress. Their method involves prophylactic disease treatments,

withholding food from the fish before hauling, hauling at cool temperatures, anesthetizing the fish, hauling with salts in the water, etc. In general, most culturists stop feeding the LMB one to two days before seining fish seine them. After the fish have been seined, they are in raceways (Fig. 7) with well-aerated, 10- to −19 °C (50- to −66 °F) water for 24 to 48 hours and are then moved to the desired location.

LMB fry can be shipped in plastic bags that contain one fourth to one third of the bag's volume in water and are inflated with oxygen and sealed with rubber or, preferably, elastic bands or a heat sealer. The sealed bags are placed in an insulated container to keep them cool (41). Densities of 2,000 to 12,000 fry per L (7,600 to 46,600 fry per gal) of water are held for one to four days. When individual pond owners pick up small quantities of fingerlings at the hatchery or from a truck at a delivery point, the fingerlings are frequently placed in plastic bags. Densities of 100 to 200 fish/3.8 L (1 gal) of water can safely be hauled for at least four to six hours if the water temperature is maintained below 20 °C (68 °F). When LMB are moved from one place to another, they should be tempered if the difference in water temperature is greater than 10 °C (18 °F). If the fish are in plastic bags, they can be floated

Figure 8. Oxygen-inflated plastic bag used to transport small LMB.

in the receiving water (Fig. 8). Plastic bags exposed to the sun warm up very quickly; this practice should be avoided. Note that when fish die in a plastic bag filled with oxygen, they do not die from a lack of oxygen, but from the buildup of carbon dioxide.

If the fish are in a hauling tank, water can be slowly pumped into the hauling tank from the receiving water. Frequently, a 10 °C (18 °F) difference in water temperature is brought to an equilibrium over a one-hour period. Larger bass and higher densities than can be transported in plastic bags are moved in truck-mounted hauling tanks equipped with aeration devices. The maximum density that can be hauled without mortality depends on the size of the fish, the condition of the fish, the water temperature, the overall water quality (including hardness), the aeration system, and the time of haul. In general, the larger the fish, the cooler the water, the higher the oxygen levels, and the shorter the amount of that time more kg (pounds) of fish per liter (gallon) of water can be hauled (Table 4). Some hauling tanks are equipped with mechanical agitators or an airblower to aerate the water, but most units now use a system that delivers oxygen. Oxygen can be purchased as a compressed gas or as a liquid. If a large amount of oxygen is used in the hatchery, the liquid form is the most economical. For a discussion of diffusion efficiency, see Williamson et al. (15).

Figure 7. Typical concrete raceway used for holding fish.

Table 4. Normal Loading Capacity for LMB Hauling Tanks Equipped with an Agitator or Blower System in Hard Water at 18 °C (65 °F)[a,b]

Size of Fish		Duration of Transport (hours)							
		1		6		12		24	
(cm)	(in.)	kg/L	no./g	kg/L	no./g	kg/L	no./g	kg/L	no./g
5	2	0.24	2	0.18	1.5	0.12	1	0.12	1
20	8	0.36	3	0.36	3	0.24	2	0.28	1.5
112	14	0.48	4	0.48	4	0.36	3	0.24	2

[b]For each 5.5 °C (10 °F) increase in water temperature, decrease the load by 25%.

PESTS AND DISEASES

Certain insects, such as notonectids (back swimmers), can kill large numbers of LMB smaller than 3.8 cm (1.5 in.), by attaching to their backs and sucking out their body fluids. Such insects have been controlled by chemicals that are not approved for aquatic use on foodfish. Since the insects are air breathers, during calm weather they can be controlled by adding a small amount of fuel oil to the water surface. Pond management is probably the best way to control insects. If the pond is filled with well or filtered water approximately 10 to 20 days before the fry are stocked, the insects will not have time to build up, and by the time that they do, the bass will be large enough to eat them. Crayfish and bullfrog tadpoles can also be a problem when harvesting small bass. Bullfrog tadpoles have to be separated from the bass in order to obtain an accurate count of the fish harvested when the weight–number or volume-to-number method is used. Crayfish also have to be separated from the bass, but, in addition, they can damage or kill a large proportion of the small bass when they are crowded too closely in the net during harvesting. Neither crayfish nor bullfrog tadpoles are a problem when raising larger bass or in bass brood ponds, since larger bass eat them.

In some areas of the United States, fish-eating birds, such as cormorants, water turkey, and blue herons, are major predators of bass. In general, killing those pests without a permit is illegal, and scare tactics, such as carbide cannons, are of limited use. The blackbird–grackle group can become quite proficient in obtaining small bass from an outdoor raceway system, but bird screens will eliminate the problem.

Bass are susceptible to a number of diseases. When stressed, bass can be killed by bacteria such as *Aeromonas* and *Cytophaga* (*Flexibacter*). The bacterial infections are frequently followed by a secondary invasion of fungus. The best solution to the problem is to avoid stressing the fish. However, in the spring, just before and during spawning, broodfish may exhibit bacterial and fungal infections. Oxytetracycline-treated food has been used to treat bacteria, and some culturalists train bass with food that contains oxytetracycline. Anchorworms, *Lernaea* spp., are often treated with Dylox® at 0.25 to 0.50 ppm at weekly intervals for four to six weeks. However, as of this writing, Dylox® is not approved for the treatment of *Lernaea* on LMB unless the treatment is done under an investigation of a new animal-drug permit. Gill flukes in the genus *Dactylogyrus* (trematodes) are treated with 250 ppm formalin for 0.5 to 1 hour. A 3% salt dip for an hour can also be used (15). Likewise, ciliated protozoans, such as *Trichodina* and *Costia*, can be treated with formalin and salt. There is no effective legal treatment for *Ichthyophthirius* or for bass tapeworm, *Proteocephalus*, at this time. Overall, very few chemicals are approved for use on foodfish (42,43).

CONCLUSION

It is possible to raise LMB economically, but only by people with experience in, or knowledge of, aquaculture.

Some other books on aquaculture are provided by (42–44). The culturist must not only raise the fish, but also develop markets where the fish will be sold. Those who are serious about entering the business should consult experts before beginning. A good place to start is the state aquaculture extension agent. Remember, a private producer is not in the business of telling you how to compete with him or her.

BLOWERS AND COMPRESSORS

JOHN COLT
Northwest Fisheries Science Center
Seattle, Washington

OUTLINE

INTRODUCTION

Compressed air is commonly used for aeration, mixing, and pumping in aquatic systems. The design of compressed air systems depends strongly on the flow and pressure required. It is possible to obtain high-pressure compressed air in cylinders, but most compressed air is produced on-site.

CLASSIFICATION OF BLOWERS AND COMPRESSORS

The following four general types of units have been used in aquaculture to provide compressed air:

Type of Unit	Head Range, m (ft)	Aquaculture Application
Fan	0.006–0.06 (0.02–0.2)	Ventilation in building; forced air packed columns
Blower	0.30–2.4 (1–8)	Aeration in ponds and tanks; shallow airlift pumps
Multistage blower	1.2–5.2 (4–17)	Aeration in deeper ponds and rearing units
Compressor	12–100 (40–350)	Building compressed air; lake aeration; deep airlift pumps

Blowers are the most common type of unit used in aquaculture because of the limited depth of most rearing systems. The pressure provided by compressors is higher than that required for most aquaculture uses, but compressors are employed for many applications because they are commonly used to provide building air and therefore, they are available.

Because pressures and flows are specified in a variety of units, conversion information is needed. Pressure may be reported in millimeters of mercury (mm Hg), pounds per square inch (psi), Pascals (Pa), and as water head (feet or meters). Water head is the pressure exerted by a column of water and depends slightly on temperature. The following list may be used to convert between the bewildering pressure units:

1 standard atmosphere (atm) = 760 mm Hg

$$= 14.73 \text{ psi}$$

$$= 10.34 \text{ m } (15\,^{\circ}\text{C})$$

$$= 33.93 \text{ ft } (15\,^{\circ}\text{C})$$

$$= 101.325 \text{ kPa}$$

$$= 101{,}325 \text{ Pa}$$

$$= 1.013 \text{ bar}$$

$$= 1{,}013 \text{ millibar}$$

$$= 1.033 \text{ kg}_f/\text{cm}^2$$

The conversions between head and pressure units are equal to 73.49 mm Hg/m, 0.434 psi/ft, and 9.799 kPa/m at 15 °C. Barometric pressures are typically reported in mm Hg or millibar.

Air flow is typically expressed in cubic meters per minute (m³/min) or cubic feet per minute (ft³/min). The most common method of specifying airflow is in terms of standard volumetric flow. In the United States, the standard conditions are 20 °C (68 °F), 101.325 kPa (14.73 psi), and 36% relative humidity, resulting in a standard density of 1.20 kg/m³ (0.0750 lb/ft³). The standard conditions for reporting airflow are different in other countries, and the differences can introduce significant errors if not considered. Ignoring the minor impact of differences in moisture content, the actual (free air) volumetric flow rate is related to standard volumetric flow rate by (1)

$$q_{\text{act}} = q_{\text{std}} \left[\left(\frac{P_{\text{std}}}{P_{\text{act}}} \right) \left(\frac{T_{\text{act}}}{T_{\text{std}}} \right) \right] \tag{1}$$

where q_{act} is the actual volumetric flow rate (m³/min, ft³/min), q_{std} is the standard volumetric flow rate (standard m³/min, standard ft³/min), P_{std} is the standard pressure (101.325 kPa, 14.73 psi), P_{act} is the actual pressure (kPa, psi), T_{act} is the actual absolute temperature (°K, °R); °K = °C + 273.15; °R = °F + 459.69, and T_{std} is the standard absolute temperature (273.15 °K, 527.90 °R).

BLOWER AND COMPRESSOR DESIGN

The theoretical power for adiabatic compression (1) is given by

$$P_{\text{ad}} = \frac{q_{\text{act}} \gamma R T_1}{An} \left[\left(\frac{p_2}{p_1} \right)^n - 1 \right] \tag{2}$$

where P_{ad} is the adiabatic power (kW, hp), q_{act} is the actual of air flow (m³/min, ft³/min), γ is the specific weight of air (kgf/m³, lb/ft³), R is the gas constant (287.1, 53.3), T_1 is the absolute inlet temperature (°K, °R), p_1 is the absolute inlet pressure (kPa absolute, psi absolute), p_2 is the absolute outlet pressure (kPa absolute, psi absolute), A is a constant (60,000, 33,000), n is $(k-1)/k = 0.283$ for air, and k is 1.395 for air.

The theoretical power for adiabatic compression (Eq. 2) is the power needed for a 100% efficient unit. The actual power need by the compression is called the brake power and is given by

$$\text{BP} = \frac{P_{\text{ad}}}{e_{\text{c}}} \tag{3}$$

where BP = brake power (kW, hp) and e_{c} = efficiency of compressor (decimal). The actual power used by the motor, drive and gearbox, and compressor is called the wire power and is given by

$$\text{WP} = \frac{P_{\text{ad}}}{e_{\text{c}} e_{\text{d}} e_{\text{m}}} \tag{4}$$

where WP = wire power (kW, hp), e_{d} = efficiency of drive and gearbox (decimal), and e_{m} = efficiency of motor (decimal). The wire horsepower is the power billed for if this unit were connected to an electrical utility. Commonly, compressor manufacturers only report the brake horsepower because they may not supply the unit with the motor or drive. Due to the significant difference between these parameters, it is important to understand clearly how the power is being reported.

The adiabatic temperature rise during compression is given by the approximation

$$\Delta T_{\text{ad}} \approx \frac{T_1}{e_{\text{c}}} \left[\left(\frac{p_2}{p_1} \right)^n - 1 \right] \tag{5}$$

where ΔT_{ad} = increase in temperature (°C, °F).

The horsepower needed to supply a given airflow will depend on the inlet air temperature (T_1), the inlet air pressure (p_1), and the outlet air pressure (p_2). It is important to note that Eqs. 1–5 are written in terms of absolute pressures (barometric pressure + gauge pressure). Most pressure gauges measure the pressure relative to the local barometric pressure.

The density of air (2) can be computed from ideal gas relationships, which are presented in Table 1 for different air temperatures and elevations. The theoretical horsepower required to supply 28.3 m³/min (1000 ft³/min) air at 2 m (6.56 ft) total head and the resulting airflow rate at standard conditions are presented in Table 2. For the supply of a given flow rate expressed in terms of standard volumetric flow, the design capacity must be based on the maximum summer temperature, but the motor must be designed for the minimum winter temperature. The capacity of a compressor decreases at higher elevations.

SYSTEM DESIGN

The preceding equations can be used for preliminary sizing of equipment, but a different procedure is used for the actual design. Many of the specific system components will depend on the actual type of blower or compressor selected.

Head-Capacity Curve

The design of compressor and blower systems is based on the manufacturer's head-capacity curves (Fig. 1). These curves show the standard volumetric flow rate as a function of water head at a single elevation, air temperature, and power frequency. While most blowers

and compressors are powered by electrical motors, it is possible to use gasoline or diesel engines as backup or when electrical power is not available. The output depends on the discharge pressure and varies from high flow at low pressures to low flows at high pressures.

System Head Curve

To determine the actual amount of air that will be supplied by a unit, it is necessary to compute the system head curve over the potential range of air flows. The system head curve defines head losses to airflow in the overall system. The total pressure that a blower has to produce depends on the depth of submergence of the diffuser, losses in the piping system, and losses in the fittings and diffusers. This relationship can be expressed as

$$\text{Total head (ft)} = \text{Submergence} + \text{HL}_{\text{pipe}}$$
$$+ \text{HL}_{\text{fitting}} + \text{HL}_{\text{diffuser}} \quad (6)$$

The submergence term is simply the submergence depth of the diffuser. The HL_{pipe} value depends on airflow, pipe size, pipe roughness, air temperature, and pipe length. The HL_{pipe} term can be computed from the Darcy-Weisbach equation and the Moody diagram (3) or from a tabular listing such as that found in Table 3. The computation of HL_{pipe} is complicated by the fact that air temperature, pressure, and flows will change within the piping system. Therefore, it is prudent to design an air distribution system conservatively by oversizing the primary distribution headers. If there is significant head loss along the primary distribution header, the rearing units farther away from the blower or compressor will receive less airflow. The $\text{HL}_{\text{fitting}}$ term accounts for head losses in elbows, tees, and valves. This term is generally very small and can be ignored for many systems. Commonly, the submergence and $\text{HL}_{\text{diffuser}}$ terms are the largest losses in indoor systems.

Head losses in diffusers depend on both airflow and pore size. Diffusers, which produce small bubbles, have larger head losses. The head losses of many diffusers are provided by the manufacturer (see Fig. 2). Many diffusers used in aquaculture have head losses in the range of 15–25 cm (6–10 in.); fine-bubble diffusers used for pure oxygen applications may have head losses as high as 14–18 m (46–58 ft).

While it is desirable to select a diffuser with low head losses, unstable operation may result if the diffuser losses are less than 10 cm (4 in.) of head (3). Diffuser head losses can increase with time due to clogging (two major sources are particulates in the air supply and corrosion products from metal pipes) and the growth of microorganisms on the external surfaces. It is very difficult to quantify the long-term increase in diffuser head losses because of the dependence on operational procedures, but doubling the published values gives a conservative estimate.
Figure 2. Head losses for a disc diffuser (cm = in. × 2.54, $\text{m}^3/\text{min} = \text{ft}^3/\text{min} \times 0.02831$).

Table 3. Frictional Head Losses for Air as a Function of Flow and Pipe Size[a]

Flow Rate in scmm (scfm)	Nominal Pipe Size

3.54 (125)				45 (1.99)	15 (0.68)
4.25 (150)				74 (3.26)	21 (0.93)
5.66 (200)				127 (5.63)	37 (1.62)
7.08 (250)					55 (2.44)

[a] Head losses are expressed in terms of kilopascal/100 m of pipe (psi/100 ft of pipe).
Figure 3. System design of a blower or compressor system. The operating point is where the system head curve intersects the manufacturer's head-capacity curve. If a larger pipe is used, the operating point will move from point A to point B and the flow will increase from Q_A to Q_B.

Operating Point

To determine the actual pressure and flow produced, the system head loss curve is computed from Eq. 6 over the expected operating range. This curve is plotted over the manufacturer's head-capacity curve (Fig. 3). The intersection of the two curves is the operating point (Operating Point A in Fig. 3). Changes in the system head curve will change the operating point. For example, increasing the pipe size will decrease the system head curve and move the operating point from point A to point B, resulting in an increase in airflow from Q_A to Q_B.

GENERAL DESIGN CONSIDERATIONS

A number of design considerations apply to all blowers and compressors and are discussed in this section. Design considerations that apply to specific types of units are presented in the next section.

Air Temperature

The density of air decreases with increasing air temperature. At higher air temperatures, less air is supplied in terms of q_{std} (standard volumetric flow rate). Therefore, the capacity of a system must be based on providing the required airflow rate during the maximum temperature period. For a given physical system, the maximum power consumption will occur at the lowest temperature. The motor must be sized large enough to supply the required power, or the discharge can be valved back to reduce power consumption.

Elevation

Increasing elevation reduces the output of compressors and blowers by about 5% per 300 m (1000 ft). This effect must be considered for high-elevation applications.

Diffuser Depth

If rearing units or holding tanks are of different depths, the system must be designed to provide air to the deepest unit. Valves must be installed on the distribution line to the shallower units to increase head losses. If this is not done, all of the air will flow to the shallower units.

Noise

Many compressors and blowers generate a significant amount of noise. These units should be placed in a separate room, if possible.

System Requirements

System requirements are very difficult to determine accurately, and they may change with time. To allow for future flexibility, the compressor building and main distribution system should be oversized. Unless the system output is constant over the year, two or more different-sized units are more economical than a single large unit. For critical applications, 100% standby capacity should be provided.

Pipe Selection

PVC pipe is probably the most commonly used pipe for primary and secondary air lines in blower systems. It is common to use plastic tubing between the secondary air line and the point of use. Air compressors and blowers result in a significant increase in air temperature (Eq. 5). The discharge temperature may be high enough to substantially reduce the strength of the discharge piping and to release potentially toxic compounds. Such problems are most likely to occur when two parallel compressors are turned on at the same time. Considerable care should be taken with the piping in the immediate area of the compressor, and a section of steel pipe may be needed.

In addition, the strength of PVC pipe is inadequate for most compressor systems, and PVC may not be allowed by some building codes. Black iron, galvanized iron, or copper pipe is commonly used in building systems. While condensation of water and oil is not a problem close to the compressor because of elevated temperature, condensation may occur in other parts of the distribution system, especially in unused feeder lines. The discharge of this condensed liquid mixture into the rearing units can be toxic to aquatic animals, and the rust and scale products will clog the diffusers.

SPECIFIC DESIGN CONSIDERATIONS

The most common types of blowers and compressors used in aquaculture are the positive displacement compressor, the rotary vane compressor, the liquid ring compressor, and the regenerative blower. Information on their specific design and operation is presented below.

Positive Displacement Compressors

Many compressors designed to provide building air at 400–700 kPa (60 to 100 psi) are not rated for continuous duty, and high-volume demand from an aeration system may result in early compressor failure as well as high power costs. A typical layout for a positive-displacement compressor system is presented in Figure 4a. While very desirable for aquaculture systems, most general building compressed air systems do not have a standby compressor, a refrigerated dehumidifier, or a particulate/oil filter. In these cases, it is necessary to install water/oil removal filters on individual air lines. One particularly useful system uses toilet paper as the filter element.

Regenerative Blower

The regenerative blower system is very commonly used to provide low-pressure air for aeration and mixing applications (Fig. 4b). A regenerative blower system produces oil-free air and is very reliable because of the small number of moving parts. Because of the low pressures produced by this type of unit, head losses in the distribution system and through diffusers must be carefully considered.

Rotary Vane Compressors

Rotary vane compressors have been used in the United States for aquaculture applications. When the rotary vanes are constructed from carbon, a small amount of fine carbon dust may be present in the air. This material can be filtered out, but is inert and should have no effect on most aquatic animals.

Liquid Ring Compressors

The liquid ring compressor is the only system that can produce oil-free and particulate-free air in the range of 400–700 kPa (60–100 psi). The unit uses a fixed-blade rotor in an elliptical casing. The casing is partially filled with water. This unit is widely used for hospital and laboratory applications but is more expensive than
Figure 4. Process flowsheet for (**a**) compressor system and (**b**) blower system.

conventional compressors. This type of compressor has been used in critical shrimp hatchery applications.

General Operation Consideration

As with all rotating equipment, proper routine maintenance will greatly increase reliability and reduce overall costs. The clogging of diffusers is a serious problem in many applications. Clogging may result from the formation of scale in the piping system or from the growth of microorganisms on the external surfaces of diffusers. Most diffusers need to be removed from the water when the air system is turned off. Clogged diffusers can be cleared with varying degrees of success; this may involve the use of strong acids and dangerous chemicals. Many times clogged units are simply replaced with new ones.

The operation of compressors is generally controlled by a pressure sensor that turns on the unit at the low-pressure setpoint and turns it off when the pressure reaches the high-pressure setpoint. Commonly, a large storage tank (receiver) is provided to reduce the cycling of the compressor.

Many blowers have a maximum operating pressure (Fig. 3). For these units, an air-relief valve is provided to protect the blower from excessive pressures (Fig. 4b). Blowers are generally operated continuously because it is not practical to provide significant receiver capacity at lower operating pressures.

INTRODUCTION

Rodolpho von Ihering, the "father of Brazilian aquaculture," predicted early in the twentieth century that we should raise fish as chickens. His first attempts to induce breeding of native fish species were in the 1930s (1,2). Yet, fish farming in Brazil only reached commercial status during the last decade of the century. The industry developed soon after induced breeding and fingerling production of tambaquí (*Colossoma macropornum*, Fig. 1) (3) at the Pentecoste Fishery Station (Ceará state) and pacu (*Piaractus mesopotamicus*; Fig. 2) (4) in São Paulo state. Those Characoidei species are well known and appreciated for their good flavor. Popular recreational fishes, tambaquí and pacu were responsible, in part, for the success of a large number of fee fishing establishments that first appeared near the city of São Paulo and then spread to all

Figure 1. Tambaquí (*Colossoma macropornum*).
Figure 2. Pacu (*Piaractus mesopotamicus*).

the southeastern provinces and are now being developed in the central and eastern regions of Brazil.

Ihering's attempts to induce breeding (which he called hypophysation) in native fish species continued in the northeastern region of Brazil, where he conducted experiments and attempted to enhance fish production by releasing the fingerlings obtained through hypophysation in reservoirs built for irrigation and as urban water supplies (5). Reservoir stocking still continues under the auspices of technicians of the Serviço de Piscicultura, a part of the agency responsible for the dam construction in the region, which is subject to severe droughts.

The first fish culture experimental station in Brazil was established in São Paulo state, at Pirassununga, near the Mogi Guaçu river. The station was put into operation in 1938, shortly before the death of Rodolpho von Ihering, its founder. Even with such facilities, the work and heritage left by Ihering was not expanded upon as might have been expected. A lack of governmental vision and, as a consequence, the absence of motivated students and researchers in the aquaculture field meant that there was little progress for many years.

Interest in fish culture rose again the 1970s with the foundation of São Paulo state Fishery Institute (Instituto de Pesca) and later when courses in fish culture began to be offered in Agronomy and Animal Sciences Colleges. In Pernambuco and Ceará states, courses in fishery engineering were established. The Pirassununga station was revitalized with support from the Food and Agriculture Organization of the United Nations. The result was the production of a number of students and researchers who became involved in efforts to develop tropical fish farming technology. As a result, farmers came to believe that fish culture could be a profitable activity. While still in its infancy, aquaculture has become the fastest growing agroindustry in Brazil. Much of the information that follows was obtained from a review by St. Paul (6).

FIRST ATTEMPTS AT AQUACULTURE IN BRAZIL

In the early 1960s, what might be called the amateur stage of Brazilian aquaculture started with the first pond rearing trials with tilapia (*Tilapia rendalli*) and common carp (*Cyprinus carpio*). Those activities can be classified as preliminary observation-level studies due to the lack of scientific method employed. In fact, the first trials consisted of testing the effect of different forages and various levels of penicillin as supplements to rations for the common carp (7,8).

At that time carp and tilapia were extensively reared in small reservoirs. Commercial production did not exist. For a period of about 20 years, fish culture in Brazil existed without any special involvement from the government or private investors, probably due to the lack of technology for rearing the two species and because of their low economic value. The SUDEPE (Superintendencia do Desenvolvimento da Pesca), at that time the Fisheries Agency of the Agriculture Ministry, only focused on capture fisheries and was not interested in the development of fish culture technology.

During the 1970s, experiments continued with carp and tilapia. Studies consisted of examining the effects of pond fertilization (organic, inorganic, or combinations) on plankton and fish production (9). Some research was conducted at the Animal Husbandry Fish Culture Section of the Agronomy and Veterinary Medicine College in Jaboticabal. There researchers were able to replace corn meal in rations for carp and tilapia (10). Additional studies at Jaboticabal were conducted to evaluate the influence of seasons on fish performance. It was found that harvested fish biomass was 60% higher during the summer (January and February) as compared with that obtained during the colder winter months (July and August) (11). An interesting trial related to the management system, and fish production was performed in a polyculture experiment with common carp, Nile tilapia (*Oreochromis niloticus*) and Brazilian catfish (*Rhamdia hilarii*) in ponds that received organic fertilization, pelleted food, or both. It was found that the latter treatment resulted in the production of almost 9 tons/ha/year in comparison with only 2.5 tons/ha/yr produced in ponds that received only chicken manure (12).

THE ROUND FISHES PACU AND TAMBAQUÍ

The so-called round fishes, pacu (from the Paraná river basin) and tambaquí (from the Amazon region), were the first native fish species to be reared commercially in Brazil. Those species received special attention from researchers in aquaculture, biology, and applied physiology. There has been some focus by biochemical geneticists on the taxonomy of those species, which were once both classified as belonging to the genus *Colossoma*. Today only tambaquí remains in the genus, though both are in the family Characidae (subfamily Mileinae). Pacu (Paraná river) and pirapitinga (Amazon river) are now reclassified as belonging to the genus *Piaractus*. These fish, at fingerling stage, are quite similar in many respects to the infamous piranha (*Serrasalmus* spp.), which belongs to the subfamily Serrasalminae (13).

The goal of producing these round fishes is to meet the growing demand by the fee-fishing establishments. In São Paulo state there currently exist more than 2,000 such operations. Two workshops relating to these species have been held in São Paulo state to provide a forum for the exchange of experiences and to transfer technology that could be used for commercial production. The first workshop was held in February, 1985 on the campus of UNESP (Universidade Estadual de São Paulo) in Jaboticabal City. The information available at the time was summarized during the workshop (14). Researchers from Mato Grosso and Mato Grosso do Sul Federal Universities presented studies related to the food habits of pacu and the characteristics of the natural environment of the species. Other papers related to the breeding season (from November to February) and compared age and growth of pacu in nature where females usually mature at 48 months and 2 kg (4.4 lb), whereas in culture where the fish are fed prepared rations in ponds, that size can be reached in 18 to 20 months.

The second workshop was held in CEPTA (Centro de Pesquisas e Treinamento em Aquicultura), formerly CERLA (Regional Latin American Training Center). Management systems for commercial production, larviculture, experimental rearing in earthen ponds, polyculture in pens and cages, and feeding and nutrition of pacu were among the topics covered (15). Papers were also presented on the qualitative and quantitative aspects of plankton in experimental ponds and on chemicals that can be used to control *Dactylogyrus* sp., a monogenetic trematode that is commonly seen in pacu-rearing ponds. Sodium chloride in a 2.5 ppt solution for 20 minutes was found to be the most effective treatment.

CESP, the energy company of the São Paulo state government, presented several papers on studies that were conducted through an agreement (convenium) with the Fishery Institute of the São Paulo state government. The papers involved induced breeding and larviculture in relation to management techniques for raising pacu in ponds. Also presented was a paper that showed a high level of acceptability of small-size fish [around 1.0 kg (2.2 lb)] as compared with those caught in the wild that were usually more than 2.0 kg (4.4 lb).

In the Symposium on *Colossoma* culture, several review papers concerning reproductive physiology and induced breeding (16), genetics (17), nutrition (18), and infectious and parasitic diseases (19–20) in the genus *Colossoma* were presented.

Other meetings in which research results on these species have been presented have been held at the São Paulo state Fishery Institute and the UNESP Campus of Jaboticabal city, as well as by the DNOCS (National Department of Actions Against Draughts) and CODEVASF (The Development Company of São Francisco River Valley) in the northeastern region of Brazil.

THE BRYCONINAE SUBFAMILY

Species in the subfamily Bryconinae are, according to Mendonça (20), widespread in most South American river basins. More than 40 species of these characins exist, which are highly valued by anglers. They can be called tropical salmonids due to their similarity in body shape and fighting behavior to fishes in the family Salmonidae.

The first attempts to induce breeding of the matrinxã (*Brycon* spp.) from the São Francisco river were performed at a Fish Culture Experimental Station near the dam of Três-Marias, in Minas Gerais state. Even before that first step toward Bryconinae domestication, the first trial related to nutrition and management with a member of this group of fishes, *B. cephalus*, had been conducted in Manaus by using wild fingerlings stocked into a recirculating water system (21).

At the UNESP Campus of Jaboticabal, a nutrition experiment was conducted in which isocaloric and isonitrogenous rations with different levels of protein from animal or vegetable sources were evaluated. Fish performance and protein digestibility were found to be independent of protein source (22).

In June, 1994 at the CEPTA meeting in Pirassununga city, São Paulo state, a seminar was held to review

Figure 3. Pirarucu (*Arapaima gigas*) or Brazilian cod.

existing information on the subfamily Bryconinae (23). A review paper summarized the breeding work conducted at CEPTA's Fishery Experimental Station. Nutrition management systems, pathology, and commercialization of piracanjuba (*B. orbignyanus*) and matrinxã (*B. cephalus*) were described. Interestingly, no papers were presented relating to the breeding, nutrition, and physiology of piraputanga, *B. lundii*, the natural habitat of which is the Paraguai river basin in the central region of Brazil. In that basin there is an annual production of hundreds of thousands of fingerlings of piraputanga, a species that is quite similar to piracanjuba (*B. orbignyanus*), endemic to the Paraná river and a few other streams. Several papers related to the use of hormones to induce breeding of piracanjuba (*B. orbignyanus*) and piabanha (*B. insignis*), a species endemic to the Paraíba do Sul river, were presented. The seminar demonstrated that the level of knowledge about the subfamily was sufficient for moving forward with culturing for the fee-fishing industry.

In addition to the species mentioned, there are other carnivorous fishes with great potential for aquaculture in Brazil, including the pirarucu (*Arapaima gigas*; Fig. 3) Brazilian cod, black-spotted, and striped catfish. Both produce good-quality boneless fillets and have high dressout percentages. However, there is still a lack of technology for raising these fish, especially with regard to diet development.

LARVICULTURE

Larviculture has played an important role in allowing Brazilian native fish culture to reach even its current modest production level, but there is still much more that can be accomplished in this area. At the end of 1989, a workshop on Larval Rearing of Finfish (22) was held in CEPTA, at Pirassununga city. The work done up to that time in Brazil, Colombia, and Central America was reviewed. Invited speakers presented talks on larval nutrition, health management, and zooplankton production in ponds. Later, several dissertations and theses on the larviculture of pacu, tambaquí, and Bryconinae (Fig. 4) species were given.

Yamanaka (24) has presented a detailed description of the early developmental stages of pacu, *Piaractus mesopotamicus*, from fry to fingerling. It was possible to obtain up to an 80% survival rate of pacu fingerlings reared within cages of fine mesh screen. Sipauba-Tavares (25) produced Chlorophycean algae to feed zooplankters

Figure 4. A school of fish in the subfamily Bryconinae.

(Cladocerans, Daphnidae, and calanoid copepod) as live feed for raising lambari, *Astyanax scabripinnis paranae*, and tambaquí, *Colosssoma macropomum*. High survival rates were obtained.

Zaniboni Filho (26) compared techniques for incubating tambaquí eggs and also identified the factors that affect qualitative and quantitative fingerling production. Funnel-shaped incubators with aeration enhanced fry hatchability. There was high variability in survival rates, but it was concluded that fingerling productivity increased with increasing doses of organic fertilization up to 620 kg/ha (528 lb/acre). Tambaquí fingerlings showed a clear preference for cladocerans. In fertilized ponds, fry only started consuming supplemental feed after 20 days of life.

Senhorini (27) experimented with chicken and bovine manure as organic fertilizers with and without supplemental feeding, compared with a control pond (without feed or fertilization). Survival rates in the fertilized ponds were around 50%, compared with 17.7% in the pond that only received supplemental feed, and only 3.6% in the pond without fertilization or supplemental feeding. Fregadolli (28) studied the effects of the availability of food and the presence of a predator, dragonfly nymphs (Odonata), on the growth and survival of tambaquí fry, in an experiment conducted in a 0.1-ha (0.04 ac) pond of CEPTA in the city of Pirassununga, in which fine-screen cages were set up for rearing fry up to the fingerling stage during a 40-day experiment. Treatments consisted of the introduction of cladocerans or chironomids as live feed and dragonfly nymphs as the predator. Tambaquí fry survival was not affected by the presence of the predator and only the availability of live feed (Cladocerans) had a significant influence on fry survival.

Cecarelli (29) set out to learn which species of fry from among pacu, tambaquí, and curimbata (*Prochilodus* sp.) would be the best to use as live feed for the production of Bryconinae. Results showed that pacu fry enhanced survival rates of Bryconinae fry due to their (pacu's) small size and slower swimming speed.

FISH NUTRITION

This area of research, considering its contribution to aquaculture development in Brazil, and a reasonable number of events sponsored by the Brazilian Committee on Animal Nutrition, deserves special comment. Experiments in fish nutrition started on the Jaboticabal campus of UNESP with a study in which the crude protein requirement for growth of tambaquí, an omnivorous Amazon species that can exceed 30 kg (66 lb), was found to be around 22% (30). On the same campus it has been determined that the crude protein required for growth of pacu is around 26% (31). In a subsequent experiment, it was shown that protein digestibility for pacu was 87% (32).

In the first symposium sponsored in Campinas city in 1986 by the Brazilian Committee of Animal Nutrition, R.T. Lovell from Auburn University, Alabama presented a paper on research in fish nutrition in which all aspects of the topic were covered (33). In 1988, the Third Mini Symposium of the Brazilian Animal Nutrition Committee was held on the Botucatu Campus of UNESP. At that event, Pezzato (34), speaking on technology of food processing for aquatic organisms, explained about the care needed during the grinding and mixing of formulated-feed ingredients and the effects of processing on the nutritive value and water stability of the ration. It is interesting to note that at that meeting nothing was mentioned about extruded rations.

In 1995 and 1997, two more symposia were sponsored by the Brazilian Committee of Animal Nutrition in Campos do Jordão and Piracicaba cities; both events were dedicated to the subject of nutrition. At the first of the two meetings (35), comprehensive overviews on fish and shrimp were presented, followed by presentations on prospects for the world's aquaculture feed supply, fish feed formulation and processing, regulation of growth, ration preparation, feeding strategies for raising carnivorous fish species, and nutrition management of nonsalmonid species.

At the second symposium (36), several aspects of fish production were covered. Topics included fish culture in Brazilian agribusiness, feeding strategies and water and feed quality in fish production, perspectives on industrial production of fish rations in Brazil, intensive and sustainable Brazilian native fish production, recent advances in the industrialization of freshwater fishes, and the raising of tilapia as an example of agroindustrial production.

CONCLUDING COMMENTS

Recently, the Brazilian National Research Council (Conselho Nacional de Pesquisas) organized a special workshop aimed at analyzing Brazilian aquaculture as a first step toward organizing this rapidly growing activity (37). The workshop pointed out that, in 1995, Brazilian aquaculture production was estimated at around 40,000 tons of freshwater fish, marine molluscs, and marine shrimp. Frogs (200 tons) and freshwater shrimp, *Macrobrachium rosenbergii* (250 tons), were also produced.

It was concluded that a more organized approach to technology development was needed (which is also under

consideration by EMBRAPA, the national Agriculture Ministry Research Agency). EMBRAPA will be responsible for increasing aquaculture production, but there is a serious lack of any organized extension (technology transfer) program, a fact which is a major constraint to increasing overall aquaculture production in Brazil. Another serious problem in Brazilian aquaculture began to be resolved in 1998 with the transfer of the administration of aquaculture and fisheries from the Ministry of Environment to the Agriculture Ministry, where the Department of Fisheries and Aquaculture was created.

In mid-December of 1998 a law was passed that allows the use of public water bodies (lakes, reservoirs, and also the littoral area of the marine environment) for aquaculture projects. This opportunity and credit stimuli, especially in the central, north, and northeastern regions, should bring Brazilian aquaculture production to over 100,000 tons by the first one or two years of the twenty-first century. Several projects involving intensive production of tilapia and *Colossoma* sp. are under consideration for establishment in lakes, reservoirs, and irrigation canals of the northeastern drought region, and also a few in the southeastern reservoirs built for hydroelectric power generation.

The last Brazilian Symposium on Aquaculture held in Pernambuco state in December, 1998 featured some 1,200 presentations and around 300 posters and demonstrated that aquaculture is becoming the fastest growing agribusiness industry in Brazil (38). Both the Brazilian Aquaculture and Fisheries Engineering Associations have sponsored symposia every two years at which the progress of aquaculture in Brazil was documented, despite the absence of a governmental policy.

Through governmental efforts, including training through the organization of formal postmedium (soon after high school) courses in aquaculture, the real start of the "blue revolution" in Brazil is anticipated. The first plants are beginning to produce tilapia fillets in Paraná and São Paulo states. That activity represents the real onset of the third stage of Aquaculture in Brazil.

BRINE SHRIMP CULTURE

GRANVIL D. TREECE
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

"Brine shrimp" is the common name of the genus *Artemia*. *Artemia* is a genus of brachiopod crustacean belonging to the order Anostracan. The genus and species name *Artemia salina* was shortened to the genus name *Artemia*, since it was proven that *salina* was the only species in the genus. Additional common names given to *Artemia* from worldwide sources include brineworm, Salztierchen, verme de sale, and Fezzanwurm. During the second half of the 19th century, several studies were published dealing with *Artemia*, and soon after, it was found to be an ideal animal for all types of scientific testing.

Today, *Artemia* is probably the single most important live food source for aquaculture hatcheries, especially for freshwater shrimp, marine shrimp, and most marine finfish hatcheries. *Artemia* eggs, or cysts, are mostly collected in the wild and sold to aquaculturists, but they have been produced under controlled laboratory conditions as well. By using particulate or emulsified products, rich in highly unsaturated fatty acids, the nutritional quality of *Artemia* can be further tailored to suit the predators' requirements by bioencapsulating specific amounts of these products in the *Artemia* metanauplii. Application of this method of bioencapsulation, also called *Artemia* enrichment or boosting, has had a major role in improving larviculture outputs in the 1990s. This contribution discusses the different aspects and importance of the brine shrimp, *Artemia*.

HISTORICAL NOTES ON BRINE SHRIMP

Schlosser first described adult *Artemia* (see Fig. 1), or brine shrimp, in 1755 (1). The average adult *Artemia*, usually after 10 days growth, is 8–10 mm (0.3–0.4 in.) in length, but it may take as long as three weeks for it to reach that length, depending upon culture conditions. Linnaeus (2) followed Schlosser in describing *Artemia*. Schlosser's drawings turned out to be more accurate than Linnaeus's description, but with the primitive eyepieces used at the time of Linnaeus's writing, this determination was not made until 1836. Long before being scientifically described, brine shrimp had been associated with better salt production in brine pools, because brine shrimp are filter feeders that remove algae and other organic particles, resulting in cleaner salt crystals (3). Seal (4) and Rollefsen (5) reported the value of freshly hatched *Artemia* nauplii as food for fish fry, and ever since, the exploitation of *Artemia* cysts has gradually increased.

Until the late 1970s, commercial supplies of *Artemia* cysts were available only from the United States and Canada. Salt pools, ponds, lakes, and salterns (also called *salinas*) with *Artemia* populations are found worldwide; however the distribution of these *salinas* is not continuous. Certain bodies of salt water lack brine shrimp, either because of a failure of natural dispersal or because of periodically unfavorable climatic conditions. However, their distribution is rapidly expanding. Since 1977, successful inoculations have been achieved in areas that previously did not have *Artemia* populations (e.g., Brazil, India, the Philippines, Thailand, and other countries). To give one example, nauplii from 250 g (0.55 lb) of San Francisco Bay cysts were introduced into a limited number of evaporation ponds on a brine production farm in the Rio Grande de Norte area, Macau, Brazil. The ecological conditions in the Macau *salinas*, with intake waters coming from a rich mangrove area, turned out to be very favorable for *Artemia* production. The population spread over several thousand hectares, and within one

Figure 1. Adult *Artemia* with cysts in the middle, male (left) and female (right).

year, over 15 MT of cysts were harvested. For several years, the yields exceeded 30 MT of cysts per year (6).

Sorgeloos (7) demonstrated the technical feasibility of *Artemia* production in temporary salt ponds in Southeast Asia. Inoculation tests with various geographical strains provided new information on genotypes and phenotypes (8). The application of these inoculation principles helped alleviate a cyst production problem, which occurred in the late 1970s. Although cyst production was the primary goal, exploitation of the adult *Artemia* biomass as a protein source for many aquaculture organisms was also vigorously pursued. By 1979, previous shortages were over, and the price of high quality cysts dropped from US$70/kg (US$32/lb) to US$35/kg (US$16/lb).

Today, there are many geographical strains of *Artemia*. More than 60 strains have been registered from areas including Algeria, Argentina, Australia, Brazil, Bulgaria, Canada, China, France, India, Israel, Iran, Iraq, Italy, Japan, Kenya, Mexico, Peru, Puerto Rico, Spain, Tunisia, the United States, the former USSR, and Venezuela. Numerous commercial harvesters and distributors exist that sell brands of different qualities. The present cost of good-quality cysts can range from US$66/kg (US$30/lb) to US$88/kg (US$40/lb), and the buyer can expect to have 200,000 to 300,000 nauplii hatch from each gram (6−9 million/oz) of cysts.

ENVIRONMENTAL REQUIREMENTS OF *ARTEMIA*

In nature, *Artemia* are found only in natural or man-made brine lakes and salterns. They have been observed swimming among precipitated crystals of sodium chloride in saturated brine (9). In the laboratory, *Artemia* have been shown to be extremely euryhaline, withstanding salinities from 3 ppt to 300 ppt (10). It has been suggested that the reason brine shrimp survive only at high salinities in nature is that competitors and predators are absent at such high salinities (11).

Artemia show good survival in temperatures ranging from 15° to 55 °C (59° to 131 °F) (12). The animal is also quite tolerant of high ammonia levels, remaining active at levels near 4.4 to 5.0 μg atoms NH_4-N/L (80 to 90 ppm) (13,14). Brine shrimp show good growth on a variety of dried, frozen, and live microscopic algae, yeast and bacteria and have even been grown on organic aggregates formed by the bubbling of water.

Larvae and adults can be reared at extremely high densities—e.g., 3,000/L (11,355/gal)—with only a moderate amount of special treatment, such as being fed plenty of algae (15,16). The environmental and nutritional requirements of brine shrimp remain approximately the same throughout their life. *Artemia* can achieve sexual maturity two weeks after hatching and are able to produce 40 larvae per day throughout their six-month to one-year life span. Their food conversion efficiencies are high in comparison with those of other animals, ranging between 20 and 80%.

RESEARCH ON THE USE OF *ARTEMIA* IN AQUACULTURE

Most of the research on brine shrimp for use in aquaculture has been done at the University of Ghent, Belgium,

since 1970. In 1970, research was conducted in the Laboratory of Ecology under Director and Dr. J. Hublé and was further expanded in 1972. It was continued in the Laboratory of Mariculture under the direction of Dr. G. Persoone in 1978. Under the direction of Dr. Patrick Sorgeloos, the facility became an independent research center, and, in view of an expansion of research and training activities, the name "Laboratory of Aquaculture & *Artemia* Reference Center (ARC)" was adopted in 1989 (Web site address: http://www.rug.ac.be/aquaculture). The University of Ghent has contributed much to our knowledge of brine shrimp. Research directly related to aquaculture has included the artificial inoculation of ponds with brine shrimp, optimization of the use of brine shrimp cysts in aquaculture facilities, controlled mass production of *Artemia* adults and cysts, comparative studies of the various geographical strains, and many other topics. Extensive literature exists on the hatching of brine shrimp (6,17).

THE TRADE OF *ARTEMIA*

As a marketing scheme, pet shops have sold *Artemia* cysts and referred to the hatching brine shrimp as "sea monkeys." With a stretch of the imagination, an *Artemia* adult could resemble a monkey to some people. Adult *Artemia* are often frozen or freeze dried and sold in the aquarium trade as fish food.

More advanced techniques for harvesting *Artemia* have evolved in recent years. As opposed to collecting the cysts on shore (Fig. 2) and separating them from the sand grains, spotter planes are now used to locate harvestable quantities of cysts, before the cysts wash on shore. Word of the cysts' location from the spotter plane is sent to a harvesting crew, and the crew generally approaches the area to be harvested by boat. The cysts windrow at the surface and can be concentrated and harvested using the

Figure 2. *Artemia* cysts on the bank or bottom of a *salina*.

Figure 3. Crew harvesting *Artemia* cysts by boat on the Great Salt Lake, Utah, USA.

same techniques used to clean up oil spills. Rubber, air-inflated booms or floating lines encircle and concentrate the cysts, which are then skimmed from the surface with vacuum heads (see Fig. 3). The cysts are placed in burlap sacks, sometimes weighing up to 2,000 pounds each. The sacks can be stored in warehouses until the cysts are processed. Processing involves separating the cysts from sand and other debris, drying the cysts, and vacuum sealing them in cans.

THE VALUE OF *ARTEMIA* IN AQUACULTURE; PHYSIOLOGICAL AND NUTRITIONAL MAKEUP

The value of *Artemia* in aquaculture is immeasurable. Due to the unique characteristics of its reproduction, development, physiology, and nutritional value, it is currently indispensable in aquaculture. Brine shrimp have two modes of reproduction: (*1*) ovoviviparous, when nauplii hatch in the ovisac of the mother and are born live; (*2*) oviparous, when embryos at the gastrula stage of development are encased in a hard capsule, or cyst. Reproduction is also parthenogenetic in some strains of *Artemia*, but sexual in most. Certain environmental conditions may trigger the adult female *Artemia* to produce cysts instead of live young. For example, the live animals may be threatened with cold weather, or the salinities of the salina may rise rapidly, thereby sending a message to the female that the water may soon evaporate. The dehydrated cysts can be stored for months or years without loss of hatchability (18). Each cyst is 200 to 300 µm (0.0078 to 0.01 in.) in diameter, depending upon the strain. Its external layer is composed of a hard, dark-brown, lipoproteinaceous chorion (19). Osmotic withdrawal of water, dehydration by air, or anoxia causes the encysted embryo to enter a resting stage with little or no sign of life. The cryptobiotic state of the cyst allows it to withstand complete desiccation, temperatures over 100 °C (212 °F) and near absolute zero, high-energy radiation, and a variety of organic solvents (20). Yet only water and oxygen are required to initiate the normal development of the embryo. This durable, easily hatched diapause stage makes *Artemia* cysts a convenient, constantly accessible source of live animals for the aquaculture hatchery operator.

Within 24 hours after being placed in seawater at 28 °C (82 °F), the chorion, or hard coating of the cyst, breaks (Fig. 4a), and the embryo, still surrounded by a transparent hatching membrane, is released (Fig. 4b). The prenauplius in E-1 stage can be seen in Fig. 4a, and the prenauplius in the E-2 stage can be seen in Fig. 4b. At this point, the embryo can be seen moving within the membrane, but still has not hatched. However, within a few hours, the nauplius breaks free of the hatching membrane and becomes free swimming (21) (Fig. 4c). It is then referred to as a freshly hatched Instar I nauplius. Within hours, the nauplius passes through the instar stages. The fifth instar stage can be seen in Fig. 4d.

(d)

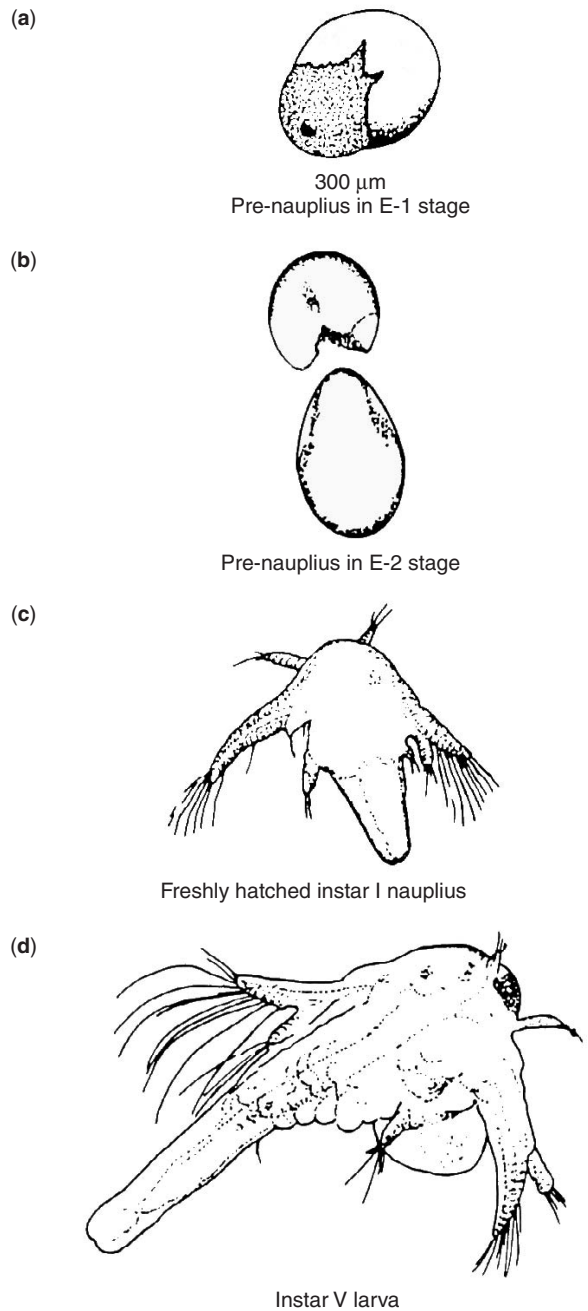
Instar V larva


Figure 4. *Artemia*: hatching cyst, embryo, nauplius and larva.

Artemia nauplii can live on yolk and stored reserves for up to five days (22), but the yolk's caloric and protein content constantly diminish during this time (23). This yolk sac is one of the main reasons that *Artemia* nauplii provide such a good food source to other animals.

The lipid level and fatty acid composition of newly hatched *Artemia* nauplii can be highly variable, depending upon the strain (24–29). The presence of highly unsaturated fatty acids (HUFAs) in *Artemia* has been the source of many studies. Most of these studies have revealed one thing: The level of HUFAs in *Artemia* is directly related to the culture performance in larval fish and crustaceans (29–31). This factor confirmed the theory by Watanabe (32), which states that the presence of essential fatty acids is the principal factor for the food value of brine shrimp. Low levels of HUFAs result in low survival and vary from strain to strain, but also vary within a strain from one harvest to another (32–34). It has also been shown, in other studies, that the type of food consumed by the parent *Artemia* greatly influences the fatty acid profiles in the cysts. Manipulation of the food conditions has thus far been limited to small-scale operations such as intensive tank systems (34–36).

The chemical breakdown of one well-known brand of *Artemia* cyst is as follows: On a dry-weight basis, the cysts contain 28.8% crude protein, 10.0% crude fiber, and 10.0% crude fat. The fatty acid profile of the cyst is as follows:

Percent Unsaturated Fatty Acids		Percent Saturated Fatty Acids	
Arachidonic	1.18	Arachidic	5.13
Clupanodonic	0.47	Myristic	2.20
Linolenic	26.42	Palmitic	10.96
Oleic	27.09	Stearic	7.28
Palmitoleic	6.23		

It is important that the *Artemia* nauplii are harvested and fed to fish and crustacean larvae in their most energetic form — i.e., as soon as possible. Holding nauplii in seawater at room temperature (mostly in outdoor conditions) results in a continual decrease in the energy content of the nauplii. The nutritional value is significantly lower for older, starved nauplii, such as those in the Instar V stage (see Fig. 4d), versus freshly hatched Instar I nauplii (see Fig. 4c). The nutritional problems are associated not only with the decrease in nutritional value (a drop in dry weight and caloric content), but also with the increasing size of the nauplii (they become too large for the larvae to consume). Other problems associated with feeding older nauplii to larvae are swimming rates (the nauplii become too fast for the larvae to catch) and color perception (freshly hatched nauplii are dark orange and are much easier to see than the starved nauplii, which are transparent) (6).

Nutritionally, *Artemia* nauplii seem to meet the necessary requirements of most fish and crustacean larvae cultured today, but, as previously mentioned, the nutritional value among different *Artemia* strains is highly variable. To document these variations in strains, an international interdisciplinary study on brine shrimp was initiated in 1978. Several techniques were used to enhance the nutritional value of the "poorer" strains. Even though these techniques are not recommended as part of best management practices for hatcheries, they may help overcome problems with inferior cysts.

The technique for improving the nutritional value of *Artemia* nauplii consists of hatching and separating the nauplii from the debris and then holding the nauplii for up to three days in an enriched medium containing marine algae, encapsulated diets, yeast, and/or oil emulsions (37). This technique applies only if the *Artemia* are being fed to older fish and shrimp.

Without *Artemia*, finfish and shrimp hatcheries would have difficulty finding a dependable, nutritionally complete, economical food source for their larval culture. Saltwater finfish and crustacean hatcheries and freshwater crustacean hatcheries generally give live feeds to the larvae in order to obtain better survival. Some producers of hybrid striped bass and freshwater perch have used live feeds such as rotifers and brine shrimp to successfully raise freshwater fish. But this method is generally considered too expensive and is not practiced as often in freshwater finfish hatcheries as it is in saltwater finfish and crustacean hatcheries and in freshwater crustacean (*Macrobrachium* spp.) hatcheries. *Artemia* are fed to numerous commercially important cultured species in all stages of development (larvae, juveniles, and adults). Even though zooplankton contain their own enzymes that aid fish and crustaceans in digesting them, *Artemia* usually are deficient in several essential nutrients, especially the n-3 HUFAs, required for good growth and development of marine fish and shrimp larvae (38). These findings have led to further research, and methods were developed that enabled the nutritional condition of live feeds to be improved. The proximate analysis and n-3 HUFA levels of some of the common feeds used in larval fish and crustacean production are listed in Table 1.

Finfish producers have become concerned with improving the quality, quantity and cost effectiveness of their live-feed production facilities. Many producers worldwide now supplement *Artemia* cultures with omega yeast, vitamins (E, D, C, and B_{12}), marine oils, and vitamin B_{12}–producing bacteria to improve the quality. Today, the *Artemia* that are fed to fish larvae are being improved, and their biochemistry is routinely adjusted by controlling their diet and supplementing the cultures with microencapsulated feeds or emulsified oils. Such adjustments have resulted in better growth and development of fish larvae, but, in some cases, malpigmentation still occurs in the juvenile stage (40). While *Artemia* is one of most widely used live food items in aquaculture, its use is not without problems and limitations. For example, when the brine shrimp harvest is cut short on the Great Salt Lake in Utah, the price of *Artemia* cysts increases.

CRITICAL PARAMETERS FOR OPTIMUM HATCHING OF *ARTEMIA*

While extensive literature exists on the hatching of brine shrimp (17), the actual procedure of hatching *Artemia* cysts is simple. When working with large numbers and

Table 1. Proximate Analysis And n-3 HUFA Levels of Some of the Common Feeds Used in Larval Fish and Crustacean Production[a]

Species/Feed	Protein[b]	Carbohydrate[b]	Lipid[b]	n-3 HUFA (% total fatty acid)

[a] From D'Abramo et al. (39).
[b] Units are % dry weight.

high densities of cysts, the following parameters should be considered to assure maximum hatching efficiency:

- Keep the cysts dry. (Place them in a desiccator after the can is open.)
- Hold the temperature constant during hatching at 25° to 30 °C (77 to 86 °F). Below 25 °C (77 °F), the cysts will hatch slowly, and above 33 °C (91 °F), cyst metabolism is greatly affected.
- Maintain the salinity at 5 ppt. [Dilute natural seawater to 5 ppt with dechlorinated tapwater, or use 2 g of technical grade salt per liter (2.2 oz/10 gal) of tapwater.] Determine the salinity with a refractometer. Research has shown that nauplii have a higher energy content when hatched at low salinity (6).
- Oxygen levels should be above 2 mg/L (2 ppm). Constant aeration is necessary during hydration and hatching; it helps disperse the cysts.
- The cyst density should be 5 g of cysts per liter (2.2 oz/10 gal) of water.
- A bright, continuous light above the cysts is necessary during hatching. [Place 2,000 lux, 186-foot candles 20 cm (7.87 in.) from the hatching containers.]
- Cyst disinfecting is highly recommended to assist with improving hatching yields and killing bacteria that are often found on the cysts and could be harmful to the larvae being fed the *Artemia* nauplii.

Note the following precautions and limitations:

- Do not use airstones to aerate cysts, because the airstones will create foam.
- Do not put more than the recommended 5 g (0.16 oz) of cysts per liter (33 fl. oz) of water, (as foaming may also be caused by the addition of too many cysts to the hatching container.)
- If a sufficient oxygen level cannot be maintained without foam formation or mechanical injury of hatching nauplii, add a few drops of a nontoxic, food-grade antifoaming agent (e.g., silicone).
- A buffer may be necessary during hatching to keep the pH above 8.0.

According to Sorgeloos et al. (6), some strains of *Artemia* nauplii (e.g., Chaplin Lake, Canada) are very difficult to separate from debris. This problem may be overcome by decapsulation. The technique is described by Sorgeloos et al. (6) and later herein. The use of decapsulated cysts eliminates naupliar separation problems, reduces surface bacterial populations and makes it possible for fish larvae to ingest and digest the *Artemia* before they are hatched. One disadvantage, however, is that decapsulated cysts are not buoyant and will settle out if extra circulation or aeration is not provided. Most hatchery managers prefer to aerate gently and not circulate or exchange water at all during the first week, since the larvae are quite fragile. The decapsulation of cysts improves the hatchability of *Artemia* (41).

RECOMMENDED PROCEDURES FOR HATCHING *ARTEMIA*

- Obtain good-quality *Artemia* cysts from a reputable company that offers a hatch guarantee.
- Set up hatching containers as follows:

(a) Determine the amount of *Artemia* required, according to the size and demand of the hatchery.

(b) Size the hatching containers accordingly. Sizing is site specific, so only the important parameters of the hatching procedure are presented here, and determining the number and sizes of containers is left to each individual hatchery. Any funnel-shaped, transparent container will do for hatching.

(c) A typical *Artemia* hatching stand for a small-scale laboratory consists of four or five Imhoff Cones (sediment settling cones), either clear plastic or glass. (See Fig. 5.) The cones can be purchased open ended, with a plastic valve inserted at the small end for draining, or the cones can be purchased without the opening, and a siphon can be used to remove hatched *Artemia* after they settle to the bottom. Aeration to the cones is provided by connecting a glass pipette to an air line and allowing the weight of the glass pipette to hold the air supply in place, at the bottom of
Figure 5. *Artemia* hatching cones and stand.

the cone. A fluorescent light is placed near the hatching containers.

Conical-shaped, clear plastic bags also work well as hatching containers, but seawater has a tendency to corrode the clips and metal ring stands used to support these bags. A wooden Imhoff cone support stand is often used for small-scale hatching of cysts. These stands can be homemade very easily. For additional ideas on the use of larger hatching containers, see Sorgeloos et al. (6). Some hatcheries utilize clear plastic, 19-L (5 gal) drinking water bottles with the bottoms removed. The bottles are inverted, and a rubber stopper is firmly placed in the mouth. A hole is drilled in the stopper to allow the placement of a tight-fitting air line, which is later used as a drain tube when harvesting nauplii. Crow (42) described the hatching of *Artemia* nauplii in 57-L (15 gal) cylindrical, conical-bottom, polyethylene tanks. That method used 100 g (3.5 oz) of cysts in each tank, which were hatched and fed to *Macrobrachium*. Large-scale efforts may involve 1,000-L (264 gal) or larger fiberglass conical tanks.

To disinfect cysts, soak the cysts for one hour in 20-ppm hypochlorite (bleach) in tapwater, or in a 200-ppm mixture for 20 minutes, if you are in a hurry. For example, adding 4 mL (0.03 fl. oz) of household bleach solution to 10 L (2.64 gal) of tapwater is effective and provides enough solution to disinfect one kg (2.2 lb) of cysts. Be sure to aerate the disinfecting solution so that each cyst is exposed to the disinfectant.

- Pour the cysts on to a 120-μm (0.004 in.) sieve, and wash them with tapwater.
- Then the cysts are ready to be placed into the hatching container.
- Start aeration, and leave the cysts in hatching medium (5 ppt seawater) for 24 hours before taking the first harvest. Remember to keep the temperature from 25 to 30 °C (77 to 86 °F) and turn the light

on, placing a 60-watt fluorescent bulb within 20 cm (9 in.) of small hatching containers. Use two bulbs for a 19-L (5 gal) container, use four bulbs for a 76-L (20 gal) container, and so forth.

RECOMMENDED PROCEDURES FOR HARVESTING AND COUNTING *ARTEMIA*

After 24 hours, remove the aeration, and let the cysts settle for 5 to 10 minutes. A distinct separation should occur. Empty cyst shells will float to the surface, and the nauplii will tend to concentrate near the bottom. There may also be some debris and unhatched cysts at the very bottom. Open the valve on the hatching tank to drain the debris. Close the valve when the newly hatched nauplii begin coming out. A graduated beaker can be used to collect the now-concentrated nauplii for a small-scale hatching or a 19-L (5 gal) bucket can be used on a larger scale. This procedure should be repeated later to ensure that all of the newly hatched nauplii are harvested. Floatation of the cyst shells can also be improved by raising the salinity. The sudden salinity change will not harm Instar I nauplii.

Cysts from some strains do not all hatch at the same time, and sometimes a number of cysts are still unhatched after 24 hours. If this is the case, place more seawater into the hatching container, aerate, and try the harvesting routine again at 36 hours and finally at 48 hours. Nauplii can also be concentrated with light, since they are negatively phototactic at this stage. One may want to take advantage of this factor during harvesting, or one may prefer just to turn off the overhead light and let gravity do the concentrating.

Some strains of *Artemia* present more difficulty than others in the separation of nauplii from their old egg cases. With these particular cysts, or whenever contamination with empty shells and debris becomes a problem, use decapsulated cysts. This is an added step that most hatchery managers try to avoid but the procedure is well documented in the literature (6).

The decapsulation procedure involves the following steps: (*1*) hydration of the cysts, (*2*) treatment in a decapsulation solution, (*3*) washing and deactivation of chlorine used in the decapsulation, and (*4*) feeding the eggs directly to larvae, or waiting until the nauplii hatch and then feeding them to larvae.

In order to prevent contamination of the larval culture tank with glycerol (which is produced by *Artemia*), hatching metabolites, and excessive bacteria, harvested nauplii are placed on a 125-μm (0.004 in.) sieve and washed with tap water prior to being fed to larvae.

Ideally, *Artemia* should be fed to larvae immediately after hatching but if this is not possible, then freshly hatched nauplii should be stored in the refrigerator at 0 to 4 °C (32 to 39 °F) in aerated containers. According to Sorgeloos et al. (6), nauplii can be maintained in this state at densities up to 15,000/mL (0.03 fl. oz) for up to 48 hours, with nauplii viability remaining at more than 90%.

After nauplii have been washed and concentrated into a container of known volume, they can be counted by mixing the thick nauplii solution and subsampling it with a graduated pipette. A count of nauplii can be made by holding the pipette horizontally, counting the number of nauplii seen swimming between two of the graduated hash marks [with a known volume, of 0.1 mL (0.0034 fl. oz), for example], and extrapolating to give the total number of nauplii harvested. A small-volume, automatic pipette can also be used to trap a known volume of concentrated nauplii. A method of determining the amount of *Artemia* nauplii to feed finfish and crustacean larvae is illustrated in Table 2.

For most larvae, a food organism has to meet certain physical and nutritional requirements. Physically, *Artemia* are relatively free of extraneous material and disease-producing bacteria (after the separation and disinfecting techniques described previously). The acceptability of *Artemia* by fish and crustacean larvae is facilitated by their good perceptibility, catchability, and palatability (if fed very soon after they have hatched). However, in some cases, *Artemia* (even freshly hatched nauplii) can be difficult to ingest, due to their size. The size of a food organism indeed determines whether a larval fish or crustacean can successfully catch and ingest it. For this reason, it is extremely important to continue feeding larvae smaller food organisms such as algae and/or rotifers, while introducing to them the larger food organisms (i.e., *Artemia* nauplii) as well. The rotifer

Table 2. Method of Determining the Amount of *Artemia* Nauplii to Feed Finfish and Crustacean Larvae

One way to determine the amount of *Artemia* to be added to a rearing tank is by following six easy steps:

1. Number of *Artemia*/mL (0.03 fl. oz) required $= A$.
2. Present density in larval rearing tank [number of *Artemia*/mL (0.03 fl. oz)] $= B$.
3. $A - B = C$.
4. $C \times$ [Volume of larval rearing tank in mL (0.03 fl. oz)] $= D$.
5. Number of *Artemia*/liter (33 fl. oz) in feed container $= E$.
6. $\dfrac{D}{E} \times 1,000 =$ no. of mL (no. of 0.03 fl. oz) of *Artemia* to add.
Figure 6. Schematic presentation of respective sizes of 12 to 13 day old predator larval red drum and freshly hatched *Artemia* nauplius.

is generally between 99 to 281 μm (0.003 to 0.011 in.) in length, whereas the brine shrimp nauplius is 428 to 517 μm (0.0168 to 0.02 in.) in length, depending upon the strain. Figure 6 depicts the size of a freshly hatched *Artemia* nauplius relative to a 12- to 13-day posthatch larval fish. The larval sketch was redrawn from Johnson (43).

Considerable differences in the size of *Artemia* have been found from strain to strain. Feeding an oversized *Artemia* strain may, therefore, explain poor growth and even mortality due to starvation of the predator larvae. Before selecting a strain of brine shrimp for use in a hatchery, it would be wise to ask other hatchery managers for their suggestions. Also read (31), which describes results of international studies on *Artemia*; the sections dealing with the culture success obtained with various marine animals fed *Artemia* nauplii from different geographical origins provide results on survival and growth.

WHEN *ARTEMIA* ARE FED: THE IMPORTANCE OF TIMING

Generally speaking, *Artemia* are fed to larval fish and some crustaceans until they are approximately 15 to 20 days old. However, some species, such as *Macrobrachium*, are fed *Artemia* during the entire hatchery phase, which could be as long as 45 days. Other finfish, such as the striped mullet and gray mullet (*Mugil* spp.), are often fed *Artemia* until they are 60 days old, but eventually hatchery managers all try to wean their species to other, less expensive foods.

Red drum (*Sciaenops ocellatus*) larvae are generally fed rotifers from day 3 posthatch to day 9 or 10, depending on the temperature and the size of the red drum larvae. It is important not to feed them the *Artemia* nauplii too soon; a gradual transition should be made to larger foods (i.e., from rotifers to *Artemia* nauplii). *Artemia* nauplii are then fed to the larvae from day 11 to day 15, and the *Artemia* nauplii are maintained in the culture tank at densities between 0.5 to 2.0 per mL (0.03 fl. oz). A shrimp puree and dry fry food diet is fed from day 15 to day 21. Weaning larvae from one feed to the next is commonly practiced in the industry for better larval survivals. Striped mullet larvae, to give another example, are fed rotifers at 5 to 20/mL (0.03 fl. oz), starting on day 2 posthatch and continuing until day 40, while *Artemia* nauplii are started on day 12 to 15 and continued through day 60. Artificial food is started as early as day 20. Grey mullet are routinely raised in fresh and brackishwater ponds in China, Hawaii, Hong Kong, India, and Israel and are fed *Artemia* in the hatchery phase. However,

heavy mortality can occur, because the mullet ingest empty cysts, or shells, until they are four weeks old. Therefore, care must be taken to remove the empty cysts before feeding. In Hawaii, the culture of the threadfin (*Polydactylus sexfilis*) involves feeding them *Artemia* starting at day 10. Juveniles are weaned to chopped squid by day 44, after a short period of being fed frozen adult *Artemia*.

Saltwater shrimp are generally fed *Artemia* nauplii starting at the late zoea stage to the mysis stage and continuing until the shrimp are stocked in ponds. Saltwater shrimp do not have the capability to seek out *Artemia*, nor do they develop the mouth parts necessary to eat *Artemia* before the late zoea stage; therefore, feeding them *Artemia* too soon would be a waste. The Kuruma shrimp (*Marsupenaeus japonicus)* can consume 50 *Artemia* nauplii per day when it is in the mysis stage and 80–100 per day in the postlarval stage. Unlike saltwater shrimp, freshwater shrimp do have the capability to catch and eat larger prey earlier; therefore, they are started on *Artemia* right away, at concentrations between 5–10/mL (0.03 fl. oz) of water, and are generally fed nauplii twice daily for 20 days or throughout the entire hatchery phase. The King Crab (*Paralithodes camtschatica*) is fed *Artemia* nauplii starting with its zoea stage. However, other creatures eat *Artemia* nauplii as well and can cause problems in the hatchery. For example, occasional blooms of inadvertently introduced jellyfish, *Moerisia lyonsi*, have caused high mortalities among *Macrobrachium* spp. larvae, because the hydrozoan feeds on *Artemia* nauplii and establishes high population densities in a matter of weeks. In the process, the medusae of the jellyfish also ingest the shrimp larvae.

Juvenile lobsters have been fed frozen *Artemia* with good results, but the greatest survival and growth are obtained when lobsters are fed live adult *Artemia*. In 1979, the author of this contribution was in charge of a shrimp feeding trial conducted in St. Croix, USVI, wherein shrimp *Litopenaeus stylirostris*, were fed 15 different diets. The best results came from feeding the shrimp live adult *Artemia*. Unfortunately, this is not practical or economical in most locations.

For most finfish species being reared, weaning from live *Artemia* to dry food should begin a few days before transformation and should be finished by the time the fish are juveniles. This process might be done in three days or take as long as two weeks. Young fish have small stomachs and must be fed often, but once they are 100 mm (4 in.) in length, fish need only one feeding per day.

SOURCES AND COST OF *ARTEMIA*

Approximately 90% of the world's commercial harvest of brine shrimp eggs come from the Great Salt Lake, Utah, USA. With wholesale egg prices at US$22/kg (US$10/lb), the Salt Lake industry sells approximately US$30 million worth of the product per year. In an average year, the lake produces 4.5 million kg (10 million lb) of raw, wet eggs (cysts), which processes into 1.1 to 1.3 million kg (2.5 to 3 million lb) of Grade A product, with a hatch rate of greater than 90%. Growth in the brine shrimp

harvest industry in Utah has been steady since 1950. Brine shrimp production from the Great Salt Lake reached a peak in 1995–1997, when the lake produced 6.75 million kg (15 million lb). In 1997, at least 32 firms had at least 80 crews on the lake harvesting cysts. Excessive rainfall in 1998 and 1999 caused a collapse in this industry and prices to rise. The cost of good-quality cysts fluctuates with supply and demand, and the buyer can expect to pay US$26.40–$88/kg (US$12–40/lb). The most common packaging form of *Artemia* cysts on the world market is the 0.45-kg (1 lb) can (see Fig. 7), similar to the size of a coffee can. Additionally, the cysts come packed in 2.2-, 4.5-, 6.7 and 11-kg (5, 10, 15 and 25 lb) pails and 103- and 126-kg (230 and 280 lb) barrels. Usually, orders of 454 kg (1,000 lb) or more qualify the buyer for substantial discounts from the wholesale suppliers. The buyer should expect 200,000–300,000 nauplii to hatch from each gram (0.03 oz) of cysts.

Once *Artemia* cysts are hatched, they can easily be separated from the shells and other debris and fed to larvae. (See Fig. 8.) The ease of feeding *Artemia* to larvae and the superior nutritional value of *Artemia* ensure that brine shrimp will be used in hatcheries for many years to come.

BUFFER SYSTEMS

Gᴀʀʏ A. Wᴇᴅᴇᴍᴇʏᴇʀ
Western Fisheries Research Center
Seattle, Washington

OUTLINE

Chemistry of Buffer Systems
Assessing Buffering Capacity
Management Recommendations
Bibliography

Chemically, a buffer is a mixture of a weak acid and its conjugate base (salt), the function of which is to prevent the changes in pH that would otherwise occur when external acids or bases are added to a solution. In aquaculture, the buffering system of interest is provided by dissolved carbon dioxide and the bicarbonate/carbonate mineral salts naturally present in water. In freshwater with low buffering capacity, (alkalinity <20 mg/L), the pH can fluctuate widely, due to the CO_2 addition and removal

caused by the natural daily cycles of respiration of fish and respiration and photosynthesis of aquatic plants, algae, and phytoplankton. In pond aquaculture, for example, nighttime production of CO_2 can be quite high, because both aquatic plants and animals are respiring. During daylight hours, intense sunlight causes rapid algal growth that may consume dissolved carbon dioxide faster than it can be replaced by fish respiration and diffusion from the atmosphere. The pH of a pond can increase from a nighttime low of 5.0 up to 9.5–10 in a matter of hours. In contrast, the pH may change by only one or two units in ponds with good buffering capacity (alkalinity >100 mg/L). Similarly, CO_2 production in fish transport tanks can be quite high, and water with good buffering capacity can help prevent the pH fluctuations that would otherwise occur if CO_2 stripping by the aeration system is inadequate. Finally, buffering capacity is important in ponds and recirculating aquaculture systems because the nitrate and H^+ (nitric acid) produced as nitrifying bacteria oxidize ammonia would otherwise cause a progressive decline in the pH of the water.

The carbonate buffer system also exists in seawater, where it is even more effective, because of the higher concentrations involved. Surface ocean water is strongly buffered near pH 8.2, and pH fluctuations are not normally an issue in mariculture operations.

CHEMISTRY OF BUFFER SYSTEMS

The buffering capacity of water in aquaculture systems is provided by the natural alkalinity of the water, the major components of which are carbon dioxide (CO_2), carbonic acid (H_2CO_3), and bicarbonate (HCO_3^-) and carbonate (CO_3^{-2}) ions. The equilibrium reaction is:

$$CO_2(gas) \rightleftharpoons CO_2(aq) + H_2O \rightleftharpoons H_2CO_3$$
$$\rightleftharpoons H^+ + HCO_3^- \rightleftharpoons 2H^+ + CO_3^{-2}.$$
In soft-water areas, CO_2 dissolved from the atmosphere provides these components by reacting with water to form the weak acid H_2CO_3, which, in turn, dissociates to form bicarbonate and carbonate ions. Water high in carbonate hardness and alkalinity (from limestone in soils and bedrock, or the use of concrete ponds) provides additional bicarbonate and carbonate, which supplement the natural buffering capacity provided by dissolved atmospheric carbon dioxide. Over the pH range important to aquaculture (6.5–9), bicarbonate is the major species present in the water. Little carbonate ion is present unless the pH is greater than 10. Carbon dioxide and H_2CO_3 predominate at pH values less than 5.

Because the carbonate system can react with both acids and bases, it provides a relatively strong buffer against increases or decreases in pH. If alkaline (OH^-) substances are added, the equilibrium shifts to the right, OH^- ions are consumed, and the pH does not increase. The increases in pH that would otherwise occur, due to the consumption of dissolved CO_2 by algae and phytoplankton, are prevented in a similar manner.

A major source of acid in aquaculture systems is the metabolic CO_2 produced by fish and plant respiration. The decrease in pH that would occur due to CO_2 production is prevented, because the equilibrium of the carbonate buffer system shifts to the left. The added acid (H^+) is tied up in H_2O, H_2CO_3, and HCO_3^-, and the pH remains constant. The oxidation of ammonia by nitrifying bacteria in biofilters or pond sediments is another significant source of acid:

$$NH_4^+ + 2O_2 \longrightarrow NO_3^- + H_2O + 2H^+.$$
Again, the bicarbonate component of the buffer system reacts with the H^+, the added acid is removed from solution, and the pH remains relatively stable.

The bicarbonate buffer is classified as an open system, because one of its components (CO_2) can enter or leave the water relatively freely. Consequently, shifting the equilibrium to the left increases the H_2CO_3 concentration, and CO_2 is released and then stripped into the atmosphere by the aeration system. Although a slow process, carbonate and bicarbonate are steadily lost to the system and must be replaced, or else the buffer capacity will be reduced. The water exchange rate may be sufficient to replenish the alkalinity, or the CO_2 produced by fish respiration may be adequate. If not, sodium bicarbonate may be added (1).

The pH of a buffered system can be calculated from the Henderson–Hasselbach equation:

$$pH = pK + \log [base]/[acid].$$

The pK, the dissociation constant of the weak acid or base in question, is temperature and salinity dependent, and its values are available from standard handbooks. Substituting appropriate numbers for the carbonate and bicarbonate buffer in freshwater yields

$$pH = 6.37 + \log[HCO_3^-]/[H_2CO_3]; \tag{1}$$

$$pH = 10.25 + \log[CO_3^{-2}]/[HCO_3^-]. \tag{2}$$

Inspecting equations 1 and 2 reveals that the pH is determined by the ratios of the buffer components, rather than by their concentrations. Conversely, the ratio of $[H_2CO_3]$ to $[HCO_3^-]$, and $[HCO_3^-]$ to $[CO_2]$, is fixed at any given pH. When the concentrations of the two components are equal, the pH will equal the pK value. This is also the pH region of maximum buffering capacity (i.e., resistance to pH change). In freshwater of moderate alkalinity, the resulting pH is usually stabilized in the mid-7 range (i.e., 7.2–7.8). Because of its high carbonate concentration, seawater is strongly buffered at about pH 8.2.

As previously mentioned, the buffering capacity of freshwater over the pH range important to aquaculture is largely due to bicarbonate. As a first approximation, the $[CO_3^{-2}]$ can be neglected unless the pH is greater than 9, and the $[H_2CO_3]$ can be taken as the dissolved CO_2 concentration (P_{CO_2}), giving us

$$pH = pK + \log[HCO_3^-]/P_{CO_2}.$$

Table 1.

pH	Bicarbonate Alkalinity (mg/L as $CaCO_3$)				
	30	50	70	90	110
6.5	18.9	31.6	44.3	56.9	69.6
7.0	6.0	10.0	14.0	18.0	22.0
7.5	1.9	3.2	4.4	5.8	6.9
8.0	0.6	1.0	1.4	1.8	2.2

Thus, the dissolved CO_2 concentration is fixed by the buffer and can be calculated from the bicarbonate alkalinity and the pH (2). Alternatively, the alkalinity can be used to determine the concentration of CO_2 needed to adjust the pH of the water to a particular value. Automatic CO_2 injection equipment is commercially available for this purpose and is widely used to stabilize the pH in heavily planted aquaria, because the added CO_2 stimulates plant growth. Approximate values of free CO_2 (mg/L) for a range of alkalinity and pH values are shown in Table 1 (at $25 °C$; no correction for total dissolved solids).

Note that allowing the pH to drop below about 7.0 in waters with even moderate degrees of alkalinity will generate free-CO_2 levels greater than the 20 mg/L generally regarded as safe (3), and adequate air stripping will be required. Detailed information for the complete range of temperature and pH important in both cold- and warm-water aquaculture can be found in Boyd (4).

ASSESSING BUFFERING CAPACITY

Most of the buffering capacity of freshwater and saltwater comes from the carbon dioxide, carbonates, and bicarbonates naturally present. Thus, either alkalinity or carbonate hardness (KH) determinations can be used to assess buffering capacity. Portable water-quality test kits give adequate results for routine assessments, but the results may be expressed in unfamiliar units. Milligrams of $CaCO_3$ per liter (mg/L) is most commonly used in aquaculture; degrees of hardness (dKH) is widely used in the aquarium industry; and milliequivalents per liter (meq/L) is used exclusively in the modern scientific literature. The conversion factors are

$$1 \text{ meq/L} = 2.8 \text{ dKH} = 50 \text{ mg/L } CaCO_3.$$

In practice, the terms alkalinity, KH, and buffering capacity are often used interchangeably, although they are technically distinct.

MANAGEMENT RECOMMENDATIONS

The buffering capacity provided by a minimum alkalinity of about 40 mg/L is widely considered necessary to provide the concentrations of bicarbonate and carbonate needed to stabilize water against changes in pH caused by (a) the addition and removal of carbon dioxide due to the daily cycle of photosynthesis and respiration and (b) the H^+ produced by nitrifying bacteria in biofilters or pond sediments. Carbonates also provide the carbon source for nitrifying bacteria in biofilters, and the alkalinity should be maintained at greater than 80 mg/L for proper ammonia oxidation in recirculating systems. Because carbonates are steadily consumed by this process, they must be replenished by either the incoming water, CO_2 injection, or addition of sodium bicarbonate. In intensive aquaculture systems, CO_2 injection is rarely considered, because economic constraints dictate high fish loadings, and thus high, rather than low, CO_2 values are the normal concern. Tables for the required sodium bicarbonate dosing levels can be found in Loyless and Malone (1).

OUTLINE

Cage Design and Use
Advantages and Disadvantages
Species Cultured in Cages
Bibliography

Confining aquatic animals in small floating cages is an attractive option in some aquaculture situations, such as ponds that cannot be drained, reservoirs, lakes, and streams. Cage culture is used primarily in freshwater situations, but also has applications in coastal regions. Cages differ from net pens in that they are much smaller and, in most instances, have rigid frames. (See the entry "Net pen culture.") Confinement of fish in cages facilitates feeding and harvesting, though crowding can have negative impacts on water quality within the cages and may increase problems associated with diseases. Cage culture has been the subject of at least one comprehensive book (1).

CAGE DESIGN AND USE

Small floating structures covered with materials that allow water to freely flow through while retaining confined animals have been used for the culture of fish and

Figure 1. Small cages of the type used for research.

other aquatic organisms in a variety of situations. Such structures, called cages, are generally relatively small (Fig. 1), commonly no more than a few meters (1 m = approximately 3 ft) on a side and perhaps 1 to 2 m (3 to 6 ft) deep. Larger structures, such as those used for the commercial culture of salmon, may be 20 to 40 m (66 to 131 ft) on a side and are called net pens. (See the entry "Net pen culture.") In most instances, cages have rigid frames, so that they hold their shape if lifted from the water.[1]

Cages have been used to some extent by aquaculturists for many decades, not only for rearing animals, but also for holding fish in advance of spawning, for rearing early life stages of various species, and for other purposes. Most cage culture involves finfish, but there have been instances wherein shrimp and other invertebrates have been reared in cages as well.

Hapas, which are small cages covered with very fine mesh netting, are used in the Philippines and other countries for spawning tilapia and rearing fry. (See the entry "Tilapia culture.") Cages woven from grasses or constructed from wood have also been used to hold fish for various periods of time and, perhaps, for at least limited growout.

In most cases, cages have ridged frames wrapped with material that allows free passage of water while retaining the aquatic animals in confinement. Frames may be constructed of bamboo, wood, or various types of metal and plastic. Hardware cloth, plastic or wire mesh, and braided nylon netting are common wrapping materials. The cost of cages can be very low (a few dollars each, in some instance) or quite expensive. Costs vary considerably, depending on the size of the cage and on the materials used to make it. One variable of cost that is associated with cage materials is whether the materials have to be purchased or can be obtained at little or no cost. Another consideration is the cost of labor associated with construction of the cage.

The standard approach to cage culture is to float cages at the surface of the water, with the cage bottoms kept above the substrate. Each individual cage can be fitted with floats, or floating platforms, from which the cages are hung, can be constructed. Popular float materials are Styrofoam, cork, and plastic. Cages can also be elevated above the bottom of the substrate from poles driven into the substrate, although this approach is suitable only in relatively shallow water.

Each cage needs to be provided with a top, to keep the animals from jumping out. Tops may be solid or constructed of the same type of mesh that wraps the sides and bottom of the cages.

Cages make sense in a number of aquaculture situations. They provide convenient experimental units and have been widely used by researchers as replicates in

---

[1] Cages can be lifted from the water intact when empty, but may rupture if any attempt is made to lift them out of the water when they are stocked with fish.

Figure 2. Commercial catfish cages in a reservoir.

various types of studies. Diet testing has been conducted in cage experiments, as have many studies on the feasibility of rearing fish in the heated-water effluents of power plants.

Fossil fuel and nuclear power plants heat water to produce the steam that turns the turbines which generate electricity. The steam is then condensed by being piped through water from a river, lake, or reservoir.[2] Water that is used to condense the steam is heated several degrees and can be used to extend the growing season for fish in temperate regions if the caged fish are moved from a large cooling reservoir into a warm discharge canal below a power plant as the temperature cools in the fall. However, problems associated with gas bubble disease (see the entry "Gas bubble disease") have occurred due to gas supersaturation when fish are confined in discharge canals. Since gas supersaturation occurs when water is rapidly heated, the problem is most severe during precisely the time that the culturist can best take advantage of the warm water in a discharge canal.

In commercial situations (Fig. 2), as well as in conjunction with research, cages can be used in any situation wherein the fish are difficult to capture or cannot be contained. Some research, and even commercial, culture has been conducted in relatively small ponds, including ponds that can be drained and seined. Once again, in the case of research, the purpose is often to provide replication for experiments. In commercial situations (and also in research), two or more species of fish that might not be compatible if released in an open pond have been separated by allowing one species to roam freely while the others were confined in cages. This technique is a form of polyculture. (See the entry "Polyculture.")

Cage culture has been conducted in streams in which confinement is necessary to keep the fish from escaping the region being used for aquaculture. Cages have also been used in irrigation canals and in impoundments. Many impoundments, including some small ponds that would

otherwise be suitable water bodies for aquaculture, cannot be drained, have debris (including trees) in them, are too deep to be seined, or have some other factor associated with them that makes capture of freely ranging fish difficult or virtually impossible. Cages provide an option in such situations.

In most regions of the United States, public waters cannot be used for private aquaculture. Leases have been granted in some coastal waters (primarily in association with net-pen salmon culture in Washington and Maine) and in portions of some public reservoirs in Arkansas. Cage culture in public waters is far more common in some other nations.

ADVANTAGES AND DISADVANTAGES

Besides providing the ability to contain fish and other mobile aquatic animals within a known volume of water, cage culture greatly facilitates harvesting fish, as compared with open ponds. For example, fish can be dipnetted from cages relatively easily (Fig. 3). Also, cages may be taken to a shoreside location, where they are tilted to further concentrate the fish, making harvest even easier. In most cases, cages are not sufficiently strong to be lifted entirely from the water without becoming ruptured, particularly as the fish approach harvest size.

There are both advantages and disadvantages associated with feeding fish in cages as compared with feeding them in raceways or ponds. The fish culturist can easily deposit feed directly into a cage, either from a boat or by walking along a platform or other structure from which cages are suspended, depending upon how the cages are moored. However, feed placed in a cage will not necessarily stay there. Sinking feed can fall through the bottom of the cage by gravity or be carried out the sides of a cage by currents before being consumed by the fish inside the cage. Floating feeds may be thrown out of cages by the actions of actively feeding fish and will also be carried out the downstream side of cages unless a fringe of fine-mesh netting is placed around the circumference of the cage; the netting must extend sufficiently above and below the waterline to retain floating feed. Feeding rings — solid metal or plastic tubes or rectangles that are typically built into the top of a cage and extend into the water column within the
Figure 3. Channel catfish cages in the discharge canal of a power plant.

cage — are also effective at keeping floating pellets in the desired location until they are consumed. Because aquatic animals confined in cages have little natural food available to them, it is necessary to provide nutritionally complete rations in order to avoid nutritional deficiency diseases and obtain a good rate of growth.

The water quality in cages can be very high if the cage site is properly selected. Cages placed in currents constantly receive water exchanges that help maintain good water quality, unless the incoming water is not of high quality. If several cages are placed in a string within a current, the most upstream cage will have the best water quality. As the water passes through each cage, the amount of dissolved oxygen will be reduced, the concentration of ammonia will increase, and fecal wastes will build up in a downstream direction. Ultimately, the water quality may be degraded to the point that growth in downstream cages is reduced. Stress associated with degraded water quality can be a precursor to diseases and even directly cause mortality. Proper separation of cages to allow maintenance of water quality is important. The appropriate number of cages in pods or strings needs to be determined for each water body. Those numbers will vary as a function of prevailing currents, tidal or stream flows, stocking densities, temperature, the level of dissolved oxygen, and the species being reared.

Animals are much more densely crowded in cages than in open ponds. As a result, there have been instances of fighting; scraping of the integument on cage sides, leading to scale loss and skin lesions; and increased levels of cannibalism and disease associated with close confinement. In theory, it is easy to treat diseases in cages. One method involves fitting a plastic bag around a cage containing diseased fish and placing therapeutants in the water. Placement of such bags around cages is, however, much more easily described than actually put into practice. Even if such a bag can be put in place, it cannot remain there long before water-quality deterioration will exacerbate the situation. Removing fish from cages to apply dip or bath treatments may not be difficult, but is an additional source of stress. If efficacious medications can be provided in feed, they can be administered quite easily to caged fish.

Biofouling of cages can be a problem in freshwater, though it tends to be a more significant source of trouble in the marine environment. Algae, bryozoans, and a few types of freshwater clams and mussels (e.g., zebra mussels) can cause significant problems in freshwater, while a wide variety of organisms, notably barnacles and bryozoans, foul cages in the marine environment. The situation can become so severe that the flow of water through cages becomes severely restricted or even stopped. As the fouling problem increases, the water quality will be negatively impacted. Frequent cleaning may be required to keep the mesh of the cage walls open.

SPECIES CULTURED IN CAGES

Nearly any aquatic animal can, at least theoretically, be reared in cages. Because cages are generally fairly small, species that are marketed at a large size, such

Figure 4. Small commercial marine cages suspended from floating walkways in Malaysia.

as tuna, are not good candidates for cages, but can be reared, as are salmon, in net pens. (See the entry "Net pen culture.") Cages have been used to rear channel catfish in reservoirs, including cooling reservoirs and the discharge canals associated with power plants (2). Tilapia are reared in very large net pens in the Philippines and are also reared in cages in various countries. Cage culture in lakes and reservoirs is often permitted in developing countries.

In the marine environment, cages have been used for rearing fish of various species and penaeid shrimp in nearshore waters. Commonly, cages are attached to walkways in shallow water, allowing ease of access by the fish farmers (Fig. 4).

Cages have also been used to hold blue crabs caught in the wild and retained until molting. Newly molted crabs are removed and sold as soft-shell crabs, which bring a premium price.

CARBON DIOXIDE

STEVEN T. SUMMERFELT
The Conservation Fund's Freshwater Institute
Shepherdstown, West Virginia

OUTLINE

Carbon dioxide (CO_2) is a gas that is relatively soluble in water; it is much more soluble than oxygen and nitrogen. When dissolved, carbon dioxide is in acid–base equilibrium with the total carbonate system, which means that its dissolved concentration is affected by the pH. Therefore, all natural waters in contact with the atmosphere or with an inorganic carbon substrate, such as limestone, will contain carbon dioxide. Carbon dioxide is also excreted by fish through their gills as a by-product of metabolism (along with ammonia). Because carbon dioxide is produced by the fish, it can accumulate in the water, depending upon the rate at which it is produced, the water exchange rate, the gas exchange rate, and shifts in pH. Shifts in the concentration of dissolved carbon dioxide can be quite dynamic; high concentrations for short periods can be toxic, and moderate concentrations over extended periods can limit fish growth and feed conversion. Elevated levels of carbon dioxide can occur in aquaculture systems using alkaline ground waters (if adequate aeration has not yet been achieved), in fish hauling tanks with no water replacement and insufficient venting, and in intensive fish culture systems that have high fish densities, inadequate water exchange, and inadequate aeration. Low-intensity aquaculture systems generally have sufficient water exchange rates and/or aeration rates to keep carbon dioxide from accumulating above safe levels. Aeration processes and alkaline chemical addition are both viable options that can be used to increase the pH and control carbon dioxide accumulation in intensive aquaculture systems. To avoid or recognize carbon dioxide problems requires an understanding of carbon dioxide production, toxicity, chemical equilibrium, and treatment options.

CARBON DIOXIDE PRODUCTION AND TOXICITY

Carbon dioxide is the end product of most catabolic pathways within fish tissue. The volume of carbon dioxide produced in respiration is about the same as the volume of oxygen consumed (1). Based on the molecular weight of carbon dioxide (44 g/mole) and oxygen (32 g/mole), the mass of carbon dioxide produced is about 38% greater than the mass of oxygen consumed; therefore, fish such as salmon and trout produce 0.3 to 0.4 g (0.0106 to 0.0141 oz) of carbon dioxide per g (0.0353 oz) of feed (2). Fish also excrete about 10 times more carbon dioxide than ammonia on a molar basis (3).

Respiration and carbon dioxide production also occur in the biological treatment processes that are used to control ammonia and organic matter when culture water is treated for reuse. The organic matter trapped in the biological filter can be metabolized by heterotrophic microorganisms, producing additional carbon dioxide and releasing nutrients. Carbon dioxide is also produced during nitrification, the two-step process in which bacteria convert ammonia to nitrate. Autotrophic organisms are mainly responsible for nitrification, and carbon dioxide is their primary source of carbon. However, the free acid produced during nitrification reacts with bicarbonate alkalinity in the water to release more carbon dioxide than the autotrophs consume (4). The

net result is a loss of 6.0 to 7.4 mg (0.00021 to 0.00026 oz) of calcium carbonate ($CaCO_3$) alkalinity for every 1 mg (3.5×10^{-5} oz) of ammonia nitrogen removed. In recirculating aquaculture systems, an alkalinity of at least 50 mg/L (50 ppm) of calcium carbonate ($CaCO_3$) should be maintained to support nitrification (5) and to prevent pH instability (6–8).

Fish excrete the carbon dioxide that they produce through their gills. The mechanism for carbon dioxide elimination across the gill surface (Fig. 1) has been summarized by Perry (9), Perry and Wood (10), Walsh and Henry (11), and Wedemeyer (12). Within fish tissue, carbon dioxide diffuses into circulating red blood cells, where the enzyme carbonic anhydrase converts the carbon dioxide into bicarbonate. Bicarbonate is the initial substrate of many biosynthetic pathways. As blood is pumped through capillaries within the gill epithelium, the enzyme-mediated process is reversed, and bicarbonate is rapidly converted back into carbon dioxide. A large portion of the carbon dioxide diffuses out of the plasma and across the cell membrane into the mucus layer coating the outsides of the epithelium. (See Fig. 1.) Extracellular carbonic anhydrase, contained within the mucus layer of the gill, rapidly catalyzes the conversion of carbon dioxide into bicarbonate to maintain a low boundary-layer concentration of carbon dioxide and an outward-directed concentration gradient. Carbon dioxide elimination through the gill has to be rapid, because a volume of blood is exchanged through the gill epithelium every few seconds (12).

Fish move relatively large volumes of water over their gills to obtain sufficient oxygen for aerobic metabolism and, at the same time, eliminate ammonia and carbon
Figure 1. Illustration of the excretion of carbon dioxide (CO_2) and ammonia (NH_3) through the gill epithelium. Carbon dioxide and ammonia freely diffuse through the cell membrane into the mucus layer coating the gill. Carbonic anhydrase (•) within the mucus layer catalyzes the hydration of carbon dioxide into bicarbonate (HCO_3^-) and hydrogen (H^+) ions, promoting the removal of carbon dioxide. Thus, the carbon dioxide and ammonia diffusion gradients are maintained in a direction away from the gill epithelium. [From Wright et al. (13).]

dioxide (9,13,14). Carbon dioxide unloading at the gill is a function of both the ventilation rate and the difference between the carbon dioxide concentration in the water and in the fish's blood (11). However, fish such as rainbow trout (*Oncorhynchus mykiss*) regulate the rate at which they ventilate and pump blood to different portions of their gills based upon the blood's oxygen content (14), not on the blood's carbon dioxide or ammonia concentrations. If levels of carbon dioxide in the water are elevated, less carbon dioxide can be transferred from the gills into the water, even with carbonic-anhydrase-catalyzing transfer. Elevated carbon dioxide levels in the fish (i.e., hypercapnia) increase blood acidity, decrease the ability of hemoglobin to transport oxygen (the Bohr effect), and, in some species, also decrease the maximum oxygen binding capacity of blood (the Root effect). In salmonids, the Bohr effect begins to impair oxygen transport when the dissolved carbon dioxide concentration in the water rises to 20 mg/L (20 ppm) (12). Tilapia (Cichlidae) and catfish (Ictaluridae) are generally less sensitive to elevated concentrations of dissolved carbon dioxide in their culture environment.

Elevated concentrations of dissolved carbon dioxide can be encountered during fish transport or during intensive fish culture, especially when pure oxygen is added to increase the concentration of dissolved oxygen. The combination of supersaturation with dissolved oxygen and a high concentration of dissolved carbon dioxide in the environment can produce hypercapnia, sedate the fish, and may be lethal. Blood oxygen transport may be unaffected, since high concentrations of external dissolved oxygen maintain a sufficient driving force for oxygen transfer into the fish, even as the hyperoxic conditions reduce the fish's ventilation rate (12). However, at concentrations of dissolved carbon dioxide approaching 30–40 mg/L (30–40 ppm), the oxygen carrying capacity of blood will be depressed to the point at which even high concentrations of environmental dissolved oxygen may be insufficient to prevent decreased blood oxygen levels (12). In rainbow trout, the clinical signs of a carbon dioxide problem are moribund fish, gaping mouths, flared operculums, and extra-bright, maraschino-red gill lamellae (15).

Carbon dioxide may also be toxic to fish by contributing to nephrocalcinosis, the formation of calcareous deposits in their kidneys (16). These deposits have been reported in salmonids, catfish, and some marine fishes and are composed of precipitates containing calcium, phosphate, fluoride, and oxides of magnesium (12). Smart et al. (17) found that concentrations of dissolved carbon dioxide that increased from 12 to 55 mg/L (12 to 55 ppm) could increase the number of calcareous deposits in rainbow trout; additionally, growth was seriously impaired at the elevated concentrations of carbon dioxide. Nephrocalcinosis may also appear at relatively lower levels of carbon dioxide if hyperoxic conditions cause hypercapnia. However, other factors, such as the mineral composition and protein content of the diet and (to a lesser degree) the bicarbonate hardness of the water, may also contribute to nephrocalcinosis in trout (12).

Although carbon dioxide is a gas that is dissolved in water, it is extremely soluble and does not contribute significantly to gas supersaturation in water; consequently, carbon dioxide is not a major contributor to gas bubble disease (18).

To culture trout or salmon safely, the concentration of dissolved carbon dioxide should be limited to 20 mg/L (20 ppm) (18). In rainbow trout, the safe upper limit for chronic exposure to carbon dioxide has been reported to range from less than 9 to as much as 30 mg/L (9 to 30 ppm) (19). However, if the concentration of dissolved oxygen in the water is near or greater than saturation levels, the 20-mg/L (20 ppm) recommended safe level may be conservative (12,18). Safe levels of dissolved carbon dioxide can also depend upon the fish species, the developmental stage of the fish, and other water-quality variables. Fish cultured in waters of low alkalinity have a lower blood buffering capacity than fish cultured in more alkaline waters (20). Due to the buffering capacity of blood and acid–base chemistry, water with a high alkalinity, pH, or both may enable fish to tolerate higher concentrations of free carbon dioxide (21).

ADDRESSING PROBLEMS CAUSED BY CARBON DIOXIDE

Problems caused by carbon dioxide in aquaculture systems are occurring more frequently as more intensive production technologies are used to boost carrying capacities and increase transport and production efficiencies (22,23). Techniques used to increase carrying capacity include increased water exchange, improved feed management, and the implementation of oxygen supplementation, pH control, and/or waste removal unit processes (24). Carbon dioxide can be especially problematic when pure oxygen is added to hauling tanks or to the flow entering intensive culture systems and carbon dioxide removal or pH control processes are not considered. The carbon dioxide accumulation in systems that supplement oxygen is exacerbated, because these systems support higher rates of fish loading, the oxygen dissolution processes that are used provide insufficient gas exchange to strip the quantities of carbon dioxide produced, and these systems often do not use standard aeration processes (7,25,26). When standard aeration units alone are used to supply oxygen, however, far less carbon dioxide can accumulate, because levels of available oxygen are limited by the saturation concentration of oxygen, and the aeration provides enough air–water contact to strip carbon dioxide before it can accumulate to toxic levels (27).

Avoiding toxic accumulations of carbon dioxide and the associated pH shift in hauling tanks and intensive water-use systems requires that the rate of carbon dioxide removal through dilution, pH control, or an aeration process be at least as great as the rate of carbon dioxide generation at steady-state operating conditions. Combining mass balances and acid–base equilibrium relations, Colt et al. (23) reported that, under intensive conditions, there are no carbon dioxide limitations (with no aeration or pH control) when the cumulative consumption of dissolved oxygen is less than about 10 to 22 mg/L (10 to 22 ppm), depending upon the pH, alkalinity, temperature, species, and life stage. After this cumulative oxygen consumption level has been reached, the water flow cannot be used again unless it is passed through an air-stripping

Table 1. Equilibrium Types, Relationships, and Constants that Control Carbon Dioxide Concentrations in Water

Equilibrium Type	Equilibrium Relationships	Equilibrium Constants at 25 °C (77 °F) (35)	
Gas–liquid	CO_2 (g) $\longleftrightarrow$ CO_2 (dissolved)	$K_H = P_{CO_2}/X_{CO_2}$	$\approx 6.11 \times 10^{-4}$ atm^{-1}
Hydration–dehydration	CO_2 (dissolved) $+ H_2O \longleftrightarrow H_2CO_3$	$K_0 = [H_2CO_3]/[CO_2]$	$\approx 1.58 \times 10^{-3}$
Acid–base	$H_2CO_3 \longleftrightarrow HCO_3^- + H^+$	$K_1 = [H^+][HCO_3^-]/[H_2CO_3]$	$\approx 2.83 \times 10^{-4}$ mol/L
Acid–base	$HCO_3^- \longleftrightarrow CO_3^{2-} + H^+$	$K_2 = [CO_3^{2-}][H^+]/[HCO_3^-]$	$\approx 4.68 \times 10^{-11}$ mol/L
Acid–base	$H_2O \longleftrightarrow OH^{2-} + H^+$	$K_W = [OH^-][H^+]$	$\approx 1.00 \times 10^{-14}$ mol^2/L^2
Dissolution–precipitation	$CaCO_3 \longleftrightarrow CO_3^{2-} + Ca^{2+}$	$K_{sp} = [CO_3^{2-}][Ca^{2+}]$	$\approx 4.57 \times 10^{-9}$ mol^2/L^2

unit or some form of alkaline chemical is added to reduce carbon dioxide accumulations.

Aeration processes and/or pH control can be implemented to reduce carbon dioxide levels and avoid potential problems caused by carbon dioxide, even under conditions of intensive water use (6–8,26).

Aeration

During aeration, air is mixed with water, so that oxygen is transferred from the air into the water. Aeration also strips carbon dioxide and nitrogen if the water is supersaturated with either of these gases.

When water is in contact with the atmosphere, the equilibrium concentration of carbon dioxide in the water is proportional to the amount of carbon dioxide in the air, according to Henry's law. (See Table 1.) Air contains a mole fraction of about 0.00032 mole of carbon dioxide per mole of air, which is equivalent to a partial pressure of 0.00032 atm. According to Henry's law, water in contact with the atmosphere at 25 °C (77 °F) has an equilibrium concentration of about 0.5 mg/L (0.5 ppm). That is,

$$x_{CO_2} = K_H \cdot P_{CO_2}$$
$$\approx \frac{0.000611 \text{ mol } CO_2}{\text{atm} \cdot \text{mol water}} \cdot 0.00032 \text{ atm}$$
$$\times \frac{55.6 \text{ mol water}}{L} \cdot \frac{44 \text{ g}}{\text{mol } CO_2} \cdot \frac{10^3 \text{ mg}}{g}$$
$$\approx 0.5 \text{ mg/L } CO_2.$$

When water is not at equilibrium with the atmosphere, the concentration of dissolved carbon dioxide in water is controlled by the closed-system carbonate equilibrium. (See Table 1.) Therefore, the concentration of carbon dioxide will depend on the pH and temperature of the water and the concentration of carbonate and bicarbonate present (28), as described in the section in this entry titled "Alkaline Addition and Chemical Equilibrium."

Oxygen and carbon dioxide can be transferred into and out of water, respectively, with any open aeration system (22,27,29,30). However, because carbon dioxide is so much more soluble in water than is oxygen (18), it takes more air–water contact to strip carbon dioxide than to dissolve oxygen. Additionally, the rate at which carbon dioxide is stripped decreases as the partial pressure of carbon dioxide in the air passing through the water increases. Because the concentration of carbon dioxide in water can be 20–40 times the ambient saturation concentration, stripping carbon dioxide from water can rapidly and significantly increase the partial pressure of carbon dioxide in the passing air flow (7). Therefore, enormous volumes of air contact the water, as compared with the air–flow rates required for oxygen transfer alone. Effective carbon dioxide stripping requires contacting from 3 to 10 volumes of air flow for every 1 volume of water flow treated. This air–water contact is often accomplished by forced ventilation of the air through 1.0- to 1.5-m-tall (3 to 4.5 ft tall) cascade columns (Fig. 2) that are sized to treat 60–84 m^3/hr (2100–3000 ft^3/hr) of water flow per square meter (11 ft^2) of column cross-sectional area (26); however, hydraulic loading rates as high as 100–250 m^3/hr/m^2 (330–820 ft^3/hr/ft^2) are also suggested (7). Carbon dioxide stripping and aeration can be improved by packing the cascade columns with high-voidage plastic media or stacked screens that break up the water droplets, to increase the air–water contact area. If high-solids loadings are expected, a stripping tower with screens (Fig. 2) may be easier to maintain than a tower packed with media.

Air discharged from stripping columns should be vented from buildings, to prevent carbon dioxide from accumulating inside the building's airspace. Concentrations of airspace carbon dioxide of 50,000 ppm are immediately dangerous to life and health, and the Occupational Safety
Figure 2. Illustration of an air-stripping tower that uses screens instead of plastic media to break up the fall of water.

and Health Administration (OSHA) limits the allowable time-weighted average exposure to carbon dioxide over an eight-hour workday to concentrations less than 5,000 ppm (31). In contrast, concentrations of ambient atmospheric carbon dioxide are about 350 ppm. However, venting this air from buildings in cold climates can result in considerable heat loss and higher operating costs, especially at the temperatures used to raise warmwater species in semiclosed aquaculture systems (31). Vinci et al. (31) have published computer software to estimate carbon dioxide stripping efficiencies, building ventilation rates, and the corresponding heating and ventilating costs. Under some conditions, a portion of the heat in air can be recovered by venting the air through an air–air heat exchanger. Alternatively, the carbon dioxide can be scrubbed from the air and the air conserved, which reduces the need for building air exchange (B. Watten, USGS Leetown Science Center, Kearneysville, WV, personal communication).

Fish transport tanks should also have a mechanism to rapidly vent air from their head space above the water level; this type of system has been shown to help maintain safe levels of dissolved carbon dioxide during long transport trips (32).

In practice, carbon dioxide stripping equipment is operated at a fixed level near its maximum capacity (8). Therefore, unless more stripping equipment is installed, any further carbon dioxide adjustments must be met through the addition of alkaline chemicals (8).

Alkaline Addition and Chemical Equilibrium

The concentration of carbon dioxide dissolved in water is governed by four types of equilibrium relationships (28): gas–liquid, hydration–dehydration, acid–base, and dissolution–precipitation. (See Table 1.) As described in the section titled "Aeration," gas–liquid equilibrium is the principal mechanism behind the transfer of carbon dioxide between air and water. On the other hand, dissolution of inorganic carbon compounds, such as sodium bicarbonate and limestone, increases a water body's pH, alkalinity, and total inorganic carbon content, thereby increasing the capacity of the water to neutralize an acid. Conversely, precipitation of inorganic carbon compounds of calcium and magnesium occurs after carbon dioxide is stripped from hard water and the water's pH has risen. Deposition of a limestone scale on tanks and equipment and of marl sediments in quiescent zones can both present operational problems to fish farms.

Several authors have reviewed the acid–base equilibrium relationships between pH and carbon dioxide within freshwater and seawater aquaculture systems (6–8,26,33,34). Dissolved carbon dioxide combines with water in a reversible hydration reaction to form carbonic acid (H_2CO_3). (See Table 1.) However, there is approximately 630 times more dissolved carbon dioxide than carbonic acid in water. Carbonic acid dissociates, releasing hydrogen ions (H^+) and bicarbonate ions (HCO_3^-). The bicarbonate ions then dissociate, releasing additional hydrogen ions and carbonate ions (CO_3^{2-}). Therefore, carbon dioxide is only one component within the dissolved inorganic carbon system $CtCO_3$, defined as

$$[CtCO_3] = [CO_2] + [H_2CO_3] + [HCO_3^-] + [CO_3^{2-}],$$

where the [] species represent molar concentrations.

Acid–base equilibrium and thus pH (i.e., $-\log_{10}[H^+]$) control the relative concentrations of each species in the inorganic-carbon system. (See Table 1.) Dissolved carbon dioxide can be calculated from $[CtCO_3]$ and the pH-dependent ionization fraction:

$$[CO_2] = [CtCO_3] \cdot \frac{1}{(1 + K_0K_1/[H^+] + K_0K_1K_2/[H^+]^2)}.$$

It is more common to classify a water based on its alkalinity than on its $CtCO_3$, because alkalinity is a measure of the capacity of a solution to neutralize an acid. Alkalinity is a function of the concentrations of the bicarbonate, carbonate, hydroxide (OH^-), and hydrogen ions:

$$\frac{Alk}{50,000} = [HCO_3^-] + 2[CO_3^{2-}] + [OH^-] - [H^+]$$

In this equation, the alkalinity is expressed in mg of $CaCO_3$/L.

Note that alkalinity is not affected by adding or removing carbon dioxide. Accumulation of carbon dioxide due to fish respiration will increase $[CtCO_3]$, build up the concentration of carbonic acid, and decrease the concentration of carbonate, causing the pH to drop to a lower value. Conversely, stripping carbon dioxide will decrease $[CtCO_3]$, shift the equilibrium as bicarbonate releases carbonate ions, and shift the pH to a higher value. Within minutes of the water exiting the stripping column, carbonic acid will have dehydrated to a new equilibrium level and thus will have replenished some of the carbon dioxide that was removed (7). This chemical equilibrium makes it difficult to strip a large fraction of carbon dioxide from well-buffered waters. The molar concentration of dissolved carbon dioxide at a given temperature can be estimated from the alkalinity and pH as follows:

$$[CO_2] = \left\{ \frac{Alk}{50,000} - \frac{K_W}{[H^+]} - [H^+] \right\}$$
$$\times \left\{ \frac{1}{K_0K_1/[H^+] + 2K_0K_1K_2/[H^+]^2} \right\}.$$

Methods that increase the pH will reduce the proportion of $[CtCO_3]$ that exists as carbon dioxide. Addition of a source of alkalinity, such as lime, caustic soda, soda ash, and sodium bicarbonate, to the water will increase the water's alkalinity and raise its pH (6,8,26). Lime, caustic soda, and soda ash react directly with carbon dioxide to produce bicarbonate alkalinity and increase the pH. Sodium bicarbonate is simply a source of bicarbonate alkalinity and a means to increase the pH and level of $[CtCO_3]$, resulting in a net decrease in levels of dissolved carbon dioxide.

The pH also controls the acid–base equilibrium between ammonia (NH_3) and ammonium (NH_4^+) in the total ammonia nitrogen (TAN) system. Methods used to
Figure 3. The pH dependence of the percent of total inorganic carbon as aqueous carbon dioxide (CO_2) and the percent of total ammonia nitrogen as ammonia (NH_3), assuming equilibrium at $25 °C$ ($77 °F$). [From Summerfelt (26).]

increase the pH and reduce levels of carbon dioxide also increase the portion of total ammonia nitrogen existing as ammonia, which is the more toxic form to aquatic life. Therefore, controlling levels of dissolved carbon dioxide by methods that increase the pH is limited to a pH range wherein unionized-ammonia concentrations are considered safe. Comparing the fractions of ammonia and carbon dioxide that exist as a function of pH (Fig. 3) indicates that levels of both can be minimized by operating in a pH range of 7.2–8.2 (26). However, the optimum pH range depends upon temperature, TAN concentration, $CtCO_3$ levels, and the relative toxicity of ammonia and carbon dioxide to the fish.

CARP CULTURE

ROBERT R. STICKNEY
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

Several species of carp (family Cyprinidae, the minnow family) are being cultured around the world. Carp may have been the first fishes cultured in the world, with a history of captive production going back millennia (see the entry "History of aquaculture") in China (Fig. 1). In addition to several species of carp popular in China, there are carp species native to the Indian subcontinent and cultured almost exclusively in that part of the world. The common carp (*Cyprinus carpio*) has been extensively cultured throughout most of the world. Eastern Europe became involved in carp culture several centuries ago. Carp culture also developed in Latin America within the last several decades. However, even though carp were introduced to the United States in the late 19th century, there is very little culture interest or activity in North America.

Figure 1. Carp ponds in China.

Carp culture, particularly with respect to common carp and grass carp (*Ctenopharyngodon idella*), was reviewed by McGeachin (1). Additional information can also be found in Avault's recent volume on general aquaculture, which includes information on Indian carp species (2). Those sources provide the foundation for this contribution and should be consulted for additional details and references. Carp production represents more than 50% of all the animal biomass being produced by aquaculture worldwide.

CHINESE AND COMMON CARP CULTURE

History

The first known document associated with fish culture was produced during the 5th century B.C. in China by Fan Li. It was only a few pages long and reported on the methods involved in rearing carp. During the period when the Holy Roman Empire ruled much of the known world, wild carp were captured from the Danube River and shipped to Rome. The practice continued into the 6th century A.D., when monks began producing carp in ponds at their monasteries. Culturing fish in ponds, rather than having them transported to the monasteries, was a considerable advancement as the fish were readily available for the many meatless fasting days dictated by the church. Carp culture spread across eastern and central Europe and was well established by the late middle ages. Carp culture in Japan did not appear until early in the 19th century (3).

Common carp were successfully introduced into the United States by the government in the latter half of the 19th century (4), though apparently unsuccessful introductions had been made earlier by private citizens. Carp culture and distribution were actively promoted by the U.S. Fish and Fisheries Commission under its first Commissioner, Spencer F. Baird, who seemed to be convinced that spreading carp around the nation was a beneficial activity. Some arguments for the introduction were based on the fact that many European immigrants to the U.S. recognized the common carp as a foodfish. Various problems associated with carp (their propensity for digging in pond banks, their often poor flavor, and their excessive number of small bones, among others) led to public rejection of carp, resulting in the cessation of government stocking in the U.S. by the end of the 19th century. However, by that time, carp had been widely distributed and many reproducing populations had become established. Today, carp appear to be here to stay.

Other carp species were later introduced to the U.S. for weed control and foodfish culture. Those introductions have been more controversial than the introduction of common carp. Various species of carp are currently banned in a number of states.

The common carp has been the subject of intense selective breeding in Europe, where several varieties have been developed. Selective breeding of European carp has been largely aimed at improving growth rate and improving other responses of the fish to culture conditions, as well as changing scale patterns. The standard common carp is covered with scales, but three other strains exist:

Figure 2. A mirror carp (*C. carpio*) produced in Israel.

(*1*) mirror carp (Fig. 2), which have a few scales located below the dorsal fin, (*2*) line carp with scales only along the lateral line, and (*3*) leather carp, which are scaleless. In China, on the other hand, there has been little activity aimed at improving the species.

Application of scientific principles to common carp breeding appears to have been started almost simultaneously in Russia (5) and Israel (6) in the mid-20th century. The studies were initiated when the observation was made that mass selection of carp was not a highly effective means of obtaining the improvements sought. In Israel, both mass and family (progeny) selection have been used.

The first attempts to induce gynogenesis in carp were in Hungary (7). Hybridization involving gynogenetic and other groups of carp led to development of a "Hungarian" race of common carp that has been widely distributed in various countries.

There have been crosses between the European and Asian races of common carp. The resulting fish have been shown to grow more rapidly than the Asian race, are easier to capture by seining, have increased disease resistance, and still perform well when subjected to polyculture.

There appears to have been less attention paid to selective breeding of the various other carp species. A great deal of information has been developed on producing triploid grass carp to produce sterile fish as discussed later.

Much more information is available on the common carp, and to a somewhat lesser extent grass carp, than on the other species in culture. In this entry, the information on culture techniques concentrates primarily on common and grass carp, and the final section briefly describes Indian carp culture.

Production

Not only does fish culture, with a primary focus on carp, appear to have originated in China, but that country continues to dominate world production of fish. Polyculture, the technique of rearing two or more compatible species in the same water body (see the entry "Polyculture"), was developed in China and continues to be widely employed there in ponds. A typical polyculture pond might be stocked with some combination of common carp, mud carp (*Cirrhinus mulitorella*), black carp (*Mylopharyngodon piceus*), bighead carp (*Aristichthys nobilis*), silver carp (*Hypopthalmichthys molitrix*), and grass carp, as well as crucian carp (*Carassius carassius*), which are also reared in China. Table 1 presents the total production of each species in China during 1995 according to FAO (8). In terms of global production rankings, silver carp ranks #1, followed in order by grass carp, common carp, bighead carp, and crucian carp. Noncarp species do not show up until sixth place (which is held by Nile tilapia, *Oreochromis niloticus*).

Various other countries produce significant quantities of carps, though none approaches China in terms of total production (Table 1). Common carp are produced in various countries, although mud carp are produced only in China and Taiwan. Silver, bighead, crucian, and grass carp have been produced in many nations, but production tends to be limited outside of China. Bighead carp are produced, for example, in Cambodia, Taiwan, Hong Kong, Iran, Laos, Malaysia, Myanmar, and Nepal (all in Asia), as well as Croatia, the Czech Republic, Germany, Hungary, Romania, and Ukraine (all in Europe) still, total production in these nations is only 22,673 tons.

The figure listed in Table 1 for the former USSR represents the combined production in the various now-independent carp producing nations that once made up the USSR. Included in that total are carp produced in Armenia, Azerbaijan, Belarus, Estonia, Georgia, Kazakstan, Kyrgyzstan, Latvia, Lithuania, Moldova, the Russian Federation, Tajikistan, Turkmenistan, Ukraine, and Uzbekistan. Each of those nations produces common carp, while fewer nations produce the other species listed in the table.

Total production of common carp from the former USSR has been declining in recent years. Between 1986 and 1995, a high of 319,766 tons was reached in 1990. A year later, production had fallen precipitously to 194,427 tons. On the other hand, in Indonesia, the production of common carp has increased annually from 1986 through 1995.

Table 1. Carp Production in Metric Tons (approximately 2,000 lb/ton) for Selected Countries During 1995, According the Food and Agricultural Organization of the United Nations (8)

Country	Species	Production (tons)
China	Common carp	1,398,618
	Mud carp	110,000
	Bighead carp	1,236,667
	Silver carp	2,473,333
	Grass carp	2,070,988
	Crucian carp	533,740
Japan	Common carp	18,272
	Crucian carp	945
Former USSR	Common carp	100,264
	Silver carp	47,660
	Grass carp	647
Indonesia	Common carp	145,500
Mexico	Common carp	27,506
Egypt	Common carp	30,895
Israel	Common carp	7,089
Poland	Common carp	19,720
	Silver carp	198
	Grass carp	3

Mexico is the leading carp-producing nation in Latin America; however, only common carp are being cultured in sufficient quantities to make the FAO statistical report (Table 1). Egypt is the largest common-carp-producing nation in Africa. Israel was a major carp producer in years past, but production was fairly constant over the period from 1986 through 1995, leaving other countries surpass the Jewish state. Tilapia (*Oreochromis* spp.) have largely replaced carp in Israeli aquaculture, although significant culture of several other freshwater and marine species also occurs. In Europe, the production of common carp exceeds 10,000 tons each in the Czech Republic, Germany, Hungary, and Poland (only Poland is included in Table 1).

In the United States, there is very little carp culture activity. Most of the small amount of common carp consumed are taken in the capture fisheries. There is a small ethnic demand associated with historical or religious consumption practices. Grass carp have been used primarily for aquatic weed control by aquaculturists, as well as small pond owners and state and federal management agencies. A small amount of commercial bighead and silver carp production exists in the United States, but it is so insignificant that it does not appear in the FAO statistics (8).

With changes that have occurred in the social structure and economy in the Peoples Republic of China in recent years, the focus on carp production has also begun to change (Li Yingren, Chinese Academy of Fisheries Science, personal communication). City dwellers are apparently demanding higher quality seafood products (shrimp and other seafoods of excellent quality can be found in the large cities of eastern China), so the primary demand for carp is associated with the rural population. Because that population is so large, demand remains high, though annual production increases can be expected to become static or even decline in the future. The government of the Peoples Republic of China has moved from a policy of stressing increased production to a policy that stresses product quality.

Common carp will root around on pond banks and cause damage, but that has not been a major problem in carp culture. On the other hand, the silver crucian carp (*Carassius auratus gibelio*), also known as the chiton, is a subspecies of goldfish (*C. auratus*) that has a reputation for causing extensive damage on fish farms. It also competes with the more desirable species. Apparently, entry of silver crucian carp into culture ponds is the result of the fish entering with incoming water, so proper filtration is recommended to reduce or eliminate the problem.

Culture Methods

Culture Systems. As the chinese begin to adopt modern aquaculture technologies, the situation is changing, but historically, prepared feeds have not been employed in Chinese polyculture ponds. Natural productivity is increased markedly by frequent, or even continuous, additions of manure and nightsoil. Organic fertilizers have been depended upon as sources of nutrition for the fishes stocked. Organic matter, in the form of agricultural wastes, has also been used, primarily for feeding grass

carp, which will feed on various types of plants of aquatic or terrestrial origin. Fertilization promotes phytoplankton, zooplankton, and benthos production in ponds. Common carp are bottom feeders that ingest benthic organisms such as worms, insects, and molluscs. Mud carp are omnivorous and will consume detritus, including decaying vegetation. Black carp feed on snails. Silver carp are able to filter phytoplankton from the water, though they also ingest zooplankton. Bighead carp selectively feed on zooplankton, while crucian carp consume plant fragments and zooplankton.

Using the traditional polyculture approach, the Chinese have found ways of recycling livestock and human wastes (some ponds actually have privies suspended over them) and of utilizing all the food resources that are available. Production rates of about 8,000 kg/ha (7,140 lb/acre) are possible, using the Chinese approach to polyculture.

Polyculture is not limited to various carp species. To some extent in China, but more common in various other nations, is culture of one or two species of carp with fishes from other families. For example, in Israel, common carp have been polycultured with grass carp, tilapia, and mullet (*Mugil* spp.). In the United States there has been some culture of bighead, silver, and grass carp (at low stocking rates) with channel catfish (*Ictalurus punctatus*).

Outside of China, monoculture is much more common than polyculture. Regardless, the vast majority of carp produced, using either approach, are reared in earthen ponds. Production levels in ponds vary considerably from country to country, and even within countries, because of the levels of intensity that exist. With no pond fertilization or supplemental feeding, a yield of only a few hundred kg/ha (lb/acre) can be expected. Fertilization with manure increases natural productivity, and consequently, fish production levels (Fig. 3). Supplemental feeding with grains has led to production levels of over 1,000 kg/ha (approximately 1,000 kg/ha) in countries such as Poland. Polyculture in Chinese ponds fertilized with manure and supplemented with agricultural wastes can produce 1,500 kg/ha (about 1,500 lb/acre). Provision of high quality prepared feeds and the use of supplemental

Figure 3. Swine, cattle, and poultry are among the terrestrial animals that have been produced in association with fish. In this case, ducks are housed adjacent to a carp pond in Nepal. The duck droppings fertilize the water.

aeration to maintain dissolved oxygen levels can increase production dramatically (Fig. 4). In Israel, for example, monoculture common carp ponds have produced as much as 30,000 kg/ha/yr (about 30,000 lb/acre/yr).

Carp production in raceways is not common, though a moderate percentage of the carp produced in Japan are reared in such systems. Cages are sometimes used to rear carp, since large natural or manmade water bodies (rivers, lakes, and reservoirs) can be utilized effectively as aquaculture systems when cages are employed (Fig. 5). For cage culture to be successful, some type of prepared feed should be provided, as natural productivity will usually not be adequate, except perhaps in the case of silver or bighead carp if plankton densities are sufficient.

Similar to cage culture, in that it employs large water bodies for fish culture, is the blocking of bays and inlets with nets that confine stocked fish. In those situations, either natural food can be relied upon, if low stocking densities are employed and natural productivity is high, or culturists can provide supplemental feed to increase fish production.

Figure 4. At the highest level of intensity, the fish are offered prepared feeds and provided with supplemental aeration, as shown here in Israel, where paddlewheel aerators are commonly employed.

Figure 5. Simple cages, such as those shown here in a reservoir in Nepal, provide an alternative type of culture system for carp and other species.

Carp have also been produced in rice−fish culture, another form of polyculture. Rice−fish culture has a long history in Asia and elsewhere in the world, though strong research programs on rice−fish farming systems dates only from the 1980s. In China alone, some 500,000 ha (1,250,000 acres) of rice paddies have been used in rice−fish culture. The approach involves stocking rice paddies with fish that will forage on insects and other organisms that become established in the rice fields. It is important, of course, that the fish do not negatively impact rice production, which is not a problem if common carp are employed. Because fish, such as carp, cannot be reared to market size at the same rate that a rice crop can be produced, it may be necessary to retain fish in the paddy while two or more rice crops are grown. That can be accomplished by digging a trench in the paddy (usually down the middle) that provides sufficient water to support the fish while the paddy is drained for harvesting. This approach works well in theory, but if it becomes necessary to apply pesticides to treat for rice pest invasions, the fish may also be killed, even if the paddy is drained and the fish are isolated in the trench during spraying. Spray drift can be a major problem.

Rice−fish polyculture is often practiced with combinations of grass carp, common carp, and crucian carp, associated with high rice production. Rice−azolla−fish polyculture has also been employed. Yet another approach employed involves rotating crops between rice and fish.

Carp ponds are typically harvested with seines (Fig. 6). Seines may also be employed to harvest fish from portions of large water bodies, such as bays, that are blocked off with nets to provide captive rearing areas. Dip nets are usually the method of choice for harvesting fish from cages. (See the entry "Harvesting.") If a trench is provided in a rice−fish farming operation, the rice paddy can be drained, thereby forcing the majority of the fish into the trench, from which they can be removed with hand nets.

Reproduction. In their native habitat, common carp spawn during the spring, when the rivers are rising due to annual floods and the water temperature reaches 18 to 24 °C (64 to 75 °F). The fish can be allowed to spawn naturally in ponds (broodfish are stocked in newly filled ponds, which mimic rising water level and help induce

Figure 6. A seine full of carp in Israel.

spawning) or they can be induced to spawn with hormones, one of the most popular and effective being carp pituitary.

Typically, spawning ponds are stocked with broodfish in the ratio of 1:2 or 2:3 (females:males). The eggs of common carp are adhesive. When spawning ponds are utilized, some type of spawning mat is provided upon which the eggs can be deposited. Various materials can be used for spawning mats, with plastics of various kinds representing the most modern materials. Once spawning has occurred, the mats may be transferred to nursery ponds; or, when large spawning ponds are employed, once spawning has been completed, the mats may be left in place and the broodfish seined from the ponds. If the eggs are obtained through hormone induction, adhesion can be broken up through the use of various chemicals.

While common carp will spawn in ponds if the appropriate techniques are employed, grass carp can only be spawned through the use of hormone injections. Induced spawning involves injecting broodfish with carp pituitary extract, human chorionic gonadotropin, or leuteinizing hormone-releasing hormone. Injections of both males and females may be required.

Once eggs from the hormone-injected females begin to flow freely, they can be expressed into a dry round basin, after which the milt from one or more running-ripe males is added. The mixture is then stirred, and water is added after about one minute of stirring.

Chemicals, which include salt and urea, salt and milk solution, and others, can be used to break down the adhesion of carp eggs during incubation. Upwelling hatching chambers are employed during incubation, which requires 28 hours or less for grass carp and 55 hours or less for common carp, depending on temperature.

Yolk sac absorption requires a few days, after which the fish will swim to the water surface to inflate their swim bladders and begin feeding. Brine shrimp nauplii (see the entry "Brine shrimp culture"), rotifers, and yeast have been used as first feeds for carp produced in hatcheries. In ponds, natural foods — the production of which is encouraged through fertilization — are depended upon during the initial phases of culture, after which supplemental or complete feeds may be introduced, depending upon the level of technology being employed.

Fertilization, Feeding, and Nutrition. Carp can, as previously mentioned, be produced at modest levels in ponds that are fertilized, but receive no supplemental feed. Fertilization promotes algae blooms that support the production of zooplankton and benthic invertebrates upon which the carp feed. Submerged aquatic vegetation will be consumed by grass carp, though fresh agricultural waste (for example, leafy waste from vegetable production) is often provided, as ponds properly fertilized to induce algae blooms often have limited, if any, rooted plants growing in them. Supplementation with live foods is not common, though silkworm pupae have been used in Japan. The pupae are readily available at low cost in the silk producing regions of that nation.

Without fertilization, polyculture carp ponds may produce from 20 to 40 kg/ha/yr (about 20 to 40 lb/acre/yr). Production can easily be increased through the addition of organic or inorganic fertilizers, though the Chinese, as previously indicated, have pushed production in intensive polyculture ponds to the thousands of kg/ha/yr (lb/acre/yr).

The next step is to provide supplemental or complete formulated feeds. Such feeds have only been developed for common carp, since in most cases, the other species are expected to consume natural foods. Most species will, in fact, accept prepared feeds, but feeds specifically designed to meet their nutritional requirements have not been produced. In fact, it is generally assumed that all the carp species have similar nutritional requirements and will perform similarly on rations developed for common carp.

A great deal of nutritional research has been conducted, particularly in Israel and Japan, on common carp and satisfactory feeds have been developed (9). Ingredients that are commonly found in carp feeds include wheat, barley, corn, rye, rice, soybeans, sorghum, cottonseeds, and fish meal. Vitamin and mineral premixes are also employed in complete feeds.

Carp appear to require between 30 and 38% protein. A dozen amino acids have been found essential for proper carp nutrition and the dietary levels of those amino acids required by the fish have been quantified.

A good deal of research has also been conducted with respect to fatty acid requirements. Both 18:2n-6 and 18:3n-3 appear to be required by common carp (9). Carp diets do not typically contain high levels of lipid, but it is known that carp employ both lipids and carbohydrates as energy sources. Starch is more effectively utilized by carp than are dextrin or glucose.

No deficiency signs in carp fingerlings have been associated with diets lacking in vitamin B_{12}, C, D, or K, though some deformities have been observed at the larval stage in fish that do not receive vitamin C (9). The requirements for various other vitamins have been determined. It has been shown that the requirement for vitamin E increases as the level of dietary polyunsaturated fatty acids increases.

Required dietary minerals include phosphorus, magnesium, zinc, manganese, copper, cobalt, and iron (9). Deficiencies are generally associated with poor growth, as is the case with vitamin deficiencies.

Diseases. Carp, like other aquatic animals, are subject to various diseases. Proper management of culture systems to reduce or eliminate environmental stress on the fish will go a long way in reducing the incidence of diseases.

Carp are susceptible to an array of disease types. Viruses include *Rhabdovirus carpio*, or spring viremia of carp (10). The signs of that disease are similar to those associated with *Aeromonas salmonicida* bacterial infections (discussed in the next paragraph), though the virus may be a secondary infection. There is also a virus, *Herpesvirus cyprini*, that is the causative agent of the so-called fish pox, a disease which was first reported in the 16th century. A disease known as grass carp hemorrhagic virus disease has been reported from China. Signs are severe hemorrhaging of the intestinal tract and various internal organs.

A common problem is hemorrhagic septicemia or infectious abdominal dropsy that is associated with

bacterial infections with *A. salmonicida* (10). Signs of infection include the distension of the abdomen and the accumulation of clear fluid in the abdominal cavity. There may also be ulcers on the liver, reduced hemoglobin levels, increased levels of leucocytes, and lesions in the intestinal tract. Columnaris disease resulting from bacterial infections of *Flexibacter columnaris* have also been reported from carp. *Pseudomonas* infections have also occurred. Terramycin can be used to treat these bacterial problems.

External carp parasites include protozoans, monogenetic trematodes, parasitic copepods, and anchor worms. Secondary fungal infections from *Saprolegnia* sp., have also been reported. Various chemicals have been found effective in treating parasites, but there are severe restrictions on chemicals approved for use in the United States. The fish culturist should attempt to remain knowlegable with regard to the chemicals that are currently approved for foodfish use, as the list is subject to change.

Controversy Surrounding Grass Carp

Grass carp are native to the Amur River in Siberia and the Yangtze River in China. They were first brought to the United States in 1963 by U.S. Fish and Wildlife Service biologists interested in evaluating the species as a biological control for aquatic vegetation. The fish were maintained at the Fish Farming Experimental Station at Stuttgart, Arkansas (now operated as a U.S. Department of Agriculture facility). Research demonstrated that stocking rates of 49 to 99 fish/ha (20 to 40 fish/acre) could effectively control aquatic vegetation in fish ponds.

Commercial production began in Arkansas during 1972, and there were virtually no restrictions on stocking the fish in that state. Other states, expressing concern that the exotic grass carp might consume desirable vegetation and, worse, could reproduce and become established in areas where they were not desired, banned the introduction of grass carp.

Studies of the life history of grass carp concluded that while the fish might spawn in large rivers in North America and elsewhere, the proper conditions for survival did not exist outside of the native range of the species. The lack of sufficiently long river reaches with the proper current speed and the presence of predators in North America rivers — which apparently are virtually nonexistent in the rivers that grass carp are native — were among the conditions cited as mitigating against survival of grass carp in the United States. Yet, within a few years, grass carp fry and juveniles began to appear in the Mississippi River. Based on the size of those fish, it was clear that grass carp were spawning successfully. Reports also came of successful spawning from the Rio Grande. Texas was among over 30 states that had banned grass carp, yet retailers were advertising and marketing the fish nationwide in trade magazines. Individual landowners usually had little difficulty having a few grass carp shipped to them for use in ponds. Escapement of those fish, and the reported presence of at least a few grass carp fingerlings in many minnow shipments from Arkansas into other states led to the diffusion of grass carp into many states where they were prohibited.

There were instances where exceptions were made to bans on grass carp in states that had once outlawed the species, or even retained a general ban on its introduction. An example is associated with Lake Conroe, Texas. By the late 1970s, that large reservoir north of Houston was becoming choked with an exotic, rooted-aquatic weed (*Hydrilla* sp.) from the shoreline out to a depth of about 10 m (30 feet) of water. Lakeside residents found it difficult or impossible to maneuver their boats through the weeds and at least one drowning was attributed to a child becoming entangled in the weeds. After mechanical harvesting and chemical control failed to ameliorate the problem, the Texas Parks and Wildlife Department commissioners voted to stock grass carp. That decision was challenged by bass fishing groups that were concerned that elimination of the weeds would negatively impact angling. The issue wound up in court, and the state lost the suit, based on a technicality surrounding a violation of its own administrative procedures (failure to provide sufficient time for comment between announcing the proposed course of action and making the final determination). The case was appealed, ultimately, to the Supreme Court of Texas. Before the Supreme Court acted, the Texas Legislature passed legislation requiring that the fish be stocked in Lake Conroe. All of this took many months, during which time the fish were being held in Arkansas, where they were outgrowing the farmer's ability to retain them.

The fish were ultimately stocked, and, as predicted, the vegetation was controlled. Fishing was going to be impacted negatively whether grass carp were present or not. With the dense weeds present, the anglers, who were concentrating on catching largemouth bass (*Micropterus salmoides*) had been enjoying unusually good fishing conditions. The bass had been impeded from getting into shallow water by the dense weeds, while their prey (smaller fish) could hide effectively in the weeds. The hungry bass were highly susceptible to angling, so for a while, at least, fishing had been excellent. However, the bass could not reach their spawning beds under these conditions, and the population was due to collapse if the weeds were not removed.

With the removal of the weeds, water clarity changed (was reduced), as plankton blooms replaced the rooted vegetation, creating the need for additional water treatment before the water could be used as a domestic supply in Houston. As it turned out, the water district had actually benefited from the presence of the weeds.

Surprisingly, there was documentation of successful spawning and survival of offspring downstream of the lake. The occurrence of young grass carp in the marshes along the coast fueled fears that valuable habitat might be destroyed. At present, the final outcome remains to be determined.

With the banning of grass carp in so many states and the intense controversy that surrounded the fish, commercial culturists soon began producing triploid grass carp (fish with three pairs of chromosomes), by hybridizing grass carp and bighead carp. The benefit of the triploid is that it will consume aquatic vegetation, but cannot reproduce. Triploids can be stocked at the appropriate

levels and will control vegetation, and after several years they will die, and the decision may be made as to whether or not restocking is desirable. The same applies to diploid grass carp, but there is little or no concern when triploids escape, as they cannot establish reproducing populations.

With the availability of sterile triploids, many states began making exceptions to their bans and now allow triploid stocking, though the use of triploids tends to be strictly controlled. Permits may be required from the appropriate state agency. The agency may require that provision is made to prevent loss of fish over pond spillways during heavy runoff periods, even if the fish stocked are triploids. Also, the agency may dictate the maximum number of fish that can be stocked in a particular water body. In most cases, the producer must certify that the fish being sold are 100% triploids. This involves examining blood (the blood cells are larger in triploid than diploid fish), which significantly adds to the cost of stocking triploids.

Indian Carp Culture

A group of carp species known as the major Indian carps are produced predominantly on the Indian subcontinent. Included are the roho or rohu (*Labeo rohita*), mrigal (*Cirrhinus mrigala*), and catla (*Catla catla*). In addition to India (Table 2), roho and mrigal are being reared in Laos, Myanmar, and Thailand; while catla is produced in India, Laos, and Myanmar. With the exception of roho production in Myanmar, where 74,000 tons were produced in 1995, production levels of these carp species are low outside of India. There has been some research on the use of Indian carps in Egypt, but production there, if it is still underway, is not sufficient to make the FAO statistical reports (8).

All three species are native to India and spawn in the rivers of that country. Roho and mrigal have a preference for vegetation and decaying plant matter as food, while catla feed primarily on zooplankton.

Historically, pond or bund spawning provides for environmental manipulations that induce natural spawning (11). Grass is grown in large shallow ponds during the dry season, in which time, the broodfish are held in a pool within the pond. When the monsoon rains arrive, the levee between the holding pool and bulk of the pond is opened, and the fish enter the grassy area where they spawn. The eggs are collected with nets for incubation in small water bodies. Alternatively, hormone injections can be used to induce spawning. Growout involves rearing in fertilized ponds, which may also receive supplemental feed.

Table 2. Production of Indian Carps (metric tons) in 1995 (8)

Species	Production (tons)
Rohu	382,050
Mrigal	370,960
Catla	379,338

The channel catfish (*Ictalurus punctatus*) is a native North-American freshwater fish in the family Ictaluridae, or bullhead catfishes. The original range of the channel catfish extended from northern Mexico and the states bordering the Gulf of Mexico up the Mississippi River and its tributaries. Long esteemed as a foodfish in the southern part of its original range, the species has been introduced throughout the world as a sport fish and for aquaculture. In fact, channel catfish aquaculture has expanded rapidly since 1975 to become the largest aquaculture industry in the United States. In 1997, 250,000 metric tons (560 million pounds) of channel catfish were produced commercially, which accounted for about half of the total United States aquaculture production for all species.

Channel catfish are typical ictalurids, with an elongated, cylindrical body, a depressed head, and scaleless skin. All ictalurid catfishes possess an adipose fin and soft-rayed fins, although the pectoral and dorsal fins have sharp, hardened spines. The barbels of ictalurid catfishes are arranged such that four are under the jaws, two are above the jaws, and one is on each tip of the maxilla. Characteristics that distinguish channel catfish from other ictalurid catfishes include a deeply forked tail and a moderately rounded anal fin with 24–30 rays. Normally pigmented channel catfish are white to silvery on the undersides, grading to grayish blue or olivaceous to nearly black dorsally. (See Fig. 1.) Albinism is rare in wild fish, but is not uncommon in certain domesticated strains. Irregular dark spots are present on the sides of young fish, but are absent in albino fish and are often lost in normally pigmented fish over about 0.45 kg (1 lb).

Channel catfish are bottom dwellers that prefer a substrate of sand and gravel. Their natural habitat is sluggish to moderately swift rivers and streams, although they also thrive in lakes and ponds. Fish less than 10 cm (4 in.) long feed on detritus, aquatic insects, and zooplankton. Larger fish feed primarily on aquatic insects, crawfish, and small fish. The optimum temperature for growth is 25 to 30 °C (77 to 86 °F), and the fish feed poorly at temperatures below 10 °C (50 °F) and above 35 °C (95 °F). In nature, from two to five years may be required for a fish to reach a weight of 0.45 kg (1 lb), although much faster growth is achieved in aquaculture. Channel catfish may live for more than 40 years and attain weights in excess of 18 kg (40 lb).

Channel catfish possess a combination of desirable qualities for commercial aquaculture. They usually do not reproduce in culture ponds, a trait that gives the culturist control over pond populations. Sexually mature fish are, however, easily spawned under proper conditions, and large numbers of fry can be obtained using simple methods. Fry accept manufactured feeds at first feeding after absorbing their yolk sac, and growth and feed conversion efficiency on relatively simple manufactured feeds are satisfactory at all phases of production. Channel catfish are hardy fish that tolerate crowding and a wide range of environmental conditions. They also adapt well to all commonly used aquaculture production systems: ponds, cages, and raceways. Channel catfish have firm, white flesh with a mild flavor that retains high sensory quality after a variety of processing methods.

Although channel catfish account for virtually all of the catfish production in the United States, there is also some interest in commercial production of blue catfish, *Ictalurus furcatus*, a close relative of channel catfish. Blue catfish (see Fig. 2) resemble channel catfish in their general appearance, although blue catfish have a smaller head and the anal fin, which contains 30 to 36 rays, is longer and less rounded than that of the channel catfish. Blue catfish grow slower than channel catfish during the first two years of life, although strain effects are important and some strains of blue catfish grow faster than many strains of channel catfish (1). Blue catfish also mature sexually at an older age and larger size than channel catfish, which is considered an undesirable trait, because large broodfish are difficult to manage. On the positive side, blue catfish have a better dressout percentage than channel catfish (2),
Figure 1. Normally pigmented and albino channel catfish fingerlings of about 0.04 kg (0.1 lb).
Figure 2. Channel catfish (top), blue catfish (middle), and white catfish (bottom), all of about 0.25 kg (0.5 lb).

are easier to harvest by seining (3), and are more uniform in size at harvest (4). Blue catfish are less tolerant of poor water quality than are channel catfish (1), but are more resistant than channel catfish to the infectious diseases enteric septicemia of catfish (5) and channel catfish virus disease (6).

Attempts have been made to take advantage of the best traits of the blue and channel catfish by making interspecific hybrids. The female channel catfish × male blue catfish hybrid possesses many of the best features of the parents and is a highly desirable fish for commercial culture (7). However, the major obstacle to the commercial use of this hybrid is the low hybridization rate, which makes it difficult to obtain adequate numbers of fry for commercial use.

At one time, there was some interest in aquaculture of the white catfish, *Ameiurus catus* (8–10). The white catfish (see Fig. 2) has a moderately forked tail, is unspotted, and the anal fin contains 19 to 23 rays. Its color is bluish to gray on the dorsal surface and silvery below. White catfish are among the hardier of the ictalurid catfishes. They tolerate low concentrations of dissolved oxygen and high water temperatures better than channel catfish do. However, relative to channel and blue catfish, the white catfish has a poor dressout percentage and grows slowly. There is little current interest in growing that species commercially.

The fish species collectively known as bullheads are the smallest of the ictalurid catfishes commonly used as human food. The brown bullhead (*Ameiurus nebulosus*) and yellow bullhead (*Ameiurus natalis*) offer some potential for culture, and the yellow bullhead has been advocated as a good candidate for small-scale, "backyard" aquaculture (11). Bullheads tolerate poor water quality, and, under the right culture conditions, they have a desirable, mild flavor. On the other hand, bullheads are small fish that have a poor dressout percentage. They also readily reproduce in ponds and may overpopulate production ponds, resulting in large numbers of small fish. Consumer demand and prices paid for bullheads are low, and they are seldom cultured for food.

DEVELOPMENT OF THE CATFISH INDUSTRY

Many of the production practices used in channel catfish aquaculture were developed prior to 1960 — well before there was significant commercial culture of the fish for food. Reliable spawning and hatchery techniques were developed between 1910 and 1960 by personnel at state and federal hatcheries, so that large numbers of fry and small fingerlings could be produced for stocking into reservoirs or sport-fishing ponds (12–14). The fundamentals of pond culture of adult fish were developed largely through the efforts of Dr. H.S. Swingle and his colleagues and students at Auburn University. In a series of studies conducted in the 1950s and early 1960s, the Auburn research group explored the potential for small-scale aquaculture of channel catfish in farm ponds in the southeastern United States. Initial efforts at growing catfish in ponds centered around increasing fish yields by enhancing natural pond productivity with inorganic fertilizers (15). Annual yields of catfish in fertilized ponds were around 100 to 200 kg/ha (90 to 180 lb/acre). Use of a crude supplemental feed, such as soybean cake, increased annual production to more than 250 kg/ha (225 lb/acre). Somewhat later, a dry, powdered diet — originally formulated for minnows — was fed to channel catfish, and an annual yield of 1,400 kg/ha (1,250 lb/acre) was achieved (16). Further developments in the nutrition and feeding of catfish included pelleting the feed and formulating the diet according to the nutritional needs of the fish. Early on, it was discovered that daily feeding rates greater than about 34 to 45 kg/ha (30 to 40 lb/acre) were not possible without causing oxygen depletions and fish kills (17). By providing mechanical aeration, oxygen depletion can be avoided, and summertime feeding rates as high as 140 kg/ha (125 lb/acre) per day are now possible. Annual fish yields on commercial fish farms now range from 3,300 to over 7,800 kg/ha (3,000 to over 7,000 lb/acre).

From 1955 to 1965, most of the growth in commercial catfish culture occurred in southeast Arkansas, where farmers found that raising fish could be a profitable alternative to growing traditional crops such as rice and cotton. The initial interest in foodfish aquaculture in Arkansas centered around growing buffalofish (*Ictiobus* spp.), a regionally popular table fish. In 1960, there were 1,500 ha (3,700 acres) of ponds used to raise buffalofish and 100 ha (250 acres) of catfish ponds in Arkansas, but by 1963, the production of channel catfish far exceeded that of buffalofish. In 1965, there were 4,000 ha (10,000 acres) of catfish ponds in Arkansas and another 1,000 ha (2,500 acres) of catfish ponds in other states in the southeastern United States. Annual production of catfish in the United States that year was about 7,500 metric tons (16.5 million lb).

Around 1975, the industry began to expand at a rapid rate, especially in Mississippi. That expansion was stimulated, in part, by declining profits from traditional agriculture (mostly cotton and soybeans) and a desire to diversify agricultural production and make use of land only marginally suited for row crops. Strong cooperation among farmers, particularly in the development of large feed mills and fish processing plants, was central to the early development of the industry. Growth was also facilitated by the formation of a national grower's association (The Catfish Farmers of America) in 1968 and by an extraordinarily effective national marketing effort directed by The Catfish Institute that began in 1986. In 1980, there were 15,000 ha (37,000 acres) of ponds devoted to catfish farming, and about 35,000 metric tons (77 million lb) of catfish were produced. By 1997, about 75,000 ha (185,000 acres) of ponds were in production, and over 250,000 metric tons (560 million lb) of fish were processed, which represented about half the total U.S. aquaculture production for all species. Over 95% of present-day catfish aquaculture occurs in the four southeastern states of Mississippi, Alabama, Arkansas, and Louisiana. Mississippi is the leading catfish-producing state and accounts for over 70% of the total U.S. production.

The success and rapid growth of channel catfish aquaculture in the southeastern United States has stimulated interest in using the farm-raised catfish industry as a model for the development of large-scale aquaculture in other regions and with other species. However, catfish farming may not be a good general model for aquaculture development, because the establishment and growth of the industry depended on conditions that may be difficult to duplicate with other species and in other locations. The success of catfish farming can be attributed to six general factors:

(1) Channel catfish are hardy and simple to grow.

(2) Techniques for reproduction and growout of channel catfish were known prior to large-scale industry growth. That is, lack of culture technology did not constrain early growth of the industry.

(3) Channel catfish were widely accepted as a food item in the region, which provided a ready market for initial production.

(4) Appropriate physical resources were available in the region that allowed the development of large farm operations that captured economies of size. These resources included a suitable climate, large tracts of flat land, and abundant underground water.

(5) Many farmers in the region had the capital needed to invest in large-scale aquaculture, and they were willing to take risks on a new enterprise. Farmers were also willing to cooperate in the development of the infrastructure, such as the feed mills and processing plants, needed to support commercial production.

(6) Rapid growth in production occurred when the industry moved from regional to national marketing of the fish. That transition was successful because of a well-conceived and extraordinarily effective generic marketing campaign.

CULTURE METHODS

Nearly all channel catfish produced commercially are grown in earthen ponds, because production costs are generally lower for catfish grown in ponds than in any other culture system. Production of channel catfish in systems other than ponds is economically viable only when some special circumstance exists, such as the opportunity to sell fish to a local market at an exceptional price or the availability of an unusual resource that makes production profitable. For instance, a unique channel catfish aquaculture industry is present in the arid, intermountain region of the western United States. In the Snake River Canyon of Idaho, large artesian springs supply geothermal water that allow production of catfish in flow-through raceways under nearly optimum temperature conditions throughout the year.

Catfish aquaculture in ponds is a straightforward process that typically involves four phases:

- Broodfish are held in ponds at relatively low-standing crops and allowed to mate randomly each spring when water temperatures rise above 20 °C (68 °F).
- The fertilized eggs are taken to a hatchery, where they hatch under controlled conditions. The fry are held in the hatchery for 5 to 10 days.
- Fry are transferred from the hatchery to a nursery pond, where they are fed a manufactured feed daily through the summer and autumn.
- Fingerlings weighing 20 to 40 g/fish (0.7 to 1.4 oz/fish) are seined from the nursery pond in winter or spring and transferred to foodfish growout ponds, where they are fed a manufactured feed until they reach a size desirable for processing [0.45−0.90 kg/fish (1−2 lb/fish)].

In the southeastern United States, 18 to 30 months are required to produce a food-size channel catfish from an egg.

In practice, the foregoing simple production scheme is complicated by a number of management decisions that must be made to optimize the production strategy for each farm. A few farmers specialize in producing fingerlings, which are then sold to farmers specializing in the production of food-size fish. Many farmers combine all aspects of production. Those farms have broodfish ponds, a hatchery, fry nursery ponds, and foodfish growout ponds. Specific management practices also differ from farm to farm. This factor is particularly evident in the variety of management practices used in foodfish growout ponds. Culture practices for pond-raised channel catfish were reviewed by Busch (18), Stickney (19), and Tucker and Robinson (20).

Facilities

Most ponds used for commercial channel catfish culture are built on flat land by removing soil from the area that will be the bottom of the pond and using that soil to form levees around the perimeter of the pond. (See Fig. 3.) The average pond size is between 4 to 6 water ha (10 to 15 acres), built on 4.5 to 7 ha (11 to 17 acres) of land. The depth of the water is 0.9 to 1.5 m (3 to 5 feet).

Figure 3. Channel catfish ponds in Mississippi.

Levee ponds built on flat land have little watershed to supply water by runoff, so a source of pumped water is required (21). Ideally, the water source should supply at least 140 L/min for each hectare of water (15 gal/min/acre). This figure is roughly twice the maximum daily pond evaporation rate in the southeastern United States and allows for maintenance of pond levels during periods of drought, with some excess water to meet moderate seepage losses. Groundwater is preferred over surface-water supplies, because groundwater supplies are of dependable availability and consistent quality over time and are free of wild fish and less prone to pollution than are surface waters. The most important water-quality criteria for catfish pond water supplies are salinity (it should be less than 4–6 ppt) and the absence of pesticides or other potentially harmful pollutants. Other desirable characteristics are moderately high concentrations of total alkalinity and calcium hardness (both at least 20 to 30 mg/L as $CaCO_3$). Ample total alkalinity provides pH-buffering capacity to the pond water, and calcium benefits fish osmoregulation and stress resistance.

Reproduction and Breeding

An important consideration in choosing a fish species for aquaculture is the ease with which the reproductive phase can be controlled or manipulated. In that respect, channel catfish are an ideal species for aquaculture. Channel catfish broodfish are easy to maintain in pond culture, and the spawning efficiency (the percentage of female broodfish that spawn in a given year) is reasonably good without any special manipulation of environmental conditions or the need for hormone treatments to induce spawning. Sexually mature channel catfish will not reproduce in ponds unless they are provided with an enclosed nesting site in which to mate. This is a highly desirable trait for a fish used in aquaculture, because uncontrolled reproduction in growout ponds leads to overpopulation and reduced yield of marketable fish. Eggs and fry of channel catfish are hardy and tolerate handling relatively well, and excellent egg hatchability and fry survival can be obtained in simple, inexpensive hatcheries. Eggs and fry develop rapidly at the proper temperature, so there is no need for a lengthy stay in the hatchery. At a water temperature of 27 °C (80 °F), yolk sac absorption by fry occurs 10 to 14 days after egg fertilization. After absorbing their yolk sac, channel catfish fry accept simple manufactured feeds at first feeding.

Channel catfish may mature sexually at two years of age and at weights as low as 0.3 kg (0.7 lb), but for reliable spawning, fish should be at least three years old and weigh at least 1.4 kg (3 lb). The most desirable broodfish are four to six years old and weigh between 1.8 and 3.6 kg (4 to 8 lb). Older fish produce fewer eggs per body weight, and larger fish may have difficulty entering the containers commonly used as nesting sites. At present, genetically improved stocks of fish are not widely available for commercial use, although some producers offer select strains of fish known to have good production characteristics. Commercial broodfish are sometimes obtained from foodfish growout ponds that contain large fish or from existing broodstock that appear to perform well on other farms. Broodfish

are selected based on general health, size, and the development of robust secondary sexual characteristics. Fish sex is determined during broodfish selection, so that females and males can be stocked into brood ponds in the desired ratio. Determining the sex of fish and adjusting sex ratios is important, because males grow faster than females, so if broodfish selection is based only on size, then relatively few females will be selected.

In large-scale, commercial reproduction of channel catfish, broodfish are held in ponds provided with enclosed nesting sites in which fish are allowed to mate randomly. This method, while giving the culturist little control over the mating process, requires minimal facilities and less technical skill than other methods and can provide large numbers of eggs at low cost. Spawning success, which is measured as the percentage of females that spawn each year, varies from 25 to 75%. Success depends on the condition and age of the broodfish, water temperatures during the spawning season, and other factors yet to be identified. The culturist has little or no control over water temperatures, but spawning success can be maximized by choosing good broodfish and by ensuring good environmental conditions by using new or recently renovated ponds as brood ponds. Other keys to good spawning include maintaining proper standing crops and sex ratios in broodfish ponds and providing broodfish with an adequate food supply.

Maintaining a relatively low broodfish standing crop is necessary to provide good environmental conditions and to minimize suppression of spawning by overcrowding. Broodfish standing crops in ponds should not exceed about 2,250 kg of fish/ha (2,000 lb/acre). Broodfish are seined from ponds and inspected every two or three years. Large fish, which may be poor spawners, are culled at that time and replaced with smaller, younger broodfish. Brood stock replacement ensures a vigorous brood population and reestablishes proper fish standing crops. Periodic inspection of broodfish also provides an opportunity for adjusting the sex ratios within brood populations. Female channel catfish spawn once a year, but males can spawn two or more times a year. Consequently, stocking more females than males makes more efficient use of pond space. Male-to-female ratios in brood ponds are typically maintained at between 2 : 3 and 1 : 2.

Poor broodfish nutrition may result in poor egg quality or reduced spawning success, so broodfish must be provided with adequate food at all times. Also, an inadequate supply of food can result in poor-quality female broodfish, because males, which tend to be more aggressive, may consume most of the limited ration. When water temperatures are consistently above 20 °C (68 °F), broodfish are fed a nutritionally complete manufactured feed with 28 to 32% crude protein (22). Most farmers use the same feed for growout of food-sized fish. Feed is offered daily at about 0.5 to 1% of the total body weight of the fish in the pond. At water temperatures of about 13 to 20 °C (55 to 68 °F), feed is offered at 0.5 to 1% of the total body weight of the fish in the pond every other day. Channel catfish do not actively feed at water temperatures below about 10–13 °C (50–55 °F). Some producers stock forage fish (such as fathead minnows, *Pimephales promelas*)

Figure 4. Three types of containers used as artificial nesting sites for channel catfish.

into brood ponds, to provide a food source in addition to manufactured feeds.

Seasonal changes in water temperature control the reproductive cycle in channel catfish (23). Exposure to water temperatures below about 15 °C (60 °F) for a month or more over winter stimulates gametogenesis. A subsequent slow rise in the average water temperature to 20–25 °C (68–77 °F) usually initiates spawning in the spring. Water temperatures of around 25–27 °C (77–80 °F) are considered optimum for spawning.

Channel catfish must be provided with an enclosed nesting site for spawning. A variety of containers have been used successfully as artificial nesting sites. (See Fig. 4.) Most containers have an internal volume of about 75 L (20 gal) and an opening 15–25 cm (6–9 in.) across. Containers are placed in the brood pond shortly before water temperatures are expected to rise into the range for spawning. When water temperatures enter the range for spawning, the male chooses a container and cleans the inside of debris and sediment. The female is attracted to the container by olfactory signals, and mating begins. Spawning occurs over a period of several hours as several layers of adhesive eggs are deposited. Females weighing between 2 to 4.5 kg (4 to 10 lb) typically lay between 6,500 to 9,000 eggs/kg body weight (3,000 to 4,000 eggs/lb). Once spawning is complete, the male chases the female from the nest and guards the eggs. The eggs are about 0.45 cm (0.2 in.) in diameter, initially are light yellow, and become brownish yellow with age.

Culturists check the spawning containers every two or three days for the presence of eggs. A container holding eggs is gently brought to the surface and drained of water. If the male remains in the container, he is allowed to swim out before the egg mass is retrieved. (See Fig. 5.) The egg mass often sticks to the floor of the container and is gently removed by scraping it from the container. The eggs collected from the brood pond are placed in insulated, aerated containers and transported to the hatchery.

Hatchery Practices

Sophisticated hatchery facilities are not needed for producing channel catfish fry. The most critical factor

Figure 5. A channel catfish egg mass being retrieved from a spawning container.

for a successful hatchery is an adequate supply of high-quality water of the appropriate temperature (24,25). The optimum water temperature for egg incubation and fry rearing is 25 to 28 °C (77 to 82 °F). If water temperatures are below 25 °C (77 °F), egg hatching and fry development are prolonged, and fungi may invade the egg masses. If the temperature is above 28 °C (82 °F), the embryos may develop too rapidly, and there will be higher incidences of malformed and nonviable fry. Also, bacterial diseases of eggs and fry and channel catfish virus disease of fry are more common if the water temperature is too warm. Heating or cooling water is expensive, so most hatcheries in the major channel-catfish-producing areas of the southeastern United States obtain water from wells 300 to 400 m (1,000 to 1,300 ft) deep that naturally provide water at a constant temperature of 25 to 28 °C (77 to 82 °F).

Shallow tanks holding about 350–400 L (90–110 gal) of water are used to incubate eggs and rear fry. The water flow through tanks is about 10–15 L/min (3–4 gal/min). Egg-hatching tanks have a series of paddles attached to a shaft running the length of the tank; the paddles are spaced along the length of the tank to allow wire-mesh baskets to fit between them. The paddlewheel shaft is then attached to a low-speed electric motor. One or two egg masses are placed in each basket, and the paddles gently

rotate through the water to provide water circulation and aeration. The motion of the paddles mimics the action of the male parent, which, under natural conditions, circulates water over the eggs by fanning the water with his tail. Some culturists have discarded the traditional paddlewheel egg-hatching tank in favor of tanks with a set of airstones or a perforated pipe that delivers low-pressure, forced air from a blower. The vigorous bubbling produced by such systems aerates and circulates water around the egg mass.

The incubation time for channel catfish eggs varies from five to eight days, depending upon the temperature of the water. At hatching, the fry, called sac fry at this point, fall or swim through the wire-mesh basket and form schools in the corners of the tank. Fry are then siphoned into a bucket and transferred to a fry-rearing tank. Fry-rearing tanks are usually of the same dimensions as egg-hatching tanks, but are not equipped with paddles. Aeration in fry-rearing tanks is provided by one or two small surface agitators or by air bubbled through airstones.

Sac fry initially are golden in color and are not fed, because they derive nourishment from the attached yolk sac. Over a 3- to 5-day period after hatching, they absorb the yolk sac and turn black. At that time, the fry, now called swim-up fry, swim to the surface of the water, seeking food. Swim-up fry are fed at a daily rate an amount of feed equal to about 25% of the total body weight of the fry in the tank, divided into 6 to 12 equal feedings a day. Fry feeds are dry, finely ground meal or flour-type feeds, containing 45 to 50% crude protein (22). Most of the protein in fry feeds is supplied by fish meal. Fry are fed in the hatchery for 2 to 10 days before they are transferred to a nursery pond.

Nursery Pond Management

After their brief stay in a hatchery, fry are moved to a nursery pond for further growth. Nursery ponds are stocked with 250,000 to 750,000 fry/ha (100,000 to 300,000 fry/acre). It is difficult to feed small catfish fry recently transferred from the hatchery to a nursery pond, because fry are weak swimmers and are not able to move large distances to areas where feed is offered. It is therefore important to prepare nursery ponds so that they contain abundant natural foods, to promote growth until the fish are large enough to feed effectively on manufactured feeds. The best fertilization program for catfish nursery ponds uses a combination of high-phosphorus inorganic fertilizer and an organic fertilizer, such as cottonseed meal or alfalfa pellets. Fertilization is initiated two or three weeks before the pond is stocked with fry and continues until the fry are vigorously accepting manufactured feed. Even though fry can meet all of their nutrient requirement from the natural foods present in a well-fertilized pond, they should be offered a finely ground feed one or two times a day at 25 to 50% of the fry biomass. Fry may not make good use of the feed for several weeks, but this regimen will help train the fish to seek feed, and the unused feed is not wasted, because it acts as additional fertilizer. A month or so after stocking, the fry, now called fingerlings, will have grown to 3 to 4 cm (1 to 1.5 in.) in length and can be fed once or twice daily to satiation, using a crumbled feed or small

pellet, containing 32 to 35% crude protein. The small feed can be fed to the fry throughout the nursery phase, or, as the fish grow, the size of the feed can be increased to the same size used for foodfish growout (22).

Fingerlings five to nine months of age, weighing 20–40 g each (0.7–1.4 oz), are harvested from nursery ponds in the autumn, winter, and early spring and transferred to foodfish growout ponds. Survival of fry to the fingerling stage in excess of 75% is considered good. Nursery ponds are harvested by seining each pond several times over a period of one to three months. Fingerlings from nursery ponds vary considerably in size and are usually graded to obtain a more uniform population for stocking. Grading is accomplished by using a seine with a mesh size that selectively retains fish of a certain minimum size, while allowing smaller fish to escape. Partial harvest of nursery ponds also serves to reduce the fingerling standing crop, which allows the smaller fish remaining in the pond to grow more rapidly to a desired harvest size.

After as many fingerlings as possible have been removed by seining, the pond is drained and allowed to dry, so that all remaining fish are eliminated. Removal of all fish from the nursery pond is important to prevent cannibalism of fry stocked in the subsequent cycle of fingerling production. Allowing the pond bottom to dry also helps reduce populations of predacious aquatic insects, such as dragonfly nymphs (order Odonata) and back swimmers (order Hemiptera, family Notonectidae), that may prey on catfish fry.

Foodfish Production

Cultural practices used to produce foodfish differ among farms to a much greater extent than do practices used in broodfish ponds or nursery ponds. This situation is due, in part, to differences in production goals between farms, as well as a lack of information on the economics associated with the various foodfish production strategies. Individual farmers have developed and used various production schemes, based on experience, personal preference, and perceived productivity and profitability.

The two fundamental production variables in food-fish growout are fish stocking density and the cropping system (20,26,27). Stocking densities in foodfish growout ponds range from about 10,000 to over 30,000 fish/ha (4,000 to over 12,000 fish/acre) and average about 15,000 fish/ha (6,000 fish/acre). The term "cropping system" refers to the stocking–harvest–restocking schedule. The two cropping systems used in commercial production are "clean harvesting" and "understocking." The two systems differ in the number of year-classes, or cohorts, of fish present in a pond at any one time.

In the clean-harvest cropping system, the goal is to have only one year-class of fish in the pond at one time. In a typical production cycle, fingerlings are stocked, grown to the desired harvest size [usually 0.45–0.90 kg/fish (1–2 lb/fish)], and an attempt is then made to harvest all fish from the pond before adding new fish. Fish are removed in two to four separate harvests, spaced over several months. At each harvest, faster growing fish are selectively removed with a large-mesh seine, and the

smaller fish remain in the pond for further growth. After harvesting as much of the crop as possible, the pond is either drained and refilled or, more commonly, restocked without draining, to conserve water and reduce the time lost between crops.

In the understocking system, more than one year-class of fish is present after the first year of production. Initially, the pond is stocked with a single year-class of fingerlings. The faster growing individuals are selectively harvested using a large-mesh seine, and fingerlings are added ("understocked") to replace the harvested fish plus any losses suffered during growout. The process of selective harvesting and understocking continues for years without draining the pond. After a few cycles of harvesting and understocking, the pond contains several year-classes of fish and a continuum of fish sizes ranging from recently stocked fingerlings to fish that may be several years old, weighing over 1.4 kg (3 lb).

Both cropping systems have advantages and disadvantages. For example, fish harvested from clean-harvested ponds tend to be more uniform in size than those harvested from understocked ponds (27), and uniform fish size is highly desired by fish processors. It is also easier to maintain accurate inventory records when using the clean-harvest cropping system, because fish populations are "zeroed out" after each round of cropping. Feed conversion efficiencies also tend to be better for fish in clean-harvested ponds (27), probably because there is little or no year-to-year carryover of big fish, which convert feed to flesh less efficiently than do small fish. On the other hand, when all of the ponds on a farm are managed with understocking, more ponds will contain fish of marketable size at any one time than if the clean-harvest system were used. This aspect is important, because pond-raised catfish often are temporarily unacceptable for processing, because of algae-related off-flavors. So, if the timely harvest of fish from a particular pond is constrained by the presence of off-flavors (or other factors, such as ongoing losses to an infectious disease), there is a greater probability of having acceptable fish to sell from another pond when ponds are managed with the understocking strategy. Economic analyses indicate that clean-harvest cropping systems generate greater net revenues than understocked ponds when fish can be harvested and sold without constraint. But in the real world, where the presence of off-flavors and other market constraints often prevent timely fish harvest, the understocking system is the more desirable of the two cropping systems (26,28). Not surprisingly, the understocking system is by far the most common cropping system in use and is likely to remain so until solutions to off-flavor problems are developed.

Although long-term management strategies differ between the two cropping systems, daily pond management practices for foodfish growout are similar in both systems. When water temperatures are above about 15 °C (60 °F), fish are offered an extruded, floating feed of 28 to 32% crude protein (22). The feed is blown over a wide area of the pond from mechanical feeders that are mounted on or pulled by vehicles. The usual practice is to feed the fish once or twice daily to near satiation, based on visual assessment of fish feeding activity. Relatively large amounts of feed are offered daily because fish densities are high in commercial ponds. Feed allowances in commercial foodfish growout ponds average between 85 and 140 kg of feed/ha (75 and 125 lb/acre) per day during the late-spring-to-early-summer period of maximum feeding activity. Feeding activity declines as water temperatures drop in late fall, and feeding rates average less than 30 kg of feed/ha (25 lb/acre) per day during midwinter, although feed allowances may be considerably higher during abnormally mild winters. Feed allowances in individual ponds vary, depending on fish biomass (they are lower after harvest, for example) and fish health. In fact, day-to-day changes in appetite are an important indicator of the general health of fish, and reduced feeding activity is often the first sign of poor water quality or an infectious disease outbreak.

Foodfish growout ponds are usually drained only when pond levees need to be renovated or when there is a need to adjust fish inventory by completely harvesting the crop. Most commercial ponds remain in production for 5 to 15 years between pond renovations. Renovation usually involves drying the pond bottom, disking to break up the dried clay, and scraping to smooth the bottom profile and restore drainage slope. Accumulated sediment on pond bottoms is derived from erosion of levee slopes by waves, so the dried material scraped from the bottom is used to rebuild the levee and restore the proper slope. Other than measures to restore proper pond morphology, no treatment of the bottom soils is undertaken during renovation.

NUTRITION AND FEED FORMULATION

Research by H.S. Swingle in the 1950s (15) showed that production of natural foods in fertilized ponds was sufficient to produce about 200 kg/ha (180 lb/acre) of channel catfish annually. Crude feeds that provided protein and energy were later used to supplement natural productivity and increase fish yields. Early supplemental feeds were deficient in some essential nutrients, but, as long as fish were stocked at relatively low densities, the requirements for those nutrients could be met by natural food organisms eaten by the fish. As commercial catfish culture intensified, the contribution of natural foods to the nutrition of the fish became less significant, and feed quality and feeding practices became increasingly important to profitable production. Feed cost is the major cost of producing channel catfish, accounting for slightly over half of the annual operating expenses for a typical catfish farm. Efficient and economical feeds, together with effective feeding practices, are therefore essential to profitable catfish farming.

Fish nutrition is the most advanced area of channel catfish culture. The general nutritional requirements of channel catfish have been established, and practical diets can be formulated from relatively few ingredients to meet those requirements. Feeding practices, which have been described in previous sections, are less well standardized than nutritional requirements or feed manufacture. Reviews of nutrition, feed manufacture, and feeding of channel catfish are provided by Tucker and Robinson (20),

Robinson and Li (22), Lovell (29), Robinson (30), and the National Research Council (31).

Nutritional Requirements

The qualitative nutritional requirements of channel catfish are similar to those of other animals. However, the absolute and relative amounts of nutrients needed by catfish differ from those needed by other animals. Also, quantitative nutritional requirements for channel catfish may vary with fish size, growth rate, stage of sexual maturity, water temperature, diet formulation, feeding rate, and other factors. Many of these interrelationships are poorly understood.

Protein. Regular intake of dietary protein is required for animal growth and repair of tissues. Inadequate intake of protein results in poor growth or weight loss. If too much protein is consumed, part of the protein will be used as a source of energy, which is wasteful under commercial conditions, because there are less expensive sources of energy, such as lipids and carbohydrates. Protein must therefore be provided in the proper overall quantity and it must provide adequate amounts of the 10 indispensible amino acids required by catfish. (See Table 1.)

Commercial feeds for growout of foodfish contain 26–32% crude protein. Smaller fish have a higher protein requirement: Feeds for fry in hatcheries contain 45–50% crude protein, and feeds for small fingerlings in nursery ponds usually contain 32–36% crude protein. The proper balance of dispensible and indispensible amino acids in practical feeds is achieved by using a mixture of high-quality protein supplements in the feed. In practice, if catfish feeds are formulated from a mixture of plant and animal protein supplements to meet the minimum requirement for the indispensible amino acid lysine, all other indispensible amino acids will be present in adequate amounts as well.

The nonprotein energy content of feed has a significant influence on the protein requirement of catfish. Catfish apparently eat to satisfy an energy requirement, so excess dietary energy may cause the fish to eat less, which will reduce their intake of protein (and other nutrients). On the other hand, insufficient nonprotein energy results in the use of expensive dietary protein for energy rather than for tissue synthesis and growth. The best ratio of energy to protein in catfish feeds is about 8 to 9 kcal of digestible energy per gram of protein (32–34). Higher levels of dietary energy may produce greater weight gain, but may also result in increased deposition of body fat.

Lipids. Lipids are important as sources of essential fatty acids and as relatively inexpensive and highly digestible sources of energy. Dietary lipids also improve the absorption of fat-soluble vitamins and may enhance the flavor of feeds.

The essential fatty acid requirements of channel catfish are not precisely known, although it appears that small amounts of n-3 fatty acids are required in the diet (35). The n-3 notation refers to the family of fatty acids in which the first double bond is three carbon atoms from the methyl (CH_3) end of the molecule. The n-3 family is sometimes referred to as the $\omega 3$ (omega three) family. Because the essential fatty acid requirements of catfish can be met with only a small amount of lipids in the diet, the amount of lipids in catfish feeds is not based on a specific nutritional requirement for lipids, but rather on achieving the proper energy-to-protein balance in the feed so that protein is spared. The source of lipids used in feeds is important, because certain lipids can have a negative effect on product quality and fish health.

Lipid levels in feeds for growout of foodfish seldom exceed 5 to 6% of the diet, although there is no conclusive evidence regarding an optimum level for growth. High-lipid feeds are, however, difficult to manufacture into pellets, and their use may cause excessive fattiness in fish, which reduces dressout and affects the storage quality of processed products. About 75% of the total lipids in practical catfish feeds is inherent in the feed ingredients themselves. The remaining 25% is derived from fat that is sprayed (top dressed) on the finished feed to increase feed energy and help stabilize the pellet, so that less dust is produced when the feed is transported. Various animal and plant lipids have been used to top dress catfish feeds. Marine fish oils are not recommended for this use, because they may impart a "fishy" flavor to the otherwise mild-tasting catfish flesh. Also, there is evidence that some component of menhaden oil (probably highly unsaturated n-3 fatty acids) suppresses the immune system of channel catfish, making them more susceptible to the bacterial pathogen *Edwardsiella ictaluri* (36).

Carbohydrates. Catfish do not have a dietary requirement for carbohydrates, but carbohydrates are the least expensive source of energy in catfish feeds and are therefore important in catfish feeds to spare protein. Channel catfish use starch or dextrin more efficiently than simple sugars such as glucose and sucrose (37), and fiber is assumed to have essentially no food value to catfish (31). Commercial catfish feeds have 30 to 40% carbohydrates, primarily in the form of starch. Carbohydrates in the feed also serve a nonnutritional role, in that starch and other complex carbohydrates aid in manufacturing a stable floating pellet.

Table 1. Channel Catfish Requirements for Indispensible Amino Acids[a]

Amino Acid	Requirement (Percent of Dietary Protein)
Arginine	4.3
Histidine	1.5
Isoleucine	2.6
Leucine	3.5
Lysine	5.1
Methionine plus cystine[b]	2.4
Phenylalanine plus tyrosine[b]	5.0
Threonine	2.0
Tryptophan	0.5
Valine	3.0

[a]See [31].

[b]The requirement for the indispensible amino acids methionine and phenylalanine can be partially replaced by the dispensible amino acids cystine and tyrosine, respectively.

Vitamins. Fourteen vitamins are considered to be metabolically essential for channel catfish. Although the characteristic signs of vitamin deficiency listed in Table 2 can be induced under laboratory conditions, overt signs of vitamin deficiency are rare in nature or commercial culture. Vitamin deficiencies in pond-raised catfish have been documented only for vitamin C (38–40) and pantothenic acid (41). Apparently, vitamins naturally present in feed ingredients and in natural food organisms in the pond provide adequate levels of most vitamins during culture. Nevertheless, commercial feeds are supplemented with a vitamin premix that provides sufficient quantities to meet the requirement and to compensate for any vitamin losses that occur during feed manufacture.

Minerals. Fourteen minerals are considered essential for channel catfish. These include seven major minerals (calcium, phosphorus, magnesium, sodium, potassium, chlorine, and sulfur) and seven trace minerals (iron, zinc, copper, manganese, cobalt, selenium, and iodine). Most of the required minerals can be obtained from the water or from feed ingredients used to formulate commercial diets. Natural pond foods may also be significant sources of certain trace minerals. Phosphorus and calcium are required by catfish in relatively large quantities, and feeds are usually supplemented with dicalcium phosphate to ensure that adequate amounts of both are present in the diet. Commercial feeds are also supplemented with a trace-mineral premix, although there is good evidence that supplemental trace minerals are not needed in feeds for pond-cultured fish, especially if the diet contains some animal protein (22).

Feed Formulation and Manufacture

Feeds used in intensive pond culture of channel catfish are formulated to provide all of the required nutrients in the proper proportions. However, no single feedstuff can supply the optimum mix of nutrients, so a combination of feed ingredients is used to meet nutritional needs. Fortunately, the number of different feedstuffs needed to formulate effective channel catfish feeds is small. Examples of formulations for practical channel catfish feeds are presented in Table 3.

Feeds for fry are prepared as meals or flours of small particle size. (See Fig. 6.) They are formulated to contain high levels of dietary protein and high levels of fish meal. Most feeds for fingerlings and foodfish growout are prepared by extrusion cooking, followed by drying. That process produces a hard, expanded pellet that floats in water. (See Fig. 6.) Extruded feeds must contain about 25% corn or other high-carbohydrate grains

Table 2. Vitamin Deficiency Signs and Minimum Dietary Requirements for Channel Catfish[a]

Vitamin	Deficiency Signs	Requirement
Fat soluble		
A	Exophthalmia, edema, ascites	1000 IU/Kg
D	Reduced bone mineralization	500 IU/Kg
E	Skin depigmentation, muscular dystrophy, anemia	50 IU/Kg
K	Hemorrhage, prolonged blood-clotting time	Required
Water soluble		
Thiamin	Dark skin pigmentation, neurological disorders	1 ppm
Riboflavin	Short-body dwarfism	9 ppm
Pyridoxine	Greenish-blue coloration, neurological disorders	3 ppm
Pantothenic acid	Clubbed gills, anemia	15 ppm
Niacin	Anemia, exophthalmia, skin lesions	14 ppm
Biotin	Anemia, skin depigmentation	Required
Folic acid	Anemia	1.5 ppm
B$_{12}$	Anemia	Required
Choline	Hemorrhagic kidney and intestine, fatty liver	400 ppm
Ascorbic acid	Scoliosis, lordosis, anemia, internal and external hemorrhage	60 ppm

[a]Generalized deficiency signs, such as death, reduced weight gain, and loss of appetite, are common to most vitamins and are not listed. [See also (22,31).]

Table 3. Examples of Practical Feeds for Channel Catfish Culture

	Percent of Feed			
	Fry	Fingerling	Foodfish	Foodfish
Ingredient	(50% protein)	(35% protein)	(32% protein)	(28% protein)
Soybean meal		40	36	26
Cottonseed meal		10	10	10
Corn grain		15	23	31
Wheat middlings	20	20	20	22
Menhaden meal	60	6	4	4
Meat/bone/blood meal	15	6	4	4
Dicalcium phosphate		1	1	1
Top-dressed fat	5	2	2	2
Vitamin premix	added	added	added	added
Mineral premix	added	added	added	added
Figure 6. Four types of catfish feed (clockwise from upper left), a meal-type feed; a crumbled feed; a steam-pelleted sinking feed; and an extruded, floating pellet.

for proper gelatinization of pellets during extrusion. Soybean meal provides most of the protein in fingerling and foodfish feeds. Small amounts of fish meal or other animal protein are added to improve amino acid balance and enhance palatability. Commercial trace-mineral and vitamin premixes are added to all channel catfish feeds to ensure nutritional adequacy.

WATER QUALITY MANAGEMENT

The best environmental conditions for fish growth exist immediately after a pond is filled with water. At that time, the level of dissolved oxygen is near saturation, and the water contains negligible levels of ammonia, nitrite, and other potentially toxic substances that accumulate during culture. But as soon as fish are stocked and fed, the environment begins to deteriorate, and conditions become less suitable for fish growth.

Water quality deteriorates over time in catfish ponds for two reasons. First, the metabolic activities of fish directly affect water quality. For example, fish consume oxygen and produce ammonia as a waste product of protein catabolism. Second, and more important, water quality deteriorates because nutrients contained in fish wastes stimulate the growth of phytoplankton blooms (42). The presence of phytoplankton is not necessarily bad; in fact, low to moderate standing crops of phytoplankton are considered to be beneficial in aquaculture ponds, because they produce oxygen in photosynthesis and prevent the growth of noxious aquatic weeds by competing for light and nutrients. Phytoplankton growth is, however, difficult to control in large ponds, and phytoplankton blooms often become excessively dense during the summer months, when fish feeding rates are high. Dense phytoplankton blooms can cause serious water quality problems, including depletion of dissolved oxygen and the production of odorous algal metabolites that give fish unpleasant tastes (43).

The extent to which environmental conditions in catfish ponds deteriorate is proportional to the amount of fish waste entering the water, which is, in turn, related to the feeding rate (44). Thus, the key to profitable catfish aquaculture is to find the optimum balance between two opposing relationships that affect fish production: To grow more fish, you must provide more feed; but as more feed is offered, the water quality deteriorates and fish grow slower. The overall goal of pond management, then, is to feed fish at the highest possible rate without causing the environment to degrade to the point at which net economic returns decrease as a result of poor fish growth, loss to disease, or excessive costs incurred in attempts to manage water quality at an acceptable level (such as aeration to supply oxygen). The point of diminishing economic returns is not known with certainty, although the foodfish culture practices outlined previously appear to be profitable. Those practices involve fish densities of 10,000 to over 30,000 fish/ha (4,000 to over 12,000 fish/acre) and summertime feeding rates of 85 to 140 kg of feed/ha (75 to 125 lb/acre) per day. Production at that level of intensification can be sustained in ponds with little or no water exchange and no technological intervention other than use of supplemental aeration. Water quality management in catfish ponds has been reviewed by Tucker and Robinson (20), Boyd (45), Boyd and Tucker (46,47), Tucker and Boyd (48), and Tucker (49).

Water Quality Requirements

Channel catfish are relatively tolerant of poor environmental conditions, which makes them a good species for pond aquaculture. Optimum and tolerated ranges for individual water quality variables have been identified in laboratory studies (see Table 4), but that information is of limited value under commercial conditions, because environmental stressors interact, and a combination of stressors may kill fish even though individual values are within a tolerable range. For example, carbon dioxide reduces the oxygen transport capacity of blood, so its presence aggravates the stress imposed by exposure to low oxygen. While catfish may survive for hours at dissolved oxygen concentrations of 2 mg/L if carbon dioxide levels are low, they may quickly die if carbon dioxide levels are high.

Although hundreds of water quality variables may potentially affect the health of channel catfish, only a few are important under routine commercial conditions. Initially, the water supply for ponds should be checked to assure that it is free of pollutants and that the salinity, alkalinity, and hardness of the water are within the desired range. Once the water is impounded and used for culture, the important variables are those affected by biological processes, because those variables can change rapidly. The key variables in pond culture of channel catfish are dissolved oxygen, ammonia, and nitrite. Algae-related off-flavors, another important water quality problem encountered in catfish aquaculture, is unique, because it affects product quality rather than fish health.

Dissolved Oxygen

Maintaining adequate levels of dissolved oxygen is the most common water quality problem in pond culture of channel catfish, because the respiration of fish, plankton,

Table 4. Optimum and Tolerated Ranges of Some Water Quality Variables for Growth of Fingerling and Adult Channel Catfish[a]

Variable	Optimal Range	Tolerated Range
Water temperature	25–30 °C (77–86 °F)	0–40 °C (32–104 °F)
Salinity	0.5–4 ppt	<0.1–11 ppt
Dissolved oxygen	5–15 mg/L	1–20 mg/L
pH	6–9	5–10
Total alkalinity	20–400 mg/L as $CaCO_3$	<1 to >400 mg/L as $CaCO_3$
Total hardness	20–400 mg/L as $CaCO_3$	<1 to >400 mg/L as $CaCO_3$
Carbon dioxide	0 mg/L	0–20 mg/L[b]
Unionized ammonia	0 mg/L	0–0.2 mg/L as nitrogen
Nitrite	0 mg/L	Depends on chloride concentration[c]

[a]Prolonged exposure to nonoptimal conditions may not lead to death, but could result in reduced growth, impaired reproductive performance, or increased susceptibility to disease.
[b]Tolerance to carbon dioxide depends strongly on the concentration of dissolved oxygen, but the relationship is poorly quantified.
[c]Maintaining a ratio of at least 20 mg of chloride/L of water for every 1 mg of nitrite–nitrogen/L of water protects catfish from nitrite toxicosis.

and benthic organisms in the bottom sediment exerts a tremendous demand for oxygen (50,51). After the nutritional requirements of the fish, the availability of dissolved oxygen is the next factor that limits the intensification of catfish pond aquaculture.

Oxygen Requirements of Catfish. Channel catfish are considered to be relatively tolerant of low concentration of dissolved oxygen (hypoxia), but they are healthiest and grow best when concentrations of dissolved oxygen are near saturation. Channel catfish eggs are particularly susceptible to hypoxia, because eggs are not motile and therefore cannot move to water with a higher concentration of dissolved oxygen. Also, channel catfish eggs are laid in a large, adhesive mass, and the oxygen supply to the interior of the mass depends on diffusion of the gas through the outside layers of eggs. The rate of oxygen diffusion into the egg mass depends not only on the ambient concentration of dissolved oxygen, but also on water currents to continuously replenish the layer of oxygen-rich water at the surface of the egg mass. In nature, a steady supply of oxygen is ensured by the male parent, who constantly fans the eggs with his fins. Eggs will begin to die after several hours of exposure to concentrations of dissolved oxygen below about 2 to 3 mg/L, and the oxygen requirement of eggs increases as the eggs mature and the embryos become more active. Healthy adult fish can survive indefinitely when the concentration of dissolved oxygen is above 2 mg/L but they may feed poorly, grow slower, and be more susceptible to infectious diseases when the concentration is below about 3 to 4 mg/L. Adult channel catfish can survive for several hours at concentrations as low as 0.5 mg/L. Fingerlings are somewhat more tolerant of low concentrations of dissolved oxygen than are larger fish and may survive short exposures to even lower levels of dissolved oxygen.

Assessing the effect of dissolved oxygen on fish health under commercial conditions is complicated by interactions with other environmental and physiological factors. Hypoxia at the cellular level is not always related simply to low environmental concentrations of dissolved oxygen. Any set of conditions that increase the demand for cellular oxygen decrease the rate of diffusion of oxygen from water to blood, or decrease the amount of oxygen carried by blood can result in tissue hypoxia, even when the environmental concentration of dissolved oxygen is near saturation. Some common factors that interact with environmental concentrations of dissolved oxygen include exposure to high concentrations of carbon dioxide, unionized ammonia, or nitrite. Structural alterations of the gill, caused by bacterial infection or infestations of protozoan parasites, also reduce respiratory efficiency.

Management of Dissolved Oxygen. The concentration of dissolved oxygen is affected by photosynthesis, respiration, and gas transfer between water and atmosphere. Oxygen is produced in photosynthesis by plants and is consumed in respiration by fish, plankton, and benthic organisms. Gas transfer with the atmosphere can be either a source or loss of oxygen. In catfish ponds, phytoplankton metabolism dominates the oxygen budget, because phytoplankton photosynthesis is the major source of oxygen and phytoplankton respiration (together with bacterial decomposition of phytoplankton-based detritus) is the major cause of oxygen loss (50,51). The metabolic activities of phytoplankton cause the concentration of dissolved oxygen to cycle over a 24-hour period: The concentration rises during daylight periods, when plants photosynthesize, and falls at night, when photosynthesis stops, but respiration continues. Water temperature profoundly affects all processes involved in pond oxygen budgets, and problems with low concentrations of dissolved oxygen are most common when temperatures are high. Oxygen budgets also vary with the standing crop of fish, plankton, and benthic organisms. Each pond therefore has its own unique oxygen budget, because standing crops of fish and microorganisms differ from pond to pond.

The critical period for managing dissolved oxygen is at night during the summer, when oxygen concentrations are falling rapidly. The key to successful management of dissolved oxygen in channel catfish ponds is early identification of those ponds that may require supplemental mechanical aeration to keep fish alive. Culturists use

portable electronic oxygen meters to measure the concentration of dissolved oxygen in all ponds at frequent intervals throughout the night. Aeration is initiated in a pond when the concentration of dissolved oxygen falls to a level considered critical by the individual farmer (usually around 3–4 mg/L). Aeration is continued until past dawn, when measurements indicate that the concentration of dissolved oxygen is increasing, as a result of photosynthetic activity. Problems with low concentrations of dissolved oxygen are rare in channel catfish ponds when water temperatures fall below 15 °C (60 °F), and most producers discontinue monitoring the concentration of dissolved oxygen in the winter, when water temperatures are expected to remain cool.

There is a trend in the catfish industry towards automation of monitoring dissolved oxygen and of aeration. Oxygen sensors can be permanently installed in each pond to continuously measure concentration of the dissolved oxygen. The data are then fed to a computer or microprocessor that is programmed to turn aerators on when the concentration of dissolved oxygen falls below a preset level.

Paddlewheel aerators (see Fig. 7) are the most common type of aerator used in channel catfish ponds (52). These devices consist of a hub with paddles attached in a staggered arrangement. Most paddlewheel aerators used in catfish farming are powered by a 7.5-kW (10-hp) electric motor and are mounted on floats and anchored to the pond bank. Current practice is to provide aeration at about 2 to 4 kW/ha (1 to 2 hp/acre); for instance, two 7.5-kW (10-hp) aerators may be placed in a 6-ha (15-acre) pond.

Ammonia and Nitrite

The use of mechanical aeration allows farmers to use high fish stocking densities and feeding rates without losing fish to depletion of dissolved oxygen. Nevertheless, aeration does not allow unlimited fish production, because accumulation of toxic nitrogenous wastes affects fish health and decreases fish growth rates as the intensity of the culture increases (44,53).

Virtually all of the combined inorganic nitrogen in unfertilized channel catfish ponds originates from nitrogen in feed protein and is excreted by fish as ammonia.

Figure 7. An electric paddlewheel aerator.

The ammonia excreted by fish is proportional to the amount of feed consumed and comes out to about 0.03 kg of ammonia–nitrogen/kg of feed consumed, so at a feeding rate of 100 kg/ha (90 lb/acre) per day, the input of ammonia–nitrogen to a typical catfish culture pond amounts to about 0.3 mg/L per day. If ammonia were to accumulate unabated, the concentration of unionized ammonia (the form of ammonia that is toxic to fish) would increase in a few days to lethal levels. The fact that culture is possible at that feeding rate indicates that transformations and losses of nitrogen act to reduce ammonia concentrations and allow the continual input of relatively large amounts of feed to ponds without dangerous accumulation of ammonia (54).

The maximum nitrogen loading rate possible without unreasonable accumulation of ammonia in the water is governed over the long term by the rate at which natural physical and microbiological processes remove nitrogen from the pond (54). Although the rates and mechanisms of nitrogen fluxes and transformations in channel catfish ponds are poorly understood, practical experience indicates that feeding rates up to about 85 to 140 kg of feed/ha (75 to 125 lb/acre) per day are possible during the summer growing season, without unreasonable accumulation of ammonia (55). This range of rates is generally accepted as the upper range for long-term feeding rates in channel catfish culture ponds managed with no water exchange. Feeding rates (and therefore fish production) could safely be increased above the ranges that are currently used if the rate of nitrogen removal from the pond could be increased. Although it is technologically possible to enhance rates of inorganic nitrogen removal from pond water, cost considerations limit the practicality of using formal filtration or water exchange to remove nitrogen from large commercial culture ponds.

Nitrite (NO_2^-) is the intermediate product in the two-step, bacteria-mediated oxidation of ammonia to nitrate. That process, termed "nitrification," occurs in all aerobic aquatic and terrestrial environments. Nitrite occasionally accumulates in channel catfish pond waters and poses a threat to fish health. Waterborne nitrite enters the bloodstream of channel catfish and oxidizes hemoglobin to methemoglobin (56). Methemoglobin is a brown-colored pigment that is incapable of binding oxygen. Fish with high levels of methemoglobin in their blood may suffocate even when the concentration of dissolved oxygen is high.

In the southeastern United States, episodes of elevated nitrite levels are most common in the spring and fall, when water temperatures are rapidly changing (55). Nitrite toxicosis is easily prevented by assuring that adequate chloride is present in the water because chloride competes with nitrite for uptake at the gills (56,57). Maintaining a ratio of 20 mg of chloride of water for every 1 mg of nitrite–nitrogen of water prevents nitrite toxicosis in channel catfish (58). Chloride is inexpensively added to channel catfish ponds as common salt, sodium chloride.

Off-Flavors

Certain algae and bacteria that grow in catfish ponds produce odorous organic compounds that can give fish undesirable "off-flavors" (59). The most common off-flavors

in pond-cultured catfish are caused by geosmin, an earthy-smelling compound, and 2-methylisoborneol, which has a musty odor. The two compounds are synthesized by species of blue-green algae (60–62) and are taken up from the water across the fish's gills. Geosmin and 2-methylisoborneol are not toxic to fish or to humans eating tainted fish, but the earthy and musty flavors that they impart to fish are highly objectionable to consumers.

Algae-related off-flavors are relatively common in pond-raised catfish, and samples of fish are always tested for taste prior to harvest, to ensure that fish with off-flavors will not reach the marketplace. The testing is conducted by trained personnel at the fish processing plants. Typically, fish samples are submitted a week or two before the desired harvest date, a day or two before harvest, and immediately prior to unloading live fish from transport trucks at the processing plant. The entire pond population of fish is rejected for processing if off-flavors are detected in any sample from that pond.

The occurrence of earthy and musty off-flavors in pond-raised channel catfish is sporadic and coincides with the appearance and eventual disappearance of the blue-green algal species responsible for synthesis of the odorous compounds (63). It is not consistently possible to prevent off-flavors, because the specific environmental conditions leading to the occurrence of odor-producing blue-green algal species are not known. Furthermore, the use of algicides is not always successful, because algicides that are legal to use, such as copper sulfate, lack selective algicidal or algistatic activity against nuisance species.

Management of off-flavors in fish relies upon natural elimination of the odorous compound from the flesh once the fish is no longer in the presence of the organism producing the compound. In other words, fish with off-flavors often are simply left in the culture pond until the odor-producing algae disappears from the plankton community. Elimination of geosmin or 2-methylisoborneol from fish flesh is rapid (64); however, an unpredictable period (weeks to months) may be required for the odor-producing algae to disappear from the community. A somewhat more dependable approach to managing off-flavors is to transfer fish to a "clean" environment, such as a different pond. The flavor quality of the fish often improves within four to seven days after moving the fish. However, moving fish from pond to pond to eliminate flavor problems is labor intensive and stresses the fish. Also, the costs associated with holding market-sized fish in ponds past their proper harvest date are a significant economic burden to catfish farmers (28).

INFECTIOUS DISEASES

High fish densities and stressful environmental conditions in channel catfish culture ponds are conducive to the outbreak and rapid spread of infectious diseases. Infectious diseases may be caused by viral, bacterial, fungal, or protozoan pathogens. Bacterial diseases account for most of the losses of fingerlings in nursery ponds, while the major diseases of fish in foodfish growout ponds are proliferative gill disease (caused by a myxosporean parasite) and "winter-kill syndrome" (a disease associated with external fungal infections). Infectious diseases of channel catfish are reviewed by Tucker and Robinson (20), MacMillan (65), Johnson (66), and Thune (67,68).

Viral Diseases

Two viruses are known to cause disease in channel catfish. Channel catfish virus (CCV) causes an infectious disease of young catfish that can lead to large losses in hatcheries or fry nursery ponds (69). The other virus—channel catfish reovirus (CRV)—appears to be of low pathogenicity and is not considered economically important (69,70).

Channel catfish virus is a highly virulent herpesvirus (71). The virus is quite host specific, and channel catfish is the only species known to sustain natural epizootics. Fish with channel catfish virus disease (CCVD) usually have a distended abdomen and exophthalmia, due to accumulation of fluid in the body cavity (72). Infected fish feed poorly and swim erratically, often in a spiraling fashion. The course and outcome of the disease are strongly affected by fish size and water temperature (73). Fish less than 1 month old are considered very susceptible to the disease. Older fish are more resistant, and fish over about 20 cm (8 in.) long (typically 9 to 12 months old) are considered resistant to CCVD. Fish do not develop CCVD at water temperatures below 15 °C (60 °F); disease occurrence is irregular and mortalities are usually low at temperatures between 20 and 25 °C (68 and 77 °F). Losses to CCVD can be devastating at temperatures above 30 °C (86 °F). There is no cure for CCVD, but losses can be reduced by controlling the water temperature in hatcheries (when possible) and by minimizing stress in susceptible fry or fingerling populations. The incidence of this disease can also be reduced by using hygienic hatchery practices to reduce the spread of the disease.

Bacterial Diseases

Three bacterial diseases are significant in channel catfish aquaculture: enteric septicemia of catfish, columnaris disease, and motile aeromonad septicemia. Enteric septicemia of catfish and columnaris disease are especially important in the nursery phase of catfish production, when they can cause large losses.

Enteric septicemia of catfish (ESC) is caused by the gram-negative bacterium *E. ictaluri* (74). The bacterium is fairly host specific for channel catfish, although experimental infections can be established in several other fish species as well (75). Fish with ESC are listless and often swim in slow, erratic spirals at the surface of the water. Infected fish may have a rash of pinpoint hemorrhages around their fins and on their ventral surface. In acute infections, fish may develop an ulcerative lesion on the top of the head, giving the disease one of its trivial names, "hole-in-head disease" (76,77). The occurrence of the disease is highly temperature dependant (78). In the southeastern United States, epizootics occur only in the late spring and early autumn when the water temperature is between 22 and 28 °C (72 and 82 °F). Channel catfish of all sizes and ages are susceptible to ESC, but fingerlings account for most of the fish lost to the disease. Prompt diagnosis

and treatment are critical to successful treatment of the disease. Therapy consists of oral delivery of the appropriate antibiotic, incorporated into a manufactured feed.

Columnaris disease is caused by the gram-negative bacterium *Flavobacterium columnare* (*Cytophaga columnaris*). The bacterium is ubiquitous in aquatic environments, and outbreaks of the disease are usually associated with some predisposing stressor, such as handling or poor environmental conditions (75). Epizootics occur throughout the warmer months of the year, particularly in spring and autumn when the water temperature is between 20 and 25 °C (68 and 77 °F). Columnaris usually begins as an external infection of the gills or body that progresses to an internal, systemic bacteremia (75). Gross lesions on the gills are characterized by yellow-brown areas of necrosis at the distal end of the gill filaments. Skin lesions appear as areas of depigmentation that progress to large necrotic ulcers. Infections of *F. columnare* can be controlled by antibiotic therapy, using the appropriate medicated feed.

Motile aeromonad septicemia (MAS) is caused by the gram-negative bacteria *Aeromonas hydrophila* and *A. sobria*. Epizootics of MAS may occur throughout the year, but are most common in spring and autumn when the water temperature is between 15 and 25 °C (60 and 77 °F). As with columnaris disease, outbreaks of MAS are usually associated with predisposing stress (79). Symptoms of the disease vary greatly, depending on the virulence of the strain of *Aeromonas* involved in the infection. Clinical signs range from external manifestations such as areas of external hemorrhage and ulcerative skin lesions to internal lesions characteristic of systemic bacteremias (80). Medicated feed therapy is used to treat MAS, but control may only be temporary unless the predisposing stressor is corrected.

Fungal Diseases

Water molds of the genus *Saprolegnia* are important pathogens of channel catfish eggs in hatcheries (20,65) and are also associated with a serious disease problem that affects adult fish in ponds during the colder seasons of the year (81). Water molds are common saprophytic microorganisms that usually cause problems only under suboptimum environmental conditions.

Problems with fungal infections of eggs are most common in hatcheries that use water at a temperature less than 25 °C (77 °F). Fungal growth begins on infertile or dead eggs and may then spread to and kill healthy eggs. Infected eggs may be treated with a 15-minute bath of 100 ppm formalin to kill the fungus. Use of water at the proper temperature for egg incubation is, however, the best solution to the problem.

External fungal infections of channel catfish are common in the winter months when water temperatures are below 15 °C (60 °F). Infections are easily diagnosed by the presence of brownish, cottony patches on the external surfaces. Areas of depigmentation and loss of the mucus layer may be present before masses of fungal mycelia are obvious. The conditions responsible for such infections are not clear (82), and mortality rates may be quite high. When losses are associated with the fungal infection, the disease is colloquially referred to as "winter-kill syndrome." There is no cost-effective treatment for fungal infections of fish in large commercial ponds (83).

Protozoan Parasites

Species of the protozoans *Trichodina*, *Trichophrya*, *Ambiphrya*, and *Ichthyobodo* are commonly found in low numbers on the external surfaces (particularly the gill filaments) of channel catfish and usually cause insignificant problems for the fish. Under certain conditions, however, the abundance of the parasite increases dramatically, to the detriment of the fish (67,68). Factors regulating fish parasitism by these organisms are poorly understood, but epizootics are commonly associated with overcrowding and poor environmental conditions. Most of these infestations can be treated with chemical therapeutants, such as copper sulfate or potassium permanganate, applied to the water. Treatments must be carefully considered, however, because the chemicals are toxic to fish at concentrations only slightly higher than the therapeutic dosage. Prevention of disease outbreaks by maintaining good environmental conditions is the best management practice for these protozoans.

Ichthyophthirius multifiliis ("Ich") can be a devastating protozoan parasite of channel catfish. Epizootics involving Ich are relatively rare, but losses may approach 100% of the affected population when conditions are optimal for spread of the disease (65). Ich is a ciliated protozoan with a biphasic life cycle. The adults, called "trophozoites," are relatively large [up to 1 mm (0.04 in.) in diameter], with a C-shaped nucleus. Trophozoites cause great tissue damage as they migrate through the epidermis, feeding on tissue fluids and cell debris. The trophozoite leaves the fish after maturing and settles to the bottom of the pond, where it encysts and divides to produce up to 2,000 infective cells, called "tomites." Ich is an obligate fish parasite, and the tomites will die if they do not locate a fish host within a few days. Epizootics of Ich are most common when the water temperature is between 20 and 25 °C (68 and 77 °F). Fingerlings are particularly susceptible, because they are held at high densities, which enhances the spread of the disease. The most obvious sign of Ich is the presence of many raised, white, pinhead-sized spots on the skin. Ich is difficult to control, because the parasite resides beneath the skin of the fish. Treatment consists of breaking the life cycle by killing trophozoites after they leave the fish or by killing the tomites before they infect the fish. Five to seven treatments of copper sulfate applied to the water daily may control the disease if the treatment is initiated early in the epizootic.

A species of the myxozoan *Aurantiactinomyxon* causes proliferative gill disease (PGD), a severe disease of pond-raised channel catfish (84). This protozoan is also found in the gut of a common mud-dwelling oligochaete, *Dero digitata*, which apparently serves as a reservoir for the parasite in ponds. The gills appear to be the initial route of infection of channel catfish. The disease is characterized by severe inflammation of the gills and varying degrees of tissue necrosis. The gill lesions reduce respiratory efficiency, and infected fish may suffocate. Outbreaks of PGD occur most commonly in spring and autumn when the

water temperature is between 15 and 20 °C (60 and 68 °F), although parasites may be found in fish throughout the year. There is no treatment for the disease; however, losses can be reduced by assuring that high levels of dissolved oxygen are maintained during an epizootic.

HARVESTING

Harvesting fish from levee ponds is relatively simple, because most ponds have regular shapes (usually rectangular) and are shallow, with smooth bottoms that are devoid of snags (20,85). Seines used for harvesting are about 2.75 m (9 ft) deep and about 1.5 times as long as the maximum width of the pond. They are usually made of knotted polyethylene, have a float line at the top and a weighted lead line on the bottom, and are built with a tapered tunnel about 45 m (150 ft) from one end. The tunnel has a drawstring closure that can be connected to the metal frame of a live car (also called a sock), which is an open-topped bag made of netting material. The netting used to construct seines and live cars is sized to capture the smallest fish size desired. Seines used to harvest food-fish use a square or diamond mesh size of about 4 cm (1.5 in.), which retains fish greater than 0.35 kg (0.75 lb) and allows smaller fish to escape and remain in the pond for further growth.

Two tractors are used to pull the seine through the pond. Once the two tractors have moved the length of the pond, the ends of the seine are brought together, and the seine is wound onto a seine reel. As the seine is pulled in, the fish become increasingly crowded in the remaining area. At that point, a live car with the proper mesh size for grading is attached to the seine. The fish crowded inside the seine then swim into the live car through the tunnel connecting the live car to the seine. The live car is detached from the seine and closed after it is filled to the recommended capacity. Another live car may then be attached to receive additional fish if the harvest is large. The detached live cars are placed near an aerator, and the fish are allowed to grade for several hours. After size grading is complete, a net attached to a hydraulic boom is used to load fish onto transport trucks. (See Fig. 8.)

Figure 8. Channel catfish crowded into one end of a live car are loaded onto a transport truck, using a net attached to a boom.

PROCESSING

Fish are transported alive to processing plants. Transport trucks carry four to nine aerated tanks, each of about 3,000 L (800 gal). The tanks are filled with about 1,500 L (400 gal) of water, and each tank can hold about 1,000 kg (2,200 lb) of fish. At the processing plant, a sample of fish from the transport truck is tested for flavor quality. If the fish are of acceptable quality, they are unloaded into large concrete tanks containing flowing, aerated water. When needed in the processing plant, fish are removed from the tank, weighed, and stunned with alternating current electricity. Stunning renders the fish immobile and makes them easier to handle in the processing line.

The individual steps involved in processing channel catfish have been reviewed by Ammerman (86). Much of the processing is done by hand, but there is a trend towards increased automation to reduce processing costs. A variety of products are marketed, with common products being fillets, steaks, and whole dressed fish. Processed catfish are available either as a fresh, ice-packed product or frozen. Frozen fillets account for the largest portion (about a third by weight) of sales.

THE FUTURE

Channel catfish production has increased over eighty-fold since 1970, and per-capita consumption, which stood at 0.45 kg (1 lb) in 1997, ranks fifth among all seafood products in the United States, behind tuna, shrimp, pollock, and salmon. Although per-capita consumption is highly skewed towards the southeastern states, where catfish have long been a traditional food, more than 0.23 kg (0.5 lb) of catfish are consumed annually per capita in states throughout the midwest and southwest and in California. Because farm-raised catfish have become a widely accepted food item throughout much of the United States, the demand for catfish should continue to increase as American consumers increasingly turn towards fish and shellfish as part of their overall diet.

The continued market demand for farm-raised catfish appears to offer a bright future for the industry. However, the market demand for farm-raised channel catfish has consistently exceeded the supply over the last few years. This situation could pose a problem in the future, because the market share could be lost to other fish species that are obtained either from harvest fisheries or aquaculture unless the supply of catfish increases to meet the steadily increasing demand. Greater production of catfish must come about through expansion of facilities and improved production efficiency in existing facilities.

Large tracts of land suitable for pond culture of catfish remain available in the major catfish-producing states in the southeast, and it is unlikely that limitations of land or water will constrain industry growth in the near future. However, significant limitation on increased facility expansion is the large capital investment required to enter the industry, especially considering that economies of size greatly favor large farms. Much of the current expansion of catfish farming therefore derives from existing producers adding new ponds, rather

than from new producers entering the industry. Another possible constraint on industry growth is increasingly strict governmental regulation of aquaculture, especially with respect to environmental effects. Pond culture of catfish can be a relatively benign form of agriculture, because current management practices are such that the volume of effluent discharged from ponds is low (87), and pesticides and drugs are used infrequently, if at all (88). Nevertheless, regulations promulgated without adequate consideration of the true effects of pond aquaculture on the environment could severely hamper growth of the industry.

Industrywide pond yields of catfish probably average about 4,000 kg/ha (3,500 lb/acre). That value is about half the yield that can be achieved from ponds using common culture practices and commercial feeds, but under controlled, experimental conditions (24). Frequent episodes of off-flavor, which reduce long-term production by delaying harvest, and difficulties in controlling infectious diseases in large commercial ponds account for most of the differences between commercial yields and yields attained under experimental conditions. Clearly, improvements in disease management and off-flavor abatement offer great potential for improving production efficiency. Also, the potential for increased yields from genetic improvement has long been recognized, but has yet to be widely implemented within the industry. This situation may change soon, however, as the products of the catfish breeding program supported by the United States Department of Agriculture become commercially available (89). Fish nutrition is the most advanced, and thus least limiting, area of knowledge in catfish aquaculture. As such, future developments in feed formulation and feeding practices may not result in great increases in production. Advances in feeding technology do, however, offer potential for substantial improvements in profitability, because feed costs represent most of the overall cost of production.

CHEMICAL OXYGEN DEMAND

DAVID E. OWSLEY
Dworshak Fisheries Complex
Ahsahka, Idaho

OUTLINE

Definition

Discussion

Conclusion

Bibliography

DEFINITION

By definition, the chemical oxygen demand (COD) is a measure of the oxygen equivalent of the portion of organic matter that can be oxidized by a strong chemical oxidizing agent. COD analysis is an important parameter for measuring the total oxygen demand in wastewater from hatcheries and other aquaculture facilities. It is an especially important tool for measuring and controlling industrial wastes. The COD also gives a better estimate of the total oxygen demand, whereas the biochemical oxygen demand (BOD) measures only 50 to 70% of the total oxygen demand present. In addition, the COD test requires only a few hours, as compared to five days for the BOD test.

DISCUSSION

COD is used to measure the pollutional strength of domestic and industrial wastes. It is based upon the fact that all organic matter can be chemically oxidized using a strong-enough oxidizing agent under acidic conditions. As with BOD, organic matter is converted to carbon dioxide and water. However, COD values are usually greater than BOD values and may be significantly greater when high amounts of biologically resistant organic matter are present. For this reason, the COD method is widely used to characterize industrial wastes.

The analytical procedure for the COD test can be found in (1). The most widely used test is the potassium dichromate method. Potassium dichromate is capable of oxidizing a wide variety of organic substances, and the excess potassium dichromate remaining is easy to measure.

Liao and Mayo (2) developed an equation for the COD of trout culture systems that use a high percentage (up to 90%) of recycled water:

$$COD = 1.89F.$$

Here, COD is the COD production rate at 10 to 15 °C (50 to 59 °F) in kg of COD/100 kg of fish per day, and F is the feeding rate, in kg of food/100 kg of fish per day.

For warmwater aquaculture, Boyd (3) reported that, even though a large amount of the feed applied to a pond is not converted to fish flesh and reaches the water as waste, most of the COD in fed ponds does not directly result from feeding waste. In data reported by Boyd (4), the total COD of phytoplankton produced during a 180-day growing season in channel catfish ponds in Auburn, AL, was 12,400 kg/hectare. The COD of all metabolic waste excreted by fish and uneaten feed during this period was 2,400 kg/hectare. Thus, the COD attributable to metabolic waste and uneaten feed was only about 20% of the COD attributable to phytoplankton: $(2,400/12,400) \times 100 \approx 20\%$. However, nutrients from excretory products and unconsumed feed were responsible for most of the phytoplankton growth. Boyd (5) also lists in Tables 1 and 2, the COD during the harvest phase of catfish in ponds.

COD can be removed from water by chemical filtration. Parkhurst et al. (6) reported on contaminant removal using granular activated carbon, as indicated in Table 3.

Table 1. Quality of Effluents from Catfish Ponds During the Two Phases of Fish Harvest[a]

| | Harvest Phase | |
Analysis	Draining	Seining
Settleable matter (mg/L)	0.08	28.5
Biochemical oxygen demand (mg/L)	4.31	28.9
Chemical oxygen demand (mg/L)	30.2	342
Soluble orthophosphate (mg/L as P)	16	59
Total phosphorus (mg/L as P)	0.11	0.49
Total ammonia (mg/L as N)	0.98	2.34
Nitrate (mg/L as N)	0.16	0.14

[a]From Boyd (5).

Table 2. Percentage Losses of Several Pollutants from A Hypothetical Catfish Pond During the Seining Phase of Fish Harvest[a]

Analysis	% of Total Released During Seining Phase
Settleable matter	94.9
Biochemical oxygen demand	26.0
Chemical oxygen demand	37.3
Soluble orthophosphate	66.7
Total phosphorus	18.8
Total ammonia	11.2
Nitrate	4.3

[a]From Boyd (5).

Table 3. Removal of Contaminants from Waste Water Using Activated Carbon

Contaminant	Influent		Effluent
Suspended solids	10.0	mg/L	<1.0
COD	47.0	mg/L	9.5
Dissolved COD	31.0	mg/L	7.0
Total organic carbon (TOC)	13.0	mg/L	2.5
Nitrate (as N)	6.7	mg/L	3.7
Turbidity	10.3	JTU	1.6
Color	30.0		3.0
Odor	12.0		1.0

Rubin et al. (7) reported that airstripping removes dissolved organic compounds by two mechanisms: (a) Dissolved, surface-active organic compounds may be absorbed at the gas−liquid interface and be concentrated in the foam; (b) dissolved, non-surface-active organic compounds may combine with surface-active solutes and be concentrated in the foam. These investigators found that airstripping removed up to 40% of the COD from sewage effluent. Also, Nebel et al. (8) reported that the COD could greatly be reduced by using ozone. The same study also showed a high reduction in the BOD using this method.

CONCLUSION

Although the COD test gives a better analysis of the actual total oxygen demand, it will not replace the BOD test, as

most aquaculture facilities are equipped to run tests on dissolved oxygen and can also do the BOD test. The COD test requires a more specialized chemical procedure that most aquaculture facilities are not equipped to handle.

CHLORINATION/DECHLORINATION

Gary A. Wedemeyer
Western Fisheries Research Center
Seattle, Washington

OUTLINE

Equipment Disinfection

Chlorine Analysis

Dechlorination

Toxicity

Bibliography

Chlorine is not a natural constituent of surface or groundwater and therefore should never be present in fish-rearing systems, unless they have been contaminated in some way. However, chlorine does play an important role in aquaculture. It is widely used to disinfect equipment, tanks, ponds, and entire facilities, and water discharged from hatcheries may be chlorinated to destroy endemic or exotic pathogens. Methods for neutralizing or otherwise removing chlorine from water are also important in fisheries work. Applications of such methods include dechlorinating municipal water so that it can be used for fish rearing, neutralizing chlorine residues on equipment that has been previously disinfected, or dechlorinating hatchery wastewater to prevent toxicity to organisms in the receiving water.

EQUIPMENT DISINFECTION

Chlorine for disinfecting nets, troughs, tanks, and other equipment is usually applied as a solution of sodium or calcium hypochlorite ($NaOCl$ and $Ca(OCl)_2$, respectively) diluted to 100–200 mg of active ingredient/L in water. Granular calcium hypochlorite (HTH), which is more stable, can also be used at the same concentration. If large volumes of water, such as hatchery effluents, must be treated, chlorine gas (Cl_2) injected at 1–3 mg/L is normally employed, because of its lower cost.

Whether chlorine is added to water as Cl_2 gas or as a hypochlorite salt, it reacts with the water to form an equilibrium mixture of molecular chlorine (Cl_2), hypochlorous acid (HOCl), and hypochlorite ion (OCl^-). The relative proportions of these species in the chlorine disinfectant solution is primarily dependent on the pH of the water. At pH values greater than 3, very little molecular Cl_2 is present, and the solution will be primarily a mixture of HOCl and OCl^-. Both of these chemicals are strong oxidants, but HOCl is the stronger germicide, because the electrical charge of the OCl^- ion impedes its penetration into microbial cells. Consequently, the pH of the water has an important effect on the efficacy of disinfection, because it controls the amount of HOCl that is present. At pH 6, about 95% of the chlorine will be in the more effective HOCl form, whereas at pH 9, about 95% of the HOCl has dissociated into the weakly germicidal OCl^-. In areas with alkaline water, dilute acetic acid is sometimes added to chlorine disinfectant solutions to reduce the pH to about 6, to maximize the formation of HOCl. Suspended particulates such as clay and organic matter tend to interfere with disinfection by protecting microorganisms from direct exposure to the chlorine. However, dissolved minerals such as calcium, magnesium, and iron generally have little effect.

For equipment and tank disinfection, a chlorine concentration of 100–200 mg/L with a contact time of at least 30 minutes is recommended (1). The amount of $NaOCl$ or $Ca(OCl)_2$ to add is calculated from the percentage of active ingredient listed on the label of the product used. For $NaOCl$ (SuperChlor®), this percentage is typically 11. HTH may contain up to 70% available chlorine. As previously mentioned, a sufficient amount of acetic acid to decrease the pH to about 6 may be added to the water in order to activate the chlorine. Never add acid to dry HTH. For fish transport tanks, a sufficient volume of water to cover the intakes of the recirculating pumps or spray agitator propellers is poured in and the calculated amount of liquid or dry chlorine added. For convenience, the chlorine is usually applied as an $NaOCl$ solution or as granular $Ca(OCl)_2$ [e.g., 15 g of HTH, with 70% available chlorine, per 100 L (0.5 oz/38 gal)]. The solution is pumped through the system for at least 30 minutes with air or oxygen flowing through the diffusers to prevent backflow. After disinfection, the equipment must be thoroughly rinsed with chlorine-free water, and any residual chlorine should be allowed to dissipate naturally (24–48 hours) or should be neutralized with a sodium thiosulfate rinse [7.4 mg/L per mg/L (ppm) of chlorine to be neutralized (2)] before

it is used to handle fish. As a precaution, commercially available chlorine test paper or a water chemistry test kit should always be used to confirm that chlorine residuals have dissipated to safe levels or have been adequately neutralized.

Occasionally, entire facilities must be decontaminated using chlorine. A detailed method for this procedure can be found in Piper et al. (1).

When chlorination is used to destroy pathogens in wastewater from aquaculture facilities, a free residual chlorine concentration of 1–3 mg/L [ppm] with a contact time of 10–15 minutes is typically recommended. If exotic pathogens are involved, residuals of 3–5 mg/L [ppm] are often suggested, with a contact time of 15–30 minutes to allow a margin of safety (3). Parasite spores, such as *Myxobolus cerebralis*, may require up to 1,500 ppm chlorine, with a contact time of several hours.

CHLORINE ANALYSIS

For most purposes, chlorine concentrations can be conveniently determined using any of several commercially available water chemistry test kits. For more precise work, specialized laboratory methods are available (4).

The individual concentrations of OCl^- and $HOCl$ are somewhat difficult to measure, and methods used to analyze chlorine, such as DPD (N,N-diethyl-p-phenylenediamine) determination, measure the sum of their respective concentrations, usually termed the "free residual chlorine concentration" (4). In addition to reacting with water to form $HOCl$ and OCl^-, chlorine also reacts with any ammonia or other nitrogenous materials present in the water to form chloramine compounds such as monochloroamine and nitrogen trichloride.

Chloramines are weaker germicides than chlorine, but their toxicity to fish is usually greater. In determinations of the amount of chlorine, the concentration of chloramines themselves is termed the "combined chlorine residual." Again, separating individual concentrations is somewhat difficult, and commonly used analytical methods measure the "total residual chlorine concentration," that is, the total concentration of the free chlorine and the combined chlorine residuals (4). If significant amounts of chloramines are present, this measurement will overstate the germicidal activity and understate the toxicity to fish. Chlorinated hatchery effluents may contain mainly combined chlorine residuals (chloramines), because of the ammonia present.

DECHLORINATION

The applications of dechlorination in aquaculture include removing chlorine from water so the water can be used for rearing purposes, neutralizing chlorine residues on equipment that has been previously disinfected, and dechlorination of hatchery wastewater streams to prevent toxicity to organisms receiving the water. The chosen dechlorination methods for a particular application should remove both chlorine and chloramines in order to be useful in aquaculture.

Small concentrations of chlorine [e.g., 0.05 mg/L (ppm)] can be removed from water by simple aeration, but ample ventilation is required, or else the chlorine will simply redissolve. Chlorine can also be allowed to dissipate naturally. As a guideline, about 20 hours per mg/L of chlorine [ppm] should be allowed. Unfortunately, both of these methods are too variable to be completely safe, and neither removes chloramines. Photochemical decomposition by ultraviolet irradiation, and oxidation using ozone, have considerable promise for removing chlorine, but high costs have limited their use. In most cases, neutralization with chemical reducing agents such as sulfur dioxide gas and sodium thiosulfate, and filtration through adsorption media such as activated carbon, are the most practical alternatives.

For large volumes of water, neutralization with sulfur dioxide (SO_2) gas is the most practical method. Dechlorination with SO_2 is inexpensive, easy to control, and the required equipment is commercially available. If necessary, commercial gas-chlorination equipment can be modified to inject SO_2 instead of Cl_2. Chemically, SO_2 reacts with water to form sulfite ions (SO_3^{-2}), which then reduce the chlorine and chloramines to nontoxic chloride ions and inconsequential amounts of acids in a 1:1 stoichiometric ratio. These reactions are so rapid that contact time is not an important consideration.

For facility wastewater discharges in the 190–380 L/min (50–100 gpm) range, the cost of sodium thiosulfate ($Na_2S_2O_3$) treatment may be about the same as that of the SO_2 needed for gas dechlorination, and with the former, the possibility of toxic gas leaks is eliminated. Equipment needs for sodium thiosulfate treatment are also simpler: a solution reservoir tank and a metering pump. Sodium thiosulfate rinses are also widely used for neutralizing chlorine residuals on disinfected equipment. This compound hydrolyzes to produce sulfite ions, which then react with chlorine in the same way as does SO_2. As mentioned earlier, a concentration of about 7.4 mg/L (ppm) of sodium thiosulfate solution will neutralize 1 mg/L (ppm) of chlorine (1,2). However, thiosulfate solutions are not completely stable and should be used within a day or two of preparation. Using a concentration of 8 mg of thiosulfate/L (ppm) per mg of chlorine to be neutralized/L is recommended to provide a small margin of safety (3).

Filtration through activated charcoal (carbon) is perhaps the most common method for dechlorinating water to be used for small-scale fish rearing. Activated carbon (C*) chemically reacts with both chlorine and chloramines, converting them into innocuous amounts of carbon dioxide and ammonium salts. Fresh activated charcoal reliably reduces the concentration of free and bound chlorine down to the range of 10–20 μg/L (ppb) but complete removal almost always requires supplemental thiosulfite injection, especially as the filters age (3). A flow-through filter containing 12 ft^3 (0.339 m^3) of granular activated carbon will reliably dechlorinate about 950 L/min 25 gpm of water containing a chlorine residual of 0.05 mg/L (ppm) for a period of about one year before needing replacement (3).

TOXICITY

The toxicity of chlorine is due to both its HOCl and its OCl$^-$ forms. Both forms are strong oxidants that destroy gill and other tissues by penetrating cell membranes and damaging cell structures, enzymes, DNA, and RNA. The OCl$^-$ ion has about the same molecular weight as HOCl, but, as previously mentioned, its electrical charge impedes penetration through cell membranes, making it slightly less toxic to fish and invertebrates. The practical importance of this difference is slight, however, partly because comparatively little OCl$^-$ is present over pH 6–8, the range that is typical of fish-rearing conditions. Environmental conditions such as temperature and the concentration of dissolved oxygen also influence chlorine toxicity, but again, the practical importance of any protection gained is slight. The end result is that the toxicity of chlorine is high. At the concentrations usually found in drinking-water supplies [0.1–0.3 mg/L (ppm)], chlorine will kill most commercially important aquatic species within minutes at any pH. Chronic sublethal chlorine exposures can induce gill damage and other pathological changes that will seriously compromise ultimate health, quality, and survival.

To adequately protect fish and invertebrates from gill and tissue damage, chronic exposure to chlorine should not exceed 3–5 µg/L (ppb). For short periods of time (up to 30 minutes), exposures as high as 0.05 mg/L (ppm) can usually be tolerated by most species important to aquaculture (3). Aquatic plants are relatively resistant to chlorine.

OUTLINE

INTRODUCTION

Artificial propagation has been suggested as a potential mechanism to aid in the recovery of U.S. Endangered Species Act (ESA)-listed stocks of Pacific salmon on the West Coast of the United States (1–4). Theoretically, one of the fastest ways to amplify population numbers for depleted stocks of Pacific salmon is through culture and release of hatchery-propagated fish (2). However, most past attempts to use supplementation (i.e., the use of artificial propagation in an attempt to maintain or increase natural production) to rebuild naturally spawning populations of Pacific salmon have yielded poor results (5). The challenge is in developing protocols that increase fitness of hatchery-reared salmonids, thereby improving survival. This article describes the potential impacts of artificial propagation on the biology and behavior of fish and a conceptual framework of conservation hatchery strategies to help mitigate the unnatural conditioning provided by hatchery rearing.

POTENTIAL IMPACTS OF HATCHERY REARING

Hatcheries figure prominently in the management of Pacific Northwest salmon. For the most part, hatcheries have been successful in producing fish for the fishery (6). However, hatcheries and hatchery management practices have often worked to the detriment of wild fish (7–10). Present hatchery practices are geared toward mass production under unnatural conditions. In Pacific Northwest salmon hatcheries, fish are most often reared in the open, over a uniform concrete substrate; conditioned to minimal raceway flow regimes; provided no structure in which to seek refuge from water current, predators, or dominant cohorts; held at high, stress-producing densities; surface fed; and conditioned to approach large, moving objects at the surface (11). Although the protective nature of hatchery rearing increases egg-to-smolt survival (12–14), the postrelease survival and reproductive success of cultured salmonids is often considerably lower than that of wild-reared fish (15–19). Hatchery practices that induced genetic changes (domestication, etc.) are often considered prime factors in reducing fitness of hatchery fish in natural ecosystems (7,10,19–22). Rearing practices that disrupt innate behavioral repertoires may also play a major role in reduced performance of hatchery fish after release.

Behavioral deficiencies in released animals have been blamed for the failure to re-establish wild populations of higher vertebrates (23–26). Current fish culture techniques (12–14) may impart similar behavioral deficiencies in hatchery-reared salmon. Studies indicate that the

hatchery rearing environment can profoundly influence social behavior of Pacific salmon, (11) and the social divergence of cultured fish may begin as early as the incubation stage. Lack of substrate and high light levels, which may occur in the hatchery incubation environment, induce excess alevin movement, lowered energetic efficiency, reduced size, and, in some wild stocks, death (27–31). Food availability and rearing densities in hatcheries far exceed those found in natural streams and may contribute to differences in agnostic behavior between hatchery- and wild-reared fish (32–38). Hatchery-rearing environments may also deprive salmon of the psychosensory stimuli necessary to fully develop antipredation behaviors (36). Evidence indicates that hatchery strains of salmonids have increased risk-taking behavior and lowered fright responses compared to wild fish (11,36). Surface feeding may condition hatchery fish to approach the surface of the water column (11,36,37), and this behavior may increase susceptibility to avian predation. Studies have also attributed increased avian and piscivorous predator vulnerability of hatchery fish in stream environments to decreased crypsis (camouflage coloration) caused by rearing against uniform (e.g., concrete) hatchery backgrounds (11,39,40). In addition, cultured and naturally reared salmonids may respond differently to habitat. In most cases, wild fish utilize both riffles and pools in streams, while newly released hatchery fish primarily use pool environments that are similar to their raceway rearing experience (33,36–38,41,42).

Seemingly, the only similarities in hatchery and wild environments for salmonids are water and photoperiod (43). Most other components of the hatchery rearing environment (food, substrate, density, temperature, flow regime, competitors, and predators) differ from what wild fish experience. It has been suggested that when a hatchery purpose includes protection of wild stocks, the operational strategy must switch from a production to a conservation mandate (4,9–11,44). A conceptual framework of conservation hatchery protocols for Pacific salmon follows.

THE CONSERVATION HATCHERY CONCEPT

The strategic role of a conservation hatchery will be to promote restoration of wild stocks of fish. This requires fish rearing be conducted in a manner that mimics the natural life history patterns, improves the quality and survival of hatchery-reared juveniles, and lessens the genetic and ecological impacts of hatchery releases on wild stocks. Conservation hatchery operational guidelines presented in the following include protocol recommendations designed to improve the survival of hatchery-reared fish in the wild.

Genetic Considerations

In order to maintain long-term adaptive traits, conservation hatcheries should provide fish with minimal genetic divergence from their natural counterparts (44). Protocols for fish culture and enhancement that reduce genetic risks (such as domestication, hybridization, inbreeding depression, and outbreeding depression) are well described (7,10,45,46). Mating strategies include random pairing, pairing in as many different combinations as possible, avoidance of pairing between siblings, crossings between different year-classes, and fertilization with cryopreserved sperm from other generations or from outside stock sources (1,14,45,46). Genetic risks of a particular strategy must be calculated on a case-by-case basis.

Broodstock Sourcing

Conservation hatcheries should use local wild broodstock whenever possible (44). For extirpated populations, the donor stock should be chosen following careful analysis of the environmental relationships and the life history parameters of the original stocks. Broodstocks should be representative of the genetics of the entire population to avoid potential reductions in effective population size by dramatically increasing only a fraction of the available genotypes in the parent population (1,14,45,46). Broodstocks can be sourced from all available life stages, including eyed eggs mined from redds, fry, smolts captured from the wild, and pre-spawning adults captured and artificially spawned (1,2). In cases where critical populations are dangerously close to extinction, a captive broodstock approach should be considered to maximize population size in the shortest time frame (2,3). Broodstock should be kept in a secure manner at one or more facilities to ensure against catastrophic loss (3). Rearing water supplies should be treated (sterilized) to remove pathogens (3,4,44), and natural water temperature profiles should be maintained to provide optimum maturation and gamete development (44).

Enriched Rearing Environments

Conservation hatcheries should use low rearing densities and base their goals for growth and size at emigration on natural population parameters (44). It is recommended they (*1*) determine spawning, hatching, and emergence times of the local population and duplicate these conditions in the hatchery by controlling water temperature to natural profiles; (*2*) simulate growth rate, body size, and body (proximate) composition by controlling water temperature, diet composition, and feeding rates. Conservation hatcheries should have incubation and rearing vessels with options for habitat complexity to produce fish more wild-like in appearance and with natural behaviors and higher survival (44). Darkened incubation systems containing substrates will produce larger fry that are more energetically efficient and alert (27–31). Fry-to-smolt rearing in enriched habitats containing cover, structure, and substrate can dramatically increase (up to 50%) postrelease survival in the stream environment (39). Natural stream-side cover can be created by suspending camouflage netting over 75% of each vessel approximately 1 m above the water surface along the margins of the raceways (44). Internal structures can be created by suspending small defoliated fir trees in rearing vessels occupying 30–60% of the surface area of the water (44). Substrates have been configured in several ways using sand, gravel, artificial rugose inserts, or painted patterns (39,44). Every

effort should be made to match the color of the substrate (which produces cryptic coloration patterns in fish) to that of the receiving-stream environment to produce the body camouflage patterns most likely to reduce vulnerability to predators.

Other potential components of an enriched rearing environment for salmonids, such as foraging training, feed delivery systems modeled after natural feeding situations, and changing flow velocities to exercise the fish, can also offer advantages for increased survival and behavioral fitness (11). In addition, studies have shown that antipredator conditioning may increase postrelease survival (36,47–50).

Reintroduction Strategies

Conservation hatcheries should release smolts with a population size distribution equivalent to the size distribution of smolts in the wild population (44). The greatest risk of releasing oversized hatchery fish is that they will outcompete the smaller wild fish. In intraspecific contests over food and space, all else being equal, the largest fish usually wins (51–54). Fish from conservation hatcheries should be released of their own volition and outmigrate during windows for natural downstream migration of the stock (44). The key assumption of volitional release is that fish will not leave the hatchery until certain physiological processes, such as smoltification, trigger their downstream migratory behavior (9,55,56). The technique is simply to provide windows of opportunity for outmigration which mimic time and age patterns found in the wild populations. Within these windows, fish may leave if they wish or remain behind to fend for themselves and smolt, residualize, or perish as natural selection takes it course.

Conservation hatcheries should adopt practices to reduce straying to no more than 5% (44,57). To maximize imprinting opportunity, juvenile salmon must experience the odors of their natal system at various times and physiological states when the odors can be learned (58–62). Conservation hatcheries should, therefore, rear fish for their entire juvenile freshwater lives in water from the intended return location (44). When this is not possible, a period of acclimation on intended return water should improve imprinting and homing and reduce straying (44). Conservation hatcheries should program their releases to accommodate the natural spatial and temporal patterns of abundance in wild fish populations and release numbers should not exceed carrying capacities of (freshwater and oceanic) receiving waters (44).

CONCLUSIONS

With the emphasis on wild fish recovery required by the ESA, there is opportunity to transfer the role of certain hatcheries from production to wild stock enhancement. Simple and practical changes to hatchery-rearing protocols will allow conservation hatcheries to produce fish with the wild-like attributes required for aiding in restoration of depleted stocks. Conservation hatcheries should employ the latest scientific information and conservation practices to maintain genetic diversity and natural behavior and thereby reduce the short-term risk of extinction. Exact application of the conservation hatchery strategies outlined in this entry will be dependent on physical and management limitations of individual hatcheries.

Blue Crabs
Egg Development and Larval Rearing
Growout
Soft-Shelled Crab Production
Cancer Crabs
Bibliography

Crabs are the focus of fishery in many regions of the United States. Most crab fisheries exhibit dramatic fluctuations in stock abundance or harvest. This phenomenon, more than any other, has prompted investigations into the possibilities for culturing regionally available species. Species that have received the most attention include the blue crab (*Callinectes sapidus*), Dungeness crab (*Cancer magister*), Jonah crab (*Cancer borealis*), and rock crab (*Cancer irroratus*).

BLUE CRABS

This economically valuable crustacean ranges from Nova Scotia to northern Argentina, including Bermuda and the Antilles (1). The blue crab is an important commercially captured species along the eastern seaboard of the United States and the Gulf of Mexico. Blue crabs are considered coastal inhabitants ranging from the shoreline to approximately 90 m (295 ft) in depth (2). Blue crabs are scavengers, and their normal diet consists of a variety of materials, including fish, benthic invertebrates, and plant material (2–4).

Blue crabs usually reach the adult stage after 12 to 18 months (1,4,5) and may live 2 to 3 years (2,6,7). Female blue crabs mate only once. Mating occurs after a terminal molt, while the crab is still in the soft shell stage. Enough sperm is received and stored in the female's spermathecae, or "sperm pouch," for two and possibly three spawns (8). Van Engel (3) described the coloration of the abdomen of immature female crabs as grayish white and that of adult females as blue green. During the last few days before the female's final molt, the dark green of the soft, inner, mature abdomen shows through the translucent whiteness of the hard, outer, immature abdomen. This change, in addition to the red line stage on the border of

the swimming paddles of the premolt female, will indicate that terminal molt is approaching. The abdomen of the immature male is tightly sealed on the ventral surface of the shell, while on a sexually mature male the abdomen hangs free or is held in place by a pair of tubercles (3). Induced mating and spawning under laboratory conditions should include a holding tank with a mud or gravel bottom that simulates the natural environment (8). A minimum of 2 to 3 months is required after mating, before ovulation and spawning occurs (8).

EGG DEVELOPMENT AND LARVAL REARING

Blue crabs produce 0.7 to 2 million eggs, which attach to swimmerets under the female's abdomen during incubation (1). Egg color can be used to determine the approximate age of the eggs (9). A yellow to orange color is characteristic of eggs that have been on the swimmerets 1 to 7 days. Eight to 15 days after spawning, the eggs appear brown to black in color. Hatching usually occurs after about two weeks.

Blue crab larvae normally go through seven zoeal stages to reach a prejuvenile stage, but they can survive with only six zoeal stages (10). Zoeae are free-swimming, but are classified as planktonic, since they lack much control over their position in tidal and strong current areas. In natural environments, eggs appear to hatch successfully in salinities of 23 to 30 ppt. Optimal salinity for zoeal development ranges from 26 to 30 ppt (10,11). Optimal temperature for zoeal development is considered to be 25 °C (77 °F) (11,12). Total time for zoeal development ranges from 31 to 49 days (11). The last zoeal stage metamorphoses into a single megalopal stage, which has both planktonic and benthic affinities (13,14). The megalopal stage lasts 6 to 20 days and precedes the first crab stage. External anatomy of the seven zoeal stages and the megalopal stage is described in detail by Costlow and Bookhout (11).

A number of unicellular algal species have been evaluated for use as larval foods (11,15). While some ingestion and development have been observed, no algae source has been sufficient as a sole food. Whitney (16) and Millikin (8) suggest that the reason algal species have failed to promote growth of zoea is that algal diets are devoid of animal sterols, which appear to be essential in crab diets. Millikin (8) recommends feeding strategies that include rotifers during Zoea I and II stages and *Artemia* nauplii for Zoea III to VII. Sulkin and Epifanio (12) concluded that food organisms no larger than 110 microns (0.004 in.) are optimal for the first and second zoeal stages.

GROWOUT

Few data are available on the culture of juvenile and adult crabs. Springborn (17) investigated the effects of salinity and temperature on juveniles and found little difference in survival or growth at salinities between 2 and 21 ppt. Mortality rates increased significantly at 1 ppt and below. Growth rates increased in the temperature range 20° to 30 °C (68° to 86 °F), with optimal growth between 28 and 30 °C (82° and 86 °F). Mortality rates increased rapidly above 30 °C (86 °F). Holland et al. (18) demonstrated that crabs readily accept pelleted commercial diets, but also concluded that cannibalism remains one of the major impediments to crab culture.

Although considerable information about the blue crab is available, culture from egg to adult has not been economical. A prolonged larval period, high mortality rates, and relatively low market value for hard crabs are the main reasons that hard-shell crab aquaculture has not been successful (1).

SOFT-SHELLED CRAB PRODUCTION

Blue crab biology and consumer tastes provide opportunities for a specialized form of crab aquaculture that has been practiced successfully. Blue crabs, as with other crustaceans, molt or shed their exoskeleton in order to grow (Fig. 1). Immediately after molting they are soft for several hours and can be consumed whole. Crabs in this state are referred to as soft-shells or soft crabs and command a higher price than hard crabs in the market.

Blue crabs are held for shedding for a relatively short period of time. During holding, they are not fed and, therefore, are not cultured in the conventional sense. Wild-caught crabs are examined for indications that they are close to molting. Premolt crabs (peelers) have a thin white, pink, or red line on the inside edge of the swimming paddles. Additionally, immature females have a mauve colored triangular apron on the abdomen. Mature females that have a semicircular apron will not molt. White-line crabs may shed within 7 to 14 days, pink-line crabs within 3 to 6 days, and red-line crabs within 1 to 3 days (19).

Premolt crabs are held in a variety of ways that range from floating containers secured to a dock to sophisticated water-recirculating systems located some distance from saltwater. Crabs are sorted daily in order to keep red-line crabs segregated from the other crabs and reduce cannibalism during shedding. Molting tends to take place at night, and operators must periodically check peeler crabs so that recently molted crabs can be removed while still soft. Once removed from the water, soft-shells remain soft and alive for 4 to 5 days if kept moist and cool. Storage temperatures of 9° to 10 °C (48° to 50 °F) are recommended (20). Soft-shell crabs left in the water more than a few hours begin to harden and lose value.

Soft-shell crab production is constrained by several factors. The supply of wild-caught premolt crabs is often irregular, seasonal, and inadequate for meeting the apparent market demand. Not all premolt crabs go on to molt, and not all that start to molt survive molting. Production is a labor-intensive effort that includes constant sorting and monitoring of crabs both day and night. Detailed manuals on blue crab shedding techniques are available from several state sea grant programs in the United States (19–21).

Most research on producing soft-shell crabs has focused on water-recirculating systems to hold crabs. Historically, crabs were held in floating trays in natural waters. Later developments included land-based systems of shallow trays with flow-through water provided by pumping.

Variations in water quality, high cost of waterfront property, and a desire to have more control led to the development of water-recirculating systems specifically for soft-shell crab production.

Recirculating systems for soft-shell crabs are similar in principle to other recirculating systems. A typical unit consists of three or four $2.4 \times 0.9 \times 0.3$ m ($8 \times 3 \times 1$ ft) holding trays, a reservoir, and a biological filter and pump. Each tray supports 150 to 200 crabs in a system with 2271 to 3407 L (600 to 900 gal) of water and a flow of 34 to 45 l (9 to 12 gal) per minute, depending on the type of biological filter (22).

Simple biological filters can be made by using small clam shells or limestone pieces approximately 1.2 cm to 3.8 cm (0.5 to 1.5 in.) in size and 0.25 m^3 (9 ft^3) of material for every 300 crabs in the system (22). More sophisticated systems may employ combinations of upflow sand filters and fluidized bed filters (22). Systems employing shell or limestone benefit from the buffering capacity of calcium carbonate, while systems using sand or other noncarbonate materials need to be monitored closely for low pH. Protein skimmers are employed in some systems to remove dissolved organic material, stabilize pH, and provide additional aeration (20).

Carrying capacity and successful shedding are dependent on maintaining good water quality in the system (23). Water quality guidelines have been developed by experimentation and practical experience (Table 1).

Salinity is usually maintained above 5 ppt and within 5 ppt of the harvesting waters. Crabs from salinities as high as 15 ppt have successfully shed in freshwater systems (24).

Hardening in soft-shell crabs can be delayed by using low-calcium water (25). Molting crabs remain soft 3 to 4 hours longer than controls when held in shedding systems maintained at 18 to 40% of normal calcium levels (26). This refinement can reduce human observation, particularly at night, but pH should be monitored and, if below 7, adjusted periodically with the use of sodium bicarbonate (22).

Table 1. Water-Quality Guidelines for a Recirculating System when Used for a Crab Shedding Operation (22)

Parameter	Recommended Range
Dissolved oxygen	Above 5 ppm O_2 in holding trays; water leaving filters must contain above 2 ppm O_2.
Total ammonia	Below 1 ppm $(NH_3 + NH_4)-N$ in holding trays
Nitrite	Below 0.5 ppm NO_2-N in holding trays
Nitrate	Below 500 ppm NO_3-N in sump
Temperature	$24-27\,°C$ ($75-80\,°F$) in holding trays
pH	Hold between 7 and 8 for normal operation
	Hold between 7.5 and 8.0 during peak loading
Alkalinity	Above 100 ppm $CaCO_3$ at all times
Salinity	Match salinity of harvesting waters within 5 ppt

Dependence on wild-caught blue crabs and the seasonal nature of supply have hindered large-scale development of shedding operations. Most soft-shell crabs are produced in small, family run operations. An economic analysis indicated that a three-tray system costing about $2,700 to build would return about $5,100 for an eight-week season after operating costs were deducted, but it did not take labor costs into account (27).

CANCER CRABS

Crabs of the genus *Cancer* occur worldwide in temperate regions with several species exploited commercially (1). In the United States, east and west coast species are harvested directly in crab fisheries or as incidental catches in other fisheries. On the Pacific Coast, the Dungeness crab (*C. magister*) is important, and on the Atlantic Coast, the rock crab (*C. irroratus*) and the Jonah crab (*C. borealis*) are of interest. Because of widely fluctuating harvests, consideration has been given to the culture potential of all three species.

Life histories of *Cancer* crabs have been described (28–31). Mating usually occurs from April through September, followed by spawning from October to June. Fecundity of the Dungeness crab is as high as 1.5 million eggs, while rock crabs produce up to about 300,000 eggs per spawn (28,30). Five larval stages and one megalopal stage have been identified (30–32). Optimum temperature and salinity for larval development have been reported to be 10° to 13.9 °C (50° to 57 °F) and 25 to 30 ppt, respectively (33). Larval development may last 80 to 90 days and megalopal development another 30 days before metamorphosis into the first crab instar occurs (28,34). Oesterling and Provenzano (1) discuss various efforts in the laboratory to develop culture techniques. Larvae of all three species have been raised on a variety of diets, including *Artemia* nauplii, *Balanus glandula nauplii*, *Skeletonema coastatum*, individually and in various combinations (31,33–37). Despite all the information available, complete culture from egg to market appears to have a low potential for any of the three *Cancer* crabs studied. Reasons for low culture potential included problems with cannibalism during larval stages and later crab stages, slow growth rates requiring two to three years for crabs to reach market size, the need to rely on wild-caught Dungeness broodstock, and the relatively low fecundity of rock crabs (1).

Even though culture of hard-shelled *Cancer* crabs is impractical at this time, there is potential for the production of soft-shelled crabs similar to what has been accomplished with soft-shell blue crabs (1). Similar procedures used for shedding blue crabs would apply to *Cancer* crabs.

Bibliography

The West Indian red spider crab, *Mithrax spinosissimus*, is a large majid crab that inhabits coral reefs and rocky outcrops of the tropical western Atlantic Ocean. Its known distribution is from the Carolinas on the east coast of the United States, through the Bahamas and the islands of the eastern Caribbean Sea, and along the continental shelf of Latin America as far south as Venezuela (1,2). It occurs from shallow waters to depths of 180 m (600 ft), and it commonly inhabits manmade canals cut in oolitic limestone, such as the Florida Keys in the United States (3,4). As with most members of the family Majidae, *M. spinosissimus* remain in hiding during the day and venture several meters (yards) from their refuge at night to browse on benthic algae and associated epifauna. The sexes are dimorphic; the males reach a greater size overall, and their chelae attain massive proportions compared to those of the female. Size frequency distributions for male and female *M. spinosissimus* captured in fish traps indicated a mean size of 133.4 mm (5.3 in.) carapace length (CL) for males and 122.8 mm (4.8 in.) for females (5). Females usually average 50% less in weight than males.

Despite its large size, this crab is taken only occasionally by fisherman, for either home consumption or local marketing. Because of their paucity and sporadic distribution, a commercial fishery for the spider crab has never developed (an exception being in Panama, where they are locally abundant along the walls of the Panama Canal) (6).

Interest in the mariculture potential for the West Indian red spider crab, *M. spinosissimus*, began in the late

1970s at a small marine laboratory on the remote island of Dos Mosquises in the Los Roques Archipelago off the coast of Venezuela. The scientists at the Fundación Scientifica de Los Roques were pioneering the mariculture of several tropical marine species that compose the most valuable fisheries resources of the Caribbean region, among them the queen conch and the spiny lobster. Although the West Indian red spider crab was not fished commercially, its large size, delicious taste, and popularity in local fishing markets attracted attention as a potential mariculture candidate. The researchers at Los Roques reported their preliminary results, including larval development and growth of early juveniles, in the Proceedings of the World Aquaculture Society in 1977 (7).

In 1983, the Marine Systems Laboratory of the Smithsonian Institution began research to develop a full life cycle mariculture system for *M. spinosissimus*, one that emphasized low-technology methods appropriate for developing countries. Their technology was based on a cage culture system, in which crabs were fed a diet of algal turfs that were grown on screens placed in the open sea. Turf algae, characterized by blue-green, filamentous red algae, and benthic diatoms colonized floating screens and produced as much as 30 g (1 oz) dry weight of algal food per day (8). After being allowed a few weeks for the algae to grow, the screens were moved to floating growout cages that housed the crabs. Algal turf mariculture of *Mithrax* crabs was initiated on Grand Turk (in the Turks and Caicos Islands), in the Dominican Republic, and on the island of Antigua, with the intention of transferring the algal turf/cage culture system as appropriate technology to island fishers.

Despite the substantial resources dedicated to the project, positive results were not forthcoming. In retrospect, the concept of rearing *M. spinosissimus* exclusively on algal turf was fundamentally flawed. The flaws can be summarized as follows:

(i) The production of algal turf on floating screens in tropical, oligotrophic (nutrient-poor) waters was greatly overestimated, particularly because inorganic sediments, which comprised more than 25% of the deposition on the screens, were not excluded from the organic weight measurements. The amount of vegetable matter provided from the algal turf screens was insufficient to sustain the biomass of crabs housed in the floating cages.

(ii) *Mithrax* crabs are not docile, obligatory herbivores, as the investigators purported, but rather they are omnivorous, cannibalistic, and highly aggressive crustaceans.

(iii) *Mithrax* crabs undergo a terminal molt at puberty, after which no additional growth occurs. The marketable size of crabs, 1 kg (2.2 lb), based on an economic analysis from the Smithsonian study (9), would be achieved by only a small fraction of crabs that were the progeny of wild-caught broodstock. Only through a selective breeding program, over several generations of crabs, would a significant proportion of the population reach one kilogram prior to terminal molt.

In 1984, the Harbor Branch Oceanographic Institution initiated a research program to evaluate the potential for *Mithrax* crab mariculture, which was to include the algal turf/cage culture system as well as alternative methods (10). The information presented below is a synthesis of the results from various studies.

REPRODUCTIVE BIOLOGY AND LARVICULTURE

Sex and maturity among female *M. spinosissimus* can be distinguished by the shape of the abdominal apron; in males it is thin and narrow, while in mature females it is broad and full enough to cover the egg mass. The apron of immature females is intermediate in width. Spider crabs undergo a terminal molt at puberty, after which no further growth occurs (11). The molt to mature female form occurs by about 75 mm (3 in.) CL. Copulation can take place any time after the final molt—a soft-shelled condition is not required. Females are able to produce successive egg masses for extended periods, to be fertilized by stored sperm in the spermatheca. However, successive spawns from females kept in the laboratory produce smaller broods, and larval mortality is higher than from spawns collected from the field.

Fecundity estimates vary widely from "tens of thousands" (7) to much higher (up to 100,000) (12,13). Creswell et al. (6) reported $18,826 \pm 3,304$ ova/female, or 59.5 ± 8.8 ova/g ($\sim$1700/oz) body weight. The ova are approximately 1 mm (0.04 in.) in diameter and weigh 1 mg (0.00004 oz). Newly fertilized eggs are deposited on the pleopods and are bright orange in color, but the gross appearance of the egg mass changes as the embryos develop. As the yolk is absorbed, yolk pigments accumulate in the embryo's integument and eyes, turning the egg mass bright red after the first week, then burgundy, and finally tan to grey when hatching is imminent, 21 to 25 days after fertilization. Orange eggs on four crabs hatched after a period of 18 days (mean value). The average hatching period of red eggs on eight crabs was 9.5 days. (14).

M. spinosissimus has an abbreviated and essentially lecithotrophic larval cycle, the egg's yolky reserves providing all the necessary nutrition required for full development of the larva to first crab stage (15,16). Hatching usually occurs at night and continues for several hours. The larvae are released by a fanning motion of the pleopods of the crab, accompanied by vigorous jerking of the abdomen. Larvae usually hatch as swimming *first zoeae* and display positive phototaxis immediately after hatching. First zoeae molt to *second zoeae* within 10 to 12 hours after hatching. Provenzano and Brownell (15) and others have also described a non-swimming prezoela stage. This stage is, however, probably an aberrant occurrence associated with stress on the females or on the developing larvae. The zoeae undergo two molts within 36−48 hours, before metamorphosing to the megalopa (post-larval stage), when they first begin to feed. After three to four days, the megalopa molts to the first crab stage, six to eight days after hatch (Fig. 1) (6,7).

Larvae have been reared intensively in shore-based hatcheries and extensively in cages floating at sea. Brownell and Provenzano (7) reared larvae in 400−600 L
Figure 1. Survival rates of *M. spinosissimus* using the shallow tray system.

Figure 2. Growth rate of *M. spinosissimus* during first 180 days after hatching.

(105–158 gal) tanks supplied with mixed cultures of phytoplankton. They reported significant mortalities during the molt from second zoeae to megalopae, with higher survival during the molt to first crab (total survival to first crab was 2–5%). The Smithsonian Institution, in Turks and Caicos and in Antigua, B.W.I., attempting to raise crab larvae in small "kreisel" tanks, reported similar discouraging results (<4% survival). The authors experienced similar high mortalities at molt from zoea to megalopa when using fiberglass tanks with upwelling currents (i.e., cone-bottomed kreisel tanks). An alternative larviculture system, utilizing screen-bottomed [500 μm (0.04 × 10⁻³ in.)] trays floating in shallow water tables, resulted in survival rates exceeding 85% during molt from zoea to megalopa and approximately 50% to first crab stage (Fig. 1), indicating that the presence of substrate may be critical for successful completion of the molt to postlarvae. By utilizing the shallow tray system, zoea can be stocked at densities of $25,000/m^2$ $(10.8\,ft^2)$, with survival exceeding 70% to first crab stage (10).

EARLY GROWTH

The 2nd and 3rd crab stages occur at around 15–20 days and 25–30 days after hatching, respectively. The water temperature during the studies described above was ca. 27–28 °C (81–83 °F). Molting frequency is dependent upon temperature (17–20), so it is likely that the intermolt period would decrease at higher temperatures [30 °C (86 °F)] and that more rapid growth would result.

Studies by Tunberg and Creswell (21) on early development (up to stage 12 crabs) showed that the intermolt period increases with stage (except between stages five and six). Stage two lasted for about 10 days; stage eleven lasted for about 20 days. Figure 2 shows the growth rate (carapace length and live wet weight) during the first 180 days after hatching. The growth rate (carapace length) at molt varies between approximately 22 and 40%, and the corresponding mean weight (live wet weight) increase varies between 90 and 135%.
Abdominal length and width measurements indicate that it should be possible, by visual observations, to distinguish between the sexes at a carapace length of approximately 12–15 mm (0.48–0.6 in.), that is, at an age of about 120–140 days.

During a long-term study (180 days) (21), only about 20% of the crabs survived throughout the period.

NUTRITION

Although the larvae of *M. spinosissimus* are facultative lecithotrophs, growth and survival were enhanced when feeding was initiated five to eight days after hatching (14). Benthic diatoms, as well as various types of macroalgae (e.g., *Enteromorpha*, *Gracilaria*, *Ulva*) and seagrasses (e.g., *Thalassia*), are provided as food for megalopae and early crab stages.

Winfree and Weinstein (22) reported that juvenile and adult *M. spinosissimus* are omnivorous and opportunistic feeders upon turf algae and seaweeds (24 species tested), marine fish and invertebrates (23 species tested), fresh beef (heart), pork (liver), chicken (muscle) and dry prepared feeds (12 varieties tested). Small juveniles [≤17 g (0.6 oz)] consume primarily macroalgae (78% of diet) when offered both algae and meat on a free-choice basis. Larger crabs are truly omnivorous and exhibit a strong tendency to supplement their macroalgal diet with meat, the relative proportions of algae and meat chosen being reversed. Crabs will consume a range of commercially available dry feeds, including homarid lobster and penaeid shrimp feeds, tropical fish flakes, and guinea pig pellets. Whether feeding on fresh or dried diets, the daily ration for *Mithrax* crabs is approximately 2.7% (dry feed to live body weight) (10).

AGRESSIVE AND CANNIBALISTIC BEHAVIOR

From postlarvae to large juveniles [approximately 50 mm (2 in.) CL; 50 g (1.7 oz)], *Mithrax* are aggressive and highly cannibalistic, even if well fed. Larger crabs appear to be less vulnerable to cannibalism, probably because of their thicker, more protective shells, except immediately

following the molt. Evidence suggests that the severity of "cannibalistic" confrontations can be mitigated by providing the crabs adequate space and protective cover, although it is unlikely that manipulating these factors alone will totally eliminate this behavior.

Most crustacea become aggressive and/or cannibalistic when crowded beyond a certain density. This crowding factor, or density index (DI), may be expressed numerically as the ratio of the area of available habitat to the area of crustacea housed there (measured as the sum of the squares of the carapace lengths of those animals). The smaller the DI, the more crowded the animal, until a critical density index (CDI) is reached and aggression begins. Ryther (10) reported that cannibalistic encounters were observed far more frequently in females and that whereas the CDI was 50 to 60 for males [8 crabs/m² (0.8 ft²) for 5 mm (0.2 in.) CL], it was 90 to 100 for females. These data suggest that elimination of females from the population at the earliest time possible [approximately 15 mm (0.6 in.) CL] would both increase survival and provide maximum system capacity for growout. Providing protective cover and/or complex, three-dimensional habitats, particularly during the early juvenile stage, may improve survival by reducing cannibalistic encounters. Unprotected open area systems, such as cages, raceways, or ponds and simple, two-dimensional structures afford little protection against aggressive behavior and are inappropriate for large-scale production of *Mithrax* crabs.

ENVIRONMENTAL CONDITIONS

Mithrax crabs tolerate a rather narrow range of environmental parameters, a fact that has practical implications for commercial production, particularly for site and stock selection (10). Survival of juvenile and adult crabs in captivity is directly proportional to salinity and temperature. Although crabs easily adapt to hypersaline conditions (40 ppt), stress becomes evident at 25 ppt and complete mortality occurs at 20 ppt. The optimal temperature range for culture occurs at 28–29 °C (83–84 °F), with poor growth at temperatures below this range and poor survival at temperatures above. Below 25 °C (77 °F), crabs are inactive, consume little feed, and are seldom agressive towards each other. At temperatures exceeding 30 °C (86 °F), lethargy, anorexia (despite active feeding), and proneness to disease and abnormal shell development occur. *Mithrax* reared in floating cages or coastal ponds may be subject to environmental fluctuations beyond ranges that are minimally required for healthy growth and survival. Terrestrial runoff could depress salinities over short time periods and cause mortality (or added stress leading to disease). Increased production time to marketable size should be expected in areas where water temperatures fall below 25 °C (77 °F) for extended periods, and unacceptably high mortality may occur in locations that experience temperatures above 30 °C (86 °F). This situation may eliminate the potential of production in northern areas, shallow bays, and tropical saltwater ponds, unless specific strains of *Mithrax* are identified that can tolerate these conditions.

INFECTION AND DISEASE

Ryther et al. (10) reported chronic bacterimia, similar to that described for other crustacea by Tubiash et al. (23), in *Mithrax* crabs cultured in recirculating seawater systems. Early signs include a loss of vigor and reduced feeding activity, which is followed by decreased joint mobility, particularly of the claws (chelipeds). Death occurs without warning, or occasionally preceded by limb loss. Postmortem examination of crabs succumbing to the infection reveals complete atrophy of the musculature and viscera, which are replaced by a spongy white bacterial mass. Application of nitrofurazone (furacin bath) and oxytetracycline (terramycin injections or bath) may be used to treat infections; however, improved water quality and nutrition will likely decrease the incidence of bacterial pathogens.

GROWTH TO HARVEST

All known species of majid crabs lose the ability to molt, and hence to grow, after they attain a specified point in the life cycle. The maricultural significance of a terminal molt in *Mithrax* depends upon whether the animal is large enough for sale at the time it occurs. Mean size of male crabs in terminal molt collected from Antigua was 125 mm (4.9 in.) CL (10); from other islands (Grenadines, Dominican Republic, Turks and Caicos), it was 131 mm (5.2 in.) CL (24).

Growth studies conducted at Harbor Branch Oceanographic Institution (10) indicate that postmolt increase in length of *Mithrax* crabs is relatively constant with age (27%), while weight increase fluctuated from 94 to 136%, with an overall average of 125%. Percentage postmolt weight change decreases as the crab increases in size, while the intermolt period tends to increase with age in a curvilinear fashion, with a greater percentage change during the later molt cycles.

Growth models suggest that male crabs grown to 650 grams (1.4 lb) (the predominant size class reached before terminal molt) would require approximately 20 months in culture (slower-growing female crabs would be discarded as small juveniles). Meat yield averages 20% of total weight (10).

CURRENT STATUS

Interest in the culture of the West Indian red spider crab, *M. spinosissimus*, has waned since the late 1980s, in large part because of some of the constraints on culture outlined herein. One commercial venture, West Indies Mariculture, Inc. (WIM), operated 1988–1994 on North Caicos, in the Turks and Caicos Islands. The project was managed by alumni from an earlier program on Grand Turk Island conducted by the Smithsonian Institution, and the culture methods employed a hybrid of algal turf screens and those later developed by Harbor Branch Oceanographic Institution. West Indies Mariculture produced softshell *Mithrax* crabs and marketed them directly to restaurants throughout the Turks and Caicos Islands.

Adult crabs were held in floating cages attached to docks in a tidal creek with strong currents. Juvenile crabs were fed algal turf until they reached 25 mm (1 in.) CL; thereafter they received a pelleted ration specifically formulated by WIM. Crabs reached 70–80 mm (2.8–3.1 in.) CL in 7–10 months and were transferred to shedding trays where, after molting, they were iced for transport to buyers.

Research into the mariculture of the West Indian red spider crab continues at the University de Oriente, Venezuela (25), but to the authors' knowledge no commercial operations exist today.

OUTLINE

Description and Life History
Culture Practices
Bibliography

Crappie, members of the family Centrarchidae and therefore relations of largemouth bass and various sunfish species, are popular recreational fish in the regions of the United States and Canada in which they are found. No commercial foodfish production of crappies exists, but crappies are cultured for stocking ponds, lakes, and reservoirs. Crappies tend to be so prolific in small ponds that overpopulation and stunting often occur, though the problem seems less severe with white crappies than with black crappies (1). The two species, black crappie (*Pomoxis nigromaculatus*) and white crappie (*P. annularis*), have similar culture requirements and respond similarly to the culture environment.

DESCRIPTION AND LIFE HISTORY

The black crappie is common in the Canadian provinces of Quebec and Manitoba and is found in the northern and eastern United States and as far south as Florida and Texas. Black crappies are more abundant than white crappies in the northern part of their range. Typically weighing up to about 900 g (2 lb), black crappies as large as 2.3 kg (5 lb) have been collected (Fig. 1).

White crappies can be found from Minnesota eastward, including into southern Ontario, Canada. Their distribution is then southward to the Gulf of Mexico and includes South Carolina along the east coast. White crappies tend to weigh from 450 to 900 g (1 to 2 lb), with some specimens reaching as much as 1800 g (4 lb).

The two crappie species have about the same overall shape. Black crappies tend to have more black pigment on their scales than do white crappies, but pigmentation is not a suitable way to distinguish between the two species.
Figure 1. Black crappie (*P. nigromaculatus*). Original drawing by Michele McGrady.

The best way to differentiate the two is by examination of the dorsal fin. In the black crappie, the length of the dorsal fin is about the same as the distance from the anterior end of that fin to the eye. In the white crappie, the dorsal fin is shorter than the distance from the anterior end of the dorsal fin to the eye (2).

Crappies generally do not live longer than four years and become reproductively active at one year of age (3). They are carnivorous and consume a variety of invertebrates along with their primary food which is minnows. Large crappies also consume young bass, so stocking crappies and bass in the same pond is not recommended (1). Male crappies, like other fishes in the family Centrarchidae, construct nests into which the female lays eggs. A large female may produce as many as 140,000 eggs (2). Spawning occurs in the spring.

CULTURE PRACTICES

Culture practices are virtually identical for black and white crappies. Two-year-old fish are usually used as spawners. The two species may, in fact, be stocked in the same pond. Fathead minnows are often provided as forage, though threadfin and gizzard shad have also been stocked as forage in areas where those species are available.

Spawning and egg incubation, which occur when the water temperature rises to above 18 °C (64 °F), are allowed to proceed naturally in open ponds. There are conflicting reports as to the most desirable age for broodfish. Some culturists support the use two year olds, while others indicate that three-year-old broodfish are preferred (1,3). Adult stocking rates have varied, with about 250 adults per hectare (625 adults per acre) being the maximum number, above which fingerling production seems to be inhibited. Once the female has deposited her eggs in the nest and they have been fertilized, they will hatch in about 48 hours at 19 °C (66 °F) (3). Black crappies are preferred by fish farmers in that the stunting problem seems to be less than with white crappies, and both black crappies and hybrid crappies withstand handling stress better than do white crappies.

Hybrid crappies can be produced by crossing female black crappies with male white crappies. This crossbreeding can be done simply by stocking the fish in ponds, since hybridization has been observed in nature (1). Alternatively, adults can be manually stripped in the laboratory. Hybrids have been observed to grow more rapidly than either parental species and, during the first generation (F_1), to strongly resemble black crappies.

In at least two instances, triploid white crappies have been produced (4,5). Triploids have one extra set of chromosomes as compared with diploid, or "normal," fish. Heat shock was not very successful in inducing triploidy (4), but exposure to cold was effective. Subjecting eggs from gravid females to 5 °C (41 °F) water for 60 minutes produced 72–92% triploids (4), while in three out of seven attempts that involved exposure to 5 °C (41 °F) for 90 minutes, over 90% of the resulting fish were triploids (5). Since triploids cannot successfully reproduce, they could hold promise in small ponds for preventing overcrowding.

Handling stress is a significant problem with crappies (1,3). The incidence of columnaris disease (see the entry "Bacterial disease agents") is high following harvesting. The stress seems to be reduced if harvesting of fingerlings takes place during winter.

Training some species of fish to accept pelleted feeds is often difficult, though crappies can easily be trained to accept prepared rations. A seven-day training period, beginning with carp eggs as a starter diet and then gradually replacing the carp eggs with a commercial feed, has resulted in a high success rate (6). Crappies have also been trained to accept a pelleted diet, after an initial period during which they were fed krill (7). When a semimoist diet is used, small fingerlings are more easily trained than large fish, while the opposite is true when dry diets are provided (7). Small raceways provide a good culture environment for training crappies to accept prepared feeds. There is no specific information available on the nutritional requirements of crappies, so feeds that meet the needs of species such as trout and salmon are employed, since experience has demonstrated that a good trout or salmon diet will meet the nutritional needs of most other types of fishes.

OUTLINE

Crawfish as a Food Item

Historical Development of Crawfish Culture

Crawfish Life Cycle and Related Aspects of Culture

    Dry Phase

    Wet Phase

Crawfish, crawdads, and crayfish are all common names for a large group of invertebrates in the phylum Arthropoda, class Crustacea, and order Decapoda. The preferred common name in the southern United States, where the aquaculture industry is centered, is crawfish (1). The term "crawfish" in this discussion is used exclusively for the red swamp crawfish, *Procambarus clarkii*, and the white (river) crawfish, *P. zonangulus*. References to other taxa are identified by genus and species.

Crawfish are characterized as having a hard, but flexible, exoskeleton; pairs of jointed appendages, including five pairs of pereopods; and gills for acquiring oxygen in their aquatic environment. Most people that have an opportunity to handle crawfish are familiar with the first pair of pereopods with enlarged pincers, called chelipeds. (See Fig. 1.) The front half of the crawfish's body is covered with an unsegmented shell, or carapace. The carapace covers the head and thorax, collectively referred to as the cephalothorax. In contrast, the posterior portion of the body, or abdomen, is clearly segmented. Appendages on the abdomen called swimmerets—or, more correctly, pleopods—are diagnostic characteristics for identifying the sex, level of maturity, and species of the crawfish. The first two pairs of pleopods on a male crawfish are modified to transfer sperm. These male reproductive structures, called gonopods, are strikingly different in reproductively active (Form I) individuals than in reproductively inactive (Form II) individuals. Gonopods in Form I males are cornified, structurally longer, and more pointed than in Form II males. Female pleopods are uniform, regardless of reproductive activity, and are adapted for carrying eggs and hatchlings. The last segment of the abdomen is expanded to form the tail, which is technically referred to as the telson. The eloquent treatise *The Crayfish: An Introduction to the Study of Zoology*, by T.H. Huxley, originally published in 1880 and reprinted several times (2), is an excellent source of detailed information about the structure and function of crawfish.

When startled, a crawfish contracts the large muscles in its abdomen rapidly, pulling the telson under the body. Repetition of this action will cause the animal to dart quickly backwards or to "jump" up from the surface on which it is standing. In addition to providing the crawfish with an escape mechanism, this large muscle provides humans with a prized food item. Typically, consumers and producers in the crawfish industry call this muscle "tail meat" when it is removed from the abdomen, rather than using the correct term, "abdominal meat."

CRAWFISH AS A FOOD ITEM

Although crawfish are harvested for fish bait and study specimens, most of the crawfish produced in the southern United States are sold for food. In Louisiana, where crawfish culture is centered, live crawfish constitutes 45–50% of the annual retail sales (3,4). Live crawfish are purchased at retail seafood stores, from wholesalers, or directly from farmers at the pond bank. Traditionally, live crawfish are cooked with ample seasoning, onions, potatoes, and corn in a common pot. (See Fig. 2.) Peeling crawfish takes some practice, but an experienced attendee at a crawfish boil can deftly remove the meat from several abdomens in less than a minute. Often adhering to the tail meat is the hepatopancreas, which is routinely consumed and is referred to as "fat" in the industry.

The ability to process crawfish allowed for the development of markets outside the traditional crawfish-farming areas. One processed product is cooked and frozen whole crawfish. Those crawfish destined for the domestic

Figure 1. Dorsal and ventral views of mature *P. clarkii*. The ventral views show the sexual structures of the female (top) and male (bottom).

Figure 2. Traditional Cajun style of cooking crawfish: boiling with vegetables and spicy seasoning.

market are cooked with Cajun seasoning, whereas dill seasoning is used with crawfish for the European market (3). However, the most common processed product is cooked, hand-peeled, deveined tail meat. The meat may be packed with or without hepatopancreatic tissue, which is an important ingredient in Louisiana (Cajun) cuisine. Abdominal meat is a much more diversified and easier product to use than live crawfish. Recipes for crawfish, such as étouffée and jambalaya, are available in most comprehensive cookbooks and special publications by the industry, such as *Louisiana Crawfish: Heads & Tails Above the Rest*! (5).

Meat yield varies greatly with factors such as sexual maturity and size. For example, Huner (6) observed that immature male and female crawfish have 4–5% higher meat yield than mature males. Immature crawfish have smaller chelipeds than mature individuals; consequently, less weight is lost when the head portion of the processed animal is discarded. Smaller individuals, regardless of sex, usually yield a higher percentage of meat than larger crawfish. Equally important to achieving maximum meat yield is cooking time and peeling technique (3). In general, abdominal meat yield is assumed to be about 15% (3).

Softshell crawfish production technology and markets were developed in the mid-1980s in Louisiana, but that industry has since waned. Processing of softshell crawfish requires only that the gastroliths, or "stones," be removed, because these hard calcium carbonate structures are retained when the crawfish molts. Consequently, the yield of edible product is much higher than for hardshell crawfish. The yield from softshell crawfish varies from 92%, if only the stones are removed, to 72%, if the carapace and hepatopancreas are also removed in processing (7). Softshell crawfish and blue crabs are similar table fare, which is one of the reasons that softshell crawfish were readily accepted.

HISTORICAL DEVELOPMENT OF CRAWFISH CULTURE

Early immigrants to the southern United States took advantage of the extensive riparian wetlands to harvest game and fish. Crawfish grow particularly well in areas that experienced periodic flooding and drying. Characteristic of this type of riparian habitat is the Atchafalaya Basin, a region extending 130 km by 30 km (80 by 20 mi) in the heart of the Mississippi River flood plain in Louisiana. Harvests from the basin vary greatly with discharge; 27,000-metric-ton (60-million-lb) harvests may occur in high-water years, whereas, during years of low discharge, the harvest might reach only 4,000–8,000 metric tons (8.8–17.6 million lb) (6). These unpredictable harvests, combined with increased consumer demand for crawfish, provided much of the impetus for crawfish aquaculture development.

The beginning of crawfish aquaculture was somewhat humble, but has grown from an incidental crop to a cultured crop from permanent ponds. Crawfish are also cultured as an integral component of rice rotational systems in Louisiana and east Texas. Viosca (8), LaCaze (9), and Thomas (10) outlined the basic management procedure for culturing crawfish in rice fields, which is still the model from which current culture practices are adapted. Thomas (10) also published the first scientific evaluation of the growth of crawfish in rice fields in 1965.

Since rice farmers had suitable flat land and much of the necessary equipment, it was an easy jump to include crawfish as a second, off-season crop. At that time, the future of the crawfish industry was promising, and the acreage in crawfish culture grew rapidly until the mid-1970s, when it slowed (11). A second expansion in the industry took place in the early 1980s, when low profits from row crops made crawfish farming more attractive. The area devoted to crawfish culture has been relatively constant in Louisiana, at about 45,000 ha (112,000 acres), since this latest expansion and through the 1990s (4). Although outside Louisiana there are only about 2,000 ha (5,000 acres) used for crawfish production (4), considerable opportunity exists for expansion in other rice-growing regions, such as Texas, Mississippi, California, and Arkansas, as well as in areas with extensive wetlands. In states such as South Carolina, the wetlands are managed with the primary purpose of attracting waterfowl, with crawfish being a secondary product of the management system (12). The economics of supply and demand will govern the future expansion of the crawfish industry in those states and other areas.

Other taxa of crayfish are cultured to a limited extent in the United States. Members of the genus *Orconectes* have been cultured for fish bait in the midwest and northeastern United States for a long time, but, recently, there has been increased interest in culturing them for food (13). A limiting factor in culturing the larger *Orconectes* species as a food item may be the time required for them to reach market size (14). *Pacifastacus* spp. are harvested from wild populations in the northwestern United States, but are not grown commercially for food. Several *Cherax* species from Australia have been promoted as freshwater lobsters for culture in the United States. Experiences with culturing those crayfish in the United States are mixed, but research on the subject is continuing (see the entry "Australian red claw crayfish").

CRAWFISH LIFE CYCLE AND RELATED ASPECTS OF CULTURE

Crawfish culture in Louisiana is dominated by two species: the red swamp crawfish, *P. clarkii*, and the white river crawfish, *P. zonangulus*. The white river crawfish was formally known as *P. acutus acutus* until Hobbs and Hobbs (15) revised the taxonomy, separating the previous complex into two different species. *P. acutus acutus* still occurs in the eastern United States, whereas *P. zonangulus* is found in southern states along the Gulf of Mexico. The native range of the red swamp crawfish overlaps that of *P. zonangulus*, but extends farther north in the Mississippi River drainage. These two species are frequently found together in culture ponds and are often indistinguishable by persons not experienced with crawfish. Although the abundance of one species may vary among ponds and within ponds over years, red swamp crawfish usually dominate culture ponds in Louisiana (16). In a study of two commercial ponds,

Romaire and Lutz (17) observed that red swamp crawfish made up 93 and 76% of the population, respectively. The investigators hypothesized that the difference in abundance of the two species was linked to the red swamp crawfish's greater reproductive potential, because growth and survival were not different between the two species. In some cases, *P. zonangulus* increase in abundance as the culture pond ages; Huner (16) observed a decline in the composition of the experimental harvests from about 90% red swamp crawfish to only 5 to 35% over a five-year period. He suggested that later flooding favors *P. zonangulus*, and repeated late floodings may be one reason for the increased proportion of *P. zonangulus* in his experimental culture ponds. *P. zonangulus* were found to regulate oxygen consumption at lower levels of dissolved oxygen than *P. clarkii*, which may also increase survival and the subsequent abundance of *P. zonangulus* in some ponds (18).

In general, the two species have environmental requirements that are conducive to low-input aquaculture systems, but there are differences between the two species. For example, *P. zonangulus* produce fewer, but larger, eggs (19,20); lay eggs (oviposite) once a year (17); may grow faster at cooler temperatures (17); reach a greater maximum size (17,19); and, overall, appear to do better in less eutrophic waters than red swamp crawfish (20,21). Some care must be exercised when reviewing the literature before the white river crawfish was reclassified, because references may represent *P. acutus acutus*, *P. zonangulus*, or a complex of more than one species.

These procambarid crawfish evolved in seasonally flooded wetlands and have a life cycle that is well adapted to fluctuating periods of flooding and drying. Wet periods permit crawfish to grow and thrive, while temporary dry periods *(1)* promote aeration of the bottom sediments, *(2)* reduce the abundance of aquatic predators, and *(3)* allow for better establishment of vegetation, which serves as cover for crawfish and fuel for the food web during periods of flooding. Crawfish survive dry periods by digging or retreating to burrows (see Fig. 3), where they can avoid predators and maintain the moist environment necessary for survival. Crawfish reproduce within the protection of

Figure 3. Typical chimney resulting from the construction of a burrow, which crawfish use to facilitate reproduction and survival during the dry season.

the burrow. Current methodology for pond production is based on the annual hydrological cycle to which crawfish have become adapted. Pond culture, however, allows for greater control of important environmental variables.

Dry Phase

In the southern United States, seasonally flooded wetlands are normally dry during late summer and autumn. Burrowing activity is initiated when females that have mated seek refuge to begin ovipositing or when the habitat begins to dry. These conditions are often synchronous, because decreasing water levels and increasing temperatures promote maturity and mating in crawfish. Crawfish mate in open water, and the female stores sperm in the seminal receptacle until she lays the eggs while in the burrow. Huner and Barr (22) give a good account of burrow ecology; in brief, crawfish dig simple, nearly vertical burrows that extend to the water table [approximately 40–90 cm (16–36 in.)]. Burrow entrances are often associated with items of cover, such as vegetation and woody debris, and may be covered with a simple chimney and/or mud plug. Burrows usually contain a single female or a male and a female, but occasionally contain additional crawfish. Crawfish are confined to burrows during dry periods until surface or rain waters reach them.

Water is usually held in crawfish culture ponds until late spring to early summer. Prior to dropping of the water level, some crawfish burrow near the waterline. As the water level drops, crawfish burrows appear lower on the levee and less frequently on the pond bottom when dry. Ovarian development requires three to five months, begins prior to burrowing, and is completed within the burrow. During ovarian development, oocytes become spherical in shape and change color from light to dark when mature. To assess the state of ovarian maturation prior to pond draining, sample crawfish can be dissected and staged by these criteria (23).

Although adults and hatchlings can survive in high-humidity environments within the burrow, free water appears necessary for successful reproduction (24). Eggs are fertilized externally with sperm from the seminal receptacle and are then attached to the female's pleopods with a cement called glair. (See Fig. 4.) The number of eggs oviposited varies with the size and condition of the female. It is not unusual for a large, healthy female to attach more than 500 eggs. The incubation period is temperature dependent and takes about two to three weeks at 23 °C (73 °F) (25). Hatched crawfish cling to the female's pleopods through two instar molts. The maintenance energy for this period is provided by the egg. Hatchlings instinctively remain with the female for several weeks after the second molt. It is critical that the female and her young leave the burrow within a reasonable time, because little food (other than siblings) is available in burrows.

With pond-reared crawfish, summer reproduction is somewhat synchronized; therefore, ponds are routinely flooded in autumn to coincide with emergence. Survival of broodstock, spawning success, and survival of progeny during the burrow period can have a significant impact

Figure 4. Female crawfish with eggs attached to the pleopodal setae on the abdomen. This condition is known as ovigerous, or "in berry."

on subsequent crawfish production, especially during harvests early in the season, when prices are usually the highest.

Since timing and duration of the dry period are controlled in pond culture, aeration of bottom sediments, elimination of predator fish, and propagation of a vegetative crop can be maximized. Two strategies exist for propagation of the forage crop. One practice uses volunteer plants, with producers exerting little control or additional input. A different strategy uses cultivated crops (such as rice, *Oryza sativa*). The latter strategy, when managed properly, ensures a greater predictability of crop establishment and vegetative biomass with desirable characteristics.

Wet Phase

Flooding or heavy rainfall is usually necessary to encourage emergence of crawfish from the burrow. Brood females emerge with young (and sometimes eggs) attached or clinging to their abdomen. These crawfish are highly susceptible to predators, because the attached brood prevent the typical tail-flipping escape response. As the female moves about, unattached hatchlings are left behind and become independent. The hatchlings, or young-of-the-year (YOY) recruits, and "holdover" crawfish from the previous wet cycle feed and grow in open water. Mature crawfish either enter the reproductive phase or the nonsexual, growing stage after molting. *P. clarkii* may reproduce more than once and in any season of the year in Louisiana, but *P. zonangulus* is classified chiefly as a seasonal spawner and reproduces mostly in the fall (17).

In crawfish aquaculture, autumn flooding is timed to coincide with the major recruitment period. The evidence of free-swimming young in burrows can serve as a gauge for timing of the flood. Recruitment is normally composed of several waves of YOY, with the primary wave occurring within the first four to six weeks of flooding. Multiple recruitment and differential growth result in several classes of different size within the population. Growth rate is affected by a number of variables, including water temperature, population density, level of dissolved oxygen, food quality and quantity, and (probably) genetic influences; however, environmental factors seem to be the most important variable (26).

Inundation begins the chain of events that establishes the food web from which crawfish obtain most of their nutrients. Crawfish have been classified as herbivores, detritivores, omnivores, and, more recently, obligate carnivores (27). Crawfish have been known to ingest living and decomposing plants, seeds, algae, microbes, and a myriad assortment of animal matter, from the smallest invertebrates to vertebrates such as small fish. However, those sources of food vary considerably in quality and quantity in the habitat. Vascular plants, often the most abundant food resource, probably contribute little to the direct nourishment of crawfish. Intact plant matter is consumed mainly when other food sources are in short supply and provides a limited amount of nutrients to growing crawfish. Decomposing plant material, with its associated microorganisms (collectively referred to as detritus), is consumed to a much greater degree and has a higher nutritional value. However, the ability of crawfish to use detritus as a mainstay food item in controlled studies was very limited (28–30). In the aquatic environment, there are numerous other animals that depend on detritus as their main food source. Molluscs, insects, worms, small crustaceans, and tadpoles consume detritus and also furnish crawfish with sources of high-quality food. Only recently have scientists realized that in order for crawfish to grow at their maximum rate, they must feed to a greater extent on these and other high-protein sources (27,31). Momot (27) established sufficient evidence for the classification of crawfish as an obligate carnivore and facultative detritivore–herbivore. Although crawfish must consume high-protein foods to achieve maximum growth, it appears that crawfish can sustain themselves by eating intact and detrital plant sources and bottom sediments containing organic debris.

Commercial aquaculture relies mostly on a self-sustaining food system, such as occurs in natural habitats, for growing crawfish. This system requires the establishment of a forage crop to serve as the basis of a detrital food chain, with crawfish as the top carnivore. Because commercial production dictates high crawfish densities and because flood duration is long (7–10 months), the food chain becomes highly taxed and requires careful management. High commercial production without supplemental feed requires adequate quantities of aquatic invertebrates in the pond, fueled by a constant supply of detritus. A continual supply of vegetative matter for decomposition is necessary throughout the production season, thereby requiring a forage crop that yields small portions of its material on a consistent basis over the duration of the season. Too much detrital material at any one time is wasted, because it cannot be stockpiled; thus, a large portion deteriorates without being consumed. The decomposition of excess detritus can also cause poor water quality conditions. On the other hand, too little detritus results in food shortages for crawfish and for organisms that crawfish rely on as high-quality food items. In severe times of shortages, the crawfish may decimate the invertebrate populations, thus
Figure 5. Newly molted (soft) crawfish (top) and the cast exoskeleton (bottom).

eliminating high-quality food sources for the remainder of the season.

As with all arthropods, crawfish must molt, or shed their hard exoskeletons, to increase in size. (See Fig. 5.) The growth process involves periodic molting (ecdysis) with intermolt periods between shedding episodes. There are five recognized phases of the molt cycle. The intermolt period is characterized by a fully formed and hardened exoskeleton. During that phase, crawfish eat and increase tissue and energy reserves. The premolt phase involves formation of the new underlying (uncalcified) exoskeleton and the dissolution of the old shell. During the latter part of the premolt stage, crawfish cease feeding and seek shelter. The molt phase involves actual shedding of the old exoskeleton, which is usually accomplished in minutes. The brittle exoskeleton splits between the carapace and abdomen on the dorsal side, and the crawfish usually withdraws by tail flipping. It is during the soft phase that the new exoskeleton expands to its new dimensions. Crawfish are most vulnerable to loss from cannibalism and predators during the soft phase, especially when the population density is high and cover is sparse. Calcification of the exoskeleton occurs during the postmolt phase. Initial hardening occurs using calcium from stored sources within the body (e.g., gastroliths) and absorbed from the water. As crawfish resume feeding, further mineralization occurs. Lowery (32) and Huner and Barr (22) provide further details of the complex processes of ecdysis.

Molting is hormonally controlled and occurs more frequently in younger animals than older ones. Increases in length and weight during molting and the interval of the intermolt period vary greatly and are affected by environmental factors, such as water temperature, water quality, amount of available food, and crawfish density. After a period of growth, both males and females molt to a sexually active phase and cease growth. Huner and Barr (22) have advised that a minimum of 11 molts is necessary for crawfish to reach maturity. Mature individuals exhibit distinct secondary sexual characteristics, including darker coloration, enlarged chelae, and cornified seminal receptacles for females and cornified gonopodia and prominent hooks at the bases of the third and fourth pair of pereopods for males (33).

In culture ponds, frequent molting and rapid growth occur during spring, due to warmer waters and adequate food sources. Crawfish can increase up to 15% in length and 40% in weight with each molt under optimum conditions (34). Therefore, it is important to pay careful attention to environmental conditions, including overcrowding, because certain factors can negatively impact growth. The abundance of mature crawfish increases as the season progresses. Rapid increases in temperature [$>21\,°C$ ($>70\,°F$)] under conditions of overcrowding and food shortages stimulate onset of maturity at smaller sizes. "Stunting," the condition whereby crawfish mature at an undesirable marketing size, is a problem for some producers.

Factors that can affect the growth and well-being of crawfish, other than those mentioned previously, include diseases and toxicants. Individual crawfish are susceptible to various pathogens, such as bacteria, viruses, fungi, protozoans, and parasites (21). However, serious disease problems associated with extensive culture of crawfish have not been documented and are thought to be rare. Procambarid crawfish are also known carriers of the *Aphanomyces* fungi that caused high mortalities in European crayfish, but are not affected by the fungus themselves. Crawfish, however, are highly susceptible to many pesticides (35), which is of great concern to producers, because much of the crawfish culture is associated with other agriculture enterprises that commonly employ pesticides.

CULTURE SYSTEMS

Crawfish are amenable to culture because they are hardy, prolific, adaptable, and do not require highly technical cultivation practices. Unlike the culture of aquatic species that require hatcheries and formulated feeds, crawfish culture is based on self-sustaining populations that use a forage-based food system (Fig. 6). Since crawfish are grown in shallow earthen ponds [25- to 76-cm (10- to 30-in.) water depth], relatively flat but drainable land with suitable levees is required. Soil with sufficient clay to hold water and to accommodate burrows is needed. Water requirements for crawfish production are similar to those

Figure 6. Crawfish pond with rice as the forage base. Note the trapping lanes used to harvest crawfish.

for other aquaculture enterprises, with the exception of the quantity of water. With the entire pond area covered with substantial amounts of vegetation, the biological oxygen demand (BOD) is sometimes great, and its effects must be overcome with timely water exchanges. Equipment requirements for culturing crawfish include irrigation systems, harvesting equipment (boats and traps), and agricultural implements to establish the forage crop and maintain levees. Sufficient labor and marketing opportunities are also essential for successful commercial operations.

Although crawfish culture systems have been categorized by pond type and dominant vegetation (22,36), categorization by major production strategy is perhaps a better alternative. The two major strategies for crawfish production are monoculture and crop-rotation systems. Whereas there are many similarities with regard to management between the two strategies, different production goals dictate different management concerns. Crawfish is the sole crop harvested in monoculture systems, and production typically occurs in permanent ponds. Crop-rotation systems involving crawfish include one or more agronomic crops (e.g., rice and soybeans). Crawfish either are rotated with another seasonal crop in the same physical location year after year or are cultured in different locations each year, to conform to typical field rotations of crops.

Monoculture Systems

Permanent ponds devoted entirely to crawfish production vary in size and intensity of production. Pond strategies range from large [>120 ha (>300 acres)], impounded wetlands with little management to small [<6 ha (<15 acres)], intensively managed systems (36). Monoculture systems are the method of choice for many small farms or where marginal lands are available and unsuited for other crops. The main advantage of this type of system is that it allows producers to design and manage for optimal crawfish production without concern for other crops or about pesticide exposure. A single-crop production system is also easier to manage. Disadvantages often include (1) the need to construct ponds, (2) the fact that the cost must be amortized over one crop only, and (3) crawfish overcrowding, which frequently occurs after several annual cycles.

Crawfish yields typically range from <225 kg/ha (200 lb/acre) in large, low-input systems to >1,120 kg/ha (1,000 lb/acre) in intensively managed ponds. Some ponds have even yielded in excess of 3,030 kg/ha (2,700 lb/acre) (36). Pond yields tend to increase with consecutive production, because resident populations usually expand annually. Ponds with higher ratios of linear levee area to pond surface area (i.e., ponds with increased burrowing space) usually have more recruitment and increased yields. Earlier and more intense harvesting is often justified in older, permanent ponds, because of the dense populations and increased numbers of "holdover" crawfish. Also, dense populations put more pressure on the forage crop; thus, forage is often depleted prematurely, which can have an adverse effect on the overall yield and size of harvested crawfish.

Production schedules vary within and between geographical regions, but permanent monocropping ponds in the Southern United States generally follow the schedule shown in Table 1. Since crawfish populations are self-sustaining, stocking usually is needed only in new ponds, when a pond has been idle for a year or more, or after extensive levee renovation. Ponds should be thoroughly drained to aid in predator control, soil aeration, and proper establishment of forage. Harvesting should be initiated and maintained when catch per unit effort (CPUE) and marketing conditions justify the effort and expense.

Rotational Systems

Crawfish are often rotated with rice and, sometimes, other crops as well in two basic farming rotational systems. In each system, crawfish culture follows the rice harvest, and the forage crop used for growing crawfish is derived from regrowth of rice stubble after grain harvest. Advantages of rice–crawfish rotational systems include the efficient use of land, labor, and farm equipment. Moreover, some fixed costs and the cost of establishing rice can be amortized over two crops instead of just one.

One rotational system, referred to as rice–crawfish double-cropping, takes advantage of the seasonality of each crop to obtain two crops in one year. Rice is grown and harvested during summer, while crawfish are grown during autumn, winter, and early spring in the same field. (See Table 2.) As with permanent monocropping systems, crawfish are stocked only initially; however, stocking occurs after the rice crop has been established (45 to 60 days after planting). Subsequent crawfish crops

Table 1. Typical Permanent Monocropping Schedule

Time	Procedures
April–May	Flood new ponds
Late April–early June	Stock mature crawfish (new ponds only)
Late May–June	Drain ponds over a two- to four-week period
July–mid-August	Plant (or encourage) vegetative crop
July–September	Fertilize and irrigate forage crop as needed
October	Flood ponds
November–May	Harvest crawfish
Late May–June	Drain ponds and repeat the cycle

Table 2. Typical Rice–Crawfish Double-Cropping Schedule

Time	Procedures
April	Plant rice and maintain the crop under a shallow flood [<15 cm (<6 in.)]
June	Stock mature crawfish (new ponds only)
August	Drain fields and harvest rice
August	Fertilize rice stubble; irrigate as needed
October	Flood ponds
November–March	Harvest crawfish
March	Drain ponds and repeat the cycle

rely on holdover broodstock from a previous cycle. An almost certain disadvantage with this production strategy is that neither crop can be managed to yield maximum production. The best rice yields in the southern United States are achieved when rice is planted in March or April. However, draining crawfish ponds prematurely to accommodate ideal rice-growing conditions decreases the total crawfish yield. Pesticide use is also a major management consideration with this system. Overall, crawfish and rice yields are variable and depend on management. Systems managed mainly for crawfish can expect crawfish yields similar to those of well-managed monocropping systems, but at the expense of rice yield, and vice versa.

The other major rotational strategy employs crawfish in field rotations of crops (e.g., rice and soybeans). Rice is often not cultivated in the same field during consecutive years, to aid in control of diseases and weeds. As with rice–crawfish double-cropping, crawfish culture follows rice cultivation; therefore, crawfish production does not occur in the same location in consecutive years. (See Table 3.) In lieu of draining crawfish ponds in March to plant rice, crawfish harvest can proceed until early May, when the pond is drained to plant soybeans, or longer if plans are to leave the field fallow. Under this system, three crops per field can be realized in two years, and a field with crawfish will be fallow for at least one year before crawfish culture resumes. Some producers elect to leave the field fallow instead of planting soybeans, but another crop could follow as well.

This type of farming system is common to south Louisiana and east Texas, where farms are large and producers are accustomed to field rotations. The advantage of field rotation systems is that all crops can be better managed. For example, crawfish can be harvested over the entire season in lieu of draining the ponds early to plant rice. Furthermore, by rotating physical locations each year, overpopulation is rarely a problem, and often, crawfish size is larger, due to lower population densities. Some disadvantages, however, are the need to restock every year and that, frequently, the bulk of the harvest occurs late in the season, when seasonal declines in prices and marketing difficulties are common.

Crawfish yields under this management approach are not commonly as high as with monocropping systems,

but with proper management, yields can routinely exceed 900 kg/ha (800 lb/acre). Note that not all management strategies fit exactly under these categories as described here; there are many variations. For example, a producer may alternate rice and crawfish production in the same field for two or three years and then rotate them into a different field.

MANAGEMENT CONSIDERATIONS

Stocking and Population Management

Unlike many aquaculture ventures, which stock juveniles, crawfish aquaculture relies on the stocking of adults. It is preferable to stock new ponds between April and June, when broodstock are sexually mature and ovarian development has commenced. *P. clarkii* is the recommended species to stock in the south, because of its preference in the marketplace and well-known culture methodology. Stocked crawfish should be in good health, sexually mature, and composed of 50–60% females. The size of the broodstock should be of little concern. Large crawfish produce high numbers of young, but there are fewer large crawfish purchased per unit weight of broodstock, whereas small crawfish produce fewer young, but more adults are purchased per unit weight. Broodstock should not be stored in a cooler and should be handled carefully and stocked within a few hours after their capture. Recommended stocking rates vary, depending on the amount of native crawfish and cover in and around the pond edge. Stocking rates of 45–56 kg/ha (40–50 lb/acre) are recommended for areas that lack native crawfish and have sufficient protection from predators.

Population management is the most elusive aspect of crawfish production. Aside from intentional stocking of crawfish, recruitment depends on survival of broodstock, successful reproduction, and survival of offspring. These factors are affected by management practices, although the practices provide little control overall, and are also largely influenced by environmental conditions. Because of continual recruitment and difficulties in sampling the population, crawfish producers have difficulty assessing the population density and structure. Sampling is crude and is currently accomplished by dip-net sweeps and baited traps. Population management entails little more than controlling the timing of the flood to coincide with normal reproduction peaks, ensuring adequate water quality and food resources, and carrying out adequate harvesting to remove market-size animals. Reducing the density to control overpopulation in ponds shows promise (37) as well, but has not yet become a common practice. In addition, supplemental stocking in underpopulated ponds sometimes occurs, but may not always be feasible.

Forage Crops and Management

Forage crops in crawfish aquaculture serve to provide cover for crawfish, a substrate for attachment of food organisms, and vertical structure. Vertical structure is important to crawfish, a bottom-dwelling animal, because it provides access to the water column and air

Table 3. Typical Rice–Crawfish–Soybean (or fallow) Rotational Schedule

Time	Procedures
March–April	Plant rice and maintain the crop under a shallow flood [<15 cm (<6 in.)]
May–June	Stock mature crawfish
July–August	Drain fields and harvest rice
August	Fertilize rice stubble; irrigate as needed
October	Flood ponds
January–April/May	Harvest crawfish
May	Drain ponds
May–June	Plant soybeans (or leave the field fallow)
October–November	Harvest soybeans
March–April	Plant rice and repeat the cycle

interface and may ease crowding and increase growth (38). Notwithstanding, the most important role of forage is to furnish small amounts of vegetative material continuously and consistently to the detrital pool as fuel for the complex food web.

Establishing rooted plants that will adequately provide a consistent supply of material to the detrital pool over the entire season is difficult. Native voluntary vegetation is the least expensive type of plant to establish and can sometimes perform satisfactorily, but is often unreliable and insufficient for maximum crawfish production. Terrestrial plants usually die when flooded, resulting in poor water quality and food shortages. Semiaquatic plants (such as alligator weed, *Alternanthera philoxeroides*, and smartweed, *Polygonum* spp.) normally thrive in crawfish ponds, but often, growth is unpredictable, and adequate biomass is not always achieved. Also, there frequently are long periods when semiaquatic plants remain intact, and thus little material enters the food chain. During winter, however, the emergent portion of the plant dies and large "slugs" of detritus result, usually at a time when need for it is reduced, because of low water temperatures. Native vegetation can sometimes be effectively used when there is an appropriate mixture of aquatic, semiaquatic, and terrestrial species; however, little control is achievable with voluntary stands.

The most dependable means of obtaining sufficient forage is to rely on planted agronomic crops and follow recommended management practices. Rice has become the standard forage crop for the industry (39). Because of its semiaquatic nature, it tends to persist well in flooded crawfish ponds. Yet, it furnishes plant fragments to the detrital pool in a consistent manner. When immature rice is flooded, older leaves gradually die and drop off, furnishing detrital material as the plant continues to grow and mature. When the portion of the plant above water dies during winter, it gradually fragments, providing a steady supply of detrital fuel until it is depleted. In contrast, mature rice ages and begins its fragmentation shortly after flooding, resulting in faster depletion and possible food shortage (40).

Sorghum−sudangrass hybrid (*Sorghum bicolor* × *S. sudanense*), first developed for use as a hay crop, also appears to be a well-suited forage for crawfish production (41). This plant displays extremely fast growth rates, produces a remarkable amount of forage dry matter (see Fig. 7), is very hardy and drought resistant, and may prove to be more reliable than rice for late-summer stand establishment. It also exhibits good persistence in crawfish ponds, with consistent fragmentation of material well into the season. Few other crops have been thoroughly screened for use in crawfish production, but preliminary evaluations of millets and other sorghums have not been especially encouraging (42).

Recommendations for establishing forage crops vary from area to area. Considerations should be given to choosing species that produce high vegetative biomass and do not rapidly deteriorate, but instead provide a steady rate of disappearance, under prolonged flooded conditions. Tall, late-maturing rice varieties that have low

Figure 7. Sorghum−sudangrass hybrid, a suitable forage crop for crawfish production, produces abundant vegetative biomass.

grain-to-forage ratios and are adapted to local conditions generally prove best for crawfish production (43). The time of planting is also an important consideration. Planting should occur early enough to achieve maximum vegetative biomass, but not so early that the plant matures and begins to die prior to frost. For rice and sorghum−sudangrass planted in the southern United States, the most appropriate planting time ranges from mid-July to early August for rice and mid- to late August for sorghum−sudangrass.

Multicropping of rice and crawfish impose different forage management strategies from monocropping systems. Varietal choices of rice are limited for this purpose, since the varieties should have good yielding and milling characteristics as well as the ability for adequate regrowth from the stubble (ratooning). Management is virtually limited to ensuring proper growth from the ratoon crop (via fertilization and irrigation) and mitigating the effects on water quality from straw and debris generated from grain harvest. The "combine tailings" can be baled and removed, burned, or chopped (to speed up degradation) prior to flooding, or timing of the flood can be delayed until cooler weather.

Water Quality and Management

Both surface and well water are commonly used in crawfish aquaculture, and either is satisfactory, provided that the quality and quantity are acceptable. Wells provide predator- and pesticide-free water, but associated costs are usually higher. Subsurface water is generally low in dissolved oxygen, may be high in dissolved iron and hydrogen sulfide, and should be aerated (see Fig. 8) for rectification. Surface water may be less dependable in quantity and quality and should be screened for predators. Water-quality variables of importance and their desirable ranges are listed in Table 4.

As with most aquaculture endeavors, dissolved oxygen is usually the most critical water-quality concern. Problems with dissolved oxygen in crawfish aquaculture are compounded by the presence of huge amounts of decomposing vegetation, which impede ready remedies (e.g., emergency aerators). Management of dissolved

Table 4. Water-Quality Variables Important to Crawfish Culture

Variable	Lethal Low	Desirable	Lethal High	Reference
Temperature (°C)	0	21–27	34	44,45
Dissolved oxygen (mg/L)	0.5–1.0	≥3	—	43,46
pH	3.0	6.5–8.5	>10.0	45,47
Total hardness (mg/L as CaCO$_3$)	*	>50	*	48,49

Figure 8. Often, water entering a crawfish pond is first passed through aeration screens.

oxygen in crawfish culture must entail preventative measures rather than corrective measures. Management options include choice of forage type and flooding dates, close monitoring and water exchange or circulation, and proper pond design. Ponds constructed with interior levees to divert water flow to all areas of the pond are effective in improving levels of dissolved oxygen throughout the pond (43). Paddlewheel aerators designed to move water, in concert with diversion levees, are especially effective (45).

Turbid water is often encountered in crawfish culture in spring, when forage biomass has declined. This event is normal and indicates a healthy crawfish population, and turbid water is not harmful to crawfish. However, pesticides in the culture environment can be detrimental to crawfish and other aquatic fauna that serve as food sources for crawfish. Refer to Eversole et al. (52), Toth et al. (53), and Huner and Barr (22) for details on the relative toxicity of various pesticides to crawfish.

Harvesting

Romaire (54,55) has provided excellent overviews of harvesting methods and strategies used in commercial crawfish aquaculture and has helped to develop many of those strategies. This subsection briefly summarizes current practices in the industry. There are several factors unique to crawfish culture that limit options and dictate harvest methodologies. Since crawfish recruitment to the harvestable population is somewhat continual, regular, frequent harvests must be carried out, as opposed to batch harvests. Seine harvesting, the most common method used for many aquatic species, is ineffective in traditional crawfish aquaculture, because of the dense vegetation normally present in culture ponds. Additionally, the presence of soft crawfish lends difficulty to seining and other active methods. Thus, crawfish removal relies on the passive technique of attracting the crawfish to baited traps. Flow trapping, a passive technique used to capture *C. quadricarinatus* (see the entry "Australian red claw crayfish"), probably also is not effective, due to the large size of crawfish ponds.

Although different types of traps have been used in the past, one trap design has emerged as the standard, used by the majority of culturists. The three-sided, three-funnel, wire-mesh trap (Fig. 9), commonly referred to as a "pyramid trap," is efficient to operate and effective in crawfish capture. Mesh size and shape govern the size of crawfish retained by the trap. Most traps are made of 1.9-cm (0.75-in.) plastic-coated hexagonal mesh, although some producers use 1.9-cm square mesh to retain smaller crawfish. The pyramid trap is designed to be positioned upright in the pond, with the top extending above water.

Figure 9. The efficient "pyramid" trap has become an industry standard for harvesting crawfish in culture ponds.

The top is open, to facilitate rapid removal of crawfish and rebating; contains a retainer band to minimize crawfish escape; and serves as a handle. The length of the neck varies to accommodate use in different water depths, and, occasionally, a metal rod is attached to the trap to increase stability in high winds.

Crawfish are attracted to the trap with bait. Two categories of bait are used: *(1)* natural baits of fish and *(2)* formulated bait manufactured from dried fish and grain by-products, attractants, and binders. Fish baits include gizzard shad, menhaden, herring, carp, suckers, mullet, and fresh by-products from fish processing facilities. Formulated baits are manufactured by several companies and are proprietary in their formulations. These baits are cylindrical pellets that weigh approximately 50–75 g (1.8–2.6 oz). Beecher (56) determined that fish is the most effective bait at water temperatures below about 16 °C (61 °F) and that manufactured baits are more effective at temperatures above 20 °C (68 °F). A combination of the two bait types seem to work best at 16 to 20 °C (61 to 68 °F). Approximately 150 g (5.3 oz) of bait per trap set, regardless of bait type, has been recommended as the most cost-effective amount (56). Most baiting regimes are based on a 24-hour trap set, but 12- and 48-hour (or longer) sets are sometimes used.

To be effective, traps must be distributed throughout the pond. The pond size often dictates the method used to empty the traps. Small ponds are often harvested by people pulling, poling, or paddling a small boat. However, most commercial ponds are harvested by one or two persons in a motorized, flat-bottom, aluminum boat designed for shallow-water propulsion. An ordinary "jon boat" on which an inexpensive, outboard motor that uses a weedless propeller attached to a long, horizontal shaft is sometimes used. Others use a larger boat designed for and equipped with a hydraulic-driven metal wheel that either pushes or pulls the boat through the pond (Fig. 10). A gasoline engine provides hydraulic pressure for power and steering. Traps are set in rows to accommodate harvest by boat. Commonly, the boat travels down the lane, and fishermen "run" the traps from the side of the boat, often without stopping at traps.

Figure 10. Hydraulic propulsion boats are commonly used to harvest crawfish in ponds. The broadcast distributor mounted on the rear was used for experimental feeding studies.

The average number of traps used is about 30 traps/ha (12 traps/acre), but can range from 25 to 100 traps/ha (10 to 40 traps/acre) for individual farms. Trapping frequency is highly variable and depends on factors such as trap density, crawfish size and density, water temperatures, and marketing conditions. Basically, because harvesting accounts for 50 to 70% of the total direct expenses of crawfish farming (55), trapping frequency is influenced largely by CPUE and marketing price. Traps are emptied two to seven days per week and for three to eight months, beginning as soon as the CPUE is justifiable after flooding. CPUE is influenced by pond population density and structure, trapping effort, indigenous food resources, bait quantity and quality, and environmental conditions (57), but rarely exceeds 1.5 kg (3.3 lb) per trap per day.

Research (55) has shown that in well-managed ponds, harvesting efficiency is most cost efficient with 50 to 60 pyramid traps per ha (20 to 24 traps/acre) fished three to four consecutive days per week. Use of a rotational or intermittent harvest strategy may also increase the CPUE. With this approach, trapping occurs in one part of a pond for one to two weeks, allowing other parts to "rest." The trapping sequence is then rotated to another part of the pond, and so on. Under this strategy, crawfish are given additional time to grow and reach harvestable size between trapping episodes. Refinement and recommendations for this approach are not yet available. Preliminary investigations also show that by alternating the bait type or manufacturer, the CPUE may increase. Finally, using nets or catch basins at the drain site when draining the pond allows recovery of some crawfish that have not been harvested.

Managing for Large Crawfish

Marketing developments during the late 1980s established a demand for large crawfish that swayed the industry to begin grading crawfish according to size. Production priorities shifted from maximizing the total yield, with little regard to harvest size above an acceptable minimum, to an emphasis on large, high-value crawfish (58). Factors that affect crawfish size at harvest have not been thoroughly characterized, but are thought to include harvesting strategy, water conditions, food quality and quantity, population density, and genetic influences. Most data indicate that environmental factors are more influential than genetic factors (26). McClain and Romaire (58) have discussed several management considerations that may increase crawfish size at harvest. These factors include supplemental feeding, intermittent harvesting strategies, reductions in population density prior to harvesting, and relay (transfer) of stunted crawfish to ponds where food and space are more abundant.

Feeding

Feeding is not regularly practiced in the crawfish industry. In the past, crawfish producers provided supplemental feeds to counteract forage depletion, which is characteristic of some ponds in the spring. Hay was placed in the pond to provide substrate and energy for the microbial-based food chain; however, this technique often

proved to be ineffective, and the logistics of frequency and distribution of hay prevented its effective use. It was not cost effective to meet current recommendations of about 7,800 kg/ha (7,000 lb/acre) of hay in more or less equal proportions across the bottom of the pond (43).

Although formulated feeds have been shown to increase crawfish growth and production under controlled conditions (59−61), feeding practices in commercial ponds frequently have proved to be uneconomical, and positive results were inconsistent and difficult to repeat. Feeding expensive pelleted feeds, formulated to meet the nutritional needs of crawfish, may not be the most cost-effective means of supplementing the natural crawfish diet with a relatively low-valued product. Since production currently relies on a forage-based system, low-cost feedstuffs used as true supplements to the indigenous food web may provide nutritional augmentation on a cost-effective basis. Recent studies found that whole rice seeds and raw soybeans provided improved growth when fed to crawfish grown in experimental units (62). Pond studies, however, indicated that feeding while harvesting reduced trap efficiency; therefore, feeding schedules would need to be altered to accommodate harvesting.

For year-round crawfish production, as some have proposed, formulated rations must meet all nutritional requirements in lieu of just supplementing forage-based systems. Recent reviews by D'Abramo and colleagues (63,64) underscored the lack of information on nutritional requirements and feeding rates of crawfish. Currently, there is not enough evidence to make a sound recommendation for the use of formulated feeds in traditional crawfish-growing areas where prices are lowest.

Handling and Marketing

Crawfish are harvested and leave the farm as a live product in 18-kg (40-lb) open-mesh plastic sacks (see Fig. 11); consequently, some stress and mortality may occur before the product reaches the consumer or processor. Some simple procedures during and following harvest can go a long way in reducing stress and

Figure 11. Open-mesh sacks that confine crawfish and restrict their movements, thereby preventing chelae-inflicted damage, are the accepted method for transporting and storing live crawfish.

subsequent mortality. For example, minimizing trap soak time; avoiding exposure of crawfish to direct sunlight; maintaining crawfish in a cool, moist environment; and tightly bagging sacks, without overfilling them, all help prevent stress and mortality. Crawfish in tightly packed sacks, are restricted in their movement and thus have less opportunity to inflict damage to each other with their chelae. Immature and recently molted crawfish do not fare well during harvesting and handling and require special care. Crawfish in good health can be stored at cool temperatures [1.6−4 °C (35−39 °F)] for four to five days without excessive mortality if the sacked crawfish are kept moist and are not overstacked (3). In one study, losses during cold storage [4 °C (39 °F)] increased from 7% to almost 22% after storing from two to six days (65). McClain (65) also observed that purging did not improve survival during cold storage; rather, it increased mortality rates. Shipping live crawfish to distant markets requires the same careful storage and handling techniques.

Crawfish markets have changed considerably since the mid-1980s, when there was no economic incentive to grade crawfish by size. The Swedish market demand for large crawfish [>30 g (>1 oz)] provided some of the impetus for grading, as well as did higher prices for large crawfish in the domestic market; therefore, grading became a common industry practice. Grading is one step in the initiation of a crawfish quality assurance program in the industry. The most commonly accepted size-grade categories are listed in Table 5. It should be noted that larger crawfish are worth up to five times more per unit weight than the smallest crawfish. Market channels are often based on size grades, with the small crawfish going to peeling plants, medium crawfish being directed to restaurants and live markets, and the largest animals heading for export. Nearly all grading occurs at processing plants and wholesaling outlets, using vegetable or self-built graders.

Another step in establishing quality assurance is purging. Purging, or depuration, is achieved by maintaining animals after harvest in a holding system without food for 24 to 48 hours. Basically, during the purging process, the digestive tract is voided and the gill chamber and exoskeleton are cleansed of mud, rendering a cleaner, more attractive product (Fig. 12). Purging leaves the characteristically dark intestine, found within the abdominal muscle, opaque and less conspicuous. This method should not be confused with the practice of bathing crawfish in saltwater before boiling, because the latter is not effective in evacuating the gut and is little more than a wash.

Table 5. Common Crawfish Size-Grade Categories[a] and Price Multiples in Relation to Small Crawfish[b]

Category	Count/kg (no./lb)	Weight (g)	Price Multiplier (%)
Large	≤31 (≤14)	≥32	200−500
Medium	30−48 (15−22)	20−31	100−300
Small	>48 (>22)	<20	—

[a]From (43).
[b]From (66).

although these percentage may vary significantly among years. In Louisiana, it is estimated that 70 to 80% of crawfish are consumed locally and the remaining 20 to 30% are sold out of state.

Figure 12. Purged crawfish (left) are more appealing than nonpurged crawfish (right) when consumed as a whole, boiled product, because the intestine of the former is mostly devoid of contents and is less conspicuous than the distended intestine of the nonpurged crawfish.

Figure 13. Nonearthen raceways with suspended baskets are effective and efficient purging systems when adequate water exchange and supplemental aeration are used.

Purged crawfish have higher consumer acceptance, particularly outside of Louisiana, and purging contributes to repeat sales.

Crawfish are purged in both spray (67) and submerged (66,67) systems. In submerged systems, crawfish are held in screened baskets, usually in raceways (see Fig. 13); however, static systems have also been used. In maintaining high crawfish densities in submerged systems, concerns, regarding the level of dissolved oxygen are mitigated by high flow rates, supplemental aeration, or a combination of the two. Spray systems involve confining the crawfish under a constant shower or mist wherein no more than 2.5 cm (1 in.) of water accumulates.

Louisiana farmers sell the vast majority of harvested crawfish to either wholesalers or processing facilities. Crawfish are often graded at these locations. Wholesalers, in turn, market the crawfish to the retail public, brokers, and processors. Approximately 60% of crawfish are sold as a shell-on product and the other 40% are processed,

DEGASSING SYSTEMS

JOHN COLT
Northwest Fisheries Science Center
Seattle, Washington

OUTLINE

Supersaturated levels of dissolved gases are common in water from wells, springs, streams, and lakes and may vary considerably between seasons and aquaculture operations. Chronic exposures of hatchery fish to supersaturated levels of gases may result in developmental problems, increased incidence of disease, and mortality. Effective degassing of hatchery water is needed for many applications.

TYPES OF AERATORS USED FOR DEGASSING

A number of different types of aerators have been used to degas water, including submerged, gravity, and surface aerators. The most commonly used aerator for degassing is the packed-column aerator (PCA). The PCA consists of a column filled with high surface-area packing (Fig. 1). Water flows down over the medium in a thin film. Because of the large gas–liquid surface area, this system is highly efficient for transfer of oxygen and nitrogen, but will not produce dissolved-gas supersaturation.

Other types of surface aerators (cascade, inclined plane, tray, screen, and lattice) may be useful in some applications, but are not as effective as the PCA and require substantially more space and head. Submerged aerators can actually produce gas supersaturation and should be avoided for most applications.

SINGLE-COMPONENT DEGASSING BASED ON CONCENTRATION

Integration of the basic two-film mass-transfer model (1) for slightly soluble gases such as nitrogen, argon, and oxygen yields

$$\ln\left(\frac{C^* - C_{in}}{C^* - C_{out}}\right) = (K_L a)t \qquad (1)$$

where

C^* = equilibrium saturation concentration at local temperature and pressure (mg/L),
C_{in} = influent concentration (mg/L),
C_{out} = effluent concentration (mg/L),
K_L = overall liquid-phase mass-transfer coefficient (m/hr),
a = interfacial surface area (m^2/m^3),
t = aeration time (hr).

Equation 1 applies to both degassing and aeration applications. If $C_{in} > C^*$, oxygen will be transferred from the water into the air. If $C_{in} < C^*$, oxygen will be transferred into the water. In both cases, C_{out} will approach the value of C^*, but an infinitely long column is needed for $C_{out} = C^*$. Because of the logarithmic transfer relationship
Figure 1. Section through a packed-column aerator.

(Eq. 1), it is generally not economically possible to reduce $|C_{out} - C^*|$ to within 0.05 C^* units. Most degassing columns are designed to operate at atmospheric pressure, so C^* is equal to the local atmospheric saturation concentration. In this case, the value of C_{out} will approach the value of the local atmospheric saturation concentration.

Based on experimental work with oxygen (2), it has been found that $(K_L a)t$ depends directly on height of the medium and, over a wide range of loadings, is independent of hydraulic loading:

$$(K_L a)t = b + KZ \qquad (2)$$

where

$b =$ a constant that depends on incidental aeration that occurs due to the distribution plate (dimensionless),

$K =$ a constant that depends on the type and size of medium used (1/m),

$Z =$ depth of medium (m).

K and b values are reported at 20 °C for clean water conditions. The values of b and K at other temperatures can be computed by using

$$(K_L at)_T = 1.024^{(T-20\,°C)}\{b_{20\,°C} + (K_{20\,°C})Z\} \qquad (3)$$

where

$(K_L at)_T =$ value of parameter at general temperature,

$T =$ water temperature (°C),

$b_{20\,°C} =$ value of b at 20 °C and clean water conditions,

$K_{20\,°C} =$ value of K at 20 °C and clean water conditions.

Values of $K_{20\,°C}$, $b_{20\,°C}$, maximum loading rates, and minimum column diameters are presented in Table 1 for various medium sizes and types (2,3). The performance of the column depends on the even distribution of flow over the medium, and the distributor should have at least 45 distribution points/m². Columns higher than 2 m should provide a redistribution plate to reduce water flow down the wall. Most degassing columns are designed to add

Table 1. Recommended Design Parameters for Packed Column Degassing Columns (1,3)

Media Type/Size (cm)	$b_{20\infty C}$	$K_{20\infty C}$ (l/m)[b]	Maximum Loading[a] (m³/m² · h)	Minimum Column Diameter (m)
Pall ring/2.54	0.40	2.50	150	0.2

Tri-Pack/2.54	0.30	1.62	>220	0.2
Nor-Pack/3.81	0.36	1.49	>220	0.3
Nor-Pack/5.08	0.20	1.57	>220	0.4

[a]The maximum loading rates were computed from head loss considerations or field experiments; these values assume even distribution of the flow over the media.
[b]Feet = m × 0.3048; gpm/ft² = m³/m² · h × 0.4090.

oxygen and remove nitrogen, argon, and carbon dioxide. To prevent depletion of oxygen in the gas phase (and low-effluent dissolved-oxygen concentration), the gas-to-liquid ratio should be maintained above approximately 2 to 3 volume of gas/volume of water. For most degassing applications, forced-air ventilation is not required as long as the columns are designed to allow air flow through the top and bottom of the columns.

MULTICOMPONENT DEGASSING BASED ON PRESSURE

Equation 1 is written for a single gas, however, the risk from gas supersaturation depends on the total gas pressure, not the concentration of a single gas. A multicomponent model for degassing of oxygen, nitrogen, and argon has been developed in terms of total gas pressure (4):

$$\Delta P_{out} = \Delta P_{in(O_2)}e^{-G(t)} + \Delta P_{in(N_2+Ar)}e^{-0.85G(t)} \qquad (4)$$

where

$\Delta P_{out} =$ effluent ΔP from column (mm Hg) (see the entry "Gas bubble disease" for a discussion of the measurement of total gas pressure and ΔP),

$\Delta P_{in(O_2)} =$ influent ΔP for oxygen gas (mm Hg),

$\Delta P_{in(N_2+Ar)} =$ influent ΔP for nitrogen + argon gas (mm Hg),

$e =$ base (2.718...) of natural system of logarithms,

$G_{(t)} =$ overall packed-column mass-transfer coefficient computed from Equation 2 and adjusted to the actual temperature by using Equation 3 (dimensionless),

$0.85 =$ a constant that accounts for the slower mass transfer of nitrogen + argon gases.

Ignoring the pressure contribution of carbon dioxide, the overall ΔP is equal to the sum of the ΔP's for the major component gases (5):

$$\Delta P = \Delta P_{(O_2)} + \Delta P_{(N_2+Ar)} \qquad (5)$$

and

$$\Delta P_{(O_2)} = \left(\frac{C}{\beta_{o_2}}\right)0.5318 - 0.20946(BP - P_{H_2O}) \qquad (6)$$

where

$C =$ concentration of dissolved oxygen (mg/L),

$\beta_{o_2} =$ Bunsen coefficient of oxygen (L/L · atm; see reference 6),

$BP =$ local barometric pressure (mm Hg),

$P_{H_2O} =$ vapor pressure of water (mm Hg; see reference 6).

Once $\Delta P_{(O_2)}$ has been computed from Equation 6, $\Delta P_{(N_2+Ar)}$ can be computed from Equation 5. For gas-supersaturation work, nitrogen and argon gases are

considered a single gas and referred to as dissolved nitrogen (DN).

DESIGN OF PACKED COLUMNS FOR DEGASSING

The performance of packed columns can be computed from Equation 4 as a function of temperature, barometric pressure, dissolved oxygen, and ΔP. For most degassing applications, the effluent must meet both a dissolved oxygen and ΔP criteria.

Column Height

Column height has a significant impact on the effluent ΔP. For an influent $\Delta P = 250$ mm Hg, the effluent ΔP was reduced to 58–68 mm Hg at 1 m and to 18–23 mm Hg for the two cases presented in (Fig. 2). For reasonable column heights, packed-column aerators can reduce the ΔP to 10–20 mm Hg. To achieve ΔP's below this range, a very high column or a pure oxygen column is needed (3). A pure oxygen column operated at a vacuum is the only type of system that can reduce the DN concentration below saturation, while maintaining high DO's. A vacuum column without the addition of pure oxygen can also reduce DN below saturation, but will, at the same time, reduce DO. Neither type of columns will remove a significant amount of carbon dioxide because of the low gas-exchange rate.

Hydraulic Loading

For a given flow, the cross-section area of the column can be computed from the water flow and maximum loading rates listed in Table 1. For example, a water flow of 500 m³/h and a loading of 150 m³/m² · h would require a crosssectional area of 3.33 m² (column diameter = 2.06 m).
Media Type

The required column height depends on the medium selected (Fig. 3). While in general, the small-sized media are more efficient at transferring gas, the column diameter for those media must be increased due to their reduced hydraulic capacity (Table 1).

Impact of DO Concentration

At low ΔP values, the column height is controlled by the dissolved-oxygen criteria (Fig. 3). Above an influent ΔP of approximately 60 mm Hg, the column height is control by the ΔP criterion.

DEGASSING OF OTHER GASES

A number of other gases may need to be stripped out of aquaculture waters. These include methane and hydrogen, carbon dioxide, hydrogen sulfide, and radon.

Methane and Hydrogen

Methane and hydrogen are two insoluble gases that may be found in groundwaters and bottom water from lakes and reservoirs. Conventional packed-column aerators are effective in removing these gases. In applications where these gases may be present, the columns should be vented to the outside.

Carbon Dioxide

The concentration of carbon dioxide gas in groundwaters is highly variable and can typically range from below saturation (less than 0.5 mg/L) to 30–40 mg/L. The concentration depends on the depth and characteristics of the soil, the subsurface geology, and the chemical reactions of dissolved carbon dioxide gas. Carbon dioxide gas is

Figure 2. Effect of medium height on effluent ΔP (Influent $\Delta P = 250$ mm Hg, temperature = 10 °C, barometric pressure = 760 mm Hg, $K_{20} = 1.71$/m, $b_{20} = 0.40$). Low DO case is based an influent DO = 2.00 mg/L and dissolved nitrogen + argon (DN) = 26.94 mg/L; the high DO case is based on an influent DO = 15.00 mg/L and DN = 19.81.
Figure 3. Effect of K on column height (15 °C, 760 mm Hg, $DO_{in} = 5.0$ mg/L, $\Delta P_{max} = 20$ mm Hg, $DO_{min} = 0.90C^* = 9.08$ mg/L).

difficult to remove because of its high solubility. Gas-to-liquid ratios in the range of 5–10 are needed to remove a significant amount of carbon dioxide (7). When carbon dioxide gas is added to water, a portion is converted to bicarbonate and carbonate ions. Only carbon dioxide gas can be removed in a gas transfer system. The kinetics of the carbonate system are slow compared with hydraulic transit time through a packed column. Therefore, while 80–90% of the carbon dioxide gas can be removed by packed column (7), this may be only 40–50% of the added carbon dioxide gas.

Hydrogen Sulfide

Hydrogen sulfide is similar to carbon dioxide, with high solubility and liquid-phase reactions with water. A forced-draft packed column is needed to strip significant amounts of hydrogen sulfide (8). Because of the liquid-phase reactions, the amount of hydrogen sulfide removed depends very strongly on pH.

Radon

High levels of radon gas have been found in hatchery buildings, resulting from degassing of groundwaters prior to use (9). The off-gas from these applications should be discharged to the outside.

DIETARY PROTEIN REQUIREMENTS

Meng H. Li
Edwin H. Robinson
Mississippi State University
Stoneville, Mississippi

Ronald W. Hardy
Hagerman Fish Culture Experiment Station
Hagerman, Idaho

OUTLINE

Proteins include a large group of chemically similar, but physiologically distinct, molecules that are important in the structure and function of all living organisms. Proteins account for about 65% to 80% of the dry weight of the soft tissues that make up the organs and muscles of fish. All proteins are composed of subunits of amino acids. Animals actually do not require the protein molecule, but rather have a dietary requirement for amino acids and nonspecific nitrogen. Generally, the most economical source of these chemicals is a mixture of proteins. Since protein metabolism is a dynamic process in which tissue proteins are continually being catabolized and resynthesized, a dietary source of amino acids and nonspecific nitrogen is required throughout the life of the organism. Ingested proteins are hydrolyzed to release amino acids that may be used for synthesis of tissue proteins. Fish rations should be balanced to assure that adequate levels of nonspecific nitrogen, amino acids, and nonprotein energy are supplied in proper proportions necessary to maximize protein deposition.

DIETARY AMINO ACID REQUIREMENTS OF FISH

Amino Acids, Defined

Amino acids, which are the structural units of protein, are generally classified as indispensable (essential) or dispensable (nonessential). An indispensable amino acid is one that the animal cannot synthesize or cannot synthesize in quantities sufficient for body needs; thus, it must be provided in the diet. A dispensable amino acid is one that can be synthesized by the animal in quantities sufficient for maximum growth. Most simple-stomached animals, including fish, require the same 10 indispensable amino acids: arginine, histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine.

Determining Amino Acid Requirements

Qualitative amino acid requirements have been determined by measuring weight gain and feed efficiency of fish fed diets containing crystalline amino acids in which a single amino acid was omitted. When fish fed a diet without a

specific amino acid did not gain weight or had a markedly reduced weight gain compared with fish fed a control diet, this indicated the essentiality of that single amino acid in their diet (1). Quantitative amino acid requirements were determined by feeding graded levels of crystalline amino acids or a combination of chemically defined proteins, such as casein and gelatin, and crystalline amino acids. The amino acid composition of the test diets was usually similar to that found in whole chicken eggs, fish eggs, or fish muscle. Growth curves generated from such feeding trials have typically been used to estimate amino acid requirements.

There has been disagreement concerning the reliability of quantitative amino acid requirements determined for various species of fish in which highly purified diets containing predominately crystalline amino acids were used. This disagreement arose because fish fed such diets grew slowly compared with those raised on diets with similar amino acid profiles prepared from intact proteins (2–5). For example, early research with juvenile salmon fed highly purified diets generally resulted in the salmon gaining 0.8% to 1.6% of their body weight per day. Fish raised in comparable conditions, but fed practical diets, had weight gains double this rate (6). The argument was that amino acid requirements determined using crystalline amino acid diets may not be representative of dietary requirements of fish fed practical diets. Thus, other methods of determining amino acid requirements have been used. For example, an inferior protein feedstuff, such as corn gluten meal (which is deficient in certain amino acids) has been used as the basic protein to which crystalline amino acids were supplemented to quantify the amino acid requirements (7,8). Similarly, diet formulations using

wheat gluten (deficient in arginine) have been used to study the arginine requirement and lysine-arginine interactions (9–11). However, this method is problematic because amino acid requirements may be affected by protein digestibility, amino acid imbalance, or transit and absorption rates of crystalline amino acids as compared with those from intact proteins. Another method suggested by Ogino (12) to estimate amino acid requirements of fish was to use the increase in retention of indispensable amino acids in whole body protein. This method is questionable because it does not include all the amino acids needed for maintenance.

Perhaps there is no perfect method to determine amino acid requirements. However, the requirements obtained from feeding trials with crystalline amino acids and a combination of crystalline amino acids and purified proteins have been widely used to formulate commercial fish diets. This method appears to be reliable. Robinson et al. (13) reevaluated the lysine requirement of channel catfish (*Ictalurus punctatus*) using both purified and practical diets containing 30% protein, and the requirement was 5.0% of protein, similar to 5.1% of protein previously determined using crystalline amino acids at 24% dietary protein (14). Similarly, the dietary requirement for arginine for coho salmon (*Oncorhynchus kisutch*), estimated using practical ingredients, was similar to that determined using semipurified diets (15). Quantitative indispensable amino acid requirements of several fish species are presented in Table 1. The values are fairly similar among species, primarily because the amino acid composition of lean fish tissue does not vary much among species. However, some variations in amino acid requirements exist among species due to differences in physiological needs. The amino acid requirements are

Table 1. Essential Amino Acid Requirements (expressed as percentage of dietary protein) of Juvenile Fish Determined in a Feeding Trial Using Chemically Defined Diets

also affected by the type of test diet offered and the method used to calculate the requirements (1,16,17).

Expressing Amino Acid Requirements

Amino acid requirements may be expressed as the amount of the amino acid needed per animal per day, as a percentage of diet, or as a percentage of dietary protein. The most precise method might be to express amino acid requirements as the amount needed per animal per day, but this is very difficult to estimate in growing animals, and there is a lack of information to accurately express amino acid requirements for fish in this manner. Perhaps the most practical way to express amino acid requirements is as a percentage of dietary protein, because a constant relationship exists between amino acids and dietary protein.

Amino Acid Interactions

The presence of dietary cystine reduces the dietary methionine requirement because methionine is the precursor of cystine. Cystine can replace 60% of the methionine requirement of channel catfish (18) and 42% of the methionine requirement of rainbow trout (*Oncorhynchus mykiss*) (19). A similar relationship exists between aromatic amino acids: Fish can convert phenylalanine to tyrosine. Tyrosine can replace about 60% of the phenylalanine requirement in common carp (*Cyprinus carpio*) (20) and 50% in channel catfish (13).

Adverse interactions may occur among amino acids that have similar chemical structures if their concentrations in the diet are unbalanced. The lysine-arginine antagonism common in certain animals does not appear to be a problem in fish. This antagonism was not apparent in channel catfish (3) or rainbow trout in some studies (11,19). However, Kaushik and Fauconneau (21) demonstrated that a metabolic antagonism between lysine and arginine may exist in rainbow trout. They found that increasing lysine intake increased plasma arginine levels and attributed that observation to a decrease in arginine degradation rate as dietary lysine increased.

Another common amino acid interaction occurs among the branched-chain amino acids leucine, isoleucine, and valine. Excesses of leucine or isoleucine in diets deficient in one of the other branched-chain amino acids cause a reduction in weight gain and feed efficiency. This interaction has been observed in common carp (20), chinook salmon (*Oncorhynchus tshawytscha*) (22), and channel catfish (23). Hughes et al. (24) found that plasma leucine and isoleucine were increased in valine-deficient rainbow trout. However, Choo (25) showed that free isoleucine and valine in plasma, liver, and muscle were not affected by an increase in dietary leucine.

Meeting Amino Acid Requirements

Amino acid requirements may be met by feeding an excess of protein, so that the level of the most limiting amino acid meets the dietary requirement, by supplementing deficient proteins with crystalline amino acids, or by feeding a mixture of complementary sources. Feeding a mixture of complementary proteins is almost always the most economical choice. To mix protein sources effectively to meet the amino acid requirements of various species of fish, one needs to know the amino acid composition of the feed ingredients and the biological availability of amino acids from each ingredient. Data on the composition of amino acid are available in feed tables for commonly used feedstuffs (17). Data on the availability of amino acid are not readily obtainable. However, data on availability for several commonly used dietary ingredients are known for a number of farmed species. For further information, (see the entry "Protein sources for feeds.") Protein digestibility coefficients may be used to estimate the availability of amino acids when data on the availability of individual amino acids are lacking. However, protein digestibility coefficients are simply the average of individual amino acid digestibility coefficients, with some being above and others below the protein digestibility coefficients. For example, average protein digestibility of cottonseed meal to channel catfish is 83% (26); whereas, lysine from cottonseed meal is only about 66% available to channel catfish (27). This is a fairly extreme example, but if protein digestibility were used to formulate a feed containing cottonseed meal, a lysine deficiency could result. Feed formulations should be designed to contain a slight excess of limiting amino acids, unless digestibility coefficients for the limiting amino acids in the feed ingredients used in the formulation are known.

Utilization of Crystalline Amino Acids

The practice of using supplemental crystalline amino acids to improve the quality of inferior protein feedstuffs in fish diets has been a subject of debate by fish nutrition researchers. As previously discussed, crystalline amino acid test diets are often poorly utilized, compared with diets containing intact proteins. In early studies with common carp, Aoe et al. (28) reported that the fish did not gain weight when fed crystalline amino acid test diets at 3% body weight divided into four equal feedings. However, Nose et al. (29) showed improved utilization of crystalline amino acid test diets by feeding the fish to satiation six times daily. Also, Yamada et al. (30) obtained a similar weight gain with crystalline amino acid test diets to that with a control diet when common carp fry were fed 10% body weight divided into 18 equal feedings per day. These researchers suggested that feeding frequency affects utilization of crystalline amino acids. It has been demonstrated that the amino acids from the crystalline amino acid test diets were absorbed much more rapidly from the intestine of common carp than the amino acids from a casein diet (31). In addition, crystalline amino acids appeared to be removed from plasma at a more rapid rate after feeding a crystalline amino acid diet than after feeding a casein diet (32). The same may be true where diets contain a high percentage of enzymatically-hydrolyzed protein, e.g., fish silage or hydrolysates (33). Increasing feeding frequency may provide a continual supply of the amino acids for protein synthesis and partially overcome this problem (1).

Murai et al. (34) reported that 36% of the dietary amino acids were recovered in the rearing water within 24 hours after feeding common carp an all-crystalline amino acid

diet. About 13% of the amino acids were recovered after feeding the fish a diet composed of both casein and crystalline amino acids, while only 1% of the amino acids were recovered in the water of fish receiving a casein or gelatin diet. The authors suggested that the poor utilization of crystalline amino acids was mainly caused by excretion of unutilized amino acids. However, Wilson (1) proposed that part of the amino acids recovered in the water may have been caused by amino acid leaching from the diet. Recently, Zarate and Lovell (35) showed that after adjusting the data for leaching, the bioavailability of crystalline lysine by channel catfish was 57% to 68% of that of intact lysine in soybean meal. Leaching accounted for 13% and 2% of the dietary lysine concentration for crystalline lysine and bound lysine, respectively. The lower bioavailability of crystalline lysine as compared with that of protein-bound lysine was supported by Zarate (36) who demonstrated that crystalline lysine passed out of the stomach of channel catfish earlier than protein-bound lysine. Thus, the crystalline lysine was absorbed from the intestine before the protein-based lysine was available for absorption. It appears that crystalline amino acids should be bound or coated to delay their absorption in order to match the absorption of intact protein.

Unlike common carp (29,30), channel catfish appear to be able to effectively utilize crystalline lysine (35,37–40) when the fish are fed once or twice daily. Zarate (36) found no differences in utilization of supplemental lysine by channel catfish fed two and five times daily. Feeding frequency apparently has little effect on lysine utilization in channel catfish.

There is evidence in land animals that supplemental amino acids improve weight gain and feed efficiency in low-protein, amino acid-replete diets. In channel catfish, Bai and Gatlin (41) showed that supplementation of low protein diets (assumed to be replete in amino acids) with crystalline lysine improved weight gain and feed efficiency. However, Li and Robinson (42) were unable to demonstrate any benefit of lysine, methionine, or both when supplemented in low protein, amino acid-sufficient diets for channel catfish. The difference between those two studies may have been that the diets used by Bai and Gatlin (41) were lysine deficient. The authors pointed out that the positive effect of supplemental lysine may have been due to the lower lysine availability of the soy protein isolate used in their study. There is ample evidence that supplemental lysine is efficacious when added to lysine-deficient channel catfish diets.

DIETARY PROTEIN REQUIREMENT

Quantitative Requirements

Because protein is the most expensive nutrient in fish diets, many studies have been conducted to establish protein requirements for various cultured fish. The dietary protein requirements of several species of fish are listed in Table 2. Most of the requirements were estimated from growth responses of fish fed various levels of protein that were presumed to be balanced in respect to amino acids. Dietary protein requirements, ranging from 23% to 55% (Table 2), vary with species and size of fish. In juvenile rainbow trout, weight gain increases linearly with dietary protein intake over a wide range of feed intake, approximately 6 g to 20 g protein/kg fish/day (43), so protein intake ought not to influence the protein requirement studies provided that feed intake is maintained within the range listed earlier.

Factors Influencing Protein Requirement

Dietary protein requirements determined in various studies vary considerably even within a species. For example, dietary protein requirements for channel catfish have been reported to be 24% to 55%. The wide variation in protein requirements for channel catfish is not surprising because of the different conditions under which the studies were conducted. Factors that may affect the dietary protein requirement include fish size and age, diet composition, feeding rate, presence of natural foods, methods used to estimate the requirement, water temperature, and stocking density.

The dietary digestible-energy-to-protein ratio (DE/P) has a profound influence on protein requirements in fish. Since the concentration of dietary energy appears to affect feed intake, diets that contain excess energy may reduce feed intake, while diets deficient in energy may result in protein being used to meet energy needs, rather than for protein synthesis. Thus, it is important that energy and protein be supplied in the proper proportions and that adequate levels of nonprotein energy be included in the diet. Nonprotein energy sources, such as lipids and digestible carbohydrates, have been shown to spare dietary protein in various species (44–49). When feed is restricted, higher protein diets usually result in better growth. Minton (50) reported that weight gain of pond-raised channel catfish was not different when the fish were fed to satiation with 30% and 36% protein diets, but feeding at approximately 75% of satiation, the fish fed the 36% protein diet gained more weight than fish fed the 30% protein diet. Similarly, Li and Lovell (51,52) also found that a dietary protein concentration of 24% to 26% was adequate for optimum weight gain when fish were fed as much as they would consume, while fish fed at a predetermined maximum level (60 kg/ha/day), a minimum dietary protein level of 32% was necessary for optimum growth. A study with milkfish (*Chanos chanos*) appears to support that contention.

Sumagaysay and Borlongan (53) demonstrated that a 24% protein diet was adequate for optimum growth of milkfish fed at 4% body weight, while a 31% protein diet provided for better growth than the 24% protein diet when the fish were fed at 2% of body weight. The reason for the interaction between dietary protein level and feeding rate may be that the protein requirement for maintenance accounts for a higher proportion of the total protein requirement in fish fed a low-protein diet compared with a higher protein diet when fish are underfed. In a recent study with pond-raised channel catfish, Robinson and Li (54) showed that a 28% protein diet supported weight gain equivalent to a 32% protein when the fish were fed at a predetermined feeding rate equal to or greater than 90 kg/ha/day.

Table 2. Estimated Dietary Protein Requirement for Optimum Weight Gain of Fish (as-fed basis)

Species	Requirement (%)	Size (g)	Environment	Reference
Atlantic salmon (*Salmo salar*)	45			80
Blue tilapia (*Tilapia aurea*)	36	0.4–9.7	Wood tank	81
Channel catfish (*I. punctatus*)	55	0.02–0.2	Aquarium	82
	32–36	7–29	Aquarium	45
	29	9.1–26.6	Aquarium	83
	25	114–500	Fiberglass tank	44
	35	14–100	Fiberglass tank	44
	24	20–517	Pond	51
	24	594–1859	Pond	51
	24	27–354	Pond	62
Common carp (*C. carpio*)	38	1.0–2.0	Aquarium	84
	31	4.3–9	Aquarium	46
	34	2.6–13	Aquarium	34
Gilthead seabream (*Sparus aurata*)	40	2.6–18	Plastic tank	85
Gold fish (*Carassius auratus*)	29	0.2–1.3	Aquarium	86
Golden shiner (*Notemigonus crysoleucas*)	29	0.2–1.4	Aquarium	86
Grass carp (*Ctenopharyngodon idella*)	41–43	0.2–0.6	Aquarium	87
	23–28	2.4–8.0	Aquarium	88
Grouper (*Epinephelus malabaricus*)	48	3.8–9.2	Aquarium	89
	44	9.2–53	Aquarium	49
Hybrid tilapia (*Tilapia nilotica* × *T. aurea*)	24	2.9–8.4	Aquarium	90
	28	21–53	Aquarium	91
Milkfish (*C. chanos*)	40	0.04–0.18	Aquarium	92
Mozambique tilapia (*Tilapia mossambica*)	40	1.8–10.3	Aquarium	48
Nile tilapia (*T. nilotica*)	30	4–10	Aquarium	93
Rainbow trout (*O. mykiss*)	40	2–10	Aquarium	94
Red drum (*Sciaenops ocellatus*)	35–44	4.1–28	Aquarium	64
	40	2.0–27	Aquarium	95
Sunshine bass (*Morone chrysops* × *M. saxatilis*)	41	125–550	Cage	65
White sturgeon (*Acipenser transmontanus*)	40	145–300	Fiberglass tank	96

The presence of natural food organisms may reduce the need to supply high levels of protein in prepared diets for certain fish. For example, tilapia and shrimp grow as well on low-protein diets (25% and below) as on higher protein diets when natural food is abundant, but they require higher protein diets when natural food is limited (16). Natural food organisms are also abundant in channel catfish ponds, but their contribution to growth of food-size fish stocked intensively may be minimal. It has been estimated that only 2.5% of the protein requirement and 0.8% of the energy needed for channel catfish grown in relatively high density in ponds was obtained from natural food (55). Fish raised in intensive production systems,

e.g., salmon and trout, do not obtain any measurable contribution to their dietary needs from natural food organisms.

There are indications that statistical methods used to estimate protein requirements affect the results (56,57). Several methods have been used to estimate nutrient requirements, including analysis of variance and multiple range tests, broken-line analysis (58), and regression analysis (58–60). Multiple range tests may not provide a precise level in some cases and may not be statistically justified (56). Broken-line analysis is based on the intersection of two lines, but not all responses are linear. Certain data may be curvilinear and a quadratic or

Table 3. Optimum Dietary Digestible Energy to Protein (DE/P) Ratio for Optimum Growth and Body Composition for Selected Species (expressed as kcal DE/g crude protein)

Species	DE/P Ratio	Size (g)	Environment	Reference
Channel catfish	11.0 (28)	20–517	Pond	51
(*I. punctatus*)	9.7 (28)	27–354	Pond	62
Common carp	10.0 (34)	2.6–13	Aquarium	34
(*C. carpio*)				
Gold fish	9.7 (29)	0.2–1.3	Aquarium	86
(*C. auratus*)				
Golden shiner	9.7 (29)	0.2–1.4	Aquarium	86
(*N. crysoleucas*)				
Rainbow trout	9.5 (38)			17
(*O. mykiss*)				
Red drum	8.8 (40)	2.0–27	Aquarium	95
(*S. ocellatus*)				
Sunshine bass	10.1 (41)	125–550	Cage	65
(*M. chrysops* × *M. saxatilis*)				

an asystotic curve may be more appropriate. Quadratic regression tends to result in a higher requirement than broken-line analysis (60). In an evaluation of nine data sets, Robbins et al. (58) found that the asymptotic curve method provided adequate fits for all data sets, while the broken-line analysis gave adequate fits only for six data sets. When both methods provided adequate fits, the estimated requirements were nearly the same. While arguments can be made in support of the various methods used to estimate nutrient requirements, broken-line analysis appears to be used most often.

Digestible Energy to Protein Ratio

The concentration of dietary protein not only affects the weight gain of fish, but also affects the composition of the gain. Research with channel catfish and trout has shown that, as the dietary protein level is decreased, body fat generally increases. The increased body fat in channel catfish fed low-protein diets (below 24%) appears to be caused by an imbalance that occurs between dietary energy and protein when protein is reduced and energy is not adjusted accordingly. Some body fat is inevitable in growing fish, and in rainbow trout the proportion of fat in their body increases with fish size (61). Past a certain dietary fat threshold, however, body fat increases as dietary fat increases. Fattiness is generally increased as the DE/P ratio of the diet is increased from the optimum range in channel catfish (44,45,51,52,62), blue tilapia (*T. aurea*) (47), common carp (63), red drum (*S. ocellatus*) (64), and sunshine bass (*M. chrysops* × *M. saxatilis*) (65). Optimum DE/P ratios for various fishes are given in Table 3.

PROTEIN RETENTION AND EXCRETION

Protein retention in farm-raised salmon and trout has increased significantly over the past decade. Protein retention refers to the percentage of ingested protein that is retained by fish as protein gain. Retention values have increased from 25%–30% to 40%–50% through the use of high-fat feeds, better formulation to match dietary amino acid levels with requirements, and the use of high quality protein feedstuffs. The theoretical maximum protein retention is approximately 65% to 75%, indicating that further improvement may be possible. Protein retention is an important response variable in research associated with protein and amino acid requirements, optimum DE/P ratios, and ingredient and diet formulation studies. It is also an important consideration in the development of "Environmentally friendly feeds" diets (see separate entry in this volume) and diets to control pond water quality. In channel catfish, increasing the dietary protein concentration within a certain range generally results in increased nitrogen retention, but also increases nitrogen excretion. However, it is not economical to use dietary protein concentrations that exceed 28% to 32% to improve nitrogen retention and reduce body fattiness in commercial channel catfish culture.

DIGESTIBILITY

SHOZO H. SUGIURA
Hagerman Fish Culture Experiment Station
Hagerman, Idaho

OUTLINE

For fish to use dietary nutrients for various physiological purposes, the nutrients must be absorbed by the fish. Therefore, knowing the digestibility of nutrients in feeds is critical to estimating the nutritive value of feeds for fish. Feeds are often the single largest variable cost in intensive aquaculture operations. For fish farmers to reduce the cost of feed without reducing the amount of fish produced, a reliable index is necessary to evaluate or compare varieties of feeds and feed ingredients. Knowing the digestibility of nutrients in feeds, as well as the nutrient content and the price, is therefore critical for selecting best-buy feeds and feed ingredients. Knowing the digestibility of nutrients in feeds is also essential to reduce excretion of undigested nutrients that pollute the aquatic environment. The digestibility values of dietary nutrients provide basic information for evaluating fish feeds and ingredients that meet biological, economical, and environmental requirements.

DEFINITION

Digestibility, Availability, and Bioavailability

The term "digestibility" is used for dietary nutrients that need to be digested before they can be absorbed from the gastrointestinal tract of animals (e.g., proteins, carbohydrates, and fats), whereas "availability" is used for nutrients that are absorbed without being digested or decomposed in the gastrointestinal tract (e.g., vitamins, minerals, and amino acids). Digestibility and availability are often expressed as the percentage of dietary nutrients absorbed by fish, which is determined by analyzing the respective nutrient contents of feeds (input) and feces (output). The difference between these values is the amount of nutrients assumed to have been absorbed by the fish. "Fractional absorption" and "percentage absorption" (of dietary nutrients) are other terms used to describe this process.

"Bioavailability" is defined as the proportion of a nutrient in a diet that is absorbed and used for one or more biological functions [1,2]. It is usually determined using biological responses, such as growth, nutrient retention, tissue levels, bone strength, enzyme activities, and other criteria that measure the degree of use of a test nutrient. However, it is difficult to measure the actual utilization of some nutrients, and, therefore, absorption is sometimes used to approximate the bioavailability of dietary nutrients, assuming that all or almost all of the absorbed nutrients can be used. This assumption is, however, sometimes questionable. For example, free-amino-acid

diets have a higher absorption of total nitrogen (91%) than does the corresponding casein–gelatin diet (82%) in carp (*Cyprinus carpio*); however, growth has been found to be markedly lower in fish fed a free-amino-acid diet than in those fed a casein diet (3). This finding suggests that, in some cases, absorption is not a good criterion for expressing bioavailability of dietary nutrients. The relative, or comparative, (bio)availability is the value of the bioavailability of a nutrient when expressed in relation to a response obtained with a standard reference material (normally of a highly available source).

Apparent and True Digestibility

The apparent digestibility (or apparent availability) of nutrients in diets, also called the (fractional) net absorption or the apparent absorption of nutrients in diets, is defined as follows:

$$\text{Apparent digestibility (\%)} = \frac{\left(\begin{array}{c}\text{nutrient intake from diet}\\ -\text{ nutrient excreted into feces}\end{array}\right) \times 100}{\text{nutrient intake from diet}}$$

Even if a dietary nutrient, such as protein, is completely digestible (and absorbed), or even if the diet is protein free, the feces will still contain a small amount of protein. This portion of fecal protein is not of dietary origin, but of endogenous origin, and includes sloughed intestinal epithelial cells, digestive enzymes, bile salts, intestinal fluid, and bacterial flora.

The true digestibility (or true availability) of nutrients in diets, also called the (fractional) true absorption of nutrients in diets, is the value for which nutrients of endogenous origin have been accounted for and is therefore defined as follows:

$$\text{True digestibility (\%)} = \frac{\left\{\begin{array}{c}\text{nutrient intake from diet}\\ -\text{ (nutrient excreted into feces}\\ -\text{ endogenous nutrient excreted into feces)}\end{array}\right\} \times 100}{\text{nutrient intake from diet}}$$

The endogenous excretion of nutrients is measured by either feeding the organism diets free of the test nutrient or by feeding the organism diets of various nutrient levels and then extrapolating the zero level by regressing the measured points (4,5). For major nutrients, such as protein, carbohydrates, and lipids, the apparent digestibility and the true digestibility are normally close to one another, unless the dietary level is unreasonably low. The distinction between apparent and true digestibility, therefore, has little practical meaning in most feeding practices (6). Studies with higher animals show that this is not the case for some minerals, such as copper, manganese, and zinc, since considerable amounts of absorbed (endogenous) portions are known to be excreted back into the gastrointestinal tract. In addition, this endogenous amount differs at different levels of intake (7). For these minerals, therefore, there could be large differences between the apparent and the true

availability (absorption). For other minerals, such as iron and calcium, intestinal absorption per se is regulated by the body's need. Thus, estimating the availability of minerals by means of their intestinal absorption requires carefully controlled experimental procedures, as discussed later. Throughout the rest of this contribution, the apparent digestibility and apparent availability are generally called digestibility and availability, respectively, unless otherwise stated.

METHODS OF DIGESTIBILITY MEASUREMENTS

Direct and Indirect Method

The direct method of measuring digestibility and availability is based on the total amount of nutrients ingested by test animals and excreted as feces. It is therefore essential when using the direct method to collect all feces excreted by the animal, as well as to record the exact amount of feed ingested by the animal. In omnivorous and carnivorous animals, some indigestible, easily distinguishable inert substance, called a marker, is sometimes used. The marker, usually a colored substance, is fed to the animal just before the beginning of ration ingestion and again at its close. Feces collection is begun when the first marker appears and is ended with the appearance of the second marker. Carmine is a frequently used marker. Ferric oxide, chromic oxide, and soot have also been employed. In herbivorous animals, with their much longer and more complicated digestive tracts, the use of a marker is not a suitable method. Experimenters have, therefore, resorted to "time collection," which entails following an extended (preliminary) period during which the ration to be tested is fed daily in constant amounts (8,9). In experiments on fish feed, however, it is technically difficult to collect feces quantitatively without losing fecal components (both water-soluble and disintegrated solid matter) in the water. Also, the direct method is a laborious and time-consuming procedure as compared with the indirect method (described next), and therefore it is no longer in common use for measuring the digestibility of nutrients in fish feeds.

The indirect method is overwhelmingly popular in nutrient digestibility studies of fish feeds. This method requires the inclusion of an indigestible indicator substance (described next) in the diet. By measuring the ratio of the amount of nutrients to the amount of indicator substance in the diet and in the feces, the percentage of dietary nutrients that were absorbed by the fish can be determined. Thus, this technique requires only a small fecal sample instead of a complete collection of feces. Also, there is no need to measure the amount of feed ingested by the fish.

Researchers have compared the apparent digestibility values determined by the direct method (complete collection of feces) with those determined by the indirect method (using chromic oxide as the indicator substance). They obtained similar values of digestibility for dry matter, crude protein, and energy using rainbow trout and chinook salmon (10,11).

Indicators

Indicator substances, also called reference substances, must be nonabsorbable, nontoxic (for both test animals and experimenters), and tasteless; must not affect normal digestion, absorption, and physiological functions and bacterial flora in the intestine; and must have a rate of passage through the gastrointestinal tract equal to that of the nutrient being tested. In addition, they have to be precisely quantified; must be easily mixed with feeds; and must have no interaction, reaction, or catalytic effect with other dietary components (i.e., they must exhibit inertness) during storage of the diet or in the digestive tract. Indicators are either exogenous (added to the diet; e.g., chromic oxide) or indigenous (contained in feed ingredients; e.g., acid-insoluble ash and fiber). The use of indigenous indicators is convenient for commercial feeds; however, since the amount of indigenous indicator in feeds is generally very small, larger amounts of feed and fecal samples are required for chemical analyses in order to reduce measurement errors.

Indicator substances used in digestibility trials with mammals and birds have been adapted for experiments with fish species. By far, the most commonly used indicator substance in the measurement of nutrient digestibility in fish and animal feeds is chromic oxide (Cr_2O_3). It is typically included in diets at levels of 0.5 or 1%. Diet and fecal samples containing chromic oxide can be analyzed colorimetrically with relatively simple and inexpensive procedures (12,13). Although chromic oxide has been questioned for its validity as an appropriate indicator, for various reasons (14–17), it is still the indicator of choice.

Various other indicators have also been used or recommended as the inert indicator for digestibility trials in fish or higher animals, including acid-insoluble ash, silica or SiO_2 (18,19), crude fiber or cellulose (20–22), lignin (23), titanium oxide (24), polyethylene (21,25), chromium-51-EDTA (26,27), magnesium ferrite ($MgO \cdot Fe_2O_3$) (28,29), cerium-144 (30,31), barium sulfate or carbonate (32,33), ytterbium acetate or oxide (34,35); yttrium-91 (27,36); yttrium oxide (35); ammonium ^{32}P-molybdate (37), cholestane ($C_{27}H_{40}$) (38), and n-alkanes (39). Each of these substances has one or more advantages over chromic oxide. Nevertheless, none of them has yet successfully replaced chromic oxide, due to various disadvantages or uncertainties (e.g., insufficient information).

Collection of Feces

Since fish live in water, feeding them diets and collecting their feces without losing soluble components requires different approaches from those used in digestibility studies in terrestrial animal species. Isotopes, which are commonly used in studies involving higher animals, are not suited for aquatic species, since the loss of such substances in water is difficult to prevent. Also, the use of a closed or recirculating water system permits fish to absorb various substances from water. Much effort has thus been directed toward collecting fecal samples with minimal losses of soluble components. The following methods of feces collection are currently used in digestibility experiments with aquatic species, all with varied efficiency

and success, depending on the type of equipment and techniques used: settling, netting, stripping, dissection, anal suction, and metabolic chamber methods.

It is important to select an appropriate method, depending on the nutrient of interest in the feces. Some investigators have developed unique apparati for collecting fish feces. Smith (40) and Smith et al. (41,42) collected feces from fish confined in metabolic chambers. Choubert et al. (43) collected feces by netting, using a mechanically rotating screen that captures material in effluent water in tanks. Cho et al. (44) used a settling column which was modified by Hajen et al. (11), to collect voided feces. Since the composition of the diet largely affects the consistency of voided feces, various indigestible binders and certain feed ingredients with binding properties (for feces) are sometimes used when formulating diets to increase the stability of voided feces in water. This technique reduces the measurement error associated with leaching of soluble components in feces before collection.

The feces of goldfish (*Carassius auratus*) collected by stripping were not different from those collected by dissection from the rectal part of the intestine, in terms of measured protein digestibility of *Chlorella* (45). Other researchers, reported that fecal samples from rainbow trout (*Oncorhynchus mykiss*), chinook salmon (*Oncorhynchus tshawytscha*), and sea bass (*Dicentrarchus labrax*) collected by stripping gave digestibility values lower than those for samples collected by intestinal dissection, anal suction, settling, immediate pipetting, continuous filtration, decantation, and complete collection (11,46,47).

Fish should be fed test diets containing an indicator for five to seven days (under normal feeding regimes and temperatures) before fecal samples are collected. The collection of feces may be extended over a few days or longer, to collect sufficient material for analyses and to reduce day-to-day variations of nutrient digestibility. Diurnal variation in the excretion of indicator substances, especially chromic oxide, has long been recognized in higher animals, suggesting that continuous collection of feces may have an advantage over a single collection (e.g., stripping and dissection). Collecting feces by stripping should not be repeated frequently, since it potentially alters the passage rate of intestinal content, and the handling stress of the previous day could affect nutrient digestibility and feed intake of the fish in the following days. Feces (plus water, if feces are collected in a settling column) are dried using an oven or freeze-dryer, depending on the nutrient being tested, and the dried material is finely ground for chemical analysis.

Measurement of Nutrient Digestibility for Each Feed Ingredient

When formulating feeds by mixing various ingredients, it is essential to know the digestibility or availability of nutrients in each ingredient. This information is critical for minimizing the risk of nutrient deficiency (a biological problem) or excess (economical and environmental problems). Three methods are currently used to measure ingredient nutrient digestibility. The first method is to

feed a single ingredient to fish, often by force feeding (40–42). Thus, the diet is generally nutritionally imbalanced, sometimes toxic, and not similar to actual feeds, and therefore it is rarely used to measure the digestibility of feed ingredients. Advantages of this method, however, are its simplicity of concept, sensitivity, and that there is no leaching loss of dietary nutrients. The second method is to feed a formulated diet in which the nutrient of interest is supplied solely from the test ingredient, but not from the other sources in the diet. The strength of this method is its sensitivity and reliability, since the diet can be formulated in a nutritionally more balanced manner than in the first method. When the concentration of test nutrient in an ingredient is low, this is the method of choice.

The third method uses a basal (reference) diet of known nutrient digestibility (9,44). The basal diet (as the complete ingredient mixture) is combined with a test ingredient at a certain ratio, generally 70% of the basal diet and 30% of the test ingredient. The combined diet is called the "test diet." By measuring the nutrient digestibility of the test diet and that of the basal diet, the digestibility of nutrients in the test ingredient can be estimated by subtraction, using the formula given in the next section. When the basal diet is free of the test nutrient, this method is analogous to the second method.

An implicit assumption for the third method is that the digestibility of the basal diet is unchanged when it is combined with test ingredients. This assumption cannot be true if there are severe nutrient interactions between the basal diet and the test ingredient, which is in fact a distinct advantage of this method over the first two methods. It thereby allows the measurement of an interactive property of a feed ingredient for each nutrient within a compound feed. For micronutrients, this information is equally, or sometimes more, important than the nutrient availability of the ingredient per se. Also, the use of a nutritionally adequate basal diet can buffer large differences in the nutrient composition among test ingredients, and therefore the digestibility can be measured without disturbing the normal digestive and physiological systems of fish. This method is more reliable and advantageous when studying nutrient availabilities in various feed ingredients of different nutrient concentrations, especially with respect to trace minerals (and carbohydrates) for which fish regulate intestinal absorption or intestinal endogenous excretion, depending on the level of intake. A serious disadvantage of this method, however, is its high vulnerability to experimental errors, especially when the percentage of the ingredient of interest in the test diet is low or the concentration of test nutrient in the ingredient is low (relative to that in the basal diet).

Calculation of Nutrient Digestibility for Diets

The first step in calculating the digestibility of nutrients in diets is to determine the concentration factor (CF), which can be obtained as follows:

$$CF = \frac{\text{indicator concentration in feces}}{\text{indicator concentration in diet}}$$

This factor indicates the portion of the feces that corresponds to a unit amount of the diet. Then the nutrient content in the feces needs to be divided by the CF, to determine the amount of nutrient excreted in the feces per diet. The overall calculation procedure of nutrient digestibility in diets is expressed as follows:

$$\text{Digestibility (\%)} = \frac{\left(\begin{array}{c}\text{nutrient concentration in diet} \\ - \text{ nutrient concentration in feces/CF}\end{array}\right) \times 100}{\text{nutrient concentration in diet}}$$

Example 1. Given that the protein concentration in a diet is 50%, the protein concentration in the feces is 25%, the indicator concentration in the diet is 0.5%, and the indicator concentration in the feces is 2.5%, the CF can be calculated as $2.5/0.5 = 5$, and the digestibility of protein in the diet is $(50 - 25/5) \times 100/50 = 90\%$. For the calculation of dry-matter digestibility, simply replace the nutrient concentration in feed and feces with 100%. The calculation is therefore $(100 - 100/5) \times 100/100 = 80\%$.

Calculation of Nutrient Digestibility for Ingredients

Calculation of nutrient digestibility for ingredients is the same as that of the diet just shown if the test ingredient is fed alone by force feeding (first method) or when the ingredient is the sole source of the test nutrient in the formulated feed (second method). When the basal diet is used to measure nutrient digestibility of ingredients (third method), however, the nutrient concentration and the digestibility of the basal diet need to be subtracted from those of the test diet (i.e., basal diet plus test ingredient) (48). The nutrient digestibility in test ingredients is therefore calculated as follows:

$$\text{Digestibility (\%)} = \frac{\left[\left(\begin{array}{c}\text{nutrient concentration in the test diet} \\ \times \text{ digestibility of the nutrient in} \\ \text{the test diet}\end{array}\right) - \left(\begin{array}{c}0.7 \times \text{nutrient concentration in the} \\ \text{basal diet} \times \text{digestibility of the} \\ \text{nutrient in the basal diet}\end{array}\right)\right] \times 100}{\left(\begin{array}{c}\text{nutrient concentration in the test diet} \\ - 0.7 \times \text{nutrient concentration in the basal diet}\end{array}\right)}$$

Example 2 (in concept). Basal diet, casein–gelatin semipurified diet (60% protein, dry basis); Test ingredient, wheat middlings (20% protein, dry basis); Ratio of wheat middlings and the basal diet in the test diet: 3 : 7 (dry basis); Protein content (dry basis) in the test diet (should be) $20 \times 0.3 + 60 \times 0.7 = 48\%$; Digestibility of protein in the basal diet: 95%; Digestibility of protein in the test diet: 85%. Then, the digestibility of protein in the test ingredient can be calculated as follows:

$$\text{Digestibility} = \frac{(48 \times 0.85 - 0.7 \times 60 \times 0.95) \times 100}{(48 - 0.7 \times 60)}$$
$$= 15\%$$

The first part of the numerator in this formula indicates the amount of protein absorbed from the test diet. The second half of the numerator is the amount of protein absorbed from the basal diet portion of the test diet. The numerator of the formula thus represents the total amount of protein absorbed from the test-ingredient portion of the test diet. The denominator of the formula indicates the amount of protein contributed from the test ingredient in the test diet and can also be written as $(0.3 \times$ protein concentration in the test ingredient). The coefficient 0.7 in the formula for digestibility is, of course, the dry-matter ratio (proportion of the basal diet in the test diet). When a test ingredient is mixed in the basal diet at ratios other than 30% (on a dry basis), the coefficient needs to be changed accordingly. If the protein (contribution) ratio is used instead of the dry matter ratio, the calculation in Example 2 will proceed as follows:

$$\text{Digestibility} = \frac{(0.85 - 0.875 \times 0.95) \times 100}{0.125}$$
$$= 15\%$$

The coefficient $\dfrac{(60 \times 0.7)}{(60 \times 0.7 + 20 \times 0.3)}$ or 0.875, is the protein contribution ratio (i.e., the amount of protein contributed from the basal-diet portion in the test diet/the total protein content in the test diet); the denominator $(1 - 0.875)$, or 0.125, is the ratio of protein contributed from the test-ingredient portion in the test diet.

The two different methods for doing the preceding calculation should yield the same value of digestibility. If the indicator substance is included in the basal-diet mixture before being combined with a test ingredient, the dry-matter ratio (coefficient) can be determined precisely and conveniently by analyzing the concentration of the indicator in dried diets (i.e., the concentration of indicator in the test diet/the concentration of indicator in the basal diet).

Example 3 (in practice)

Procedure. The basal diet mixture, containing an indicator at 1%, was mixed with a test ingredient at a 7 : 3 ratio (not on a dry basis).

Analytical Data (minimum required data). The indicator concentration (dry basis) In the basal diet is 1.05%, in the test diet is 0.76%, in the feces of fish fed the basal diet is 8%, and in the feces of fish fed the test diet is 4%.

The protein content (dry basis) in the basal diet is 50%, in the test diet is 40%, in the feces of fish fed the basal diet is 10%, and in the feces of fish fed the test diet is 20%.

Then, the digestibility of protein in the test ingredient can be calculated as follows:

Digestibility =
$$\frac{\{40 \times (40 - 20/(4/0.76))/40 - (0.76/1.05) \times 50 \times (50 - 10/(8/1.05))/50\} \times 100}{\{40 - (0.76/1.05) \times 50\}}$$
$$= 25.19\%$$

where $(40 - 20/(4/0.76))/40$ $(= 90.5\%)$ represents the digestibility of protein in the test diet; $0.76/1.05$ $(= 72.38\%)$ is the precise proportion (dry basis) of the basal diet in the test diet; and $(50 - 10/(8/1.05))/50$ $(= 97.38\%)$ represents the digestibility of protein in the basal diet.

The foregoing information also provides us with the following:

> Digestibility of dry matter = 65.60% (by replacing the protein contents of feeds and feces in the foregoing formula with 100%);
>
> Protein content in the test ingredient (dry basis) = $\{40 - (0.76/1.05) \times 50\}/(1 - 0.76/1.05) = 13.79\%$;
>
> Moisture content of the basal diet mixture (x) is found from $1/(1 - x) = 1.05$, so $x = 4.76\%$;
>
> Moisture content of the test ingredient (y); is found from $70 \times (1 - x)/\{30 \times (1 - y) + 70 \times (1 - x)\} = 0.76/1.05$, so $y = 15.20\%$.

It is not worthwhile to simplify the formulas just presented, because it is essential to understand the calculation process and thereby to understand the meaning of the obtained values. Also, it should be noted that these estimated values are less accurate than those measured directly. The degree of error associated with indirect determination (calculation) is dependent upon measurement (analytical) errors and the nutrient contribution ratio in the test diet.

Although a precise ratio of a test ingredient to the basal diet needs to be known for calculation purposes, the ratio per se is not critical for measuring nutrient digestibility of test ingredients. When the inclusion level of the test ingredient is too low, however, it will cause a larger experimental error than when the inclusion level of the ingredient is high. The same problem will arise when the concentration of test nutrient in the test ingredient is very low relative to that in the basal diet. This is because a small difference between the measured nutrient digestibility values of the test diet will be responsible for the small amount of nutrient contributed from the test-ingredient portion. Using Example 2, we find that the protein digestibility of the test diet cannot be below 83.1% or above 95.6% when the protein digestibility of the test ingredient is calculated to be 0% and 100%, respectively. This result indicates that a small experimental error of the measured digestibility value of the test diet will be magnified into the calculated digestibility value of the test ingredient. When the inclusion level of the test ingredient into the test diet is too high, however, it will increase differences in the nutrient composition between test diets, depending on the test ingredient incorporated into the diet. Such diets may well be nutritionally inadequate or imbalanced, thereby lessening the advantage of this method. The appropriate ratio of test ingredients to the basal diet therefore depends on their nutrient-contribution ratio within the test diet.

Interpretation of Digestibility Data

The level of one nutrient (or antinutrient) in a diet always affects the absorption (availability) of other nutrients

in the diet by antagonistic or synergistic interactions and dilution or concentration of dietary nutrients. These processes may happen during feed processing and storage, as well as after the ingestion of feeds within the diet or between the diet and endogenous excreta in the gut. Nutrient interactions, however, become obvious only when the degree of interactions is relatively high. For example, when the basal diet contains 10 mg of available nutrient A per 100 g of diet, and this diet is to be mixed with a test ingredient at a 7 : 3 ratio (the basal diet to the test ingredient), then the mixed diet should contain at least 7 mg of the available nutrient A per 100 g of diet, even if the same nutrient A supplied from the test ingredient is totally unavailable. If the net absorption of nutrient A from the diet is below this level (7 mg/100 g), then this is clear evidence of (antagonistic) interaction. In other words, the test ingredient reduced the absorption of nutrient A supplied from the basal-diet portion in the test diet. In this case, the original assumption of this method — i.e., that the digestibility of nutrients of the basal diet is unchanged — can no longer be supported. Alternatively, assuming that the digestibility of nutrients in the test ingredient is zero, the nutrient digestibility of the basal-diet portion in the test diet can be recalculated to express the degree of inhibition (antagonistic interaction) by the test ingredient (48). The substances in the test ingredient that might be responsible for the lowered absorption of the nutrient A could be other minerals (e.g., calcium, phosphorus, and iron); phytic acid; or fiber or other dietary components that have binding, precipitating, or oxidation/reduction properties. The absorption of some trace elements, especially that of iron and manganese, is substantially reduced by many feed ingredients, compared with the absorption from the casein basal diet alone (48).

In formulating feeds, the interacting property of each feed ingredient needs to be considered, especially for the antagonistic interactions, as seen in many ingredients having negative availability values. The calcium, manganese, and iron contained in many feed ingredients are not only unavailable, but also reduce the absorption of calcium, manganese, and iron supplied from the other part of the diet, including inorganic mineral supplements. Thus, feed ingredients have two distinct and opposing effects: (*1*) supplying minerals and (*2*) supplying substances that reduce or increase the absorption (availability) of minerals. Available mineral contents in feed ingredients could, therefore, be below zero (i.e., negative digestibility or availability) or exceed the total amount (i.e., higher than 100% digestibility or availability), due to this second effect of the ingredients in formulated feeds.

When fish are fed diets that contain nutrients in an amount higher than that required the fish may regulate their absorption of the nutrients. For protein, fats, and some minerals whose regulatory sites are not at the gastrointestinal level, fish metabolize any excess as an energy source or simply excrete the excess portion via urine or through their gills. This process does not interfere with the measurement of digestibility or availability values. For carbohydrates and some other minerals, such as iron, (water insoluble) phosphorus, and calcium, however, absorption appears to be regulated at the gastrointestinal level, due to limited digestive capacity, gastric acid output, or homeostatic regulations. Other minerals, such as manganese, copper, and zinc, have been shown to be absorbed in higher animals (49), and the excess amount is subsequently excreted into the intestinal lumen (endogenous loss). Long-term feeding will eventually allow fish to adjust the amount of net absorption of the elements, bringing it toward a more balanced level, which may be close to the required levels of the elements.

Measuring nutrient availability at this stage, however, cannot be justified, since fish regulate either the absorption or the excretion of the minerals. Conversely, taking a long acclimation period with diets that are marginally deficient in test nutrients may also cause problems, such as the depression of growth, feed intake, or normal physiology in metabolic processes. The acclimation (adaptation) period to the test diet therefore should be minimized when measuring the availability of minerals, and the collection of fecal samples should be completed before the fish start regulating the absorption of dietary minerals. However, there should be a sufficiently long conditioning period preceding the feeding of test diets (50). This period is critical to neutralize any carry-over effect of previous dietary regimes, to replenish body pools for each of the minerals and vitamins, and to normalize the growth rate and feed intake. The use of the 30/70 ratio to determine mineral availability coefficients for feed ingredients has an advantage of buffering the direct effect of the fish's regulatory system by standardizing (calibrating) the availability coefficients using the basal diet which is normally fed at the same time to a separate group of fish from the same initial that which have the same nutritional and physiological background. For the same reason, using relative availability is more appropriate than using absolute availability for studies involving micronutrients, because the conditioning of fish cannot be complete or confirmed in reality, and there always are physiological differences between fish from one study to another.

The basal diet should be formulated carefully, to minimize any unwanted interactions between the basal diet and test ingredients. In a sense, the basal diet is a dietary indicator unlike other indicators; it is digestible, but, because its digestibility is precisely known, we can calculate the digestibility of test ingredients based on the basal diet. The basal diet, therefore, needs to meet the requirements of the dietary indicator (given in the preceding section). The use of acidic salts of minerals (e.g., monobasic potassium and sodium phosphates) in the basal diet may not affect the availability of minerals in the basal diet per se, but when combined with a test ingredient, these substances may increase the availability of minerals in the test-ingredient portion in the test diet, due to the acidity of the basal diet and increased solubilization of minerals in the test ingredient. Thus, adding these substances causes an overestimation of the availability of minerals in test ingredients, especially for ingredients of high ash content. The use of fish meal in the basal diet, on

the other hand, may precipitate or coprecipitate minerals in the intestine, due to the high fraction of calcium from bone in the fish meal, causing an underestimation of mineral availabilities in test ingredients. Due to various interactions, plant ingredients containing phytic acid may also have a similar effect. For minerals and carbohydrates, for which fish appear to have some regulatory functions, the level of nutrients in the test diet affects the absorption of nutrients. The low availability of phosphorus in high-ash ingredients, for example, is primarily due to the high (greater than dietary requirements) calcium and phosphorus content in the ingredients rather than to their inherent availability, since reducing the fraction of bone increases the absorption (in the percentage of intake, not in the absolute amount) of calcium and phosphorus in the ingredients (51).

FACTORS THAT AFFECT MEASUREMENT OF DIGESTIBILITY

Various biological, environmental, and dietary factors have been shown to affect the absorption and use of dietary nutrients. It is necessary to understand and control these variables in order to measure the digestibility of dietary nutrients and to interpret and use digestibility data in a meaningful way.

Biological Factors

Different species have different abilities to digest dietary nutrients, especially carbohydrates and minerals. These variations are associated with differences in feeding habits, as well as in digestive and metabolic systems (e.g., carnivores, herbivores, agastric fish). In addition, genetic differences within species appear to influence protein and carbohydrate digestibilities in salmonid fishes (52,53).

In the early stages of life, typically the postlarval stage, the digestive functions of many fish are not fully developed. This is especially the case for many seawater fish, which lay large numbers of small pelagic eggs. The digestion of food during this stage is largely aided by the autolysis of prey plankton. The poor performance of microparticulate diets in marine fish larvae is due to an incompletely developed digestive tract and a lower attractability of microparticulate diets than that of live foods (54). In herbivorous fish, an increase in the relative gut length in the early stages of life is associated with an increase in the capability to digest macroalgae (55).

Homeostatic mechanisms of organisms have profound effects on the absorption of some dietary nutrients, especially trace minerals. Animal species, including fish, regulate the uptake of some nutrients (e.g., iron) from the intestine when the amount of intake is in excess of the dietary requirement. For some nutrients (e.g., trace minerals), excess portions of absorbed nutrients are excreted into feces. Thus, true availability ≫ apparent availability. Diet history (i.e., previous diet regime or habit) also has important effects on the absorption of nutrients, especially trace minerals, which may cause a negative balance (excretion > intake) for an extended period.

Environmental Factors

In rainbow trout, high salinities have been shown to decrease the absorption efficiency of dietary protein (56). In Arctic charr (*Salvelinus alpinus*), digestibilities of protein and lipids were found to be lower in seawater than in freshwater (57). In Atlantic salmon (*Salmo salar*), digestibility of nitrogen [sic] was found to be 9–10% lower in seawater-adapted smolts than in smolts adapted to freshwater (58). Digestibilities of energy and protein were lower in rainbow trout reared in saltwater as compared with those reared in freshwater (59). The rate of food movement was faster and the protein digestibility was lower when milkfish (*Chanos chanos*) were raised in seawater, rather than in freshwater (60). No difference was observed in protein digestibility between cod (*Gadus morhua*) acclimated to low salinity (14 ppt) and to seawater, even though low salinity provided higher growth rates and higher feed conversion ratios (61). Low salinity (10 ppt) did not affect the digestibility of protein by tilapia (*Oreochromis niloticus*) fry (62). The digestibility of casein and fish meal by prawn (*Penaeus monodon*) did not change with salinity (16 ppt vs. 32 ppt), but the digestibility of soybean meal significantly decreased at 32 ppt (63).

Water temperature did not alter protein digestibility in pacu (*Piaractus mesopotamicus*) (64). The digestibilities of protein, lipid, and energy in rainbow trout were lower at 7°C (45°F) than at 11 or 15°C (52 or 59°F) in small fish [18 g (0.040 lb)], but not in larger fish [207–586 g (0.456–1.292 lb)] (65). Digestibility of protein was higher in rainbow trout at 18°C (64°F) than at 9–15°C (48–59°F) (66).

Hypoxia did not change the apparent digestibility of protein, energy, and dry matter in rainbow trout (67,68). In prawns, a significant reduction in growth was obtained at a dissolved-oxygen (DO) level of 1 ppm; however, no significant differences were observed for apparent feed digestibility (69).

Ration size (feeding rate) had no significant effect on the digestibility of protein or lipid in rainbow trout (65). However, other observers noted that a larger daily meal size reduced the apparent digestibility of most amino acids and crude protein in rainbow trout (70) and that increasing the feeding level reduced the apparent digestibilities of dry matter and protein in commercial feeds fed to African catfish (*Clarias gariepinus*) (71). Digestibility of protein in Atlantic salmon smolts was about 10% higher when the fish were fed to excess in four hours daily than when the fish were fed to excess continuously (58).

Feeding frequency (two, four, or six times a day) did not affect digestibilities of dry matter, protein, and energy in rainbow trout with a body weight of about 100 g (0.22 lb) (72). Reducing the frequency of feeding increased the availability of phytate-phosphorus in a soybean-meal-based diet supplemented with microbial phytase (51).

Infection of rainbow trout by the bacteria *Aeromonas salmonicida* reduced the feed intake and the apparent digestibility of all nutrients and several amino acids (68). In largemouth bass (*Micropterus salmoides*), the presence of the intestinal worms (acanthocephalans) lowered both the protein digestibility and the amino acid availability of herring meal (73).

Dietary Factors

Heat (cooking extrusion) processing increases the digestibility of raw starch by many fish and animal species. For many fish, however, the digestibility of cooked starch and dextrin decreases as their content in the diet increases. Cooked starch also reduces protein digestibility when included at high levels in the diet, especially for carnivorous fish. The availability of niacin from corn was increased by about 57% when the corn was extrusion cooked (74). Crude (raw) starch in the diet reduces amylase activity in rainbow trout. Amylase is adsorbed to crude starch, so that starch hydrolysis is inhibited. Crude starch also accelerates the passage of the feed through the intestine, thus reducing the time available for absorption (75). Retrogradation of cooked starch (known as resistant starch) may reduce digestibility, as shown in higher animals. This change may be important in moist pellets, since moisture is necessary for retrogradation of gelatinized starch. Heating is necessary to inactivate trypsin inhibitors in soybeans, which otherwise reduce the digestibility of protein and amino acids (76,77). Excessive heating, especially with reducing sugars or aldehydes of lipid oxidation, causes serious losses of lysine, arginine, and cystine, due to the Maillard browning reaction, which reduces protein digestibility and amino acid availability.

Phytate (phytic acid and phytin), contained in all plant seeds, reduces protein digestibility and mineral availabilities in many monogastric animals, including fish. Phytase is an enzyme specific to phytate hydrolysis. This enzyme occurs naturally in some feed ingredients, such as wheat bran, and is also produced in a small amount by microbial flora in the intestine, but by far the most common source is fungal phytase, which is now commercially available as a feed additive. High processing temperatures of feeds generally inactivate endogenous or supplemental phytases, while low temperatures may preserve phytase activity. Phytate in soybean meal is very resistant to dry heating, steam heating, pressure cooking, and microwaving, regardless of the heating intensity (51). Certain nonlethal mutant grains containing lower levels of phytate have a higher availability for phosphorus and some other minerals than do ordinary grains (78).

The digestibility of fats generally decreases as the melting point increases. The digestibility of hydrogenated (hardened) oil is lower than that of liquid oils. Oxidized fish oil has a lower digestibility than that of the fresh oil in red seabream (*Chrysophrys major*) (79). Lipid hydroperoxide of methyl linoleate was not well absorbed by carp; however, the addition of vitamin E increased the absorption of the hydroperoxide to a level equivalent to that of methyl linoleate. But, ethoxyquin was not effective for increasing the absorption of hydroperoxide (80). Cholesterol was absorbed at a rate of only 28% in a lipid-free diet; however, the inclusion of palmitic acid, tripalmitin, or chicken-egg lecithin markedly increases the absorption of cholesterol to 85–98% in prawns (81).

The apparent absorptions of chelated minerals (i.e., copper proteinate, iron proteinate, manganese proteinate, selenium proteinate, and zinc proteinate) are all higher than those of the corresponding inorganic sources (i.e., copper sulfate, ferrous sulfate, manganese sulfate, sodium selenite, and zinc sulfate, respectively) in both semipurified diets and soybean meal diets fed to channel catfish (*Ictalurus punctatus*) (82). The bioavailability of heme-bound iron (e.g., blood meal) is much higher than that of inorganic sources of iron in fish and higher animals. Various chelating agents can either increase or decrease the absorption of dietary minerals, depending on the stability constant of the chelate formed.

Dietary calcium appears to reduce the availability of many minerals in diets, as the dietary concentration of calcium (as well as that of phosphorus, ash, and bone) is inversely correlated to the apparent absorption of other minerals (48). Tricalcium phosphate decreases zinc and manganese availability in carp (83) and zinc availability in rainbow trout (84). Citric acid (17) and inorganic acids (51) markedly increase the availability of phosphorus and some other minerals in fish meal. Ascorbic acid increases the absorption of inorganic iron in diets. Further, numerous interactions among minerals or other dietary components have been shown to affect the intestinal absorption of dietary minerals in various animal species (85).

Crude fiber or cellulose (up to 15%) appears to have no major effect on protein digestibility in goldfish (86) and carp (87). Alginate and guar gum reduced the apparent digestibilities of protein and fats in the diet fed to rainbow trout (88). Various alginates differing in gelling property all reduced the apparent digestibilities of nitrogen, fat, ash, and calcium when fed at a concentration of 5.0% in moist diets for rainbow trout (89). Other researchers, however, found that sodium alginate does not have a negative effect on protein and lipid digestibilities in sea bass at concentrations up to 8% in the diet, while at a concentration of 15% in the diet, the apparent digestibilities of both protein and lipids decreased (90). Agar included in the diet at a concentration of 10% reduced carbohydrate and dry-matter digestibilities in fingerling tilapias (91).

Particle sizes of feed ingredients may affect the digestibility of nutrients. With channel catfish, higher digestibilities of carbohydrates and protein were reported for feeds formulated with fine ingredients than for feeds formulated with coarse ingredients (92).

For protein, fats, and some minerals, the digestibility coefficients in individual ingredients are additive, so that the content of digestible nutrients in a diet and in fecal waste can be predicted from the digestibility coefficients of each ingredient and the nutrient concentrations in the diet. For carbohydrates and many minerals, however, the same prediction is more difficult to prove, due to the regulation of digestion or absorption of dietary nutrients, which depend on the dietary levels of the nutrients and the various interactions of the nutrients with other compounds in the diet and in the digestive tract.

CONCLUSION

Digestible (available) nutrients in diets are either used or, when the amount of nutrients is greater than the dietary requirement, are excreted or not absorbed by the fish, to avoid abnormal accumulation or overdose toxicity. The route of excretion can be via either feces (thus reducing the

measured digestibility), urine, or gills. Due to increasing concern about environmental pollution, formulated feeds should not contain digestible or available nutrients in an amount greater than the dietary requirement. This standard indicates that data on both digestibility and dietary requirements will be critical sources of information for formulating biologically, economically, and environmentally optimal feeds for successful aquaculture operations.

DISEASE TREATMENTS

JOHN H. SCHACHTE
New York State Department of Environmental Conservation
Rome, New York

OUTLINE

INTRODUCTION

Treatments for diseases of fish generally refer to the administration of chemical and/or antimicrobial agents to combat infectious disease. These may involve the administration of chemicals directly to the water to eliminate ectoparasites and external bacterial infections or the oral administration of antibiotics in or on the feed. The latter are usually a treatment for one or more systemic bacterial infections. They are usually employed as a result of failure of management practices that would otherwise prevent or avoid the introduction of clinical disease. Once the onset of clinical signs of disease is evident, the fish culturist must respond with the appropriate therapy. Treatment of infectious diseases of fish requires knowledge of a number of areas of aquatic health management as well as the nature of the cultural system and the species of fish being treated. It is not sufficient to only identify the pathogen, look up the appropriate therapeutic agent, and then conduct the treatment. This article attempts to identify those critical factors that must be considered to conduct successful fish disease treatments. Additionally, those

compounds frequently used for specific disease agents, their method of administration, sample calculations, and specific precautionary details are discussed.

PRETREATMENT CONSIDERATIONS

Choice and Availability of Therapeutic Agents

Historically fish culturists have used a wide variety of chemical and antimicrobial compounds to treat infectious diseases of fish. Salt was probably the earliest therapeutic agent used as a dip to treat external diseases. Formalin was first reported for use as a parasiticide in 1909 (1). Until the past ten years or so, many compounds were tried experimentally and, following successful field trials, were employed by fish culturists as acceptable therapy. More recently however, the U.S. Food and Drug Administration (FDA) Center for Veterinary Medicine (CVM) has become actively involved in the enforcement of laws regulating the use of therapeutic agents on fish. As the federal agency responsible for regulation of such activity with food animals, the FDA has established a framework to interact with aquaculture. Specific guidelines identifying compounds available for use on food fish have been generated. A mechanism to facilitate the evaluation and approval of additional compounds has been put into place in the last several years. The latter, the investigational new animal drug (INAD), exemption process provides a vehicle for legal field and laboratory testing of therapeutants to allow accumulation of safety and efficacy data sufficient for the FDA to make a determination of approval or rejection of use on food fish. Under this process, government agency hatcheries and/or academic institutions are named as coordinators with cooperators authorized to use and collect data on certain fish disease treatment agents. Presently a number of agencies cooperate under INADs issued for such compounds as chloramine-t and diquat, used for external bacterial infections of fish. At present there are very few therapeutic chemicals and antimicrobials available with FDA approval for use on food fish. Schnick et al. (2) have provided a list of the current status of therapeutic agents. Additionally the International Association of Fish and Wildlife Agencies is currently sponsoring a multistate-funded initiative to support research to facilitate the FDA approval of a list of key fish disease treatment compounds. It is incumbent upon the fish culturist to determine the appropriate chemical for a particular use and to adhere to label instructions regarding use and withdrawal times prior to harvest.

A final note with respect to regulation of fish disease treatment chemicals deals with discharge of those chemicals into adjacent waters. In the mid-1970s the Environmental Protection Agency (EPA) established the National Pollution Elimination Discharge System (NPDES) that sets standards for the quality and quantity of chemical discharges into adjacent waters. These standards, which may be more stringent depending upon in which state you reside, may influence which disease treatment you use. In flowing water aquaculture, depending upon the size of your annual production, you may be restricted in the concentration and or duration of a particular treatment. Amounts may be dictated by your state regulatory agency based upon receiving stream flows and resultant dilution. It would be prudent to check with the appropriate agency in your state to see if your operation must comply.

The Host, Pathogen, and Environment

Any discussion of fish diseases, whether it be diagnosis and identification or treatment and control, requires some basic understanding of the host pathogen relationship. Here I refer to necessary information about the characteristics of the host fish, the disease agent involved, and the environmental factors that influence the outbreak and severity of disease or lack thereof. It is well established that in the absence of clinical disease in fish, equilibrium exists between the host and a pathogen that may be present in the water or in the fish. In 1973, Snieszko (3) described the host, pathogen, environment relationship, and equilibrium. Any management failure on the part of the culturist or other event that upsets this balance can precipitate clinical disease. Specifically with regard to the host, some infectious diseases may be host specific. Some species of fish may be more or less resistant to a particular disease. Certain pathogens, protozoan parasites for example, require specific temperature ranges for maximum activity. The same applies for certain bacterial pathogens. Various environmental factors such as dissolved oxygen levels, temperature, and free ammonia levels can influence the outbreak and/or severity of a particular disease. Many of these same factors must be evaluated by the fish culturist prior to treatment. He or she must also answer some basic questions with regard to the impending treatment. What is the species of fish I'm treating and for which particular disease? What is this fish's reaction to the treatment of choice? Do some combinations of treatments offer advantages or disadvantages? What about multiple infections? Is there any order of priority in the treatment regime? Are there any complicating environmental factors that could influence the toxicity of the treatment chemical to the fish? Could any of these factors render the treatment ineffective?

METHODS OF ADMINISTRATION

Depending upon the type of fish culture facility, it may be necessary to employ one or more of the different techniques of delivering therapeutic compounds to fish. Earthen pond fish culture, for example, may require the use of a method quite different from that used in flowing water aquaculture. The following represent the most common methods for administration of therapeutic agents to fish.

Prolonged Bath Treatment

Prolonged bath treatment is a static treatment method where water flow is interrupted. The volume of water to be treated is determined and the appropriate amount of chemical is added for a predetermined duration, usually up to 60 minutes. Following the time expiration, the chemical bath is subjected to a rapid flush returning the fish

to fresh water. This technique will usually result in a very accurate administration of the treatment chemical. Some precautions must be observed when employing this method:

- Oxygen levels should be monitored and provisions made for aeration if needed.
- Treatment should be conducted at a time when minimum stress due to environmental factors is present and personnel are available for continuous observation.
- Uniform distribution of chemical should be ensured.

This method, most frequently used in flowing water aquaculture, is usually administered in concrete raceways or other tanks of similar configuration. The size and shape of these units may influence uniform mixing. It is usually advisable to administer the chemical in several locations and mix thoroughly where possible.

Indefinite Bath Treatment

This technique is most often used to treat ponds where essentially static water fish culture is conducted. Large warmwater fish ponds are most frequently treated in this fashion. This method employs a lower level concentration than the previous method relying on natural decomposition and/or detoxification to terminate the treatment. The chemical may be added to the pond water by a variety of methods. Once the volume of water to be treated is determined, a standard solution of known concentration is delivered via pumps, gravity flow, or venturi apparatus from a power boat. Certain precautions with regard to the pond environment must be adhered to when using this method. Time of day and concomitant water quality should be considered. Low dissolved oxygen and/or heavy algal blooms may contribute to adverse effects or overt toxicity to fish. Chemicals such as formalin can further depress oxygen levels through its toxicity to aquatic plants. Depending upon the severity of the infection and the volume of the pond, such treatments may become prohibitively expensive. As a result, the culturist may want to consider an available alternative.

Constant Flow Treatment

This method is most frequently used in flowing water aquaculture. Because of hatchery design or weight of fish present, interruption of flow may not be feasible in this situation. Such treatments consist of administration of a standard solution of the therapeutic chemical by a constant flow device calibrated to deliver for a predetermined duration. In trout and salmon culture this is the most frequently used method. The device used may be as simple as a chicken waterer consisting of an inverted plastic or glass jar with a screw-on base that has a small hole drilled near the edge of the horizontal portion of the base. Since the base maintains a constant level of solution until the last few seconds of delivery, a constant flow is maintained. Where even smaller volumes of chemical are required, such as egg incubators, flexible plastic intravenous solution bags fitted with a flow metering valve can be effective.

The alternate delivery device is some type of constant flow siphon vessel. The latter is usually a larger volume container which allows treatment of larger volume flow situations. We have found that a 5-gal plastic pail fitted with a simple wooden circular float and a calibrated plastic siphon tube provides a very satisfactory treatment unit. Alternatively, metering pumps of various design have been employed to accurately deliver the desired chemical directly into the water supply for a series of fish holding tanks. This method seems to have particular application on indoor or covered early life-stage rearing operations.

The use of the constant flow siphon method requires the accurate determination of water flow and accurate calibration of the delivery container. It should be noted that large flows may require prohibitively large amounts of chemical and concurrent expense. Where chemical volume delivery becomes a problem, multiple delivery units may be employed simultaneously. One should also be aware of the potential influence of the shape of the fish rearing unit. Such units of irregular configuration may result in so-called cold spots where fish may escape the desired concentration of the treatment chemical.

Feeding

In most situations where systemic bacterial infections occur, the administration of antibiotics can be accomplished orally by incorporation either in or on the feed. The antibiotics terramycin and Romet may already be incorporated into the diet in feed obtained from feed manufacturers. This is obviously the most efficient method of purchase and administration. Terramycin is incorporated into the feed at such a rate that if feed is administered at the recommended rate (usually 0.1% body weight per day) based upon 2 to 4 mg of active terramycin per 100 lb of fish fed, the desired dosage rate of active antibiotic is achieved. There are some precautions that should be considered with premedicated feed. Only the amount of feed expected to be used in a 30- to 90-day period should be ordered and stored. Depending upon time of year and ambient storage temperatures, such feed has a finite shelf life with regard to the potency of the antibiotic. At high summer temperatures where cool storage is unavailable, the antibiotic may be degraded below desired dosage level after only 30 days. Premedicated feed from the manufacturer usually is available in one or very limited sizes. Consequently, fish feeding on a small pellet experiencing a bacterial disease epizootic may not be able to utilize the premedicated feed size available.

Where premedicated feed is unavailable or undesirable, the fish culturist may buy the FDA-approved antibiotic of choice and add it to the feed. Such substances as gelatin and vegetable oils have been used. The latter, as described by Petrie and Ehlinger (4), requires the preparation of an oil–antibiotic premix slurry in a pail, wheelbarrow, or small cement mixer. Upon the addition of the appropriate amount and size feed, the fish culturist has a fresh preparation of medicated diet of the size needed.

In all cases where antibiotics are used, accurate diagnosis is paramount. Several of the common systemic infections may be precipitated by strains resistant to the usual antibiotic treatment. Failure to recognize this fact

can result in excessive loss of fish and waste of valuable antibiotic. It is also important to remember that it is vital to complete the duration of treatment. In a 5- or 10-day treatment regime, it is not unusual to see marked improvement in 3 to 6 days. In the interest of economy some may be tempted to cease treatment. Such action may well result in reappearance of clinical signs in a few days. The purpose of the 5- or 10-day regime is to ensure that the level of infective organisms is reduced below that which might allow the disease to regain epizootic proportions. Conversely, one should be aware of the fallacy that if a large amount of antibiotic will cure the disease in 5- or 10-days, then a smaller amount periodically should keep it away permanently! Such a medicated feed regime encourages the development of resistant forms of bacterial pathogens by eliminating the dominant and more abundant sensitive individuals in a population. As a result, the less dominant antibiotic resistant individuals become the dominant strain present. Subsequently, when the culturist needs the compound to treat an active epizootic, the antibiotic may not be effective.

Injection

Where manageable numbers of large valuable fish are at risk for infection with certain bacterial diseases, injection with antimicrobials may be appropriate. Examples of this method can be found in adult spawning Atlantic salmon where such diseases as furunculosis caused by the bacterium *Aeromonas salmonicida* threaten restoration efforts. Intramuscular (IM) or intraperitoneal (IP) injection of an antibiotic can result in ability to hold and spawn such fish. Other examples may be found where subclinically infected adults held for spawning may be candidates for injection. Chinook salmon in the Great Lakes infected subclinically with *Renibacterium salmoninarum*, the causative agent of bacterial kidney disease (BKD), have been shown to experience a marked reduction of vertical transmission of the disease following experimental injections with erythromycin sulfate. Care must be taken not to cause internal injury to vital organs during administration. In the case of IP injections, fish should be held with ventral surface up. Internal organs settle to the backbone and allow injection in the region of the ventral fins with minimal risk.

Vaccination

This method of disease control relies upon taking a proactive approach to prevent the outbreak of clinical disease by the administration of a biological agent designed to stimulate the fish's immune system. Vaccines generally contain inactivated forms of the causal organism with the addition of other proprietary agents to enhance the stimulation of the fish's response. Most vaccines available today for use in both warmwater and coldwater fish are referred to as bacterins. These contain inactivated bacteria of the causal organism for the disease in question. Inactivated viral protein has also been employed for vaccination against viral disease. Plumb (6) provides an up-to-date list of the vaccines currently available for finfish aquaculture. The vaccine is usually administered to the fish at a suitable time in the early stage of development by one or more routes. These may include injection, oral or immersion techniques, or some combination thereof.

TREATMENT GUIDELINES

The conduct of any disease treatment must be preceded by attention to certain factors that can influence success or failure. Lassee (5) and Poupard (7) have provided lists of precautions that should be considered both prior to and during disease treatments administered to fish.

1. Fish should be examined prior to treatment to determine the disease agent to be treated. If in doubt, consult a trained fish health professional. The "shotgun" approach to treatment is poor policy which may hasten the development of drug resistant microorganisms.

2. Determine the general condition of the fish and existing water quality. Environmental conditions such as low dissolved oxygen (DO) and hardness may cause further losses if certain chemicals are used. Formalin, for example, may cause a further reduction of DO where existing levels are less than 5 mg/L (ppm).

3. Any parasitism or infection of the gills should be treated first. Failure to do so may affect the respiratory capability of the fish resulting in increased treatment toxicity.

4. Eliminate feeding 24 to 48 hours prior to treatment. Oxygen consumption is reduced and resultant stress reduction enables fish to better withstand any negative treatment effects.

5. In the case of concrete raceways, tanks, etc., rearing units should be as clean as is practical prior to treatment. Excess organic waste may contribute to lack of treatment effect by tying up treatment chemicals.

6. Where fish densities are excessive they should be reduced, if possible, prior to static treatment. Supplemental aeration and/or ability to provide rapid inflow of fresh water should be available.

7. During warm weather, treatments should be administered early in the day during the period of coolest temperatures. Such action also facilitates ability to observe and respond to any adverse treatment effects.

8. Always check calculations before commencing any treatment. Take care to consider the stock chemical concentration and adjust calculations accordingly to achieve desired final concentration. In a chemical bath treatment, an error factor of ten may result in no treatment effect or acute chemical toxicity.

9. Prior to treatment, check the condition of the chemicals. Improper storage or length of storage may alter chemical composition and result in errors in final treatment concentration. Ensure that any container used to deliver the chemical is clean and properly rinsed prior to use. Inadvertent mixture

of certain therapeutic agents such as quaternary ammonium compounds and formalin can result in acute toxicity to fish.

10. Always comply with local chemical discharge regulations to prevent any inadvertent toxicity to nontarget aquatic organisms.
11. Ensure proper mixing and distribution of chemicals in the water column of the rearing unit. This is particularly important in static water treatments of larger ponds.
12. Continually monitor fish throughout the treatment period for signs of distress.
13. Ensure that predisposing factors for stress mediated infection are identified and remedied. Failure to do so will usually result in reappearance of clinical signs of disease in a short period following initial treatment.
14. Adhere to all label required clearance times following treatment.
15. Keep records of all treatments, their purpose, and results for future reference.

APPROVED TREATMENT THERAPEUTIC AGENTS

Previous discussion has emphasized the importance of using FDA label-approved compounds when treating fish intended for human consumption. The federal Joint Subcommittee on Aquaculture (8) has generated a list of approved therapeutic agents current as of 1994. Table 1 is modified from that list with categories established by the USFDA.

Table 2 presents a list of unapproved drugs of low regulatory priority for the FDA. The FDA is unlikely to object at present to the use of these substances if the following conditions are met:

1. The drugs are used for the prescribed indications, including species and life stages where specified.
2. The drugs are used at the prescribed dosages.
3. The drugs are used according to good management practices.
4. The product is of an appropriate grade for use in food animals.
5. An adverse effect on the environment is unlikely.

The FDA's enforcement position on the use of these substances should be considered neither an approval nor or an affirmation of their safety and effectiveness. Based upon information available in the future, the FDA may take a different position on their use.

Classification of substances as new animal drugs of low regulatory priority does not exempt facilities from complying with other federal, state, and local

Table 1. FDA-Approved New Animal Drugs

Trade Name	Sponsor	Active Drug	Species	Uses
Finquel (MS-222)	Argent Chemical Laboratories	Tricaine methanesulfonate	Ictaluridae, Salmonidae, Esocidae, and Percidae	Temporary immobilization (anesthetic)
Formalin-F	Natchez Animal Supply	Formalin	Trout, salmon, catfish, largemouth bass, and bluegill; salmon, trout, and esocid eggs	Control of external protozoa and monogenetic trematodes; control of fungi of the family Saprolegniacea
Paracide-F	Argent Chemical Laboratories	Formalin	Trout, salmon, catfish, largemouth bass, and bluegill; salmon, trout, and esocid eggs	Control of external protozoa and monogenetic trematodes; control of fungi of the family Saprolegniacea
Parasite-S	Western Chemical	Formalin	Trout, salmon, largemouth bass, and bluegill; trout, salmon, and esocid eggs; cultured pained shrimp	Control of external protozoa and monogenetic trematodes; control of fungi of the family Saprolegniacea; control of external protozoan parasites
Romet 30	Hoffmann-LaRoche	Sulfamethoxine and ormetoprim	Catfish, salmonids	Control of enteric septicemia and furunculosis
Sulfamerizine in Fish Grade[a]	American Cyanimid	Sulfamerizine	Rainbow, brook, and brown trout	Control of furunculosis
Terramycin for fish	Pfizer	Oxytetracycline	Catfish	Control of bacterial septicemia and pseudomonas disease
			Lobster	Control of gafkemia
			Salmonids	Control of ulcer disease, furunculosis, bacterial hemorrhagic septicemia, and pseudomonas disease
			Pacific salmon	Marking of skeletal tissue

[a]According to sponsor, this drug is not presently being distributed.

Table 2. Unapproved Drugs of Low Regulatory Priority for the FDA

Common Name	Permitted Use
Acetic acid	Used as a dip at a concentration of 1,000–2,000 mg/L (ppm) for 1–10 min as a parasiticide for fish
Calcium chloride	Used to increase water calcium concentration to ensure proper egg water hardening; dosages used to raise hardness to 10–20 mg/L (ppm) calcium carbonate
Calcium oxide	Used as external protozoacide for fingerling to adult fish at 200 mg/L (ppm) for 5 sec
Carbon dioxide gas	Used as an anesthetic for cold, cool, and warm water fish
Fuller's earth	To reduce the adhesiveness of fish eggs to improve hatchability
Garlic (whole)	For the control of helminth and sea lice infestations in marine salmonids at all life stages
Hydrogen peroxide	Used at 250–500 mg/L (ppm) to control fungi on all species and all life stages of fish, including eggs
Ice	To reduce metabolic rate of fish during transport
Magnesium sulfate (Epsom salts)	Used to treat external monogenetic trematode and crustacean infestations in freshwater fish at all life stages; immersion at 30,000 mg/L (ppm) magnesium sulfate and 7,000 mg/L (ppm) sodium chloride for 5–10 sec
Onion (whole)	To treat external crustacean parasites and deter sea lice from infesting external surface of fish at all life stages
Papain	To remove the gelatinous matrix of fish egg masses to improve hatchability and decrease incidence of disease; 2% solution
Potassium chloride	Used as an aid in osmoregulation to relieve stress and prevent shock; dosages used to increase chloride concentration to 10–2,000 mg/L (ppm)
Povidone iodine compounds	Used as a fish egg disinfectant at rates of 50 mg/L (ppm) for 30 min, during water hardening and 100 mg/L (ppm) for 10 min, after water hardening
Sodium bicarbonate (baking soda)	Used at 142–642 mg/L (ppm) for 5 min as a means of introducing carbon dioxide into the water to anesthetize fish
Sodium chloride (salt)	Used as a 0.5–1% solution for an indefinite period as an osmoregulatory aid for the relief of stress and prevention of shock; used as a parasiticide at 3% solution for 10–30 min
Sodium sulfite	Used as a 15% solution for 5–8 min to treat eggs in order to improve hatchability
Urea and tannic acid	Used to denature the adhesive component of fish eggs at a concentration of 5 g urea and 20 g NaCl/5 L of water for approximately 6 min, followed by a separate solution of 0.75 g tannic acid/5 L of water for an additional 6 min; volumes sufficient for 400,000 eggs

environmental requirements. For example, facilities using these substances would still be required to comply with National Pollution Discharge Elimination System requirements.

DISEASE TREATMENT CALCULATIONS

The preceding discussion of treatment applications revealed that therapeutic agents are added directly to the water or, in certain situations, may be added to or incorporated into the feed. In the former case, a final concentration of the chemical agent is achieved by the direct addition of the chemical or a standard solution of that agent to the water. In general, calculations for such treatments are expressed as weight-to-weight or volume-to-volume relationships. They require, for example, that one determine the weight of the water in relation to the weight of the chemical added to the water to achieve the final desired concentration of the chemical in the solution to which the fish are exposed. In the case of flowing water aquaculture where it is inadvisable to interrupt water flow, the volume of water per unit of time must be determined with respect to the volume of therapeutic agent administered per unit of time. Both methods imply the equivalent weight of the solvent (chemical/drug) in the weight of the solution (water). Concentrations of chemicals administered to fish in water are usually expressed as parts per million (ppm). They may also be referred to in the metric as milligrams per liter (mg/L). In a weight-to-weight relationship, 1 ppm (mg/L) is that quantity of a substance that makes a concentration of one pound per million pounds of water. Lasee (5) has provided a table (Table 3) which presents the amount of chemical that should be added to various volumes of water to result in a final concentration of 1 ppm (mg/L).

Prolonged or Indefinite Bath Method Calculations

In both cases, prolonged or indefinite bath method calculations require the treatment of a static water situation. The volume of water to be treated must be determined. The prolonged bath treatment in a tank or raceway where water flow is interrupted requires the calculation of the volume and corresponding weight of the water column to be treated. Volume calculations are as

Table 3. Amount of Chemical Added to Various Volumes to Achieve a Final Concentration of 1 ppm (mg/L)

1 ppm (mg/L) =	1 ppm (mg/L) =
2.72 lb/ac-ft	0.0584 grains/gal
1233 g/ac-ft	1.0 mg/L
1.0 oz/100 ft³ (cubic feet)	0.001 g/L
0.13 oz/1,000 gal	8.34 lb/1,000,000 gal
3.78 g/1,000 gal	1 g/m³ (cubic meter)
0.0283 g/ft³	1 mg/kg
0.0000624 lb/ft³	10 kg/ha-m
0.00378 g/gal	

follows for a rectangular raceway, tank, or pond:

$$V = L \times W \times D$$

Here L = length (ft), W = width (ft), and D = depth of water column (ft).

Example. A rectangular raceway is 20 ft long by 10 ft wide with a water depth of 18 in.

$$V = 20 \times 10 \times 1.5$$
$$V = 300 \text{ ft}^3$$

In large earthen ponds, the calculation of the volume of the water requires determining the number of acre-feet present. An acre-foot is one surface acre, one-foot deep. Since large ponds of this type may not have uniformly deep bottoms or margins, one may determine the volume by multiplying the number of surface acres by the average depth of the pond. The volume is expressed as ac-ft.

Example. A two-acre pond has an average depth of three feet.

$$V = 2 \text{ ac} \times 3 \text{ ft average depth}$$
$$V = 6 \text{ ac-ft}$$

Calculation of Concentration (Dosage Rates) Examples

In the calculation of dosage rates for the treatment of fish diseases, it is useful to determine the number of gallons of water to be treated. The following conversions facilitate that determination: 1 ft³ = 7.48 gal; 1 ac-ft = 325,851 gal; and 1 L = 0.26 gal. It is also important to remember that many therapeutic agents are supplied in concentrations other than 100% active ingredient. Active ingredient, usually expressed as a percentage of the final packaged product, can be found on the product label. All recommendations for treatment imply a 100% active product for administration to the fish. Where such product concentrations are not 100% active, calculations must be adjusted to account for that difference. Where 2 lb of a chemical at 100% active ingredient is required to treat a tank at 1 ppm, 4 lb would be required to treat that tank if only a 50% active ingredient product is available. It is important to note at this point that there is a common exception to this rule for a frequently used FDA approved chemical. Formalin, which is supplied as a 37% solution, is considered to be 100% active when calculating concentrations for treatment.

Example of a Prolonged Bath Treatment

A rectangular holding tank that is 3 ft wide and 10 ft long with a 1.5 ft water depth requires a static hydrogen peroxide treatment at 75 ppm (hydrogen peroxide is supplied in a 35% active solution). Thus,

$$\text{Volume} = 3 \times 10 \times 1.5$$
$$= 45 \text{ ft}^3$$

Referring back to Table 3, we find that 1 ppm = 0.0283 g/ft³. Therefore,

$$\text{Amount of H}_2\text{O}_2 = (45 \text{ ft}^3 \times 0.0283 \text{ g/ft}^3 \times 75 \text{ ppm})$$
$$\div \text{AI (active ingredient)}$$
$$= 95.5 \text{ g} \div 0.35 \text{ active}$$
$$= 272 \text{ mL hydrogen peroxide}$$

For liquids, divide grams by specific gravity of liquid to obtain ml required (i.e., for H_2O sp. Gr. = 1).

Peroxide should be diluted in 1 to 2 gal of water and mixed into the tank. At the end of the treatment period the fresh water should be turned on to flush the tank. The same general calculation may be used to treat a circular tank. Only the determination of volume differs in that the formula for the volume of a cylinder is used. Thus,

$$\text{Volume} = \pi \times R^2 \times D$$

where π = 3.14 (pi constant), R = radius of tank (one-half the diameter), and D = diameter of the tank.

The volume of a round tank 10 ft in diameter with a depth of water of 4 ft would be

$$V = 3.14 \times 5^2 \times 4$$
$$V = 3.14 \times 25 \text{ ft}^2 \times 4 \text{ ft}$$
$$V = 314 \text{ ft}^3$$

Example of an Indefinite Bath Treatment

An earthen pond of two surface acres with an average depth of three feet requires a formalin treatment at a concentration of 15 ppm:

$$\text{Volume} = 2 \text{ ac} \times 3 \text{ ft average depth}$$
$$= 6 \text{ ac-ft}$$

From Table 3, we determine that 1 ppm = 2.72 lb/ac-ft. Therefore

$$\text{Amount of formalin} = 2.27 \text{ lb/ac-ft} \times 15 \text{ ppm}$$
$$= 40.8 \text{ lb}$$

One gallon of formalin weighs 10.56 lb. Therefore 40.8 lb ÷ 10.56 lb = 3.86 gal of formalin required per ac-ft to achieve a 15 ppm concentration, or 6 × 3.86 gal for the entire pond.

Constant Flow Treatment

This method of treatment administration requires the calculation of the weight of the chemical agent based upon the flow rate of the water to be treated and the time. The basic formula for such a treatment is as follows:

$$\text{Wt} = [\text{Flow (gpm)} \times (\text{ppm}) \times \text{T} \times \text{CF}] \div \text{AI}$$

where flow = rate of water inflow (gal/min), ppm = concentration in parts per million, T = treatment time (min), CF = correction factor (no. g/gal), and AI = active ingredient.

Example of a Constant Flow Treatment

A rectangular trough 4 ft long, 1 ft wide, and 6 in. deep with a flow of 5 gpm containing eyed-trout eggs requires a 1667 ppm treatment of formalin for 15 min.

$$\text{Flow} = 5 \text{ gpm} \times 15 \text{ min}$$
$$= 75 \text{ gal}$$

$$\text{Trough volume} = 4 \text{ ft} \times 1 \text{ ft} \times 0.5 \text{ ft}$$
$$= 2 \text{ ft}^3$$

$$\text{Volume} = 2 \text{ ft}^3 \times 7.48 \text{ gal/ft}^3$$
$$= 14.96 \text{ gal}$$

These values illustrate the rate of exchange of water during the treatment.

The amount of formalin required to treat a flow of 5 gpm for 15 min is as follows:

$$\text{Wt (vol) of formalin}$$
$$= 5 \text{ gpm} \times 1667 \times 15 \text{ min} \times 0.00378 \text{ g/gal}$$
$$= 472.5 \text{ g (mL)}$$

Since formalin is considered to be 100% active, the results just obtained are divided by one. The formalin used (472.5 mL) should be diluted in a volume of water sufficient to flow from the delivery vessel in 15 min. As described earlier, a plastic chicken waterer with a small hole drilled in the base of the delivery cup provides a satisfactory vessel to administer this type of treatment.

Drugs Added to the Feed

The previous discussion of treating systemic bacterial infections with drugs in the feed requires the culturist to be familiar with adding medication to existing rations. Time or unavailability of the appropriate size premedicated diet may dictate the need to prepare a medicated ration on site. Oxytetracycline–HCl, generally referred to by the trade name Terramycin (TM 50), and Romet B are the approved antibiotics usually added to fish feed. The treatments are administered on the basis of weight of drug (in grams) per unit weight of fish per day. This will usually be expressed in grams of active drug per 100 lb of fish fed per day. The calculation for determining the amount of antibiotic required is

$$\text{Amount of drug/day} = \text{Wt} \div (100 \times D) \qquad (1)$$

where Wt is the weight of fish in pounds and D is the daily dosage rate in grams.

$$\text{Adjustment for active ingredient (AI)}$$
$$= [\text{Amount of drug (g/day)}] \div (\text{g AI/lb premix}) \quad (2)$$

where AI is the active ingredient in grams active per pound of premix.

$$\text{Amount of drug/lb feed/day}$$
$$= [\text{Amount of drug/day (g)}] \div \text{lb feed consumed/day} \tag{3}$$

Fish may be fed between 1 and 3% body wt/day. It is usually advisable to use the lowest rate possible to ensure that fish consume all of the medicated ration. A 1% rate is usually acceptable.

Example 1. What is the amount of terramycin required to treat 4000 lb of fish at a rate of 4 g active terramycin per day? Assume TM 50 available at 50 g active ingredient per lb of premix. Standard treatment is 10 days duration.

Using Eq. 1,

$$\text{Amount of drug/day} = 4{,}000 \text{ lb}/100 \times 4 \text{ g}$$
$$= 160 \text{ g/day}$$

Using Eq. 2,

$$\text{Adjustment for AI} = (160 \text{ g/day}) \div (50 \text{ g/lb})$$
$$= 3.2 \text{ lb (1453 g)}$$

Using Eq. 3,

$$\text{Amount of drug/lb food} = 3.2 \text{ lb} \div 40 \text{ lb}$$
$$= 0.08 \text{ lb (36.3 g)/lb of food}$$

The drug should be added to feed with corn oil. A slurry of oil and drug is prepared using approximately one quart of oil per 50 lb of feed to be medicated. This mixture can then be applied manually in a wheelbarrow or similar sized container for 50 lb or less of feed. Larger amounts of feed may be mixed with the drug slurry in a small portable cement mixer.

As a final note in the determination of treatment rates, one should always double check calculations. If another party is available, he or she should also check the results. A slight math error can either result in no treatment effect or one of toxicity to the fish. If the fish culture operation has access to a computer, it may be desirable to acquire a program such as SAMCALC (9) to assist in treatment calculations. The latter DOS-based program provides calculations for standing and flowing water treatments as well as other useful fish culture calculations.

SUMMARY

Some infectious diseases of fish will not respond to treatment. There are no effective therapeutic agents to treat or control viral diseases. Certain parasites such as the causal organism for whirling disease, *Myxobolus cerebralis*, will not respond to any approved therapy. In some cases, as with the aforementioned pathogens, quarantine, destruction of fish, and facility disinfection are the only choices for control.

There are many chemical agents and drugs that have been employed through the years to treat various diseases. Many have been effective in controlling serious infectious diseases and parasites. However, with the aforementioned entry of the FDA's Center for Veterinary Medicine in the regulation of aquaculture therapeutic agents, many of those compounds used in the past are now prohibited for use on food fish. Chemical discharge regulations of federal and state agencies may also restrict uses that have been acceptable in the past. One should also be aware that ongoing research on chemicals used in fish health may reveal new information on efficacy and/or safety. Such information may change the status of current FDA approval. Consequently, the fish culturist should always read and follow label instructions on any therapeutic agent used to treat food fish.

DISINFECTION AND STERILIZATION

S.K. Johnson
Texas Veterinary Medical Diagnostic Laboratory
College Station, Texas

OUTLINE

Cleaning
Freezing and Heating
Filtration
Radiation
Chlorination and Ozonation
Formalin and Formaldehyde
Quarternary Ammonium Compounds
Iodophores
Miscellaneous Disinfectants
Dehydration and Fallowing

Sterilization involves the destruction of all forms of life on and in an object. Viable microorganisms, including their spores, are the usual targets. To kill the highly resistant spores of bacteria is challenging and is usually accomplished by steam under pressure or, in the case of removal from fluids, by microfiltration. Some chemicals also sterilize objects under suitable conditions, given that the chemicals are strong enough and in contact with the objects for a sufficient length of time. Effective sterilization prevents spoilage of products and the occurrence of disease.

Disinfection destroys pathogenic microorganisms associated with inanimate objects. Physical or chemical means are used to treat solid surfaces, solutions, or air. Chemical agents called disinfectants kill the vegetative stage of pathogenic microorganisms, but not necessarily their spore stage. Antiseptics are chemicals applied to living tissue for the purpose of preventing or retarding the growth of microorganisms without necessarily killing them.

In aquaculture, disinfection has widespread application as a method of sanitation. With regard to epidemiology, sanitation attempts to eliminate or suppress the presence of the initial infective unit, the inoculum. The presence of an inoculum in sufficient quantities is a requisite for disease. Other methods of sanitation include quarantine, the removal of alternative hosts, the rotation of species, and letting systems dry out or lie fallow. As a sanitary application, a narrow use of disinfection could be a foot bath, and a broader one might be the periodic distribution of chlorinated lime in growing units.

Eradication may be the goal of disinfection when intolerable disease agents are present within stocks. The decision to use eradication may come from farm management or by regulatory directive.

The term "disinfection" as commonly used in aquaculture is not as restrictive as the definition that limits the application to inanimate objects. Disinfection in the first instance could mean, for example, chemical applications to living eggs, fish, and food, as well as to equipment, supply water, and facilities. Perhaps aquaculturists use the term "disinfection" instead of "antisepsis" or some other term because the objective is usually to destroy the inoculum rather than to restore animal health. Thus, we usually find that in aquaculture, an effort to destroy all vegetative stages of pathogenic microorganisms, particularly in one short interval of time, is called disinfection. Strong chemical application to the fishless water medium of a confinement system, for example, is disinfection. On the other hand, chemical applications intended to destroy surface-dwelling parasites on swimming hosts are said to be treatments.

The effectiveness of disinfection is scalar in many situations in aquaculture. An effective method must not be too expensive and cannot involve unacceptable human or

environmental risk. Further, the use of an effective, safe, and inexpensive application is not practical in cases where reinfection is highly probable. Contaminated surface water supplies, replacement stocks, and vectors are common sources of reinfection.

Survivability and longevity of pathogens in host-free environments are an important part of disinfection strategy. *Edwardsiella ictaluri* and *Edwardsiella tarda* infections, for example, may become serious over time, due to the ability of these pathogens to survive for long periods in pond mud. Following release from a fish, myxosporan spores and nematode eggs are able to survive for relatively long periods prior to consumption by a second host. Disinfection may not be an appropriate option if environmental persistence of the pathogen is very short. On the other hand, if the pathogen can survive for a long time, one must determine the economic feasibility of disinfection.

Following the removal of stock from culture systems, environmental conditions, especially temperature, affect the persistence of agents. Generally speaking, obligate microbial parasites (i.e., viruses) remain viable for several days in water of 25 °C (77 °F), but at 4 °C (39 °F), they may be viable for weeks or months. Particularly for viruses, and also for many other obligate parasites, knowledge is greatly lacking about reservoir organisms and their possible influence on environmental persistence of the viruses or parasites.

Except when a facility is out of production, disinfection of growing systems must take into account the infected stock. Market-size animals that have been infected may be sold commercially under certain circumstances. Otherwise, an acceptable practice is removal of the animals and burial or incineration. If the target of disinfection is a parasite that uses a secondary or a reservoir host in its developmental cycle, the application must be able to destroy any remaining alternative hosts.

A variety of system components are subject to disinfection: equipment, such as buildings, pipes, tanks, biofilters, nets, floors, boots, and a variety of fomites; culture water and pond soil; in put of water food, stock, and air; and output of effluent, pests, debris, and dead fish.

CLEANING

A preliminary cleaning accompanies many kinds of equipment disinfection. Cleaning removes the garden of sessile organisms and the buildup of organic grime that coat solid surfaces and make up part of sediments. Organic coatings, both living and dead, cover, occlude, and shield potential pathogens, often sustaining their viability and making them less vulnerable to actions that aim to disinfect. Tanks and other equipment are normally scrubbed with brushes or scrub pads of various designs. Extensions such as poles on brushes or pads make for easier scrubbing. Following the initial scrubdown, further cleaning with detergents may be beneficial if detergent properties include compatibility with ionic constituents of the water and ease of removal.

FREEZING AND HEATING

Freezing temperatures in drained pond systems have a disinfecting effect on certain cold-sensitive parasites, such as coccidians. Otherwise, viruses, bacteria, and many parasites tolerate freezing conditions for rather lengthy periods.

Heat exchangers of some hatchery systems heat water to temperatures that are intolerable to some microbial pathogens. Heating of water is suitable only for very small systems or system components. The cost of heating is higher than that of applying of ultraviolet radiation.

Applications that employ steam sterilization are rarely used. Application of moist heat (steam) at room atmospheres to tanks, floors, and object surfaces typical of aquaculture operations is ineffective in destroying many kinds of microbes, because the high temperature is not held for a sufficient duration.

FILTRATION

The primary use of filtration in aquaculture is to remove solids from supply water; it rarely is used for water sterilization. However, the effect of filtration may greatly determine the success of subsequent applications of disinfection. Removing particulate matter also removes a large complement of microbial associates, adding efficiency and economy to methods that follow.

RADIATION

Ultraviolet light at wavelengths of approximately 2500 to 2650 Å effectively destroys vegetative stages of many pathogens. However, practicality, output, and cost limit application to small systems, such as hatcheries, where the use of ultraviolet radiation is especially common. Surface water supplies must receive some pretreatment by sedimentation or filtration to make the water suitable for radiation, as ultraviolet light does not penetrate very far into water, and solids can block its path to a target.

CHLORINATION AND OZONATION

Chlorination and ozonation are useful for disinfecting water supplies. Introduction of chlorine to a water supply is accomplished by feeding it directly or, more commonly, by introducing it as a solution. In either case, an effort is made to attain a concentration of 0.2 to 0.5 mg of chlorine per liter of water (0.2 to 0.5 ppm) for 20 to 30 min of contact time or 3 to 5 mg/L (5 ppm) for 1 to 5 min. The water may then be passed over charcoal for chlorine removal. Calcium hypochlorite is used as a chlorine source in the disinfection of some small systems. Application is achieved by addition to head tanks or by use of dispensers.

When chlorine dissolves in water, it reacts to form hypochlorous acid, hydrogen, and chloride. Hypochlorous

acid then forms an equilibrium with hypochlorite ions. Water acidity affects the presence of the stronger disinfectant, hypochlorous acid, producing a more favorable level in acidic pH ranges. The alkaline nature of seawater and, to some degree, the ionic constituents therein diminish the effectiveness of chlorine.

Electric discharge and ultraviolet irradiation of a suitable wavelength produce a three-atom form of oxygen (ozone) from the ubiquitous two-atom form. Ozone has strong oxidative properties. As air flows past the irradiation tubes, some conversion of oxygen to ozone occurs. Ozone output from electric discharge (corona discharge) equipment is much greater. The electric-discharge method uses either gaseous oxygen or atmospheric air. If air is used, it goes through pretreatment to remove impurities and moisture. Contacting devices are of many designs, but bubbling of the ozonator output is a common feature of most. As with chlorine, the concentrations of ozone needed to kill pathogens are near those that are harmful to culture animals. A special head tank is commonly placed between a supply source and the animal unit to control contact and avoid over-exposure of the animals. Contact concentrations are around 3 mg/L (3 ppm) of water, with residuals of below 0.15 mg/L (0.15 ppm). Ozone may also be removed with charcoal prior to use.

Ozone produces clear water and improves biofilter function. In good management design, it is safe for fish. However, the cost of equipment and use is relatively high. The diligence required to monitor residuals can also be costly.

The general organic content of water quickly reduces the oxidative power of both ozone and chlorine. In practice, an effective attack on viable pathogens requires certain adjustments to compensate for the influence of dissolved and suspended organic matter.

Chlorine, in the form of calcium and sodium hypochlorites, and chloramines are commonly used for disinfection of equipment, standing water, and, occasionally, soils. However, organic substances greatly compromise the effectiveness of these agents in ponds. Nevertheless, typical applications attempt to maintain available chlorine at 200 mg/L (200 ppm) of water for 30 minutes, 100 mg/L (100 ppm) for 1 hour, and 10 mg/L (50 ppm) for 24 hours. Calcium hypochlorite, also known as chlorinated lime, has wide use and contains 50 to 70% available chlorine. All chlorine compounds pose a risk to human safety.

FORMALIN AND FORMALDEHYDE

Formalin, water containing dissolved formaldehyde, is a readily available industrial chemical. It has promise for virus destruction in many kinds of systems, including ponds. Concentrations for virus disinfection are poorly established in aquaculture, but some disinfecting activity may take place at less than 50 mg of formalin/L (50 ppm) of water. Formalin is not very effective for disinfection of gram-positive bacteria. A 1:100 mixture of formalin and water is sometime used to disinfect standing water in tanks. Formaldehyde gas has been used for the disinfection of sealed buildings. Usually, the gas is generated by heating paraformaldehyde, the polymerized solid of formaldehyde.

QUARTERNARY AMMONIUM COMPOUNDS

Quarternary ammonium compounds are widely available in numerous brands and strengths. They have widespread use in aquaculture for equipment disinfection at active-ingredient concentrations that approximate 1200 mg/L (1200 ppm) of water. They are effective to a degree in standing water at 2 mg/L (2 ppm) for one hour of contact. Quaternary ammonium compounds are effective on gram-positive bacteria and some viruses, but are less effective on fungi and gram-negative bacteria.

IODOPHORES

Iodophores are generally available at 1% solution. They are organic compounds that release free iodine. Application of iodophores gives an amber tint to the water and causes the pH of soft water to drop. Acidity of the water promotes disinfectant activity, the iodine being more effective in more acidic conditions. A customary concentration for disinfection of standing water is 50 mg of active ingredient per liter (50 ppm) of water and, for equipment, 250 mg/L (250 ppm). Iodophores effectively disinfect bacteria and some viruses.

MISCELLANEOUS DISINFECTANTS

Application of calcium hydroxide and calcium oxide to ponds provides a degree of disinfection to the bottom mud of empty ponds. Their effectiveness is uncertain, but surely the abrupt shift in pH destroys many life forms. Similarly, 2% sodium hydroxide exposes microbes to an extreme pH when applied to nonmetallic equipment. Phenols and cresols sometimes find use in foot baths, but troublesome residuals deter other uses in aquaculture. Ethyl and isopropyl alcohol at strengths of 50−70% are effective disinfectants for equipment, but their volatility and flammability may restrict some applications. A dilute solution of hydrochloric acid also has potential as a disinfectant.

DEHYDRATION AND FALLOWING

Dehydration of equipment or entire culture systems provides a degree of disinfection, and in some cases, it may be the most practical action. Drying easily destroys fragile stages of many parasites, and dry surfaces have greater exposure to the effects of ultraviolet light and oxidation. Excessive sun exposure, however, greatly shortens the life of equipment such as seines. The combination of dryouts and certain lengths of time is often successful against obligate disease agents, which have a limited amount of time for which they can survive without a host. Reservoir and secondary hosts also may perish using this method.

DISSOLVED OXYGEN*

Robert R. Stickney
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

The level of dissolved oxygen (DO) available to the animals in an aquaculture system is perhaps the most critical among the water quality variables routinely monitored. If a sufficient level of DO is not maintained, animals become stressed and may not eat well. In addition, their susceptibility to disease can increase dramatically. In the worst instance, the animals may die. Even slight reductions in DO below the minimum desirable levels can lead to reduced growth rates and suboptimal food conversion efficiencies (FCE). DO depletions can be exacerbated when the culturist provides food to animals that are not eating properly since waste feed decomposes and increases the oxygen demand on the system.

A few aquaculture organisms such as walking catfish (*Clarias* sp.) and tilapia (*Oreochromis* spp.) are able to tolerate low DO without apparent consequence, but most are not. Aquaculturists must measure the level of DO in their water system frequently, be familiar with the minimum DO level tolerated by the species with which they are working, and be prepared to take remedial action when a DO deficiency is detected.

SOURCES, SINKS, AND ACCEPTABLE LEVELS

Oxygen is dissolved in water by diffusion from the atmosphere and through release into the water as a byproduct of photosynthesis in aquatic plants. Diffusion from the atmosphere is aided when turbulence occurs.

For example, during windy weather, more water surface area is placed in contact with the atmosphere than when the water is calm. The greater the surface area of water in contact with the atmosphere, the more diffusion will occur.

When air or pure oxygen is bubbled into a water body, the action increases the amount of water surface that is in contact with the gas. The small bubbles produced from an air stone in an aquarium provide a large amount of surface area. Oxygen transfers from the bubbles to the water by diffusion.

All aquaculturists recognize that respiration is a normal physiological function of animals and that the removal of oxygen from water through respiratory activity

* This entry was adapted from Stickney (1) with permission.

can greatly impact the DO level. Many do not realize, however, that plants respire continuously. During daylight and above the compensation depth (1% light level), photosynthesis should produce more oxygen than is being consumed by both plant and animal respiration. In some instances, oxygen production is so great that the water becomes supersaturated. Oxygen may then be lost to the atmosphere. At night, no oxygen is produced, so only diffusion is operating to replace the oxygen removed through plant and animal respiration. Usually, the respiratory demand during the night is not sufficient to reduce the DO to critical levels, but under some circumstances a deficiency can occur.

Oxygen can be removed from water as a result of certain inorganic chemical reactions (chemical oxygen demand or COD) and through the decomposition of organic matter by microorganisms. The oxygen required by the microbial decomposition plus the oxygen demand associated with plant and animal respiration is called the biochemical oxygen demand (BOD). The BOD test is empirical and has been standardized for use in many types of water (2). The BOD in aquaculture systems becomes important when large amounts of aquatic vegetation are decaying (e.g., after a pond has been treated with a herbicide) or when dead animals are allowed to decompose in the water system. A high BOD can trigger an oxygen depletion.

As a general rule, if the DO concentration is greater than or equal to 5 mg/L (ppm), conditions relative to this parameter should be acceptable for aquatic organisms (3). None of the species currently being reared by commercial aquaculturists seem to require a level above 5 mg/L (ppm), and some species can tolerate DO levels well below 5 mg/L (ppm) with little or no resultant stress or impact on growth. Even so, many culturists prefer to see DO levels at or near saturation at all times. Several species of tilapia survive at DO concentrations as low as 1 mg/L (ppm) (4,5) and continue to grow rapidly, even if exposed to periods of such low levels on a daily basis (6). Other species suffer severe stress or die if exposed to such low concentrations, though most perform well at 4 mg/L (ppm) and may survive for extended periods at 3 mg/L (ppm). While most fish species can tolerate 1 to 2 mg/L (ppm) for brief periods, mortality occurs if exposure to those levels exceeds a few hours (7). Salmonid culturists worry when DO levels fall below 5 mg/L (ppm), while catfish farmers usually find levels of 3 mg/L (ppm) or higher acceptable.

The amount of oxygen that can be dissolved in water under ambient equilibrium conditions is called the saturation concentration. DO solubility is dependent on various factors, with temperature, salinity, and altitude being the most important. The DO saturation concentration decreases as temperature, salinity and altitude increase. At high temperatures and salinities, the DO saturation value exceeds 5 mg/L (ppm) at sea level. Thus, unless some other factor leads to an oxygen depletion, the water utilized in most aquaculture facilities should have the capacity to hold sufficient oxygen to support the species being reared. A mariculture facility located at high altitude (e.g., a recirculating system located in the mountains), could face a chronic oxygen problem

because of the inability to maintain the desired level at saturation without supplemental oxygen.

Supersaturated oxygen conditions can occur, as previously indicated, when the rate of photosynthesis by aquatic plants is high. Levels of DO as high as 30 mg/L (ppm) are not uncommon under some conditions.

Supersaturated oxygen is not usually a problem in aquaculture.

MEASURING DISSOLVED OXYGEN

The aquaculturist should routinely monitor DO to ensure that depletions in the water system are not occurring. Daily measurements should be made at or before dawn, particularly in culture chambers where oxygen depletions are anticipated. Details regarding the causes and steps that can be taken to alleviate problems are presented in the next two sections of this entry.

DO concentration can be measured by Winkler titration (2) or with an oxygen meter. Both methods can determine DO to within 0.1 mg/L (ppm). Oxygen meters provide readings within seconds, while the titration procedure requires a few minutes, the availability of several chemicals, and some items of glassware including a burette or calibrated eyedropper for titration. Oxygen meters are quite reliable. Maintenance of models used by scientists usually involves infrequent battery replacement and periodic replacement of the membrane covering the end of the probe and the fluid within the probe.

Selection of a DO meter should be made with consideration of the environment in which it is to be used. For freshwater culture systems, temperature and altitude compensation are required, while mariculturists should employ a DO meter that is salinity and temperature compensated. For DO meters that do not have built-in compensation features for each of the desired parameters, conversion tables are generally provided by the manufacturer.

A good-quality DO meter costs a few hundred dollars, while titration kits are less expensive. DO meters save time, however, and the need to replace chemicals and broken glassware used for titration may make the meter the more economical choice in the long run.

With the advent of computerized monitoring systems for aquaculture operations, continuous monitoring of various water quality parameters has become routine in some situations. DO meters are among the types of equipment that are used for constant monitoring of culture systems. Computers can be programmed to process data collected through the meters, and alert the culturist by telephone in the event that the DO dips below the critical level (as determined by the aquaculturist).

CAUSES OF OXYGEN DEPLETIONS

Changes in the behavior of many aquatic species can indicate to the aquaculturist that an oxygen depletion is occurring. Feeding activity often decreases or ceases completely (decreased feeding activity can also be a response to other problems or an aspect of normal behavior). When DO becomes critically low, many fish will rise to the water surface and appear to gulp air. Crawfish climb on emergent vegetation to place their gills in contact with the atmosphere. Shrimp often move to shallow water when the DO level is low. Shrimp farmers frequently check their ponds at night by shining a flashlight into the water. If shrimp are concentrated in the shallow water, the oxygen may be low. When the shrimp move quickly away from the light, the situation is typically not critical. However, when the animals ignore the light, the problem may be severe.

In ponds, sufficient oxygen is usually provided by photosynthesis during daylight and atmospheric absorption at all times to maintain the DO above the critical level. Flowing water systems may require continuous aeration in order to maintain the desired DO level. As biomass and the amount of feed put into the culture chambers increase during the growing season, maintenance of the required DO level may become increasingly difficult. In ponds, the problem is exacerbated by high primary production rates because of the added respiratory demand at night. Temperature plays an important role due to the direct effect it has on the solubility of oxygen in water and also because a rise in temperature increases the metabolic rate of the organisms in the system.

In temperate climates, DO problems in ponds are fairly predictable. During spring, primary production may be high, but animal biomass tends to be relatively low and the water temperature is cool, so DO depletions tend not to be a problem. In the fall, the water temperature cools once again, and primary production may show a somewhat lower peak than observed in the spring. Biomass may be reduced from the higher summer levels through harvesting and a reduction in feed rate, thus, DO problems are not too common. During winter, the temperature is low, the feeding rate may be reduced (or feed may not be offered), the biomass may be further reduced due to harvesting, and primary productivity is slowed because of temperature. Unless a pond is ice covered and subjected to winterkill from oxygen depletions, DO deficiencies should not occur.

Summer is the season when most factors work against the maintenance of high DO levels in ponds. The temperature is at a maximum, so the solubility of oxygen is lowest. Biomass and feeding rates are typically approaching maximum levels for the year, and while primary production may have declined considerably from the spring high, crashes in phytoplankton blooms can occur leading to greatly increased BOD as the cells decompose. Respiration by all the organisms in the pond is at its highest level, and the decomposer community places a considerable demand on the available oxygen.

Declines in phytoplankton are also associated with periods of cloudy weather that reduce the amount of available sunlight and restrict the photic zone. During cloudy periods, the water temperature might cool somewhat, thereby increasing the solubility of oxygen. However, the aquaculturist should be aware that cloudy weather can trigger the crash of a phytoplankton bloom.

Typically, the lowest level of DO that occurs in a pond over any 24-hour period will coincide with dawn because

respiration takes place in the absence of photosynthesis from about dusk the day before. Throughout the day, oxygen should increase as photosynthesis occurs. In a system at equilibrium, the diel pattern in DO may lead to a minimum level that is acceptable [5.0 mg/L (ppm) or more] at dawn. At about dusk, the level may be a few milligrams per liter higher, and the pattern will continue with little change from day to day. Ponds do not tend to be at equilibrium. As discussed previously, the photosynthetic rate can change significantly with temperature, the level of nutrients present, and the amount of light as influenced by cloud cover. At the same time, the demand on oxygen from respiration is constantly being altered as biomass changes. These and other factors tend to lead to a net change in DO concentration from one day to the next. The change may be either upward or downward and varies among ponds.

By monitoring pond DO early in the morning, preferably, close to dawn, the culturist will be able to predict when a problem may be imminent. To the delight of aquaculturists, particularly those with a large number of ponds, few ponds respond in exactly the same way, even when stocked at the same rate and subjected to the same management practices. It has been said that no two ponds are alike, and that tends to be true with respect to DO curves. Thus, a culturist may see critically low DO levels in one or two ponds on a given day, but it is rare when a large percentage of ponds at a given facility experience depletion problems.

In aquaculture facilities other than ponds, primary productivity is not usually a major factor, although cages and net pens are sometimes an exception. For tanks and raceways in flow-through or recirculating configurations oxygen depletions often occur due to the increasing respiratory demands of biomass increases. Failure of a biofilter can quickly lead to DO problems in a recirculating system, as can a reduction or loss of water input in any flowing system. Routine determination of DO can be accomplished at any time of the day in systems that are not subjected to diel fluctuations related to the photosynthetic cycle.

OVERCOMING OXYGEN DEPLETIONS

When a DO depletion is detected, immediate action should be initiated to restore the DO to a safe level. Several means can be used to accomplish that restoration. The addition of large amounts of well-oxygenated new water to a culture system will quickly raise the DO level. New water often comes at a premium, and if it comes from a well, it may contain little or no oxygen. Thus, other means of aeration are commonly used.

Any technique that increases the surface area of water in contact with the atmosphere increases the amount of oxygen in the exposed water. Aeration with compressors or air blowers is typically used in small systems. While such systems can sometimes be used in ponds, they are often not practical. Other ways of getting oxygen into water include aeration with compressed air, bottled oxygen, and liquid oxygen. Again, while commonly employed in tank and raceway systems, those sources of oxygen are not usually

used on ponds or with cages and net pens. Aquaculture aeration systems and their efficiencies have been reviewed by Boyd and Watten (8).

An excellent means of aerating ponds is to circulate the water. By continuously bringing deep water to the surface, the entire water volume can be put into motion. Splashing water increases the amount of surface area in contact with the atmosphere, but it may not completely mix the pond. Some commercial aeration devices draw water from below and throw it up in the air, where it becomes oxygenated. The water then falls back into the pond and is recycled through the aerator. The net result is an improved DO level in the immediate vicinity of the aeration device but not in the entire pond.

Total pond mixing can be accomplished with paddle-wheel aerators which are typically operated by electric motors or from the power takeoff of a tractor. Tractor-driven paddlewheel aerators are commonly used in the United States where stocking levels are not so high that all ponds in a complex require daily aeration. Most farmers only have one or two such aerators available (no more than the available number of tractors) that can be quickly moved from pond to pond as the need arises. If very high densities are stocked, and the farmer knows that DO problems will be chronic in a number of ponds, it may be necessary to provide an aerator for each, in which case, electric devices are preferred. Engle (9) reported that when a pond requires less than 250 hours of aeration per year, a tractor-driven paddlewheel is more efficient from an economic standpoint than an electric one, but that the electric motors are more efficient when more than 250 hours of aeration are required. Pond size influences efficiency as well, with floating electric paddlewheels being the more efficient choice in large ponds.

Paddlewheel aerators do not need to splash a great deal of water to be effective since their primary purpose is to turn over the pond. The splashing action may provide some psychological benefit because the farmer can clearly see that something is happening. Boyd and Watten (8) discussed a number of paddlewheel designs along with other methods for aerating ponds.

When an oxygen depletion is anticipated, preventative measures can be taken. Paddlewheel or other types of aerators can be operated through the night. Oxygen-rich new water can also be added to flush the pond. Both the addition of new water and aeration are often used by the catfish farmers in Mississippi during the period of the year when biomass and feeding rates are at their highest levels and the water quality is difficult to maintain. The addition of new water reduces the amount of suspended organic material by flushing it from the pond. As a result, the BOD is significantly reduced.

Culture animals should not be fed when an oxygen depletion is anticipated or has recently occurred. The stress associated with oxygen depletion often causes the animals to reject feed, so the ration will only serve to increase the BOD when it decomposes. Stress that does not result in death of the animals may make them susceptible to diseases. Epizootics may occur as soon as 24 hours after an oxygen depletion or as much as two weeks later. The culturist should be aware of that time frame and watch the

animals closely. Treatment is more effective if a disease is detected early rather than after a full-blown epizootic develops.

Potassium permanganate ($KMnO_4$), a strong oxidizing agent, has long been used by fish culturists at the rate of about 2 to 3 mg/L (ppm) in instances where oxygen levels are low. The theory supporting the use of potassium permanganate is that the oxidation of organic matter will lower the BOD and chemical oxygen demand (COD). Tucker and Boyd (10) found that 2 mg/L (ppm) of $KMnO_4$ killed over 99% of the gram-negative bacteria present and a considerable percentage of the gram-positive bacteria. In addition to the oxidizing activity, potassium permanganate will release free oxygen directly into the water.

Boyd (11) reported on studies of the effectiveness of potassium permanganate and concluded that ponds treated with the chemical early in the morning actually recover more slowly than untreated ponds. He also examined the chemistry of the permanganate ion in water and found that free oxygen is released; however, the number of milligrams per liter of potassium permanganate that would be required to release 1 mg/L (ppm) of O_2 is at least 6.58 mg/L (ppm). In order to increase the DO in a pond, the amount of $KMnO_4$ needed to oxidize the organic matter present would have to be supplemented by over 6 mg/L (ppm) for each milligram per liter (ppm) of O_2 increase required. Thus, before any meaningful increase in DO could be obtained, the level of potassium permanganate required would be toxic to the fish.

Unlike ponds, the oxygen dynamics in raceways are highly predictable. Because of the rapid turnover rate that exists in most raceway systems, there is little opportunity for phytoplankton and other photosynthetic organisms to become established. As indicated by Boyd and Watten (8), the sources of oxygen in raceways are the incoming water and supplemental aeration. The amount of oxygen used by fish in respiration can be related by a proportionality constant (K_1) that correlates with the weight of oxygen consumed per weight of feed offered. Oxygen demand increases dramatically during feeding and for a period thereafter because of the increased metabolic rate associated with feeding activity and digestion.

Hydrogen peroxide (H_2O_2) can be used to generate oxygen gas and has been evaluated as a source of oxygen in conjunction with live hauling. Innes Taylor and Ross (12) described a technique by which hydrogen peroxide was used to generate oxygen in a container that was separate from the fish hauling tank.

Pure oxygen in the form of compressed gas or liquid oxygen (LOX) is increasingly being used in aquaculture systems, particularly high-density tank and linear raceway systems. LOX is often available within easy trucking distance of even remotely located fish farms in the United States. It is generally more economical to have LOX delivered than to manufacture it on site. By continuously injecting oxygen into a raceway system, much higher standing crops can be supported with a given water flow rate than with the same system operating without such supplementation.

Aquaculture of the dolphinfish (*Coryphaena hippurus*), or mahimahi is probably one of the most challenging endeavors to be undertaken by the fish farmer. These highly aggressive, yet relatively sensitive, fish are one of the most difficult species to raise in controlled environments, because of stringent water quality, nutritional, and facility design needs, as well as the constant care required throughout all stages of their life. The mahimahi has generated interest as a potential aquaculture candidate because of its reputation as a high-value fish,

large worldwide consumer demand, good feed conversion, spontaneous spawning, and rapid growth rate. Although difficult to culture, mahimahi can be raised using relatively streamlined methods. Successful culture requires placing emphasis on appropriate facility design and paying close attention to details throughout all stages of production.

WATER QUALITY

Mahimahi are a fast-swimming, primarily oceanic fish. They are distributed worldwide in tropical and subtropical oceans within 20 °C (68 °F) isotherms and usually within the 30°-latitude range (1). Culture is generally restricted to temperatures between 18 and 30 °C (64 and 86 °F), but most research has been conducted at temperatures between 24 and 28 °C (75 and 82 °F). The mahimahi's growth rate varies greatly with temperature, particularly during early developmental stages. Its growth rate to 40 days of age doubles with a 2 °C change in rearing temperature, from 26 to 28 °C (79 to 82 °F) (2). Differences in the growth rate during growout between 24 and 28 °C (75 and 82 °F) are less apparent (3), but temperatures much below 20 to 24 °C (68 to 75 °F) will limit growth (4,5).

Mahimahi are physiologically adapted to open-ocean environments that are generally highly oxygenated and virtually free of bacteria and sediment. This species can be successfully cultured only in pristine environments that have very low levels of dissolved organic and particulate matter and are devoid of parasites. Mahimahi appear to be poorly adapted to hypoxic (i.e., low oxygen) conditions, and it is recommended that they be maintained in waters as oxygen saturated as is practical, and not below 82% oxygen saturation [i.e., 5.5 parts per million (ppm)] (6). Signs of stress begin to occur at oxygen saturation levels below 90% (5.97 ppm) (7,8). Hypoxia-related mortality occurs at an oxygen concentration between 4.3 and 4.4 ppm (between 65 and 66% saturation) (6–8). Also particulate matter causes gill aneurysms in mahimahi, which lead to death (9).

BROODSTOCK

Mahimahi reach sexual maturity at approximately 5–6 months of age [with a standard length of 45–55 cm (17.7–21.6 in.)] in captivity and produce 100,000–250,000 eggs every other night (2,10–12), with spawns of greater than 500,000 eggs possible. Fecundity (the number of eggs released) is related to fish size (Fig. 1), but egg quality is highly variable (9,13). Mahimahi spawn in captivity without artificial inducement.

Both wild-caught and hatchery-reared mahimahi can be used as broodstock. Wild-caught animals adapt readily to life in captivity and, if sexually mature, may begin releasing eggs within a few weeks after being caught in the open ocean. Mahimahi are easily excitable and prone to rapid swimming bursts. Care must be taken to avoid mortality caused by fish ramming themselves head first into the side walls of tanks. Doughnut-shaped tank designs (10) for holding broodstock have proven especially
Figure 1. Relationship between weight (kg) and age (D = days after hatching) of female mahimahi and the number of eggs spawned. Data from The Oceanic Institute (9).

useful for preventing this problem, as they restrict perpendicular movement (Fig. 2). Reproductively active males are highly aggressive, and, typically, only one male is paired with one to three females. Broodstock are usually fed a raw diet of chopped squid and fish, either with or without supplemental vitamins (2,10,11,14), or are fed raw mashes of raw ingredients and some fishmeal. Successful spawns have been obtained from fish fed pelleted diets (2), but pelleted diets are not preferred by either wild-caught or hatchery-raised broodstock. Broodstock usually eat from 5 to 14% of their body weight daily in raw feed (2,9,11).

Mahimahi broodstock are easily stressed and intolerant of poor water quality, rapid changes in water quality, parasitic infection, and disease. Gaping of the jaws, labored swimming, and darkening of the body are indicators of potential problems in fish. Mahimahi are particularly susceptible to skin and gill parasites, including the dinoflagellate *Amyloodinium ocellatus* and the ciliate *Cryptocaryon irritans* (9). Mild infestations in which fish have not lost their appetite can be treated with brackish water [10 parts per thousand (ppt)] over a 12-hour period, or with freshwater dips for five minutes.

EGG INCUBATION AND HATCHING

Although mahimahi spawn frequently, poor egg quality (e.g., small yolk, multiple oil droplets, and asymmetry of embryos) is not uncommon among broodstock and is largely unpredictable between spawned batches (9,13,15). Survival prior to first feeding is typically monitored. Larval rearing will either be maintained or abandoned, depending on the survival rate, and a new batch of eggs or larvae stocked. Mahimahi eggs are 1.4–1.6 mm (1/18–1/16 in.) in diameter and contain a single oil droplet about 0.3 mm (1/83 in.) in diameter. Viable eggs are buoyant at 30–35 ppt salinity and hatch within approximately 40 hours after fertilization at 25–27 °C (77–82 °F). Kraul et al. (16) have reported that the hatch rate and yolk sac survival are higher in tanks with turbulence. High concentrations of calcium and magnesium are important for hatching and larval survival (17). Survival rates during
Figure 2. Mahimahi broodstock tank design with egg collector. The doughnut tank is 6.1 m (20 ft) in diameter, with an inner ring that is 3.0 m (10 ft) in diameter. Adapted from Kim et al. (2) and the Oceanic Institute (9).

incubation can range from 40 to 70% (2). Broodstock nutrition and stress are generally thought to play key roles in egg quality, while the physical and chemical factors of water quality compound the survival of prefeeding larvae.

LARVAL REARING

Widely diverse methods have been successfully employed in mahimahi larviculture. For example, publications by Kraul et al. (16), Kraul (10,18), and Szyper (10) describe feeding methods that employ rotifers (with algae), copepods, and yolk sac larvae of mahimahi as live foods. Kim et al. (2) have described a more streamlined method that utilizes *Artemia* (brine shrimp) as the sole live food source, and no algal inputs. Feeding trials have shown a 14% greater survival rate through first feeding when rotifers are offered instead of *Artemia*, although the additional cost of culturing rotifers and their algae feed is not offset by the potential increase in first-feeding success (19). Similarly, mass culture of copepods may not be practical for commercial hatcheries, due to low yields (20). Pilot farms have focused on use of *Artemia* as the first, and generally only, live food item, with no algal inputs during larviculture (21,22). Rotifers (with algae) are preferred when rearing temperatures are below 26 °C (79 °F) (9).

High mortality and fast growth rates are characteristic of larval mahimahi culture. Survival rates of up to 40% have been reported from stocked larvae (16), but rates of 10−20% are more common (9,10,22). Larvae are typically raised in 5,000-L (1,323-gal) circular tanks and stocked directly as eggs or prefeeding larvae. Separate, 1,500-L (397-gal) tanks have also been used for egg incubation and first feeding to concentrate prey, with larvae being transferred to clean 5,000-L (1,323-gal) tanks during the second week of development (9). Stocking densities in 5,000-L (1,323-gal) tanks range between 1 (10,18) and 5 larvae/L (4 and 19 larvae/gal) (9).

Mahimahi larvae undergo continuous, rapid organogenesis and tissue differentiation during the early larval stage and are extremely sensitive to environmental change. (See Table 1.) Mahimahi do not possess a swim bladder, and emphasis is placed on digestive system development to support rapid larval growth. During the third week, weight gain increases dramatically, corresponding with the completion of metamorphosis and an increase in feeding rates. Overall, larval mahimahi grow from 0.5 to 60.0 mg (1.8×10^{-5} to 2.2×10^{-3} oz) wet weight from day 0 to day 20, yielding an instantaneous gain in weight of approximately 25% wet body weight daily (9).

Dietary lipids (fats) play a key role in growth and survival of mahimahi larvae, and an understanding of lipid nutrition during early developmental stages has helped advance the use of more streamlined methods of production. Lipids are the primary endogenous energy source of eggs and prefeeding mahimahi larvae (23), and it appears that mahimahi eggs and larvae are well adapted to exploiting diets high in lipids upon transition to exogenous food sources. During the first week of development, the total amount of dietary lipids is more important in supporting good survival and growth of larvae than is the fatty acid profile (i.e., the exact makeup of the fat). The rate of survival to seven days of age was higher in mahimahi larvae fed rotifers high in lipid content than those with a low lipid content, regardless of the fatty acid profile (24). A higher algal-lipid

Table 1. Timetable for Mahimahi Larval Development at 26−28 °C (79−82 °F)

Days of Age	Morphology	Standard Length (mm)
0	Hatching	2.8
3	Onset of feeding	4.2
7	Gut coiling	6.0
8	Notochord flexion	6.3
10	Red blood pigmentation	6.7
12	Onset of metamorphosis	8.0
17−20	Completion of metamorphosis	14.8
20	Yellow pigmentation	18.5

content may have explained better first-week survival rates of mahimahi that were fed rotifers cultured on the algae *Tetraselmis chuii* than mahimahi fed rotifers cultured on *Nannochloropsis oculata* (25), despite the suggestion of a poor fatty acid profile in the former. During the second week of development, however, the fatty acid profile of the lipid becomes important, and larvae must obtain a dietary source of the essential highly unsaturated fatty acid (HUFA) docosahexaenoic acid (DHA), to support good growth, survival (26), and stress resistance (27) through metamorphosis. Like other marine species (28), mahimahi larvae are unable to manufacture DHA from endogenous (24) or dietary precursors (24,26), but instead contain an endogenous store that supports survival over the first week of life (24). Typically, the DHA content of rotifers and *Artemia* is fortified with commercially available enrichment products. The presence of replete endogenous stores allows unenriched rotifers or newly hatched *Artemia* (which cannot be enriched) to be used successfully as first-feed items. Ostrowski and Divakaran (24) have recommended that diets for first-feeding larvae be high in both lipids and DHA, for maximum benefit.

The timing of live-food additions and enrichments is of utmost importance in mahimahi culture. A composite feeding schedule from the various methods employed is presented in Figure 3. As indicated in the figure, mahimahi can be fed diets deficient in DHA through the first week of development, but must receive either copepods (which are high in DHA) or enriched *Artemia* toward the beginning of the second week (5–7 days of age). Preferential retention of DHA in body phospholipid (biomembrane) fractions appears to be related to survival over the first week of development (24), but the DHA becomes diluted to low body levels as fish grow (24,26). Mass mortality occurs between 8 and 12 days of age if larvae are continued on DHA-deficient diets (26,27,29). A pulse-feeding technique in which discrete, large doses of 2- to 3-day-old (36 to 48 hours) enriched *Artemia* are fed to larvae throughout the day, beginning around 5 days of age, has been described by Kim et al. (2). Since *Artemia* rapidly lose the benefits of enrichments, pulse feeding ensures consumption of nutritionally replete *Artemia* and delays gut evacuation time, to ensure that digestion is maximized. Larvae will typically gorge and ingest the majority of *Artemia* offered within a half hour of their presentation.
Figure 3. Various feeding schemes used to produce fingerling mahimahi from the hatchery. Adapted from Kim et al. (2) and the Oceanic Institute (9); schemes B and C are adapted from Kraul (10) and Szyper (11). Weaning denotes the period of transition from live or raw food to pelleted feeds.

A break from the normal grouping pattern of sated larvae indicates when a pulse of *Artemia* should be applied (9). It is generally believed that mahimahi have very high DHA requirements, and enrichments containing at least 30% DHA are recommended for use (2,9). By the beginning of the third week (ca. day 15), larvae are nearing completion of metamorphosis (postflexion stage), and emphasis should be placed on ensuring that larvae consume sufficient amounts of live feed, to support rapid growth. *Artemia* alone (2), or combinations of *Artemia*, newly hatched mahimahi or other fish larvae, and copepods are used (5,10,11,16,18) as feed.

NURSERY

The period between 20 and 45 days of age is often marked by unacceptably high mortality rates, often nearing 80% of all fish stocked (2,5,9,16,21,22,30). During that period, fish are trained to accept dry, pelleted feeds, and natural agonistic behaviors peak. Juvenile mahimahi frequently chase and nip siblings during daylight hours. Cannibalism typically occurs when there is a sufficient size disparity among siblings, although individuals who are attacked and killed are not always eaten. Fish that are too small or weak are especially vulnerable, although aggressive behavior can be exhibited by any individual, regardless of size. It is not uncommon for fish that cannabalize to die from attempting to consume too large a sibling that then becomes lodged in the fish's mouth.

Research has concentrated on ways to improve survival in the nursery stage through manipulating system design, feed type, feeding rate, and stocking density, but the issue has yet to be fully resolved. Brownell (31) has indicated that, although tail nipping was immediately halted by the introduction of food to fish that had been deprived for more than one hour, nipping occurred to prefeeding levels within 15 minutes, whether food remained or not. No effect on nipping frequency was observed when refuges or floating objects were introduced into tanks, or when the fish density increased. Kim et al. (32) obtained best growth and survival rates of fish at an initial stocking density of 0.5 fish/L (1.9 fish/gal); however, growth and survival rates were better at 3.0 fish/L (11.3 fish/gal) than at other intermediate densities [i.e., 1.0, 1.5, 2.0 fish/L (3.8, 5.7, 7.6 fish/gal, respectively)] tested. Crowding appears to be beneficial in a commercial setting, because aggressive individuals have difficulty targeting and chasing victims.

Shallow-water tank designs coupled with continuous feeding regimens have proven successful in improving nursery survival rates to 60% for mahimahi (2) and almost eliminating cannibalism in other marine carnivores (33) (Fig. 4). Shallow water with a strong, directional current facilitates the transition of fish from live to pelleted feeds by making pelleted feeds more attractive and available to the fish: Shallow water increases the contact between
Figure 4. Shallow-water tank designs used to wean juvenile mahimahi to pelleted feeds in the nursery (20−40 days of age). Oval and circular designs are shown in the overhead view. Details of the circular design is shown in the side view. From the Oceanic Institute (9).

the feed particles and the fish, and strong water current animates the feed particles. The current also forces fish to occupy their time by swimming against the directional flow, which makes them less prone to attack their siblings, and provides a means by which an attacked individual can quickly escape an aggressor. Other methods, such as using protracted weaning periods and combinations of several live feed items, including yolk sac larvae, yield survival rates of up to 50% (5,10,11,18). Overall survival from stocked larvae through the nursery phase typically ranges from 2.5 to 10%.

GROWOUT

Successful growout is the most critical component of profitability in a mahimahi farm. During this phase, the cost and value of an individual fish increases ten- to twentyfold, depending upon the size of the fish at harvest. Thus, each fish represents a substantial investment in feed, labor, capital, equipment, and utilities.

Mahimahi are the most rapidly growing species yet that has been considered for intensive aquaculture development (34,35). They reach a harvest weight of about 1.7–2.0 kg (3.7–4.4 lb) at 180 days of age (12,21,22,30,35), yielding an instantaneous increase in the rate of weight gain of 4.0–4.2% body weight daily from an initial 5 grams (0.2 oz) at stocking at 40–45 days of age. Successful growouts to 4.5 kg (9.9 lb) have been achieved at eight months (240 days) of age (21), and growouts to 5.4 kg (11.9 lb) have been found at 8.7 months (261 days) of age (13). Ostrowski (30) has reported good growth of males to 4.0 kg (8.8 lb) to 240 days of age, but the average growth of females and the mixed population was much slower. On average, males are typically 15–35% larger than females by 180 days of age (9,30). The slower growth of females may be due to the energy required in gonadal development prior to and during maturation (120 to 180 days of age): At 150 days of age, ovaries makeup 6.0% of the total body weight of females, while testes make up only 0.5% of the total weight of males (30).

Mahimahi have been raised at commercial densities in sea cages and onshore in both flow-through and recirculating tank systems. Nel (21) raised 2-kg (4.4-lb) fish in onshore flow-through tanks 4.0–8.0 m (13.1–26.2 ft) in diameter to a harvest density of 25–30 kg/m^3 (1.6–1.9 lb/ft^3). Kraul and Ako (13) used doughnut-shaped tanks to raise fish to 10 kg/m^3 (0.6 lb/ft^3). Ostrowski (30) achieved densities as high as 20 kg/m^3 (1.2 lb/ft^3) at loading rates of 1.0 kg/L/min (8.3 lb/gal/min) in trials conducted in circular tanks 7.3 m (24.0 ft) in diameter. Hagood (22) raised fish to 12–15 kg/m^3 (0.7–0.9 lb/ft^3) to final harvest in circular tanks (both flow through and recirculating) 5.4 m (17.7 ft) in diameter. The Oceanic Institute (9) achieved densities of 19 kg/m^3 (1.2 lb/ft^3) and raw-water loading rates of 4.2 kg/L/min (34.9 lb/gal/min) with near-85% water recirculation in a semirecirculation system.

Several growout attempts in circular, salmon net pens [ca. 8 m (26.2 ft) in diameter, 4.0 m (13.1 ft) deep] have been conducted in Australia (21), the Bahamas (4,22), and Tahiti (37), and the use of these pens for growout of mahimahi appears promising. However, problems that have been encountered in these areas include parasitic infections (22,37), and predators (22), and low seasonal water temperatures [less than 21 °C (70 °F)] that limit growth (4,21).

Practical, pelleted diets have been successfully used in mahimahi growout, yielding very low feed conversion ratios (FCRs), or the amount of dry-matter feed consumed to the wet body weight gain of the fish. FCRs increase with fish age (Table 2), but overall, are less than 1.7 for growout to all sizes. Nel (21) has obtained an FCR of 1.2 from two to eight months of age, yielding a final mean weight at harvest of 4.5 kg (9.9 lb). Kraul and Ako (13) have reported an FCR of 1.6 for growout of 8.7-month-old fish to 5.4 kg (11.9 lb).

Feed type is of utmost importance in mahimahi culture, and because of stringent requirements, there are few commercial formulations presently available that promote good feeding and growth rates for this species. Pilot farms have used commercial diets, in-house formulations, or a combination of both (21,22). The most important factor in a mahimahi diet is the quality of the fishmeal (38). Only those diets made with high-quality, low-temperature-processed fishmeal are sufficiently palatable to mahimahi to promote high feeding rates, good feed utilization, and rapid growth. Chemical quality indices for choice of fishmeal for mahimahi culture are defined in (38).

Research has shown that mahimahi grow most rapidly and efficiently on diets that are high in protein and moderate in lipids and carbohydrates. Practical diets containing between 55 and 60% protein (dry-matter basis), 10 and 14% lipids, and less than 12% carbohydrate balanced at 32–35 mg of protein/MJ (132–147 mg of protein/kcal) metabolizable energy (values for rainbow trout) are recommended for rapidly growing juveniles (39). In practice, mahimahi have been successfully raised with diets containing between 53 and 60% protein and 12 and 22% lipids (5,22,40,41). Primary protein sources are either fishmeal or other marine animals products, although mahimahi can use some level of plant-based proteins as well. Soybean meal can be used effectively at up to 20% in diets (40–43). Soybean or corn oil can also be used,

Table 2. Composite of Estimated Feed Conversion Ratios^a for Periods of Mahimahi Growth at ca. 26–28 °C (79–82 °F)^b

Age (days)	Change in Weight (grams–grams)	Specific Growth Rate (% body weight/day)	Feed Conversion Ratio (dry feed fed/gain in wet body weight)
40–60	5–40	10.4	0.7
60–90	40–250	6.1	0.7–0.8
90–120	250–700	3.4	0.8–1.0
120–150	700–1250	1.9	1.0–1.4
150–180	1250–1800	1.2	1.5–2.1

^{a}FCR = dry feed fed/wet body weight gain.
^{b}The changes in weights have been rounded to the nearest whole number and are based on typical numbers reported. Specific growth rates {SGR = [(final weight/initial weight)/(days in period)] × 100} are calculated as a percentage of the body weight gain per day from the beginning of each period. The overall FCR from 40 to 180 days of age ranges from 1.0 to 1.2.

but the diet should contain between 1.0 and 1.3% HUFAs (30,44). The amino acid requirements of mahimahi have been estimated from body tissue analyses (45). Mahimahi are unable to synthesize taurine (46).

Mortality in growout is a key issue that must be overcome for commercial success of mahimahi culture. Reported growout survival rates to 180 days of age range from 62 to 80% (a mode of 70%), depending upon what age the fish were stocked at, the density of the stocked population, and the system used (13,21,22,30). Major causes of mortality have been identified (3,30) and are usually associated with a particular period or stage of development. Mortality is generally higher during the early stages of growout. Chronologically, the first potential problem encountered in mahimahi growout is caudal peduncle (47), or red-tail disease, which is most prevalent in nursery fish and 40- to 90-day-old fish in growout (30). Red-tail disease occurs after opportunistic *Vibrio* sp. (48) and *Myxobacteria* sp. (47) bacterial infections of wounds caused by tail-nipping. Bloating, or a gross enlargement of the stomach, is caused by an accumulation of fluid in the stomach one to two hours after feeding. It occurs in fish fed pelleted diets and most often in fish between 40 and 90 days of age (9,49). The exact cause of bloating is not known, and the percentage of affected fish varies, but the extent of the condition is accentuated under conditions of stress — e.g., low dissolved-oxygen levels, excessive handling (9), and poor diet quality (5,9).

Mortality due to physical trauma and shock associated with the impact of fish ramming head first into the side walls of tanks is especially prevalent during the latter stages of growout (after 120 days of age), when fish reach over 500 g (1.1 lb). Hemorrhages within the brain cavity have been observed in fish examined soon after death by such an incident. Foam padding installed in tanks 6.1 m (20 ft) in diameter reduced collision mortality from 34% to 13% of the total mortality observed in growout (9,30). Doughnut-shaped tanks proved very useful in nearly eliminating all collision mortality (13,37).

MARKET AND ECONOMICS OF PRODUCTION

Commercial-scale production of mahimahi is technically feasible, but profitability relies largely on mastering commercial-scale production methods and optimizing the market price received for the product. Wild-caught mahimahi support major commercial and sport fisheries within their range and are found on the menus of many upscale restaurants worldwide. Cultured mahimahi is considered a quality product, but there is reluctance to pay higher prices for the cultured product when wild fish are normally obtained cheaply through commodity channels (50). Additional problems encountered include the fact that a product smaller than 4.5–6.8 kg (10–15 lb) is generally considered inferior, largely due to processing concerns. Production of larger [4.5-kg (10-lb)] fish, establishment of niche markets ("pan-sized" mahimahi), and increased awareness of the advantages of the cultured product [e.g., consistent supply; quality control; and a 50–60% fillet yield (4,12,21), as compared with 40–45% in wild fish]

need to be pursued (50). Market studies in Australia in 1995 (51) indicate that it is unlikely that the price for cultured fish will fall below A$8.00/kg (A$3.64/lb), yielding an internal rate of return of 26%, and that a price of about A$10.00/kg (A$4.55/lb) is more likely. Several attempts to establish farms in Hawaii (22,37), Australia (21), Florida, the Bahamas (4,22), Tahiti (37), and Greece (5) did not advance to fruition, because various technical, financial, and market assumptions were not met. Currently, one mahimahi pilot farm is in operation in Tahiti (37), and the potential for production is still being pursued in Australia (21) and Florida (22).

OUTLINE

Types of Drugs
Regulatory Concerns
Implementation and Cost
Bibliography

This entry provides a general introduction to the use of drugs for achieving optimum aquatic animal health, including a discussion of drug approval regulations related to fish treatment. The intent is to provide essential background information that will help the managers of modern intensive aquaculture production facilities to understand the complex drug approval process and to participate effectively in the decision to treat their fish. As the author is most familiar with the North American situation, readers in other areas may wish to review requirements for their particular jurisdiction.

Various chemicals have been used as drugs to treat fish since the first person reared fish in a captive environment, and trial and error over many years has produced a cupboard full of these traditional chemical treatment options. Examples of such traditional treatments are malachite green to control fungal infections and potassium permanganate for external parasites. For a very good detailed discussion of these chemicals and their use, the reader is referred to Herwig (1). That comprehensive reference summarizes an exhaustive amount of material on treatments, dosages, and indications for a broad selection of chemicals.

Surprisingly, few of the traditional chemical treatments are approved for use in the treatment of aquatic animals today. The reasons for this situation are frequently more a consequence of the regulatory approach for drugs than the nature of the chemicals themselves. However, some traditional chemical treatments can be toxic and have untoward side effects. Caution is required when considering any chemical treatment of foodfish.

Selection of a drug for treatment requires first that the producer obtain a correct and complete diagnosis of the problem. Accurate diagnosis is usually the result of close cooperation between the producer and a professional consultant with fish health experience. Specific drugs and treatment dosages in use in contemporary aquaculture are not listed here, because the most straightforward and safest method for determining the dosage of drugs is to use only approved drugs and to follow precisely directions on the drug's label. The list of approved drugs also differs in each country, and a single list provided here would not be correct for all readers. The consequences of unapproved drug use can be devastating for an intensive food-producing aquaculture business. For specific information on drugs approved for use in aquaculture in the United States, the reader is referred to the *Guide to Drug, Vaccine and Pesticide Use in Aquaculture* (3). An excellent summary of drugs used internationally is also available (2).

TYPES OF DRUGS

A drug can be broadly defined as any chemical that modifies a physiological process in an animal. Regulatory agencies adopt this type of broad definition in deciding whether a compound is a drug and therefore whether it requires regulatory approval before it can be manufactured and sold for use. Food and Drug Administration (FDA) officials in the United States determined, after their opinion was sought, that some surprisingly common substances, such as ice and salt, are drugs. These common substances have since been classified by the FDA as of "low regulatory priority," as their use is not going to generate concern; a list of these compounds is readily available (3,5).

For the purposes of this article, a drug is considered to be a chemical that has, in addition to the aforementioned physiological effects, enough potential to cause harm such that its manufacture, sale, and use are controlled through regulatory restrictions. Pesticides are a very similar class of chemical, with the subtle distinction that they are generally applied externally to animals or the animals' environment with the intent to kill a specific targeted pest. However, this distinction between drugs and pesticides is not sufficient to merit independent consideration in this article, and the term "therapeutant" is occasionally used to include both drugs and pesticides that are used for animal treatment. A drug may be applied prophylactically, to prevent a disease outbreak, or therapeutically, to control an outbreak already underway or to produce a physiological change (e.g., as anesthesia or to induce spawning). Vaccines, also called biologics, consist of immunologically active material derived from modified remnants of disease-causing organisms suspended in a liquid carrier. Vaccines are almost always applied prophylactically, to prevent outbreak of a disease by "jumpstarting" the fish's immune system.

Therapeutants can be classified according to their different biological properties, including antibacterial, antiparasitic, antiviral, antifungal, anesthetic, and hormonal activities. Therapeutants from each of these groups are used in terrestrial agriculture and are finding similar opportunities for use in aquaculture (except for antiviral drugs, which have great potential, but are not used, because the few products available for animal use are cost prohibitive). Also, there are many other varieties of drugs used in human and companion-animal medicine that have not found a place in the treatment of food animals, for health and economic reasons.

Antibacterial drugs, often called antibiotics, are perhaps the best known group of drugs in use in agriculture and aquaculture and are discussed by another author in this text. Readers may also consult a recent scientific review of the use of antiinfective drugs in aquaculture (4).

Antifungal drugs are also very important in aquaculture, because of the rapid invasion of *Saprolegnia* fungi into the skin and eggs of freshwater fish. A traditional,

and very effective, antifungal treatment has been topical exposure to malachite green (sometimes mixed with formalin) in a bath (1). However, malachite green has some drawbacks that make it unlikely ever to receive regulatory approval. First, it is not a pure substance, as it represents a mix of related dyes, and it has teratogenic potential (that is, it may cause defects in developing embryos). Additionally, malachite green residues are very persistent in the tissues of treated fish. Therefore, use of malachite green is now discouraged, even in some countries where it had previously been accepted. However, there are a few alternative candidates under development for fungal control as bath treatments, including hydrogen peroxide and formalin. In aquaculture, antifungal drugs are not presently used in feed, although systemic fungal infections occur sporadically.

Antiparasitic drugs are an increasingly important treatment category for fish producers. Parasitic infestations that occasionally need to be managed through chemotherapy include ectoparasitic (on the outside of the fish) crustaceans (e.g., sea lice), ectoparasitic protozoa (e.g., *Trichodina*), intestinal helminths (e.g., *Eubothrium*), and intestinal or systemic protozoa (e.g., *Hexamita*). Antiparasitic treatments may be administered topically (e.g., formalin baths for control of *Trichodina*) or as in-feed preparations (e.g., fumagillin for treatment of sporozoan infections). Organophosphates and pyrethroids are used as baths to control sea lice infections, while insect growth regulators (chitin inhibitors) and avermectins have been used systemically. Systemic anthelmintic and antiprotozoal drugs are likely to become increasingly important for future fish culture industries, just as helminth and coccidial controls are critical components of terrestrial agriculture health management.

Anesthetics and sedatives have important roles in aquaculture production. Fish anesthesia and sedation are essential for reducing the stress of management procedures, such as handling, grading, weighing, vaccinating, and transporting fish. Formulations of tricaine methane sulfonate are approved in many countries and are frequently used as fish anesthesia. A new development is the use of sedatives that do not require a withdrawal period because they do not result in unacceptable tissue residues. One example of this kind of drug is Aqui-S, licensed in New Zealand for sedating salmon. This type of drug can be used for sedating aquatic animals before they are transported to the processor, resulting in better flesh quality and shelf life.

Hormonal treatments alter the physiological state of the fish by causing an increase or decrease in levels of the chemicals that regulate normal bodily functions. These treatments can increase growth rates, induce a fish to initiate spawning, or force a young genetically female fish to develop into a male adult. Generally, hormonal treatments must be used at the right time to be effective, so that they work in conjunction with natural developments in the fish. For example, administration of additional growth hormone will not have the desirable effect on a fish that has reached its full body size and is not growing. Hormonal treatments have found uses in aquaculture in controlling the timing of spawning in intensive production

facilities and assisting in the production of single-sex populations, which are essential for optimum fish production in some situations. Use of hormones for growth promotion is not a standard practice in aquaculture.

Drugs can also be classified according to their route of administration. Some are administered to aquatic animals topically, by application to the skin surface, while others are given systemically (that is, for distribution throughout the body). However, these distinctions are not as clear-cut for aquatic animals as for terrestrial animals. This is because a topical treatment for fish is applied as a bath, with the result that some of the drug will be absorbed by the gill tissue, and some of the drug could also be swallowed. The most practical method for systemic treatment of intensively cultured aquatic species is through addition of medication to the feed. This technique is known as oral administration and in most systems will also result in some drug exposure to the gills and skin. Systemic treatment by injection is rarely used in aquaculture, because of the labor cost, and is a procedure that is generally reserved for an all-out attempt to save particularly valuable animals, such as ornamental koi carp. However, injectable vaccines have become important in the last few years, because of the effectiveness of these products in controlling gram-negative bacterial infections of salmon — particularly furunculosis and vibriosis.

Pharmacokinetics is the study of what happens to a drug after it is applied to an animal. This discipline is still at an early stage for aquaculture species, and most of the available information was developed in the last 10 years. However, the general stages of a drug's journey through an aquatic animal are analogous to the stages described for all other animals and include absorption, distribution, metabolism, and excretion phases.

Drug entry into a fish begins with absorption through the skin, gills, intestine, or other surface tissue. In some cases, the drug's chemical may be changed before absorption — for example, through the action of intestinal enzymes and stomach acids — and these changes may have significant impacts on its biological activity. Following absorption, the drug is distributed throughout the body by blood flow, and most drugs will then selectively concentrate in particular tissues. Knowledge of this selective concentration is very important in choosing an appropriate drug treatment. An ideal treatment (sometimes termed the "silver bullet") will target the tissue affected by a particular disease problem, while building up minimal residue in the edible parts of the fish, particularly the muscle. Once the drug is absorbed into the body, the fish begins to metabolize it by breaking it down into components or binding it to other molecules. These changes convert the drug into an inactive, or perhaps more toxic, "metabolite." Finally, the fish eliminates the drug by excreting it and its metabolites. Elimination may occur through a variety of routes, including excretion in the feces or urine or across the skin or gills.

The pharmacokinetic behavior of drugs is usually extremely complex, with an unlimited possible range of different behaviors. The limited current knowledge of aquatic-animal pharmacokinetics is a factor that contributes to the uncertainty of regulatory agencies and increases the cost of developing new therapeutants for

aquaculture. One example of such limitations is the lack of information on how well-detailed pharmacokinetic data for one aquatic species can be used to predict drug behavior in another species. For example, will the drug-residue depletion time measured in a salmon be the same in a halibut a catfish, or an oyster? The answer to this question has important implications for determining the amount of data required to develop a list of approved species for inclusion on the drug's label. Answers to such questions are being sought through significant "crop grouping" research projects currently underway and should help to reduce the cost of drug approvals for aquatic animals.

Another pharmacokinetic complexity is that aquatic animals are poikilotherms (cold blooded), and as such, their metabolic rate and activities are affected by changing water temperature. This complexity is not found in the much better understood mammalian and avian (homeotherms) physiological systems, which remain within a nearly constant temperature range. Decreasing the water temperature generally slows the metabolic actions of aquatic animals, causing slower drug absorption, metabolism, and excretion. One important consequence of this effect is the possibility of longer residue retention in aquatic animal tissues following treatment. Also, fish eat less when the temperature cools below their optimum level, leading to lower dietary intake of a drug in feed. Lower intake, combined with slower drug absorption because of a reduced metabolic rate, may lead to both reduced drug effectiveness and lower tissue residue levels. These factors require that the metabolic state of the fish and the predicted changes in the environment of the fish over the weeks following treatment be considered carefully when planning the treatment. Scientists have begun to develop physiologically based pharmacokinetic models that map out drug behavior under changing environmental conditions, and these models offer the promise of providing much more specific treatment plans and withdrawal periods for medicating aquatic animals, based on the specific circumstances anticipated for each treatment.

Increasing the dose of a drug does not lead to a proportionally greater change in the effect on the aquatic animal being treated. Biological systems have a very limited number of response options, and there tends to be a limited range of possible changes within these options. Negative responses, such as lost growth, poor reproductive performance, and increased mortality, will result if biological systems are pushed beyond their capabilities. A graph of the changing effects on a fish exposed to different drug doses is called a dose response curve. The one consistent feature of dose response curves is the indication that "if some is good, more is not necessarily better." The optimal treatment effect is achieved by carefully following the recommended drug dosages, which have been calculated based on scientific evaluation of the dose response curve.

The drug that a producer buys is rarely a pure substance. Most drugs are part of a formulation that includes the active ingredient together with other compounds that act as carriers, dispersants, stabilizers, etc. These other compounds are called excipients, and they may have an impact on how the drug behaves in treated fish. Regulatory agencies approve the complete drug formulation, rather than just the active ingredient, thereby taking into account the total effect that the treatment will have. The formulation will have a trade name that is different from the chemical name of the active ingredient, which is the pure drug substance. For example, the fish anesthetic drug tricaine methane sulfonate may be bought in two different formulations that have government approval in the United States: TMS and Finquel.

The drug dosage is often expressed on the label in terms of the amount of active ingredient to be applied per unit of body weight (e.g., milligrams active ingredient per kilogram fish weight). This dosage would be very different if it were expressed in terms of the amount of formulation per unit of body weight. Therefore, producers need to know the concentration of active ingredient in a drug formulation when calculating how much substance to add to the water or feed (the inclusion rate). A second key number when calculating in-feed medication dosages is the feeding rate, which is usually expressed as a percentage of body weight (e.g., 2% of body weight per day). This number indicates how much feed the animals will consume and therefore the weight of drug that must be included in the feed such that each fish will receive the correct dosage. These calculations always need to be rechecked before mixing feeds or administering treatments, and, ideally, a second knowledgeable, independent person should review the figures.

REGULATORY CONCERNS

Consumer concerns regarding drug safety and the potential for chemical contamination of foods are the driving force for substantial regulatory oversight of therapeutants worldwide (although there is no single regulatory system in use globally). These consumer concerns are perhaps greater than warranted, considering how remarkably little evidence there is that treatment of food animals has caused harm; instead, treatments help to provide abundant high-quality produce. Perhaps the success of treatments is a result of the stringent regulatory controls, which allow producers to ensure that their food products are safe by scrupulously complying with regulatory requirements regarding therapeutant use. Unfortunately, these regulatory approval requirements significantly increase the cost of approved therapeutants; however, confidence in the safety of approved therapeutants is a benefit to the aquaculture producer. Approved drugs have been shown through rigorous scientific examination to be safe and effective. The label on the container of a therapeutant lists appropriate cautions to follow in order to protect the workers administering the drug and to ensure the quality of aquatic-animal products subsequently shipped to consumers. The prudent producer will reread the label of every therapeutant before every use and then be sure to follow all of the precautions and heed all of the warnings listed on the label.

One problem for aquaculture producers around the world is the lack of approved safe and effective drugs for treatment of aquatic animals. This problem is the result of two conflicting forces: the high regulatory approval costs and the low potential sales values within different countries. The company that sponsors a therapeutant for

approval is required to pay for development of the complete scientific data package needed to obtain approval, as well as to cover the costs of subsequent regulatory requirements associated with keeping the therapeutant on the market. As a result, it simply is not cost effective for some companies to market their therapeutants. For example, one formulation of the active ingredient sulfamerazine is approved for use in aquaculture in the United States; however, the manufacturer reportedly no longer makes this product available, because the market is insufficient to cover the costs of meeting ongoing regulatory requirements. If the estimated potential sales are insufficient to justify the research investment required for approval, then drug sponsors will not develop new treatments for aquaculture.

Regulatory agencies recognize the economic pressures that prevent drug approvals for aquatic animals. Similar problems are seen in other animal-production operations, and these disadvantaged groups are often grouped together and termed "minor species." Drug manufacturers do not develop new treatments for minor species, with the result that drugs approved for use in aquatic animals are almost always formulations of different chemicals that have already received approval for use in other food animals, often called "major species."

Aquatic animals are a minor species in most countries, including all of North America and Europe, and approved drug availability for aquatic animals is a problem that will not be easily resolved without a significant change in the present regulatory approach. A new public understanding is required that recognizes the potential benefits to society of ensuring that approved safe and effective drugs are available to aquatic-animal producers. Additional public funding, carefully directed, is also essential to complete the necessary scientific data for approval. Gaining this public understanding will be an important step forward in facilitating the development of new food-producing activities, such as aquaculture.

Research and data requirements for therapeutant approval have very similar general outlines in developed countries. However, there can be considerable variation in the specific details that regulatory agencies want to see. These differences are another factor that increases the costs of drug approval, and further advancements toward internationally harmonizing the specific approval requirements are needed. Streamlining the scientific research requirements among several countries will help to solve the economic dilemma that discourages sponsors for aquatic-animal therapeutants and will lead to a better climate for developing the necessary scientific data for approval.

Drug regulatory approval requirements are divided into the general categories of manufacturing, human safety, environmental impacts and target-species efficacy and safety. The manufacturing data prove that the drug's active ingredient is a pure and stable compound that is prepared under standardized conditions and that the active ingredient is mixed only with other standardized compounds in the final formulation. These data ensure that the producer who purchases a drug receives the exact product identified on the drug label and that the product has a known shelf life, as indicated by the expiration date.

Human safety data are frequently the most costly part of the data package. Specific short- and long-term toxicity tests must be performed on the drug and its major metabolites, to determine the level of risk that the drug poses to humans. If the results of the toxicity tests are acceptable, then the sponsor must provide data that show exactly how rapidly residue levels decrease in a treated aquatic animal and that identify the tissues that contain residues for the longest period of time.

Key numbers that are calculated from the drug residue depletion and safety data are the allowable tissue tolerance level [or maximum residue level (MRL)] and the withdrawal period for the drug. The withdrawal period is the amount of time required following the administration of the last treatment for measurable residues of the drug or a metabolite to decrease to below an established safe level. This safe level is the MRL, or tolerance. The withdrawal period begins on the day after the last treatment has been administered. In some countries, withdrawal periods are provided in degree–days—to account for the impact of water temperature on fish metabolism—and in other countries, they are provided as calendar days, sometimes with recommended changes in the withdrawal period for different water temperature ranges. Careful attention to the withdrawal period is a very important aspect of treatment administration, and producers need to maintain complete records that show the treatment completion dates on aquatic animal stocks. These stocks must be identifiable from the time of treatment until harvest. If a group with one withdrawal completion date is mixed with a second group that has a later date, then the whole group must now be assumed to have the later withdrawal date. If a particular group is unidentified or mislabeled, then it should be assumed to have the latest withdrawal date of any treated group on the production site.

Occupational safety data are another part of the regulatory human safety consideration. Producers reduce drug administration hazards through appropriate employee training on safe drug handling. Failure to ensure that necessary precautions are in place and to abide by all warnings and cautions on the drug label can have harmful consequences. For example, repeated exposure to some treatments without appropriate protection—for instance, the organophosphate parasite treatments developed for sea lice control—could result in injury to aquaculture production—site employees.

Approval data relating to the potential environmental impact of drugs for aquatic animals is the basis for increasing regulatory action—and confusion. The challenge is to develop data that will accurately measure the environmental effects of drug use and then to assess the acceptability of these effects to society. There is no doubt that drugs which are used because of their effects on the physiology of aquatic organisms will also affect other animals (nontarget organisms) in the environment. However, determining the level of impact on nontarget organisms that is acceptable is a challenging task and is more a question of subjective opinion than a scientifically measurable number. Laboratory tests can show that a drug has a toxic impact on selected aquatic animals at specific concentrations, but how is this information to

be interpreted? At present, regulators look primarily for evidence that the chemical is broken down readily in the environment and does not accumulate in the food chain.

Further regulatory confusion arises in assessing the environmental impact of a drug when more than one government agency is involved in giving a decision on chemical use. Separate agencies frequently have very different perspectives on acceptable impacts, with one group of scientists typically having responsibility for drug approval and another having responsibility for pollution control. As a result of their different perspectives and responsibilities, the agencies may arrive at different answers to the same request for approval, based on the same data. For example, a drug may be approved for use in aquatic animals, but discharge of water will not be permitted if the drug is actually used at a production site. This situation has occurred, for example, in the United Kingdom, where drug approval authorities accepted a sea lice drug, while the Environmental Protection Agency did not approve discharge of the same drug. This contradiction will not be resolved until government authorities determine when an impact is acceptable, recognizing that it is impossible for any drug to produce no impact at all.

Drugs for aquaculture use have come under greater scrutiny for environmental impact than have drugs that have been submitted for approval for terrestrial food-animal agriculture. This is partly because of the increasing public concern about environmental degradation and partly because the addition of drugs to water is perceived to have a greater potential impact, due to greater distribution in the fluid medium. The validity of these concerns remains to be evaluated; however, the situation has substantially increased the costs for aquaculture drug development packages.

Finally, the regulatory data on the target species are usually the least expensive part of the approval package. These data are also of most interest to the producer and include results of research on the safety and effectiveness of the drug for its intended use in aquatic animal species. Treatment safety is assessed by exposing fish to multiples of the proposed dosage and through prolonged treatment beyond the proposed duration. Additionally, an adverse-reaction reporting system is in place in many countries, to collect relevant information on occasions when a treatment has apparently resulted in an unwanted side effect. Drug efficacy is shown through rigorous laboratory tests against the intended target, followed by dosage determination studies to find the most appropriate treatment level. These studies are followed by field trials that assess the performance of the drug for its intended use under production conditions.

The lack of approved aquaculture drugs in many countries has resulted in an increased need for interim regulatory mechanisms that allow drug use on a temporary or experimental basis. In the United States, the Investigational New Animal Drug (INAD) exemption has permitted producers to assist in the development of drug approval data, while providing controlled interim access to an unapproved drug. The Investigational New Drug (IND) exemption in Canada and Animal Test Certificate (ATC)

in the United Kingdom provide similar opportunities in these countries. In Norway, the drug regulatory authority provides an exemption that allows a drug manufacturer to sell the drug for commercial use after several key portions of the data package have been reviewed, but before full approval is granted.

New changes in regulatory requirements for drug use in fish production facilities are occurring as a result of the introduction of mandatory hazard analysis critical control point (HACCP) regulations for seafood safety inspection. The European Union, Canada, and the United States have all recently introduced seafood safety regulations based on variants of the HACCP principles. These mandatory food safety regulations are directed at fish processors, but they have an effect on aquaculturist drug-use practices, because of the concern that chemical residues in treated fish could present a hazard.

The fish processor, under the HACCP regulation, is required to have in place a plan to evaluate aquaculture animals (including lobsters from a pound) received at the plant loading dock and ensure that these products are free of residues beyond allowable tolerances. This change puts more responsibility on the processor to ensure that producers comply with safe and effective drug-use procedures. Good record keeping, good communications between the producer and processor, and the use of approved drugs according to the directions on the label are important components for managing under the new regulatory requirements. For details on this topic, the reader is referred to Chapter 11 of the *Fish & Fisheries Products Hazards & Controls Guide* (5).

IMPLEMENTATION AND COST

Safe and effective chemical treatments need to be available as options for the producer to manage fish health when problems arise. However, the objective of the producer is to avoid drug treatment unless it is necessary, because even if the treatment is cost effective, avoidance of a health problem in the first place is even more cost effective. The producer can work with fish health professionals to develop a sound health maintenance program for the operation that reduces the probability of later intervention and treatment.

When treatment becomes necessary, there are many considerations to keep in mind while administering the medication, in order to achieve a positive result. The first step is to make sure that any preexisting conditions that predispose aquatic animals to the occurrence of disease are corrected. For example, a treatment for infectious bacteria or parasites will knock back the agents of a disease for a while, but it is important to ensure that preexisting problems or situations are corrected to allow the fish to continue to fight off the pathogens once the treatment is complete. Drug treatments cannot be a substitute for good management, and they cannot make a poorly cared-for animal prosper.

If the proposed treatment has not previously been tried on the production site or is not a standard industry treatment procedure, it is wise to pretest the intended dosage on a small group of representative animals. Treated

animals should be closely observed during the hours after administration has been started, and farm workers need to be prepared to discontinue the treatment immediately if there is any evidence of an adverse effect. Fish mortality data can be closely monitored during a longer treatment application.

The producer also has a responsibility to minimize the development of resistance to treatment among local populations of pathogenic parasites and bacteria. Sensitivity testing is an essential part of effective management of infectious agents, although emergency treatment may sometimes need to be initiated before laboratory results are obtained. The limited range of therapeutants approved for use in aquaculture is an unfortunate circumstance that predisposes aquatic animals toward developing resistance to the available therapeutants. However, management approaches can help to avoid this problem — for example, salmon farmers using single year-class sites (all in or all out), farm-site fallowing, and area management agreements among farms to reduce the occurrence of resistance and to permit continuing effective control of diseases such as furunculosis and sea lice.

A treated population should be monitored closely during the drug administration period, and treatment should be stopped if an adverse effect is suspected. Monitoring may include extra dives to check for problems that are not visible from the surface. Regulatory agencies generally have a reporting requirement for registering and publicizing observed adverse effects. Knowledge of adverse effects helps to ensure that other producers are aware of the potential for a problem and helps the whole industry to effectively manage animal treatments.

A sufficient number of trained personnel must be available to conduct a treatment, while enough staff must remain to manage routine farm duties. A crew specifically trained for the procedure may best handle certain types of treatment applications, such as tarpaulin baths for floating net pens. (Administering a tarpaulin bath to a large net pen is a very difficult and dangerous task if there are currents or winds.) Applicator training needs to address the risks of drug treatment, the appropriate precautions to take, the correct use of safety equipment, typical problems that might come up, and essential first aid if toxicity is encountered. At a minimum, the staff needs ready access to, and familiarity with, the safety information sheet, such as the MSDS, and the label on the drug.

Availability of a range of safe and effective drug treatment options will improve the producer's ability to provide a correct treatment for any problem that occurs. Additional treatment options will also help to prevent the development of resistance in local populations of parasites and bacteria. Although the number of available approved drugs may be limited, use of approved drugs helps aquaculture producers in several ways. First, the drugs meet their specific responsibilities under the country's food safety regulations, and using them encourages drug sponsors to shepherd new treatment options through the regulatory process. Producers' associations can help their members by developing a list of their top-priority fish health treatment needs and ensuring that these priorities are brought to the attention of governments, research funding agencies, researchers, and pharmaceutical companies. This action will encourage these organizations to cooperate in providing the resources necessary to develop and approve additional treatments.

One important producer concern that is not comprehensively addressed by the rigorous regulatory process is drug efficacy. An approved drug is used under a great variety of field conditions, and experience is the only way to develop a thorough understanding of the best way of using the drug under the different conditions encountered. Therefore, the producer needs access to more information than can be made available through the regulatory process. The best way to obtain this information is to work with a professional who has experience with drug treatments on similar aquaculture production operations. The essential calculation is that the cost of treatment must be less than the benefits from the improved fish survival that results from the treatment. Some costs of treatment are obvious, including the cost of the drug and the labor to apply it. Other costs are less obvious, including the impact of reduced harvesting options because of withdrawal periods following treatment, and the setback weight gain when fish are taken off feed, or are on reduced rations, during treatment. Also, some costs of treatment may be hidden, including potential long-term impact on the production-site environment from multiple treatments, and reduced drug effectiveness through resistance development in the local population of target organisms.

The best strategic approach for producers is to use approved drugs and to work scrupulously within the restrictions imposed by the label of the drug. These requirements may at times seem onerous, but they are based entirely on sound scientific evaluation. Cheaper, unapproved drug formulations may be tempting to use and may appear, superficially, to be similar to approved drugs. However, using these products is a very shortsighted strategy, as negative public opinion, which is a very real potential consequence of consistent use of unapproved drugs, poses a very high cost to the whole aquaculture production industry.

The average wholesale price of fresh Japanese sea urchin roe is approximately 14,000 ¥/kg, making it one of the most valuable seafoods in the world. Increasing demand for sea urchin roe in Japan has spurred the development of extensive domestic fishery enhancement techniques (1,2). It has also provided the incentive for a worldwide expansion of sea urchin fisheries (3–9).

With a total production of 60,000 live-weight tons of whole sea urchin per year, the world's supply of wild sea urchins has reached a plateau. However, this production level is probably not sustainable at the current population of sea urchins, since the declining productivity of exploited sea urchin stocks no longer can be offset by further geographical expansion of fisheries. To maintain or expand the world's supply of high-quality sea urchin roe is a major aquacultural opportunity awaiting commercial-scale trials.

Echinoderm culture refers to the cultivation of both sea urchins (Echinoidea) and, to a lesser extent, sea cucumbers (*Holothuroidea*). As sea urchins are more valuable than sea cucumbers, and their cultivation is more advanced, this contribution concentrates on sea urchins, although the cultivation of sea cucumbers is considered as well.

CATCH AND CONSUMPTION

The total Japanese catch of sea urchins (of which there are six species; see Table 1) and sea cucumbers (*Stichopus japonicus*) peaked in the late 1960s at approximately 27,500 tons per annum for sea urchins and 13,000 tons per annum for sea cucumber. (See Fig. 1.) Over the two next decades sea urchin landings fluctuated between 20,000 and 27,000 tons, until the catch dropped to 14,000 tons in 1991. The cause of this recent decline remains unknown, although it coincides with observations of disease-related sea urchin mortality. Even so, sea urchin landings remain two to three times greater than the steadily declining sea cucumber landings. (See Fig. 1.)

The gonads are the primary soft tissue and the only edible part of the sea urchin. The harvested gonads of both female and male sea urchins are called "roe," regardless of sex. As the most important market for sea urchins, Japan imports approximately 5,000 tons of sea urchin gonads per annum (see Fig. 2), the equivalent of 40,000–50,000 tons of whole, live sea urchins. In addition Japan imports a moderate amount of whole, live sea

Figure 3. Japanese sea urchin consumption from domestic catch and imports. The gonad index value is a conservative estimate based on the average gonad yield in commercial sea urchin fisheries in northern Japan.

urchins. (See Fig. 3.) Thus, total Japanese consumption, including the domestic catch, is approximately 60,000 tons of whole sea urchins per annum. (See Fig. 3.) The second largest consumer nation is France, with an annual consumption of approximately 1,000 tons of whole sea urchins.

PRICE

The wholesale price of whole Japanese sea urchins (all six species) was similar to the price of the Japanese sea cucumber in the 1960s, but although the price of both sea urchins and sea cucumbers continued to increase, by 1990 sea urchins were twice the price of sea cucumbers, reflecting increasing demand for quality urchin gonads. (See Fig. 4.) Fresh Japanese sea urchin gonads fetch approximately 10 times the price of whole, live sea urchins, where the average wholesale price of the gonads was almost 14,000 ¥/kg in 1993. Fresh imported sea urchin gonads fetched an average wholesale price of only 6,000 ¥/kg the same year, due to their inferior quality. (See Fig. 5.) These quality problems are related to the nutritional and reproductive status of the source population, as well as the processing and shipping routines of the suppliers. Furthermore, some harvested species of sea urchins do not produce superior quality gonads under any circumstances.

SEA URCHIN CULTIVATION

Sea urchin aquaculture in Japan is part of a multispecies fisheries enhancement effort organized by local fishery cooperatives. The three limiting factors of the sea urchin fishing industry have been identified as (*1*) insufficient food supply, (*2*) lack of suitable habitat, and (*3*) insufficient recruitment.

Sea urchin transplantation and seaweed reforestation are aimed at improving the gonad yield of undernourished adult sea urchins by providing increased access to food. Undernourished sea urchins, transplanted from barren grounds off the northwestern coast of Japan to seaweed-dominated feeding grounds off the northeastern coast, are usually ready for recapture after three months (10). The objective of seaweed reforestation is to improve the
Figure 4. Echinoderm prices in Japan.
Figure 5. Sea urchin prices in Japan.

Figure 6. Catch and cultivation of Japanese sea urchins.

Figure 7. Seedstock production of *S. intermedius* in Japan.

local food supply of undernourished sea urchin stocks by establishing algae in barren areas, through a combination of algal cultivation and overgrazing control (11). Seaweed reforestation is still an experimental technique, and transplantation of adult sea urchins is gradually being replaced by release of juvenile seedstock. Feeding of captured sea urchins is also being attempted on a small scale.

Habitat improvement and habitat creation are part of a larger ongoing fisheries enhancement program that is aimed primarily at the construction of artificial reefs (4,12). The main purpose of artificial reefs is to improve the productivity of soft substrates by creating new fishing grounds for the kind of flora and fauna that are normally associated with rocky shore habitats (e.g., edible seaweed, abalone, top shells, sea urchins, and rockfish) In a related effort, the effective surface area and habitat complexity of existing natural reefs have been increased by blasting, adding rocks, and constructing shallow channels with wave-powered water circulation (2,13).

The third limiting factor, insufficient recruitment, is still a major problem, even though the Japanese sea urchin fishery is strictly regulated to ensure that spawning stocks are not depleted. To improve recruitment, a large-scale seedstock release program has been implemented. Juvenile seedstock is produced in land-based nurseries from hatchery-reared larvae and from wild larvae collected on suspended settlement plates (10). Although seedstock production has increased rapidly in the past decade, to the current level of more than 60 million individuals per annum, the total catch of sea urchins has remained at a relatively low level since 1991. (See Fig. 6.)

The single most important species of sea urchin in Japan, *S. intermedius* (*ezo bafun uni*), accounts for
approximately 80% of total seedstock production. (See Fig. 7.) The remaining 20% is divided among the five other species, of which *P. depressus* (*aka uni*) is the most important. (See Table 1.)

BROODSTOCK MANAGEMENT

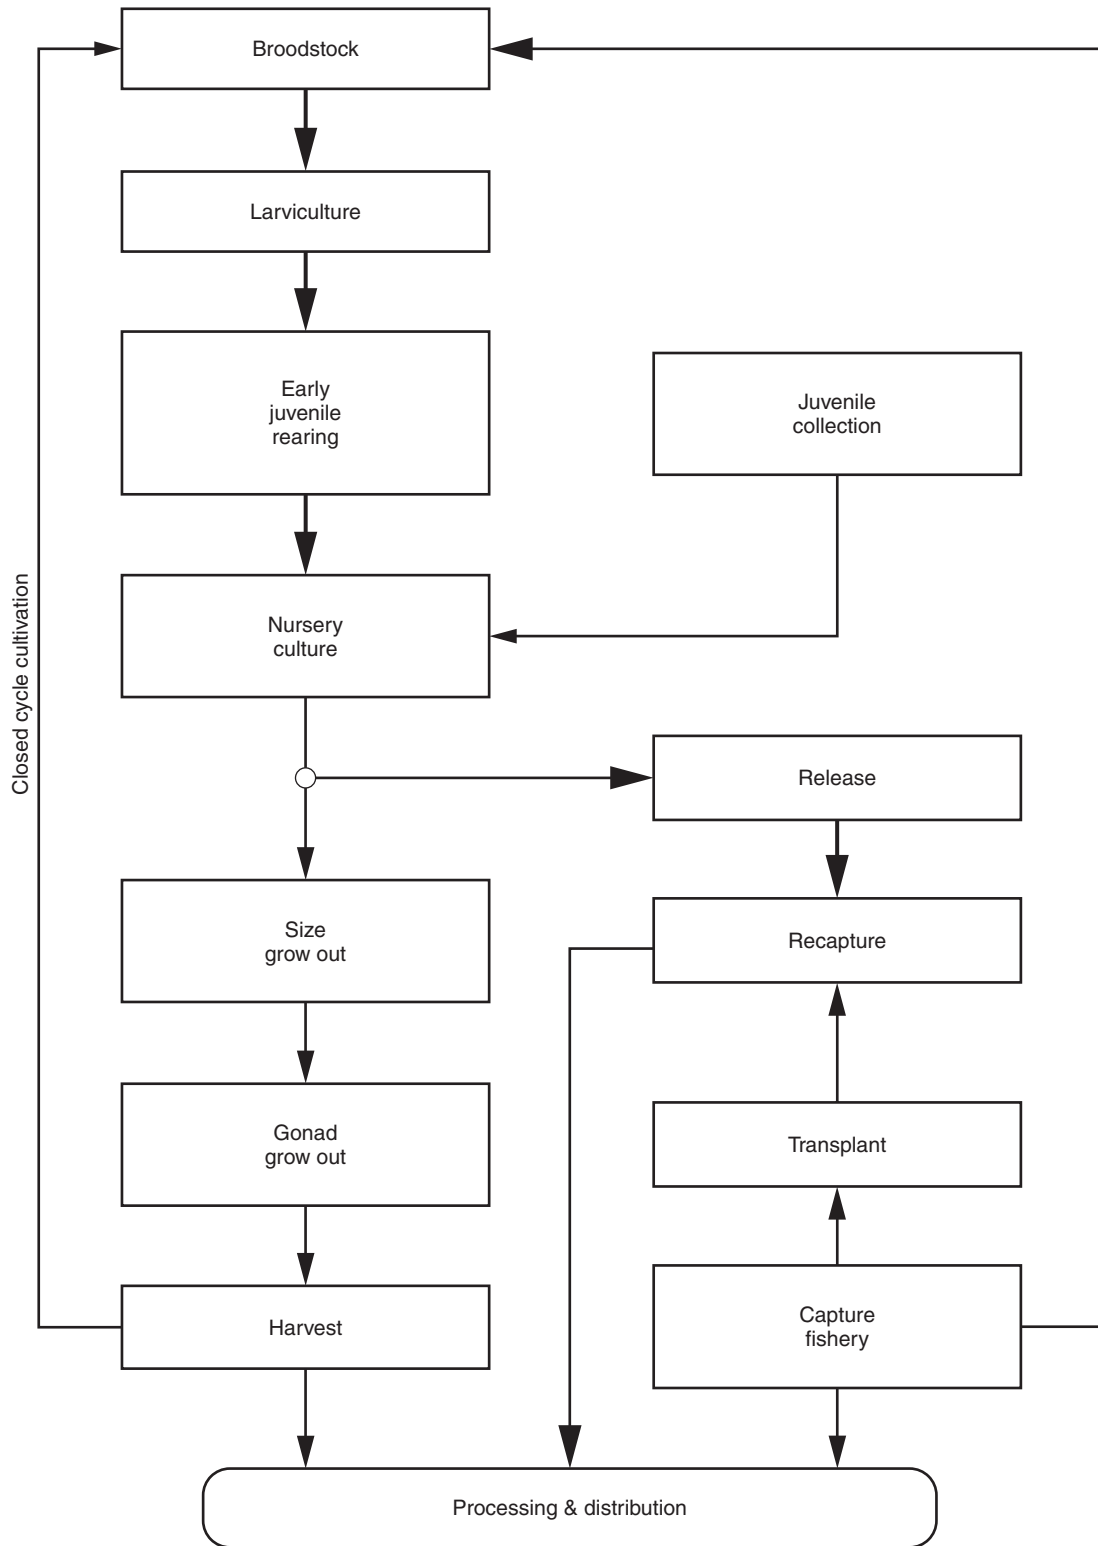
Japanese sea urchin cultivation is based on the spawning of wild broodstock (see Fig. 8), with the availability of mature sea urchins, in most places, restricted to the annual breeding season. However, a local population of


Figure 8. Principal sea urchin cultivation techniques.

S. intermedius, in the southern part of its range, has biannual reproduction, which allows some hatcheries to produce two annual batches of sea urchin larvae. For example, the largest sea urchin nursery in Japan, located in Shikabe municipality, southeastern Hokkaido, obtains broodstock from this source population and produces one batch of juveniles in the spring and another in the fall, for a total of 11 million juvenile *S. intermedius* per annum (10).

The factors the control reproductive maturation are not entirely known for most sea urchin species, but the

photoperiod and water temperature are considered to be important (14–16). Experimental broodstock cultivation has shown that multiple spawning is possible when well-fed sea urchins are cultivated in darkness in relatively warm water (17).

Mature sea urchins are easily induced to spawn by injecting 1–2 ml (0.03–0.07 oz) of a 0.53-mol KCl solution (18,19). A new technique for individual identification of sea urchins, using electronic passive induced transponder (PIT) tags, has the potential to facilitate cultivated broodstock management (20).

LARVICULTURE

Larviculture in Japanese hatcheries commences with the mixing of gametes from several animals. Excess sperm is rinsed off, and the fertilized eggs hatch after approximately 20 hours. Three to four days later, the hatchlings have developed to the early pluteus stage and require planktonic microalgae as food. The diatom *Chaetoceros gracilis* is commonly used in commercial sea urchin hatcheries, whereas the green flagellate *Dunaliella tertiolecta* is popular in research laboratories (19). *C. gracilis* is cultivated in 3-L (0.52 gal) batches in a separate microalgae cultivation room and is fed to the larvae at an initial rate of 1.5 L (0.26 gal), or, 5000 cells/ml, per tank per day (142,857 cells/oz/tank/day). The amount is gradually increased to 10 L/tank/day (2.6 gal/tank/day) in the final stages of cultivation. The larvae are cultivated in 1,000 L (260-gal) tanks, with continuous flow of 1 μm (0.00004 in.) of filtered seawater. The water flow is increased from 15% water exchange/day to 100% at the time of settlement, which occurs 16–30 days after fertilization, depending on the water temperature. Circulation in the larvae tanks is provided by two large air stones with a gentle flow, one on the bottom and another near the surface. The central water outlet is covered by 100 μm (0.004 in.) of plankton net [later, 150 and then 200 μm (0.006 and then 0.008 in.)]. The density is initially 1.5 larvae/ml (42.8 larvae/oz), but decreases to 0.8 larvae/ml (22.8 larvae/oz) at the time of settlement. The metamorphosed juveniles are approximately 0.3 mm (0.01 in.) in diameter (2,21).

EARLY JUVENILE REARING

Settlement is induced by introducing wavy settlement plates covered with the minute green alga *Ulvella lens* (21) or the benthic diatom *Navicula ramosissima* (22), which serve as the initial food source for the juvenile sea urchins. The plates are made of transparent polycarbonate, which facilitates the growth of benthic microalgae on both sides of the plates. The settlement plates are prepared in tanks inoculated with the desired algae. Nutrient salts are added to stimulate algal growth, and the tanks are occasionally drained and rinsed to eliminate unwanted benthic diatoms. Feeding with soft seaweed, such as *Ulva lactuca*, commences when the juveniles reaches 3–4 mm (0.12–0.16 in.) in diameter (2,21).

NURSERY CULTURE

The larvae are transferred from the settlement plates to nursery culture when they reach 4–5 mm (0.16–0.2 in.) in diameter. Most juveniles are transferred to nursery tanks with open-mesh cages or to habitat modules made from nontransparent wavy plates, but some are transferred to hanging cages suspended 1–2 m (3–6 ft) below the surface of the water. The juveniles are fed with kelp (*Laminaria* spp., *Undaria pinnatifida*, *Eisenia bicyclis*) and other locally available seaweed, supplemented by food pellets or knotweed leaves (*Oita dori*, *Polygonum* sp.). Food pellets come in different sizes, but their food value is still inferior to that of fresh kelp. Some juveniles are released six months after fertilization, when they are 7–10 mm (0.3–0.4 in.) in diameter. Six months of additional nursery cultivation produces larger [15–20 mm (0.6–0.8 in.)] seedstock with higher survival rates. The large juveniles are ready for recapture two years after release, when they have reached a diameter of more than 40 mm (1.6 in.). Survival rates are variable, but have been estimated at 20–50% for large seedstock. Approximately 80% of the survivors are captured, yielding a total recovery rate of 16–40% (10).

CLOSED-CYCLE CULTIVATION

Closed-cycle cultivation requires growout facilities. These facilities can be constructed by expanding existing nursery techniques, adapting technology developed for the intensive cultivation of abalone (23), or developing of new technology. The French adopted the last alternative and developed a prototype of a multilayered growout tank that consists of four stacked, sloping shelves. Water is pumped to the top shelf from a reservoir tank under the shelves and then runs down through the stack of shelves in a zigzag pattern. The accumulation of sea urchin feces in the reservoir tank is siphoned off at regular intervals. The recirculated water is gradually replenished by marine groundwater (24,25).

An important factor when considering closed-cycle cultivation is the choice of a good target species. The gonads of the green sea urchin, *Strongylocentrotus droebachiensis*, for example, are popular in Japan, despite quality problems commonly caused by food limitation of wild stocks. Highly similar to the *S. intermedius*, which is found only in the northwestern Pacific, *S. droebachiensis* is a coldwater species with a wide distribution throughout the north Atlantic and the northeastern Pacific (26). The larvae of *S. droebachiensis* must be cultured at temperatures below 10–11°C (50–52°F) (27,28), but juveniles and adults can tolerate somewhat higher temperatures (20). Other potential candidates for closed-cycle cultivation are the Chilean sea urchin *Loxechinus albus* (29,30) and the European sea urchin *Paracentrotus lividus* (24,25).

A commercial-scale growout facility requires a stable food supply, with kelp as the major ingredient. Kelp is necessary for good flavor and coloring of the sea urchins' gonads, but a protein supplement can enhance growth and improve overall food conversion as well (30,31). The most

important determinant of gonad quality, besides food, is the reproductive state of the sea urchin. Sexually mature gonads have an undesirable soft consistency and bitter taste, due to the reduced number of glycogen-containing nutrient cells. Closed-cycle production offers the potential to inhibit sexual maturation through manipulation of the photoperiod and water temperature, thereby extending the harvesting season and improving gonad quality, gonad yield, and food conversion rates. Closed-cycle cultivation also offers the opportunity for growth acceleration through systematic broodstock selection and breeding.

Closed-cycle cultivation is capital intensive and has high operational costs, but requires only a modest investment in research and development. Full-scale hatchery and nursery technology is well established in Japan, and prototype growout facilities already exist in France. A recent profitability analysis of a hypothetical Norwegian growout facility, using pessimistic, realistic, and optimistic parameter estimates, was unable to demonstrate nonprofitability. In fact, there was a large potential for profit when realistic and optimistic parameter estimates were used.

SEA CUCUMBER CULTIVATION

Sea cucumbers are consumed in Japan, as well as in Chinese markets, including Singapore, Hong Kong, and Taiwan. The Japanese sea cucumber market is largely self-sufficient, whereas the Chinese markets are more import oriented. Sea cucumber landings peaked at 13,000 tons in the late 1960s and subsequently declined to the present level of approximately 6,000 tons. To supplement natural recruitment, seedstock production commenced in the early 1980s, but is still at a modest level of 2–3 million individuals per annum. (See Fig. 9.) Most of the seedstock
is being released, but some is being used for experimental closed-cycle aquaculture.

Sea cucumber broodstock is captured in spring when it is sexually mature. Spawning is induced by temperature shock — for example, by raising the water temperature from 16 to 21 °C (61–70 °F). The planktonic larvae are then cultivated in 1000-L (260-gal) tanks and fed a planktonic microalgae, most commonly the diatom *C. gracilis*. Settlement occurs after approximately two weeks. At this stage, the larvae measure approximately 800 μm (0.003 in.) in length, but after metamorphosis they measure only about 200 μm (0.0008 in.). These tiny juveniles are then fed an initial diet of mixed benthic diatoms (*Navicula* spp.) before being transferred to outdoor nursery tanks filled with unfiltered seawater. There, they feed on the natural growth of benthic diatoms on the tank walls, supplemented with dried seaweed powder (*U. pinnatifida*, or in Japanese, *Wakame*). Mortality is high during the hatchery and nursery stages. The juveniles are released after six months, when they measure 2–8 cm (0.8–3.1 in.) in length, and are recaptured one year later, when they measure approximately 20 cm (8 in.) in length.

Sea cucumbers feed on detritus and suspended particulate matter, including the fecal pellets of sea urchins. Intensive polyculture of sea urchins and sea cucumbers appears feasible, but has yet to be investigated.

In conclusion, it appears that closed-cycle cultivation of sea urchins for the Japanese market is an emerging coldwater aquaculture opportunity awaiting commercial trials, whereas sea cucumber cultivation is still in the experimental stage. However, joint development of urchin and cucumber polyculture is an interesting possibility, since sea urchin waste can be used as sea cucumber food. In addition, echinoculture has the potential to become a long-term sustainable industry, with ecologically and environmentally sound production, since both sea urchins and sea cucumbers are primarily herbivorous organisms.

ECONOMICS, BUSINESS PLANS

WADE L. GRIFFIN
Texas A&M University
College Station, Texas

OUTLINE

The development of many aquaculture businesses has been based on "gut feelings" rather than on sound business planning. In most cases, such businesses are predestined to fail. The attitude of the developers has often been "I want to raise fish," instead of "I want to run an aquaculture business." Potential new entrants typically ask, "How do I start a farm?" and "What does it cost?", and if they can afford to start the business, then off they charge, without asking any further questions. Later, as struggling fish farmers; they ask, "How can I pay my bills and keep the farm going?" The result of their endeavor is often frustration and financial failure. The intent of this entry is to help prospective aquaculturists evaluate the real potential of their "gut feelings" and communicate that potential to others, using a business plan. The purpose here is to provide a framework for preparing a business plan in the aquaculture industry (1–8).

BUSINESS PLAN

A business plan describes what we expect to happen in the future of our business and the things that have to be done to bring those expectations to reality. During preparation of a business plan, things that make the aquaculture venture a poor investment may be discovered. The result may be that considerable heartache, embarrassment, and financial distress are avoided.

A business plan explains how a particular idea can be accomplished. Everything from site selection for production to selling the product must be put to the "Will this really work?" test. The test simply examines

the tasks in the aquaculture venture and asks what factors need to be considered and whether the tasks can be performed economically. Investors and lenders are more apt to provide capital to aquaculture ventures that have withstood the rigors of thorough analysis of a well-prepared plan than to ventures that have not.

A business plan can be used for many purposes. Among the more important uses are to:

(1) critically evaluate a business idea,
(2) obtain money from lenders or investors,
(3) establish a track record to demonstrate business expertise, and
(4) communicate plans internally within a firm.

It is important to understand that developing a business plan can be tedious and cumbersome. Many areas of business expertise and a considerable amount of time spent on gathering information are required for a particular idea to be properly evaluated and acted on. Unfortunately, many potential aquaculturists omit critical steps in developing an aquaculture business plan. Many have no clear direction or objectives. For others, the overwhelming desire to start the business has led to a distortion of facts. Yet others, intentionally misrepresent facts or are overly optimistic, in order to "sell the project" to investors or lenders. For the best chance of business success, a logical, honest effort from concept to business plan should be employed. The steps for developing an aquaculture business plan are as follows:

(1) Make sure that the business idea is worth pursuing.
(2) Convert the idea into what needs to be accomplished.
(3) Identify specific product(s) and market(s).
(4) Design the facility, and plan operations.
(5) Produce various alternatives for accomplishing the goals established in the initial facility and operation design.
(6) Analyze the alternatives, based on unfavorable events that could occur.
(7) Decide which alternative is the best, based on the particular circumstances.
(8) Finally, write down the business plan, with an organized purpose and logical plan of action.

IS THE IDEA ANY GOOD?

Many potential aquaculturalists begin by immediately calculating revenue and costs, to determine if the venture will be a success or a failure. Depending on how badly they desire to go into business, they might falsely raise the revenues or lower the costs in their calculations, in order to force a successful outcome. The excitement of a potential aquaculture project has too frequently overwhelmed the normally cautious, sensible individual, and many failures have resulted from using overly optimistic assumptions and expectations in developing a business plan. Therefore, "running the numbers" at the outset of preparing a business plan should not be done. Start instead by examining the source of the idea to go into aquaculture, and then confirm the idea as legitimate by checking it with a trustworthy expert. The following is a checklist for determining the reliability of the source that generated the idea to start an aquaculture business:

(1) Is the source affected by whether aquaculture in general develops or not?
(2) Is the source affected by whether or not you in particular are involved in aquaculture?
(3) Is the source involved directly in aquaculture? If yes,
   (a) Is the source a producer?
   (b) Does the source market aquaculture products?
   (c) Has the source been involved in aquaculture more than five years?
(4) Is the information provided by the source factual? (That is, does the information come from actual observation or documentation, or just from "a feeling?")
(5) Is the source's information less than three events away from actual observation? (That is, did the idea come from at least a reputable secondhand information source?)
(6) Can the source's information be substantiated through a knowledgeable, independent third party?
(7) Is the source's information less than one year old? If not, is the source's information still valid?
(8) Is this idea original? If yes, was the idea developed because of a market need? If your source does not check out, seek out other sources until a reliable one is found.

The following list of common providers of information on aquaculture may help in confirming or researching aquaculture business ideas:

(1) Actual acquaculturists, or people involved in businesses closely associated with acquaculture.
(2) Industry publications: *Aquaculture* magazine, *The Progressive Fish-Culturist (now North American Journal of Aquaculture), Journal of the World Aquaculture Society, Seafood Leader, and The Seafood Business Report.*
(3) Government personnel: state agricultural extension services, state agricultural experiment stations, state fish and game agencies, National Marine Fisheries Service, and Natural Resources Conservation Service.
(4) Private consulting services, which are available through many aquaculture consulting firms.
(5) Academic sources: textbooks and universities with aquaculture programs.

DESIGNING THE BUSINESS

After the idea has been determined to be worth pursuing, the aquaculture business should be designed. Before

drafting the physical facility, however, complete the following three tasks, to provide direction: (1) decide what is wanted from the business, (2) define exactly the nature of the business, and (3) determine how much to spend. The results of these activities will help guide the physical design of the operation.

If the culturist identifies exactly what is wanted from his or her effort, a better operation to capture the desired outcome can be planned. All of the tasks and activities that have to be accomplished are more clearly defined, and therefore, unnecessary costs and changes can be avoided.

The prospective aquaculturist should ask the following questions of himself or herself:

(1) Financial
   (a) Can I stand to lose everything I put into the business? If not, how much can I afford to lose?
   (b) How long can the initial invested sum of money be tied up in the business?
   (c) How much of a return do I expect on my investment?
   (d) Do I require a salary?
   (e) Do I plan on selling the business? If so, at what stage?
   (f) Will I be seeking any outside financial support? If yes, am I planning on using investors or lenders? If yes, what are the terms, conditions, and expectations of the investors or lenders?
   (g) Do I plan on substantial growth of the business? If yes, must it grow on internally generated funds?
(2) Other
   (a) How much time do I have to succeed?
   (b) How much control (ownership) must I keep?
   (c) What position would I like to have within the industry (e.g., leader, follower, etc.)?
   (d) Do I plan on doing something that has never been done before in aquaculture?
   (e) Why is aquaculture a good idea for me?
   (f) Does aquaculture complement any other operations I might have, in terms of making the existing operations more profitable?
   (g) Am I looking at aquaculture because I have idle resources that I think could be used, such as land? If so, what do I expect from using the resources?
   (h) What are my strengths and weaknesses as a manager?
   (i) How have I compensated for or covered and perceived weaknesses?

It is best to confirm business goals through introspection and by contacting the expert or information provider that helped confirm the aquaculture business idea.

The goals of others either involved in or affected by your decision should also be considered, to ensure that future barriers are minimized. Some features of others' goals in an aquaculture business setting are given in the upcoming list. Clearly identifying these goals is essential to evaluating the feasibility of a venture. It is extremely important to accomplish this task before designing the physical attributes of the aquaculture operation.

(1) *Governmental agencies.* Depending on the type of aquatic species being cultured and the location of the aquaculture facility, various governmental agencies can have conflicting goals. Protected fish and wildlife may exist at the site. If exotic species are to be cultured, special procedures may have to be in place in order to prevent them from entering the environment. Special soil and water conservation practices may have to be used. In many cases, special licenses and permits will be required.

(2) *Competitors.* Competition may be friendly or hostile. If it is friendly, common objectives may lead to shared equipment, labor, or marketing efforts, providing a chance to reduce costs. If it is hostile, independent strength in production and marketing should be planned.

(3) *Customers.* The customer is always concerned about the product, and it is important to understand why the customer wants certain things and thereby determine how these desires can be met. For instance, a restaurant owner may need the product to be consistent in size, because of the price of a plate. Determining acceptable quality and consistency is another major consideration.

(4) *Suppliers.* Typically, suppliers of goods and services are after your business, which means they are more concerned about meeting your needs than you are about meeting theirs. However, they may have other goals that you can exploit, such as when a supplier needs your advice for technological improvements or assistance in entering the marketplace for the first time.

(5) *Investors.* Investors are interested in the amount and timing of returns. Therefore, their objectives may not be the same as those of management. For instance, selling the business may provide the best returns, but doing so means that managers lose their jobs or control over the operation.

(6) *Lenders.* Lenders are interested in the amount of risk involved and in getting their principal and interest in a timely fashion. Like suppliers, they may also have an interest in learning the nature of the aquaculture business.

(7) *Employees.* Often overlooked, but vitally important to aquaculture, are the skilled employees. Their goals usually include a higher salary, more benefits, increased responsibilities, and a sense of worth.

Clearly identified goals are essential to evaluating the feasibility of your venture. It is extremely important to accomplish this task before designing the physical attributes of the aquaculture operation.

What Business are You in?

A common mistake made in aquaculture business plans is the lack of sufficient attention placed on marketing.

Many plans are developed from the viewpoint of the aquaculturist who is interested in production, and sales frequently are an assumed item. However, selling the product in large quantities and at a price that will provide adequate returns is equally important.

The aquaculture business person must identify where and to whom the product will be sold. Local and regional markets are the usual places of sale in aquaculture. For instance, catfish are most popular in the southeast United States, whereas trout dominate in the northwest. Determining customer preference for the product and then identifying where those customers are located, where they shop, how much they buy, etc., are all parts of the process of identifying the market. The following is a list of several considerations for identifying an aquaculture-related market:

(1) Physical characteristics
   (a) Who are the buyers?
   (b) When do the buyers buy?
   (c) How many potential buyers are there?
   (d) Where are the buyers located?
   (e) How much can the buyers reasonably buy, in total?
   (f) How often do the buyers buy?
   (g) What are the buyers doing with the product?
(2) Buyers
   (a) Why are the buyers interested in the product?
   (b) What is important to the buyer?
   (c) Why should buyers buy from you in particular?
   (d) How long have the buyers been in business?
   (e) What is the future of the buyers interest in the product?
   (f) Do the buyers buy more at some times than at others?
   (g) Are there particular ethnic or religious groups that buy the product?
   (h) What proof is there that someone will buy the product at your price?
   (i) Is a dependable supply a major factor?
   (j) Do the buyers require purchase contracts? If so, what are the terms? Can you get a contract?

Many seemingly good ideas have not met with consumer acceptance. Therefore, once the product and market have been carefully identified, they should be confirmed. For relatively large endeavors (for instance, statewide), professional marketing agencies should be employed to conduct surveys and market tests and to substantiate the product and market. Other market confirmations could involve negotiating with a local processor or restaurant owner who might purchase the product.

How Much Money do You have to Spend?

Knowing how much you intend to spend on an aquaculture project helps direct planning, by keeping the business plan within reason. Your investment will be determined by the amount that you are willing to risk, either directly or through borrowing, and by the portion of the business that you are willing to share. The amount that you are willing to risk is the amount that you can afford to lose.... Not an easy decision! Also, the more of the business you are willing to share, the less funds you will need to invest. This decision requires serious thought, however, because outside investors will want something in return. Some of the considerations associated with sharing the business are as follows:

(1) Can the aquaculture business be created without bringing in outside investors?
(2) Could the size of the venture be reduced and objectives accomplished without outside investors? If so, what problems are there in doing so?
(3) How much control over operations will be lost if outside investors buy in?
(4) Can you obtain additional management expertise in exchange for some business ownership?
(5) Why do the outside investors want to be involved?
(6) What will be the reporting requirements for the outside investors?
(7) Are there any legal risks in bringing in outside investors?
(8) What form of legal organization is required?
(9) Are the investors risk and return requirements reasonable?
(10) Are the investors reputable?

If you are considering borrowing part of your investment, you need to give careful thought to how much you will be able to borrow. In particular, you must consider what the lender requires. The following questions, often asked by lenders, should be answered when converting your business plan into a financing proposal:

(1) How much money is to be borrowed?
(2) When will the money be needed?
(3) What is the money going to be used for?
(4) How will taking out a loan affect the borrower's financial position?
(5) How will the loan be secured?
(6) When will the loan be repaid?
(7) How will the loan be repaid?
(8) How will alternative possible outcomes for the business affect repayment ability?
(9) How will the loan be repaid if the first repayment plan fails?

Business Operations: Facilities and Processes

A business plan needs a clear description of the facilities (including equipment) and processes to be relied upon. There should also be a good fit between these items, such as matching equipment (e.g., pumps) of an appropriate size with the time and quantity of production.

Facilities. Many facility-design errors can be eliminated by knowing your business goals and limitations, detailing

the facility, and confirming the design of the facility. Knowing your management and investing limitations will keep you from planning a facility that is too big to handle. It is usually preferable for the size of the operation to grow in line with management's physical and financial capabilities.

Design the facility with as much detail as possible, given the situation. A common mistake is that too many assumptions are made regarding the facility: "I assumed that anyone could use river water!" "I assumed these ponds would hold water." Don't get caught in these types of situations. Plan the facility in detail, and confirm the details with an expert. A checklist of areas to detail for many aquaculture facilities should include the following:

(1) The source of water
  (a) History
  (b) Physical characteristics
  (c) What it takes to obtain it (e.g., pumps, power, etc.)
(2) The site
  (a) History
  (b) Physical characteristics
  (c) Location
(3) The environment
  (a) Historical patterns
  (b) Labor conditions
  (c) Support businesses (e.g., processors, suppliers, etc.)
(4) The production facility
  (a) Size and type of water impoundments
  (b) Transport of water
  (c) Hatchery and/or tempering facilities
  (d) Special harvest provisions
  (e) Troubleshooting provisions
  (f) Feeding provisions
  (g) Storage
  (h) Miscellaneous equipment
(5) Permitting
(6) Administrative facilities
(7) Special marketing facilities
(8) The fit between facilities and provisions
(9) Provision for emergencies

Processes. After designing the facility, you must decide how you intend to operate it. Specifically, you will need to estimate the inputs, outputs, management, and marketing. It is imperative to know the limiting factors. For inputs and outputs, this means understanding what inputs (such as fingerlings, water, and feed) are available, how much the facility can produce, and the conversion process.

The conversion process (how you end up with more money than you started with each year, after you bought, produced, and sold the product) deserves special attention in the business plan. It is this process that the business depends upon for day-to-day survival. The technical aspects of this process should be well defined with respect to feed conversion ratios, survival rates, growth rates, etc. In addition, how you intend to accomplish this conversion should be described — that is, management and marketing.

Management will make or break the business. Management must see that the various tasks in the conversion process are coordinated and carried out. One way of presenting this aspect in the business plan is to write job descriptions for each manager, to organize your thoughts about operations. To do so, define major tasks, and assign them to the appropriate manager. Be careful not to give any manager too few tasks, that practice can result in "too many chiefs." The process of dividing up tasks and recording job descriptions will give you the basis for developing an organizational structure that shows who reports to whom and where ultimate responsibility and accountability lie. A clear set job descriptions and a chain of command should be documented.

Last but not least, it is important to state how you intend to accomplish your marketing ideas. Describe each step of the process, from where the product goes as soon as it is harvested to the point at which you receive payment. Include the amount of time that you are responsible for the product and what arrangements must be made at each step.

Monitoring and Control. A business entity needs a feedback system to monitor its activities, so that problems or potential problems are detected and appropriate remedies are taken. Feedback should take the form of a well-organized accounting and record-keeping system. For many aquaculture operations, a simple bookkeeper and a production manager, dedicated to documenting the financial and physical activities of the business, will be appropriate. More complicated operations may require the use of a computer and a formal accounting and records department. At minimum, records should be kept concerning the financial and production activities in your aquaculture business. These records include such items as payroll, purchases, sales, open accounts, debt and equity capitalization, quantities produced, and production inputs. Periodically, these records should be summarized in the form of financial statements and production reports and should be reviewed by management.

ANALYSIS

Once you have designed your aquaculture business, you must put it to the test. First, develop several alternative ways in which you might be able to obtain your goals. You can determine these alternatives by making changes in the initial design.

Next, decide what tests you want to make on each alternative and what results are acceptable. "What if" tests, such as "What if the growth rate is less than expected." should be considered. A useful set of tools for testing aquaculture business designs is *pro forma* (projected) financial statements. These statements typically include a *pro forma* cash flow, income statement,

balance sheet, and statement of changes in financial position.[1]

The cash flow statement shows the movement of cash through the business. It is valuable for determining when cash is needed and when it can be withdrawn. By using a cash flow statement, timing and amounts to borrow may be better planned. The cash flow statement can point to weaknesses, such as when revenue from the sale of the product in a particular month is insufficient to cover a loan payment. It can also be used to determine the return on investment and the amount of time necessary to get your investment back (payback period).

The income statement is used for demonstrating the profitability of the business. It includes all revenues and expenses (including income tax) of the firm, whether or not (i.e., depreciation) they involve cash. The income statement shows which revenues and expenses are most important and tells how efficiently the operation is run, from a financial standpoint.

The balance sheet shows the financial position of the business at a particular point in time. It is useful in identifying the liquidity structure of various assets and liabilities (i.e., how quickly they could be turned into cash) and determining relative financial strengths. The balance sheet shows how much equity the business carries (i.e., what you own minus what you owe).

The statement of changes in financial position is used to show where the business got and used its cash in going from one balance sheet to the next. It can tell whether the sources of funds are properly matched with the uses of funds. For example, was the cash that you got from the short-term operating note used for purchasing operating supplies, or was it used to purchase a tractor instead?

All of the aforementioned financial statements are a good source of information for measuring and evaluating your aquaculture business designs. The types of information provided by the statements include such measures as the internal rate of return, (IRR), payback period, debt-to-equity ratios, times-interest-earned ratio, current ratio, and net-profit margins. Other measures that you may want to consider are the rate of growth in equity, risk measures, and production efficiency measures.

The final step in the analysis of the project is to select the best designs. Compare the designs by using the measurements you've taken from your *pro forma* financial statements. The best design will be the one that most closely matches your business goals. Testing may point to needed modifications in the designs, or it may be that none of the designs are good enough for you to commit time or money to the project. Keep an open mind to design failure! Better that you find out that your design is not feasible after spending only a small fraction of time and money;

instead of actually building the aquaculture facility and then discovering that it doesn't work.

SOME OUTSIDE FACTORS TO CONSIDER

Most of the factors discussed thus far have been related to the internal aspects of an aquaculture business. This section describes factors that are outside of the business, but important to consider and include in the business plan. There are two areas outside of the aquaculture firm that need to be considered: the general environment and the industry. The general environment can be viewed through sociocultural, economic, governmental or legal, technological, and international issues. The industry can be examined by assessing competitive forces, including new entrants, supplier power, buyer power, substitute products, and competitive rivalry. Some of the questions that you should consider in analyzing outside influences to your business are as follows:

(1) How many suppliers of seafood similar to yours are there in the area?
(2) Can you produce what the market demands? Is there a minimum quantity to produce?
(3) Are you aware of other new ventures being planned or expansions of existing producers?
(4) Is there existing or potential foreign competition?
(5) What are your comparative advantages?
(6) Can you distinguish your product in the minds of the consumers?
(7) Are there trade or technological constraints restricting potential competitors? If so, are they likely to change? How soon?
(8) Are necessary processors, suppliers, and distributors available? How much market power do they have? What is their likelihood of staying in business? How dependent are you on those processors, suppliers, and distributors?

Sociocultural issues include general attitudes about farm-raised fish and seafood products, religious beliefs, dominant family forms, education, etc. Economic issues center around the end user's ability to purchase your seafood product. Disposable income, leisure time, priority spending, changes in interest rates, the rate of inflation, and the rate of unemployment are some specific economic considerations. Governmental or legal issues sometimes can play a major role in an aquaculture project and should be examined with great care. Rights to water, exotic-species permits, environmental control agencies, and taxing authorities must all be considered in the project. Aquaculture is an emerging industry, with constant innovation and technological improvements. You should weigh the costs of using the latest technology with its potential benefit. International issues are important for some products, such as shrimp and salmon, but are less important for products that are more local in nature, such as catfish and tilapia. Specific international considerations, if applicable, should include topics such as import/export potential; foreign exchange rates; foreign

---

[1] Two sources of information that provide an in-depth understanding of financial statements are (*1*) *Coordinated Financial Statements for Agriculture*, by Thomas L. Frey and Danny A. Klinefelter, available through Agri Finance, Suite G, 5520 West Touhy Avenue, Skokie, IL 60077, and (*2*) *How to Analyze Financial Statements in Agriculture*, by John B. Penson and Clair J. Nixon, available through Agri-Information Corporation, P.O. Box M-21, College Station, TX 77844.

demand and supply; and practical barriers, such as language and customs.

The competitive forces in the industry deserve close attention. The ease with which new competitors can come into the industry should be considered; that is, if the industry is attractive, can outsiders come into the industry easily and compete away profits? If the aquaculture project relies on outside sources for different inputs, such as feed, stock, special management, etc., special attention should be given to the market power (e.g., number and quality) of those suppliers. For example, if there is only one feed company that can supply the type of feed required, the price of the feed will be relatively high, and it could be necessary to hold more feed in inventory. Likewise, buyer market power should be assessed. Buyers may have more or less power, depending on how much seafood is needed and how much is available for purchase. Also, the number of and relative power among buyers should be considered.

Competitive advantage is reduced when there are more substitute products in the market. The number of available substitutes should be examined, including surimi and other imitation seafood products. Finally, the degree of competitive rivalry in the industry should be closely examined. The more destructive the competition, in terms of price cutting and increased service, the more difficult it will be to attain higher profits. If you find an aquaculture business design that satisfies your goals, then you are now ready to begin writing the business plan.

WRITING THE BUSINESS PLAN

If you have followed the previous sections of this contribution closely and have collected the required information along the way, then you are ready to prepare a business plan that you can take to a lender or investor or use as a guide in developing your business. Above all, be sure that *you* are convinced that the aquaculture business is going to be a success *before* writing the business plan.

Business plans can have different formats, depending on the type and source of funding being sought and the general purpose. (If funding is already in place, a plan is still worth writing; as it can easily be used as a guide for strategy.) A suggested format for an aquaculture business plan is as follows:

Title page
Table of contents
Statement of purpose
Executive summary
The business
    History
    Description
    Market
    Marketing
    Competition
    Operations
    Management
    Research and development (optional)
    Personnel

    Loan or investment application and effects
    Development schedule
    Summary
Financial plan
    Sources and applications
    Capital equipment list
    Break-even analysis
    Pro forma balance sheet
    Pro forma income statement
    Pro forma cash budget
    Historical financial statements
    Equity capitalization
    Debt capitalization
Supporting documents

The rest of this contribution discusses the contents of each item of the suggested format.

Title Page

The title page should include at least four pieces of information: the name of the proposed project, the name of the business, the principals involved, and the address and phone number of the primary contact.

Table of Contents

The table of contents should include the major topics of the body of the business plan and list critical tables and figures of which the investor should take particular notice. Do not include every detail of the plan in the table of contents. The main function of the table of contents is to guide the reader to the critical areas of the business plan.

Statement of Purpose

This section is a brief statement of the aquaculture venture: what is to be accomplished, why this project was chosen, and how the project is to be done. The statement should include requirements for outside funding and describe the repayment plan and source of repayment.

Executive Summary

This section is dedicated to presenting the key elements of the business plan to prospective lenders or investors. Its length should be kept under five pages, in order to increase its likelihood of being read. The summary should begin with a brief restatement of the purpose of the project. Next, the venture's specific products, markets, and business objectives should be described, along with proof that the particular idea possesses a competitive advantage. The specific details of the management team should then be presented, along with the various strengths and weaknesses (and solutions for the weaknesses). Lastly, the financial aspects of the venture should be summarized, showing projected returns, outside financing requirements, and the basic timing of cash flows.

The Business

This section of the business plan provides details of the venture. The following points should be addressed:

History. Describe your present organization, including when it was founded, progress made to date, present form (e.g., partnership, corporation, etc.), past financing, and prior aquaculture successes and experiences.

Description. Concisely lay out the proposed venture. Describe the location, size, products, facility design, and installation procedures. This section discusses in detail what the venture intends to do, such as the type of production technique that will be used, the water conditions of the chosen site, etc. Certain justifications for the facility and products should be given when these aspects are a critical assumption of the business. For example, the production technique (intensive, extensive, or semiintensive) should carry a cost/benefit justification.

Market. This section provides a description of the market in which the aquaculture product will be sold.

Marketing. This section discusses how the venture will specifically cater its product to the market. It should include a product description and details on how the product will be taken to the market described in the "Market" section.

Competition. This section presents an analysis of significant competitors. It includes a listing of direct competitors (such as other aquaculturists within the market segment) and indirect competitors (such as fisheries products, imitation fish products, and fish imports). Possible reactions from competitors and the effects that the product will have on the market should be addressed, and strategic moves by the venture in relation to competitors should be discussed and explained.

Operations. This section provides a detailed explanation of production processes and limitations. Assumptions about the growth of the particular production, the population characteristics, and biomass levels should be identified. Managerial techniques in the different phases of the growth cycle should be discussed. The life cycle of the product should be described in detail, with the appropriate risks and strengths highlighted. A suggested technique for describing operations is to divide the project into its separate functions. Each function can be explained in detail along with its importance. The functions can then be brought together to form the whole system of operations.

Management. This section discusses how the venture will run. The organizational structure is described to show lines of authority and responsibility. An organizational chart should be presented that depicts clear functional duties and communication lines. Each critical functional area (e.g., pond, hatchery, maintenance) requires descriptions of managerial control and feedback. The type and style of management can also be discussed. For example, a fish farm may be run by a sole proprietor who subcontracts most of the labor or by a highly integrated team that performs all functions internally. Depending on the purpose of the business plan, you may want to discuss key personnel and include their credentials. Describing this information is standard when obtaining funds from lenders or investors.

Research and Development (Optional). If the aquaculture venture is involved with new techniques or new animals that have not been raised before, this section should be included. It should discuss whether expertise is to be hired or developed from within and should describe details such as costs, expected accomplishments, and timing.

Personnel. The complete personnel plan shows the expected hiring needs and personnel policies over the planning horizon of the venture. The expected number of full-and part-time employees, the amount of overtime, and any seasonal trends should be included. Also, fringe benefits and control policies need to be listed, as well as whether or not it is critical to keep employees. A demonstration of knowledge of any laws that may affect employees should be included as well.

Loan Application and Effects. This section presents any source of external financing and describes why it is necessary and what benefits are expected. Amounts to be borrow for equipment, land, feed, etc. should be listed, with an explanation of the terms, critical aspects (such as options), required collateral, and why borrowing makes sense. Also, any assumptions concerning financing should be spelled out.

Development Schedule. The timing of the venture development can be presented as a chart or in some other form that shows critical dates. This section should include the decision milestones and guide the reader through each stage of the venture. For example, this section could provide a calender chart that shows various stages of the venture and any completion dates. Any information such as dependence on governmental agencies, weather, or equipment manufacturers should be included.

Summary. This section should present, in an abbreviated form, the information provided in all of the previous sections and general information about the business. It is important to highlight the most important facts and assumptions and to exclude the details.

The Financial Plan

Once the basic business has been presented, it is necessary to demonstrate its economic feasibility over the planning horizon of the venture. Certain information is desired by banks and investors for determining the financial success of the venture. This information is as follows.

Sources and Applications. This section presents a summary of where funds are to be obtained and where they are to be applied. It is a good way to introduce the business to financial intermediaries, who are concerned with the use of the funds that they may be providing and what other funds you plan to obtain. There are four categories of investment: capital assets, initial inventories, working capital, and contingency reserve. The farm firm

may reduce assets (a source of funds) or increase assets (a use of funds). Other sources of funds include increasing a liability (borrowing) or obtaining more paid-in capital. Other uses of funds include decreasing liabilities (paying back loans) or paying back of equity capital.

Capital Equipment List. This section provides the lender or investor with a detailed listing of the major equipment items. Some general categories can be used, such as hand tools, office furniture, etc., but all major items should be listed separately. A listing of tractors, hatchery tanks, gate valves, computers, feed silos, seines and nets, and so forth should be provided in order to inform the reader about the depreciability, maintenance, extent of involvement, and collateralization of assets.

Break-Even Analysis. This section gives a good idea about what minimum levels the venture must perform at to meet all of its obligations. The break-even point is the level of production that achieves zero profit (i.e., the revenue minus the variable and fixed costs equals zero). If there is more than one product, the analysis becomes somewhat more difficult, because it is necessary to find out each product's break-even point, which requires the allocation of certain fixed costs. Break-even analysis involves showing the break-even point for varying venture scenarios.

Pro Forma Balance Sheet. A balance sheet should be provided as of the end of each year in the venture's planning horizon. The purpose of this statement is to show the financial position of the venture at various points of time. The assets and liabilities should be as detailed as possible, with proper notes and assumptions provided.

Pro Forma Income Statement. An annualized accrual-based income statement should also be provided over the length of the planning horizon, in order to show profitability of the venture. Supportive data, such as production estimates, learning curves, and feeding efficiency ratios, should be listed. It may be necessary to give month-by-month or quarterly statements for the first few years of the operation, to demonstrate seasonality of the business.

Pro Forma Cash Budget. This financial statement indicates the cash flows of the operation and its ability to meet cash obligations. Each year of the planning horizon should be included in the business plan. The first few years should be presented on a monthly basis, to show seasonality and critical points of cash flows. The cash budget should also indicate the amount and timing of cash flows to and from investors and financial intermediaries.

Historical Financial Statements (Optional). If you have been in business on other projects, or if this venture is an existing business (e.g., for buyouts, expansions, etc.), it may be necessary to provide historical financial statements. This is particularly the case when personal or corporate guaranties are being relied upon for collateral.

Equity Capitalization. This section summarizes the total amount and timing requirements of invested capital. Its purpose is to show the lender or investor the degree of financial risk being taken by the principal(s). The method of payback of capital should also be reported.

Debt Capitalization. This section is similar to the previous one, and the two can even be combined. The purpose of this information is to highlight the extent of involvement by lenders. The types of borrowing, terms, amounts and timing, and percentage of the total capital that the borrowed money amounts to should be indicated. Also an annual ratio of debt to equity should be provided in this section for the planning horizon.

Supporting Documents. This is the final section of the business plan and should include any pertinent information left out of the main body. Documents such as personal resumés of the principal(s), personal financial statements (if not already provided), credit reports (if the venture is already in business), letters of reference, relevant articles, and copies of contracts and legal documents should be placed in this section.

OUTLINE

How Do Culture Fisheries Compete with Capture Fisheries?

U.S. Consumption of Seafood and Markets

The introduction to a 1988 study conducted by the U.S. Department of Commerce (1) to comply with a Congressional request begins as follows:

> Recent strides in aquaculture have raised troublesome questions for commercial fishermen. At issue is whether gains in aquaculture output will disrupt markets now supplied principally by the traditional "capture"-type commercial fisheries. Cultured salmon and shrimp already have won important market positions, particularly in the United States and Western Europe. Advances in aquaculture technology promise success for other species.

The introduction concludes by stating the following:

> The impacts of aquaculture will be reflected in prices at all market levels for species that are supplied from both commercial fishing and aquaculture sources, such as salmon and shrimp. There is speculation that a surge in supplies of cultured products will devastate the market and jeopardize traditional suppliers. The salmon/shrimp experience is still too new to use as an empirical basis for determining whether cultured products are a significant threat to the interests of commercial fishing.

More than a decade has elapsed since that Congressionally requested study was conducted and published. During the intervening years, the salmon and shrimp culture industries, as well as some others, have moved from a stage of infancy toward one of maturity. Associated with the increased maturity of many of the culture industries is an increase of available information (data) and subsequent analyses. This entry examines the competition between capture- and culture-based fisheries in the market place and, in particular, the impact of increased cultured supply on captured prices, related markets, and support sectors. Constraints on and degradation of the natural environment, resulting from certain culture practices, can also result in competition with respect to the production of species. This aspect of competition is not treated in this paper, but the reader is referred to Naylor et al. (2) for information. The primary emphasis is placed on the U.S. markets but, where relevant, other markets are examined. All money amounts in this entry are in U.S. dollars.

HOW DO CULTURE FISHERIES COMPETE WITH CAPTURE FISHERIES?

To see how changes in the supply of cultured product affect the price of captured product, consider Figure 1. For a more detailed economic analysis of the effect of cultured seafood products on wild-based products, the reader is
Figure 1. Hypothetical demand and supply curves for seafood from captured fisheries.

referred to (1). Economists generally portray consumer demand for a good (commodity) through the use of a "demand curve," graphically illustrated by the line labeled $D-D$. This curve, which is generally downward sloping, shows the quantity of a given good that consumers are willing and able to purchase at alternative market prices. The downward slope of the curve implies, as one would expect, that, as price declines (increases), the quantity of the good demanded by consumers increases (decreases). The overall position of the demand curve, reflecting the level of demand at any given price, is generally considered to be influenced by such factors as: income; tastes and preferences; and the price of substitute products. For most goods, increases in income will result in an upward shift of the demand curve. Increases (decreases) in the price of substitutes, by comparison, will generally result in a upward (downward) shift in the demand curve because the *relative* cost of purchasing the original good has now become lower (higher).

In counterpart to the demand curve, economists generally portray industry supply for a good (commodity) through the use of a "supply curve," graphically illustrated by the line labeled $S-S$ in Figure 1. This curve, which is generally upward sloping, depicts the quantity of a given good that industry producers are willing to place on the market at alternative market prices. The upward sloping nature of the curve implies, as one would expect, that, as the market price increases (decreases), producers would be willing to place additional (less) quantity of the good on the market. The overall position of the supply curve, reflecting the level of supply at any given output price, is generally considered to be influenced by such factors as input prices and technology. Improvements in technology, for example, will allow for a higher level of production for any given level of inputs. This effect is represented by the supply curve's shifting downward (equivalently, to the right), a movement implying that more product will be placed on the market at any given output price. Advances in technology in both shrimp and salmon culture since the early 1980s have, in fact, resulted in significant increases in the quantity of the product being offered at a given output price [see, for example, Asche (3), with respect to salmon.]

The market *equilibrium* is determined by the intersection of the demand and supply curves. At the intersection, labeled as A in Figure 1, the quantity demanded by buyers at the stated market price (P_0) is equal to what the producers are willing to place on the market at that price. At any price above P_0, the quantity demanded by consumers is less than what producers are willing to provide. Conversely, at any price below P_0, the quantity demanded by consumers exceeds the amount that producers are willing to supply. Associated with the equilibrium price, P_0, is the equilibrium quantity, denoted Q_0.

Culture-based products can compete with capture-based products in the market in two ways: as perfect substitutes, or as imperfect substitutes. The effect of perfect substitutability is illustrated in Figure 2. The supply curve for the captured product is represented by the curve $S-S$. The supply curve for the captured plus cultured product is represented by the curve $S'-S'$. The natural market price of the captured product, in the absence of cultured product, is equal to P_0, and the quantity offered on the market is equal to Q_0. With the addition of the cultured product on the market, the equilibrium price is reduced to P_1, while the equilibrium quantity is increased to Q_1. The greater the advances in culturing technology (other factors being held constant), the more one would expect the equilibrium price to fall below that which would be observed in the absence of competition from a perfectly substitutable cultured product.

Cultured product can also be an imperfect substitute for the captured product. If so, changes in the quantity of cultured product produced, and the related change in what would be the market price of the cultured product alone, will result in a change in the position of the demand curve for the captured product. Assume, for example, that the quantity of a cultured seafood product experiences a significant increase that, in turn, causes a reduction in the product's market price. Under this scenario, consumer demand for the cultured product would be expected to increase and to, in turn, cause a reduction in the demand for the imperfectly substitutable captured product. While not illustrated, the reduction in demand for the captured product can be expressed by a downward shift in the
demand curve for the captured product. As a result of the downward shift in the demand curve for the captured product, the equilibrium price received for the captured product will decline, as will the equilibrium quantity.

When dealing with the seafood market, it is important to recognize that competition between cultured and captured products is often global, rather than local, in nature. This situation reflects the large amount of international trade that occurs in fishery commodities. For example, as examined in greater detail in the next section, a sizeable portion of the seafood consumed in the United States tends to be of imported origin, and the percentage is considerably higher for some of the more "desired" species such as shrimp and spiny lobsters. Hence, when one is examining the impact on captured-product markets resulting from competition between cultured and captured species, it is necessary to take an international perspective. When evaluating competition between cultured and captured shrimp, for instance, one must first recognize that the majority of the shrimp consumed in the United States is of imported origin and that much of it is cultured. These imports can affect the domestic capture fishery through their impact on domestic prices. At the other extreme, much of the United States captured-salmon product is destined for overseas markets. Hence, cultured-salmon product that competes with the U.S. wild product in overseas markets is likely to reduce the dockside price of the U.S. product.

It is also important to recognize that competition between cultured and captured products can extend well beyond the species (or group-of-species) level. It is intuitively obvious, for example, that cultured shrimp is likely to compete with captured shrimp in the market place. Can it be said, however, that cultured shrimp competes with, say, cod or flounder? The answer is yes. Consumers have a limited food budget, a certain percentage of which tends to be allocated to seafood products. An increase in cultured production of shrimp that results in a reduction in the price of shrimp to consumers, therefore, is likely to result in a greater percentage of the seafood budget being directed toward the purchase of shrimp and a smaller percentage being directed toward other species, such as cod and flounder. This discussion tends to neglect potential income effects. Specifically, it is possible that the reduction in shrimp price is large enough that real income is enhanced to the extent that it allows consumers to purchase more of all seafood products. The extent to which this kind of very imperfect substitution occurs depends upon the *cross-price elasticity* of demand.

In the light of the foregoing discussion, the next section briefly examines some trends in U.S. seafood consumption and markets, trends from which some inferences are drawn regarding the competition between cultured and captured products. At the end of the next section, some attention is given to competition with respect to individual species.

U.S. CONSUMPTION OF SEAFOOD AND MARKETS

Per-capita consumption of fish and shellfish in the United States, which equaled 5.67 kilograms (12.5 pounds) of

Figure 2. Hypothetical demand and supply curves for seafood, assuming perfect substitutability between captured and cultured products.

edible weight in 1980 (Fig. 3), peaked in 1987 at 7.35 kilograms (16.2 pounds). Since 1987, per-capita consumption has been gradually trending downward; the 1997 per-capita consumption, 6.62 kilograms (14.6 pounds), was only 90% of that observed in 1987 (4). Wessels and Anderson (5) suggest that the downward trend may reflect increases in relative prices of (or decreased demand for) luxury goods during the recessionary period of the early 1990s, as well as perceived increase in the health risk associated with the consumption of seafood. It is noteworthy that, despite large increases in the U.S. real disposable income since the early 1990s, no increase in U.S. per-capita consumption is evident. It has also been suggested that a lack of supply, a lack of marketing activities that would permit the seafood industry to compete better with other, more established industries (such as beef), and a lack of product development (to enhance the convenience of preparing the product for at-home consumption) also play a role in the observed decline in per-capita seafood consumption in the United States (6, 1998).

Despite the downward trend in U.S. per-capita consumption in recent years, total consumption, expressed on an edible-weight basis, has remained relatively stable in the 1.7 to 1.8 billion kilogram (3.75 to 4.0 billion pound) range, as a result of an expanding population base. The product required to meet these consumption needs consists of both domestic and imported product and of both captured and culture product. In 1980, for example, the U.S. supply of edible fishery products (round weight) consisted of 1.66 billion kilograms (3.65 billion pounds) of domestically harvested product and 1.97 billion kilograms (4.35 billion pounds) of imported product; these figures indicate that approximately 55% of the U.S. supply was import-based (Fig. 4). The percentage of imports reported herein likely under represents the proportion used in domestic consumption, because a sizeable percentage of the domestic supply is exported. The ratio of imported to domestic product in overall edible supply peaked in 1985 and 1986, when imports represented approximately 65% of the total supply. Since 1986, the ratio of imported to domestic product has fallen, with imports representing only 40% of the total edible seafood supply by 1993. In 1997, domestic product equaled 3.29 billion kilograms (7.25 billion pounds), or almost 60% of the U.S. edible seafood supply; imports equaled 2.94 billion kilograms

Figure 4. U.S. Supply of Edible Fishery Products (round weight), by domestic and imported sources, 1980–1997. *Source*: (4).

(6.5 billion pounds). It is noteworthy that much of the increase in the domestic supply has been the result of increased pollock landings off the coast of Alaska. Specifically, pollock landings increased from less than 2.3 million kilograms (five million pounds) annually in the early 1980s to in excess of 1.36 billion kilograms (three billion pounds) annually between 1990 and 1993, before falling to 1.13 billion kilograms (2.5 billion pounds) in 1997 (4).

U.S. per-capita consumption of selected seafood items is provided in Table 1 for the years 1987 and 1997. Several features are highlighted by the information. First, domestic consumption of canned tuna, though falling on a per-capita basis, dominates total consumption, accounting for in excess of 20% of the total of the 10 most-consumed species in both 1987 and 1997. Second, per-capita consumption of many of the "traditional" capture-based fishery products — such as cod, flatfish, and clams — has fallen sharply during the period of analysis, at least in part on account of overfishing and the subsequent reduction in the overall supply of these species. The one capture-based fishery wherein per-capita consumption has advanced by a substantial amount is that of Alaska pollock. The harvest of this species is used primarily in surimi-based products, such as crab analog. While only

Table 1. U.S. Per-Capita Consumption (in kilograms) of Selected Seafood Items

	1997	1987	% Change[b]
1. Canned Tuna	1.41	1.59	−11.4
2. Shrimp	1.23	1.04	17.4
3. AK Pollock	0.74	0.40	84.3
4. Salmon	0.59	0.20	203.5
5. Cod	0.48	0.76	−37.1
6. Catfish	0.46	0.27	69.3
7. Clams	0.21	0.30	−30.4
8. Crabs	0.19	0.15	31.3
9. Flatfish	0.15	0.33	−54.6
10. Halibut	0.13	0.11[a]	15.3

[a] Per-capita consumption of halibut was unavailable for 1987. The number presented here is from 1988 data.
[b] Percentage change may not quite agree with the numbers given in the table, because of rounding.
Source: (6, various issues).

recently developed, the fishery is already showing sign of overfishing: landings declined, from 1.5 billion kilograms in 1993 to 1.13 billion kilograms in 1997 (4). Finally, the information contained in Table 1 suggests that three of the top ten species—shrimp, salmon, and catfish—are all associated, to a greater or lesser extent, with culture activities. Per-capita consumption of these three species accounted for only 21% of the total per-capita consumption in 1987, but almost 35% of the total in 1997. Overall, U.S. per-capita consumption of salmon tripled during the period, while per-capita consumption of catfish and shrimp increased by 170% and almost 20%, respectively.

At least two inferences, with respect to market impacts resulting from competition between cultured and captured product, can be drawn from the information presented above. One is that cultured products appear to be increasingly being substituted for the traditional captured products in the American seafood diet. The implications of this process are two-fold. First, the increased consumption of cultured products, because they are in general imperfect substitutes, has likely resulted in a reduction in demand for some of the traditional captured species, all other things being equal. This reduction implies that prices for some of the more traditional captured species are likely lower than they would have been in the absence of the increased availability (and consumption) of the cultured species. The second implication is that the increased availability of cultured species, to the extent that their increased acceptance has resulted in a reduction in demand for the captured species, has helped to alleviate at least some of the fishing pressure (and resultant, overfishing) generally associated with many of the captured fisheries. As one example, Keithly et al. (7) estimated that the number of vessels in the U.S. Gulf of Mexico shrimp fishery would have been approximately 7,100 in 1988 rather than the reported 5,930, if there had been no shrimp aquaculture (and concurrent increase in U.S. imports) that subsequently led to a decline in the (constant dollar) dockside shrimp price.

The second inference that can be drawn from the information presented earlier is that U.S. consumption of seafood products is, to a large extent, driven by the import market—and that, in turn, is driven largely by global activities. Consequently, changes in activities in other countries that result in increased culture production and subsequent export of this product to the United States can significantly reduce captured production in the United States. As discussed in greater detail in later sections, this is the situation facing several of the larger capture-based U.S. fisheries, particularly shrimp and salmon. Specifically, increased cultured production of these species in other regions of the world has significantly reduced the U.S. prices of these captured species (as measured at the dockside).

ANALYSIS OF INDIVIDUAL SPECIES

Six species are examined in this section of the paper. Two species, shrimp and salmon, are examined in considerable detail, because of their significance in world trade as well as in the U.S. seafood budget. Other species considered include crawfish, alligator, catfish, and tilapia. These six species, while not all-inclusive, represent many of the more relevant species, for which cultured product competes with captured product, and their story provides adequate "flavor" regarding the different ways in which the cultured product can compete with the captured product.

Shrimp

World exports of shrimp, valued at $8.1 billion, constituted about 15% of the $52 billion international trade market in fisheries commodities in 1996 (8) (1996) and were the largest single item in seafood trade. Trade in shrimp has expanded considerably since the 1980s, in response both to increased world production of the commodity, primarily from culture activities, and to favorable economic conditions. To examine the extent to which cultured shrimp competes with the captured product in the market place, some basic production trends are first considered for the period 1980–1996. Then, attention is given to the trade market in shrimp. Finally, the competition between the two products is considered.

Production Trends. Shrimp production, as with the other seafood commodities discussed in this section, is a combination of wild harvest and farming activities. Estimated total annual shrimp production (i.e., capture and culture production) throughout the world, as indicated in Figure 5, expanded from 1.57 billion live-weight kilograms (3.48 billion pounds) in 1980 to 2.9 billion kilograms (6.41 billion pounds) in 1996. Production of *Acetes japanicus*, a species harvested primarily in China and used for paste, has been excluded from total production figures presented herein. This increase translates into a growth rate of approximately 78 million kilograms (170 million pounds) per year.

In general, shrimp production can be segmented between warm-water species and cold-water species. The warm-water species tend to grow considerably larger than the cold-water species and also tend to command a much higher price per unit weight on the world market (7). Production from Asia, Central America, and South America tends overwhelmingly to be of the warm-water species. The United States produces significant quantities of both warm-water and cold-water species. Shrimp production in most other producing areas of the world is primarily of cold-water species.
Figure 5. Estimated World Shrimp Production (live weight), by primary producing regions, 1980–1996. *Source*: (9).

The majority of world production, as is indicated in Figure 5, is Asian based. In 1980, an estimated 55% of the world shrimp production was of Asian origin. With a doubling in production since 1980, Asia's production of 1.91 billion kilograms (4.23 billion pounds) in 1996 represented 65% of the total world output of captured and cultured shrimp. Shrimp production in Central America generally fell into the relatively narrow range from 100 million to 125 million kilograms (220 million to 275 million pounds) annually during the period 1980–1992. After 1992, however, production advanced by a substantial amount, to about 133 million kilograms (294 million pounds) in 1996. South American production, more than doubled during the period of analysis; 85 million kilograms (187 million pounds) in 1980, compared to 232 million kilograms (512 million pounds) in 1996.

Combined production from Central and South America (194 million live-weight kilograms, or 428 million pounds) represented 13% of estimated world output in 1980. In general, little change in the share of world production from this area has been evident, despite substantially higher production in recent years (366 million kilograms in 1996). While production from Central and South America represents a relatively small percentage of the world total, Latin America plays a significant role in the international shrimp market because much of its output is destined for the U.S. market (10). This relationship is examined in greater detail next.

The United States, although one of the world's two largest importers of shrimp (along with Japan), nonetheless produces significant quantities of shrimp (Fig. 5). With exceptions, annual live-weight production of shrimp in the United States generally ranged from about 135 to 165 million kilograms (300 million to 365 million pounds), and no discernible trend in U.S. production was evident, during the period 1980–1996. Shrimp production from "other" areas tended to average 15% to 20% of the world production during 1980–1996. Most of the production is of cold-water species, with Europe generally accounting for approximately one-half of the total.

Much of the growth in world shrimp production since 1980 has been the result of successful culture activities throughout the world, particularly in Asia and, to a lesser extent, in South and Central America. World production of cultured shrimp equaled about 90 million live-weight kilograms (200 million pounds) in 1980, about 6% of total world production then. By 1996, culture production had advanced to about 0.91 billion live-weight kilograms (2.0 billion pounds), approximately one-third of the total world production of shrimp at that time. The penaeid shrimps account for more than 95% of the cultured production (11). Wild harvest during the same period advanced from about 1.6 billion kilograms (3.5 billion pounds) to 2.0 billion kilograms (4.4 billion pounds), or by about one-quarter. It is thus evident that the overwhelming majority of shrimp production growth during the period 1980–1996 has been the result of expanded farming activities.

When examined on a regional basis, world production and growth in cultured shrimp is dominated by Asia. Estimated Asian production of cultured shrimp in 1985 equaled about 180 million live-weight kilograms, which accounted for about 85% of the world supply of cultured shrimp for that year and about 15% of the region's total shrimp production (i.e., wild plus cultured). By 1996, Asia's production of cultured shrimp had increased to 0.78 billion kilograms, which represented almost 80% of the world's supply of cultured shrimp and about 40% of the region's total shrimp output (12). Major Asian producers of cultured shrimp in 1996 included Thailand (223 million kilograms; 491 million pounds), Indonesia (156 million kilograms; 343 million pounds), India (87 million kilograms; 192 million pounds), Philippines (78 million kilograms; 172 million pounds), and China (89 million kilograms; 195 million pounds).

South American shrimp culture advanced from an estimated 32 million live-weight kilograms (71 million pounds) in 1985 to 125 million kilograms (275 million live-weight pounds) in 1996 (12). The cultured production's share in relation to the total production from the region for the period ending in 1996 advanced from less than one quarter to more than one half. Ecuador, the primary producer of cultured shrimp in the region, accounts for about 85% of the South American total. Production of cultured shrimp in Central America is relatively minor compared to that in either Asia or South America. It did, however, increase from a negligible amount in the mid-1980s to about 35 million kilograms (80 million pounds) in 1996. Mexico accounted for more than a third of the 1996 farm-based output; Panama and Honduras also contributed sizeable amounts (12).

Trends in World Exports and Imports. World exports of fresh and frozen shrimp (the two categories constituting the overwhelming majority of trade) equaled 387 million product weight kilograms or 854 million pounds in 1980 (Fig. 6). By 1996, exports had increased by about 170%, to 1.09 billion kilograms (2.4 billion pounds). The fact that the percentage increase in the world shrimp trade from 1980 to 1996 greatly exceeded the 75% increase in world production during the corresponding period suggests that an increasing proportion of world production is being traded on the world market. Keithly and Diagne (10) estimated that about 40% of the world production entered the world trade market in 1980, compared to 60% currently.

The value of world shrimp exports in 1980 equaled $2.3 billion. The Food and Agriculture Organization of the United Nation's estimates that this value represented 15% of the total world trade in seafood products. By 1996, the current value of world shrimp trade had more than tripled, to $8.1 billion. Much of the apparent increase in the value of world shrimp trade during the period of study was due to currency inflation. After adjusting for inflation, and in terms of the 1982–1984 Consumer Price Index, the value of world shrimp trade advanced by 85%, from $2.8 billion to $5.2 billion. This 85% increase in constant-dollar value was significantly lower than the 175% increase in export quantity, indicating a sharp decline in the real price of the exported product during the period of analysis. Overall, the 1996 constant-dollar price, $4.78 per product-weight kilogram ($2.17 per pound), reflects a one-third decline
Figure 6. World Exports of Shrimp (product weight) and associated export price (in constant dollars), 1980–1996. *Source*: (8).

in export price when compared to the $7.25 per kilogram ($3.29 per pound) price observed in 1980 (Fig. 6). This decrease would tend, all other things being equal, to suggest that growth in supply from 1980 to 1996 exceeded the growth in demand and caused a downward trend in the real price of the product.

The five largest shrimp exporters by value in 1980, as is indicated in Table 2, were Mexico ($495 million), India ($233 million), China ($180 million), Indonesia ($178 million), and Australia ($131 million). Exports from these five countries represented 53% of 1980 global exports by value and 40% by weight. Of these five countries, only Indonesia and India had any sizable cultured-shrimp activities at the time. In conjunction with growth in cultured production in many countries throughout the world, export sources changed. By 1996, Mexico had fallen from being the largest exporting country to being only the fifth-largest, while Thailand, which was not even among the top five exporters in 1980, replaced Mexico as the largest exporter of shrimp. All of the five largest exporting countries in 1996, with the exception of Mexico, reported cultured production in excess of 68 million live-weight kilograms (150 million pounds), and two of the countries, Thailand and Indonesia, had cultured production surpassing the 136 million kilogram

Table 2. World Exports of Fresh and Frozen Shrimp by Principal Countries, 1980 and 1996[a]

Country	Million Kilograms	$ Million
	1980	
1. Mexico	43.6	495.0
2. India	47.8	233.3
3. China	21.7	180.2
4. Indonesia	30.5	177.9
5. Australia	12.1	130.7
	1996	
1. Thailand	162.2	1,721.9
2. Indonesia	84.3	848.3

Source: (8).

(300 million pound) mark. As noted by Csavas (13), cultured shrimp is of greater importance than wild shrimp in export markets. The reasons cited by the author include the following: (*1*) the cultured product has greater "freshness" than the wild product; (*2*) cultured shrimp production is less seasonal in nature, and more reliable, than its wild counterpart. As noted by Csavas, the seasonal nature of wild-based product results in idle capacity among processing establishments over extended periods of time and has increased storage costs for importers and exporters, who must keep higher supplies to satisfy consumer needs. (*3*) species and sizes can be controlled better in a cultured-based system than in a wild-based system; and (*4*) the current trend towards vertical integration in the cultured system lends itself to better adaption to consumer needs.

While the primary exporters of shrimp are many and have changed substantially over time, two countries, the United States and Japan, have long dominated the import market. These two countries accounted for almost three-quarters of world shrimp imports, by value, in 1980, and about 60% in 1996 (8). In general, Japan and the U.S. prefer the warm-water species that account for the vast majority of cultured shrimp production (10). Shrimp imports by the European countries, which account for much of the remaining trade in shrimp, have historically been dominated by the cold-water species, though this situation is gradually changing. In particular, the European countries are reportedly purchasing an increasing share of the Ecuadorian product. Jacobson (14), for example, reported that 31% of the 1992 Ecuadorian shrimp exports went to the European market, 67% to the U.S. market. Annual U.S. shrimp imports, expressed on a *headless shell-on equivalent* basis, approximately tripled during the 17-year period ending in 1996, from 118 million kilograms (260 million pounds) to 327 million kilograms (721 million pounds) (Fig. 7). Imports from Asia advanced from about 32 million kilograms (70 million pounds) in 1980 to 175 million kilograms (385 million pounds) in 1996, while imports from South America advanced from 14.5 million kilograms (32 million pounds) to 69 million kilograms (152 million pounds). Increased U.S. imports of shrimp from both of these regions have largely been in response to increased output, particularly cultured production (10). Annual U.S. shrimp imports from Central America, unlike those observed from Asia

Figure 7. U.S. Imports of Shrimp (headless shell-on equivalent weight), by primary regions, 1980–1996. *Source*: (15).

and South America, exhibited little or no upward trend over the period 1980–1996. This period coincides with the relatively long-run stable production in the Region (see Fig. 5). Overall, the United States imported an estimated 13% of the total world shrimp production (excluding U.S. production) in the early 1980's, about 20% by the mid-1990s. This increase primarily reflects the greater U.S. utilization of cultured Asian and, to a lesser extent, South American production.

Japan's imports of fresh and frozen shrimp advanced from 144 million product-weight kilograms (318 million pounds) in 1980 to 289 million kilograms (636 million pounds) in 1996 (16). Japan's imports cannot be converted to a headless shell-on weight, as was done for the United States, because of insufficient information. Niemier and Walsh (17) report that about 70% of Japan's total shrimp imports are in the form of a headless shell-on product. The vast majority of Japan's shrimp imports are of Asian origin—from 75% to more than 80%. As importers, Japan and the U.S. compete primarily for the Asian product. As was the case for the United States, increased culturing activities in Asia have provided additional shrimp supply for the Japanese market.

Competition Between Wild and Cultured Shrimp. The United States, as noted, harvests sizeable quantities of shrimp. These harvests are composed of both warm-water (panaeid) and cold-water (pandalid) species. The warm-water species are harvested primarily in the Southeast (the coastal states extending from North Carolina through Texas); the cold-water species are harvested in the New England and Pacific Regions. Farm-raised shrimp are primarily of warm-water species and compete primarily with the U.S. captured warm-water shrimp production.

The annual capture of warm-water shrimp in the United States (i.e., Gulf of Mexico and South Atlantic landings) is illustrated in Figure 8 for the 1980–1997 period. It varies considerably on an annual basis, and no discernable trend in annual production is evident. It has been suggested that the large variation is primarily induced environmentally, largely by changes in salinity and water temperature during the shrimp's growth cycle—many factors contribute to the number and average size of shrimp caught (18).

While the U.S. annual capture of warm-water shrimp has exhibited no discernable trend between 1980 and 1997, the constant-dollar price of the landed product has clearly fallen; as with landings, however, considerable variation in the dockside price is also evident. Overall, the 1995–1997 constant-dollar dockside price, $2.82 per live weight kilogram ($1.28 per pound), was approximately 30% below the constant-dollar 1980–1982 average annual dockside price, $4.01 per live-weight kilogram ($1.82 per live-weight pound) (approximately $2.95 per headless pound). This decline is particularly striking in the light of the fact that U.S. per-capita income has risen sharply since the early 1990s. There is general agreement (1) that most, if not all, of the decline in real price since 1980 is the result of increased imports, primarily-farm based in nature, which compete directly with the domestic wild catch in the market place and (2) that, in the absence of the increased cultured production, prices in 2000 would be significantly higher than those observed in the early 1980s.
Figure 8. Annual U.S. Gulf of Mexico and South Atlantic (i.e., warm-water) shrimp landings (live weight), and associated dockside price (in constant dollars), 1980–1997. *Source*: (4).

In one of the few studies that attempted to evaluate the impact of cultured shrimp on U.S. dockside prices, Keithly et al. (7) estimated that, in the absence of farm product, the 1988–1989 Southeast U.S. dockside shrimp price would have been approximately 70% above that actually observed during the period, and import supply would have been approximately 30% below observed levels. The authors also suggested that, in the absence of significant income expansion in the United States, further increases in cultured shrimp production would result in further erosion of the domestic U.S. real dockside price.

Using monthly time-series data covering the period 1981–1995, Gillig et al. (19) analyzed the U.S. Gulf of Mexico shrimp *ex-vessel* prices by size classes. Overall, three size classes of shrimp were examined: under 30 count to the pound (0.45 kg), 30–67 count to the pound, and over 67 count to the pound. The authors found that South American exports to the United States (lagged one month) significantly influenced the dockside prices of all three classes, a fact implying that South American shrimp substituted for all size classes of domestic landings. The authors found that a 10% increase in South American exports to the United States would be expected to result in a decrease of less than 1% in the dockside price of the large shrimp, but one of almost 2% in the price of the small shrimp. The fact, that (a) South American exports to the United States approximately tripled during the period 1980–1996 (from 23 million kilograms to 69 million kilograms) and (b) the vast majority of this increase was in increased cultured product from Ecuador suggest that increases in cultured product in South America have significantly reduced the Gulf of Mexico dockside prices in all classes. Exports to the United States from Asia (lagged one month) were found to reduce the dockside price of only the midsize [i.e., 30–67 count to the pound (0.45 kg)] shrimp; exports from Central America (lagged one month) were found to reduce the Gulf of Mexico dockside price of only the small size [i.e., over 67 count to the pound (0.45 kg)].

Keithly and Diagne (10) used a slightly different technique to examine the impact of increasing imports on the Gulf of Mexico dockside price, using quarterly data covering the period 1980–1995. Assuming that the imported shrimp from the different regions were imperfect substitutes for domestic production, the authors specified the Gulf of Mexico dockside price (deflated to constant dollars) as a function of the deflated prices of the imported product from the three primary exporting regions (Central America, South America, and Asia), of the quantity landed in the Gulf of Mexico, of the average size of shrimp landed in the Gulf of Mexico (i.e., estimated number of shrimp to the pound), and of other exogenous variables. The authors found that the Central American import price had the greatest effect on the Gulf of Mexico dockside price: a 10% increase (decrease) in Central American price resulted in a 7.2% increase (decrease) in the deflated Gulf of Mexico dockside price, all other variables being held constant. By comparison, a 10% increase (decrease) in the South American import price was found to result in only a 4.7% increase (decrease) in the Gulf of Mexico dockside price; a 10% increase (decrease) in the Asian import price was estimated to result in only a 2.5% increase (decrease) in the Gulf of Mexico dockside price. Both the Central American and the South American real export prices to the United States fell sharply during the period 1980–1995; these declines help to explain the decline in the Gulf of Mexico dockside price.

The Southeast U.S. harvesting sector is one component of the shrimp industry that generally has been unable to make the adjustments needed in response to the growing import base and the resulting suppression of prices. Not unexpectedly, therefore, requests for relief from perceived problems associated with increasing imports originate primarily from the harvesting sector. In the southeastern United States, harvesters have frequently sought regulatory relief from burdensome imports.

The first of three such attempts occurred in 1975, when the U.S. International Trade Commission (USITC), through the public hearing process, reacted to a petition filed by the National Shrimp Congress. The subsequent investigation in 1976 sought to determine whether shrimp products identified in item 114.45 of the Tariff Schedules of the United States were being imported in quantities that caused serious injury to the domestic shrimp industry. The initial investigation, it should be noted, occurred before cultured shrimp production was a significant factor. The analyses and public testimony resulted in a finding of serious injury to the native capture fishery. Adjustment assistance permitted under Title II of the Trade Act was approved, to allow shrimp-boat operators to obtain loans or loan guarantees. This action, it was reasoned, would help domestic shrimp producers become competitive with foreign producers. Approximately five years later, it was pointed out that this action had actually failed to provide a remedy. In response, John Breaux of Louisiana (then a U.S. Representative and later a U.S. Senator), authored a bill to formulate policy, including a temporary quota combined with a 30% ad-valorem tariff, to provide for domestic shrimp industry protection (H.R. 4041). Although the bill failed to attain the support necessary for passage, it was significant, because it was introduced at the time that cultured shrimp was becoming an increasingly significant factor, and because attention was focused on the harvesting sector.

The focus remained on the shrimp harvesting sector when, in 1985, the International Trade Commission again evaluated the shrimp import situation. Renewed supply increases, primarily from cultured activities, were being experienced. The frequent forecasts of overseas successes of shrimp-farming companies were becoming a reality. The prospect of additional shrimp farming successes in Central America, South America, and Asia loomed on the business horizon. In explaining the situation to the U.S. International Trade Commission (20), the U.S. Gulf of Mexico and South Atlantic shrimp harvesters claimed (a) that harvesting businesses were being injured as a result of imports, and (b) that shrimp industries in foreign countries benefit from government assistance, which artificially allows their products to be more competitive in U.S. markets.

Following a staff review of the information and a public hearing, the USITC chose to issue a report rather than

to recommend actions. Through these activities, it became apparent that United States policy and regulations would not be used to protect capture-fishery participants; the implication was that the harvesting sector would have to compete with a growing import base and further price suppression.

The impetus for trade investigations for shrimp, as noted, emanated from the southeastern U.S. shrimp harvesting sector. Other components in the industry, most notably the processing sector, did not actively pursue import restraints; they were benefitting from the increased imports at the time of the investigations. Some anecdotal evidence of this fact was presented by Roberts et al. (21), through the examination of secondary data available on the shrimp processing sector. The authors reported that during the period 1970–74, southeastern U.S. landings of shrimp averaged 66.7 million kilograms (147 million headless pounds) annually, while headless shell-on equivalent weight processing activities equaled 94.4 million kilograms (208 million pounds); the discrepancy suggested an annual deficit, in domestic supplies relative to processing requirements, of about 27.2 million kilograms (60 million pounds). This deficit had expanded to almost 32 million kilograms (70 million pounds) by 1980–1984, and it exceeded 40 million kilograms (90 million pounds) by 1985–1988. The increasing deficit between domestic landings and processing activities led the authors of that study to conclude that imports were playing an enhanced role in the southeastern U.S. processing activities during the period of analysis. In addition, the authors found, through collection of primary data, that (a) while Florida and Georgia shrimp processing establishments exhibited a long history of imported shrimp usage, firms in Alabama, Mississippi, and Louisiana had begun using imported shrimp in their processing establishments more recently, in conjunction with the increased cultured shrimp exports to the United States; (b) processing establishments that used imported shrimp more than doubled their output during the period 1974–1987, while firms not using imported shrimp, by comparison, showed no growth; and (c) among plants not using imports, growth occurred only in the raw peeled shrimp category, but among processors of imported shrimp, the shell-on, raw-peeled, and breaded activities all exhibited large quantity increases. In general, the authors concluded that imports of cultured shrimp permitted the processing sector to increase overall processing activities significantly, by providing an additional source of raw-material supply.

In a subsequent analysis, in 1991, Keithly and Roberts (22) found that, while the southeastern U.S. shrimp processing sector depended primarily on domestic landings for the production of raw headless and peeled raw product, production of the peeled cooked and breaded products relied primarily on imported raw material to satisfy processing capacities. Specifically, imported raw material constituted more than 90% of the input used in the production of both breaded and peeled cooked product, but only about 20% of the raw headless and peeled raw product. Overall, three countries (China, Ecuador, and Thailand) were found to account for approximately two-thirds of all the imported shrimp used in the southeastern

U.S. shrimp processing activities in 1991. All of these countries were major producers of cultured shrimp at the time of the study. Year-round availability of the imported (primarily, cultured) product was one of the reasons most frequently cited for the use of imports.

Recent analysis by Diop (23) suggests that the southeastern shrimp processors may no longer be benefitting from the increased import supply, because of a continued narrowing of the marketing margin between the price of the processed product and the price of the raw input used to produce the processed product. Overall, this study found a pronounced decrease in the number of processing establishments between 1988 and 1996 (a 37% decline), along with little or no increase in processed quantity (product weight). To adjust to the declining marketing margins, the remaining processors have increased the output per establishment. This analysis suggests that, if increases in cultured shrimp production and subsequent export of the product to the U.S. market continue at the rate observed during the past decade, the marketing margin between raw and processed product, as well as the number of firms in the industry, will further erode.

Salmon

Growth in the per-capita consumption of salmon in the United States during the 1987–1997 period, as earlier noted, has been substantial. That growth reflects large increases in the production of cultured salmon throughout the world, much of which is destined for the U.S. market. There exists, however, a sizeable capture fishery for salmon in the United States, and much of its product is exported to European nations and Japan. The increased cultured production, on top of the increases in the captured product, has resulted in a significant decline in the constant-dollar U.S. dockside price of the different salmon species. To examine this phenomenon, trends in world production of cultured and captured salmon will first be reviewed; then, the export market for salmon will be analyzed; finally, competition between the captured and the cultured product will be investigated.

Production Trends. World production of salmon has expanded, from an estimated 568 million kilograms live weight (1.25 billion pounds) in 1980 to 1.56 billion kilograms (3.4 billion pounds) in 1996 (Fig. 9). As with shrimp, much of the increase has been the result of successful culture activities. In 1980, culture product equaled approximately 7.2 million kilograms (16 million pounds), approximately 1% of the total world production. By 1996, cultured production, equal to 643 million kilograms (1.4 billion pounds), accounted for 40% of the total world salmon supply. As noted by Anderson and Fong (25), a sizeable, but unknown, percentage of the wild salmon production is attributable to ranching. Inclusion of this ranched production would increase the culture share.

Three species of salmon—Atlantic, chinook, and coho—account for virtually all of the farming activities in recent years (12). Farm production of Atlantic salmon in 1996 equaled 556 million kilograms (round weight) and represented 85% of the global farm production of
Figure 9. Estimated World Production of Salmon (live weight), by wild and cultured product, 1980–1996. *Source*: (24,9, and 12).

salmon for the year. Production of farm-raised coho salmon equaled 76 million kilograms (167 million pounds) and represented approximately 11% of the farm-based output. Production of chinook salmon was relatively small (12 million kilograms) and accounted for less than three percent of the world farm-raised production of salmon in 1996.

Production of farm-raised salmon is dominated by Norway (301 million kilograms), which accounted for almost 50% of the world's total in 1996 (12). All of the product raised in Norway is Atlantic salmon. Chile, the world's second-largest producer of farm-raised salmon, produced 145 million kg (319 million lb) of product in 1996, approximately one-fifth of the world's farm-raised product. Almost one-half of Chile's farm-based output in 1996 was coho salmon; Chile's production of this species represented the vast majority of the world's production of this species. Other major world producers of farm-raised salmon include the United Kingdom (83 million kg 1,83 million lb), Canada (45 million kg, 99 million lb), the United States (14 million kg, 31 million lb), and the Faroe Islands.

Six species of salmon — pink, chum, sockeye, coho, chinook, and cherry — compose the majority of wild harvest (9). Pink salmon (295 million kg, 649 million lb) accounted for almost a third of the 1996 wild harvest; chum salmon production (411 million kg, 904 million lb) accounted for an additional 40% of the total. Sockeye and coho salmon, both of which are harvested primarily in the United States, accounted for 20% and 3%, respectively, of the 1996 global supply of wild product. Overall, approximately 40% of the 1996 world wild harvest of salmon was produced in the United States (398 million kg, 876 million lb); an additional 35% was produced in Japan (342 million kg, 752 million lb). Most of the remaining production was from the Russian Federation (163 million kg, 359 million lb).

World Exports and Imports. World exports of fresh and frozen salmon, which equaled 89.2 million product-weight kilograms (197 million lb) in 1980, advanced to 665.3 million kg (1.47 billion lb) in 1996 (Fig. 10); that change translates into a growth rate of about 35 million kg (77 million lb) per year. On a percentage basis, the increase exceeded 600%. With few exceptions, growth in exports occurred throughout the entire 17-year period ending in
Figure 10. World exports of salmon (product weight), and associated export price (in constant dollars), 1980–1996. *Source*: (8).

1996; that growth parallels the growth in cultured salmon production.

The value of fresh and frozen salmon exports advanced from $408 million in 1980 to $2.6 billion in 1996 (8). After adjusting for inflation (based upon the 1982–1984 U.S. Consumer Price Index), the increase was from $495 million to $1.6 billion (230%). The fact that the percentage change in the quantity exported during the period 1980–1996 greatly exceeded the percentage change in constant-dollar value over the same period suggests a sharp decline in the constant-dollar price of the exported product. As indicated in Figure 10, the constant-dollar export product weight price fell from $5.54 per kilogram ($2.51 per pound) in 1980 to $3.86 per kilogram ($1.75 per pound) in 1985, before advancing sharply to the original price ($5.54 per kilogram) in 1988. Since 1988, however, the price has again fallen sharply, to just $2.46 per kilogram ($1.12 per pound) in 1996.

The five largest exporters of fresh and frozen salmon in 1980, as indicated in Table 3, were the United States [55 million kg (121 million lb)], Canada [20 million kg (44 million lb)], Norway [four million kg (8.8 million lb)], Denmark [two million kg (4.4 million lb)], and Greenland [one million kg (2.2 million lb)]. Combined, these five countries accounted for more than 90% of the world total of fresh and frozen salmon exports in 1980, on the basis of either poundage or value. By 1996, Norway's exports had advanced to 214 million kg (471 million lb), an amount constituting almost one-third of the world's exports of fresh and frozen salmon in that year. Essentially all of the growth in Norway exports was the result of increased

Table 3. World Exports of Fresh/Chilled and Frozen Salmon by Principal Countries, 1980 and 1996[a]

Country	Million Kilograms	$ Million
1980		
1. United States	55.4	198.4
2. Canada	19.6	99.7
3. Norway	4.2	48.0
4. Denmark	2.0	17.9
5. Greenland	1.3	8.7
1996		
1. Norway	214.1	882.6
2. United States	124.5	464.8
3. Denmark	57.2	243.2
4. Canada	47.8	240.4
5. Chile	70.2	240.0

Figure 11. U.S. Imports of Salmon (round weight equivalent), by primary countries, 1980–1997. *Source*: (15).

culturing activities in the country. Similarly, 1996 exports from Chile, which ranked third in terms of volume and fifth by value, were essentially all of a farmed nature. While the available statistics do not allow the separation of the exported wild product from the cultured product, much of the growth in Canadian exports between 1980 and 1996 likely reflects increased cultured product entering into the international market. One can surmise that most of the increase in U.S. exports of salmon between 1980 and 1996 reflects increased exports of wild product, from the fact that U.S. production of cultured salmon equaled only 14 million kg (31 million lb) in 1996. In general, the information in Table 3 clearly demonstrates the increasing role of cultured salmon production in international trade, when it is evaluated on a country-by-country basis.

Japan and the United States have traditionally been the world's primary salmon markets. As a result of rapid expansion in culture activities, however the market for salmon in the European Community has advanced rapidly during the past decade (26). On the basis of imports, Japan, which imported almost 192 million kg (422 million lb) of fresh and frozen salmon product in 1996, accounted for almost 40% of the trade in these products by volume. The second and third largest importers of fresh and frozen product in 1996 were France and Denmark, respectively. The majority of the product imported by Denmark is subsequently re-exported. While being a major exporter of (mostly wild) salmon, the United States imports of (mostly farmed) salmon (round weight converted basis) expanded from 3.6 million kilograms (eight million pounds) in 1980 to 150 million kilograms (332 million pounds) in 1997 (Fig. 11). In 1980, Canada accounted for virtually all of the salmon imported by the United States. By 1997, Canada's share of salmon exports to the United States, 64 million kilograms (274 million pounds), had to approximately 40%.

In lockstep with advances in salmon culture activities in Norway, salmon exports from Norway to the United States expanded from virtually nothing in 1980 to almost 17 million kilograms (37 million pounds) in 1989. In 1990,
a dispute between the United States and Norway arose, regarding allegations that the Norwegian salmon industry was dumping product onto the U.S. market and thereby potentially undermining the viability of the U.S. cultured salmon industry. The details of this dispute can be found in (25). On 25 February 1991, the U.S. International Trade Commission (USITC) ruled that the Norwegian industry was selling its farm-based product at below market value and that Norwegian imports were benefitting from subsidies provided to the industry. A countervailing duty of 2.27% was placed on fresh Norwegian product imported by the United States as a result of these findings by the U.S. International Trade Commission; in addition, an antidumping duty ranging from 15.65% to 31.81% was levied on selected companies. The effect of these actions was a significant decline in Norwegian exports of salmon to the United States. By 1991, specifically, Norwegian exports to the United States had fallen to less than 2.25 million kg (five million lb) and by 1997 had recovered only to the 3.6 million kg (eight million lb) mark.

Chilean exports to the United States were nonexistent in 1980. In conjunction with culturing activities in the country, however, exports of Chilean salmon to the United States advanced rapidly, exceeding the Norwegian peak of 17 million kilograms (38 million pounds live weight equivalent) by 1993. Chilean exports to the United States of 68 million kilograms (149 million pounds) in 1997 accounted for almost one-half of the total U.S. imports of 151 million live-weight kilograms (332 million pounds) for the year. The United States is by far the largest market for Chilean salmon. According to the United States International Trade Commission (27), the United States accounted for more than 90% of the dressed and cut Chilean salmon exports (i.e., steaks, fillets, etc.) in 1996, and one-third of the whole product that was exported, though the U.S. share of this latter product has been declining. Home-market consumption of the Chilean production is only about 2%.

As was the case with the Norwegian product, the rapid rise of Chilean salmon exports to the United States resulted in an investigation by the USITC, pursuant to section 735(b) of the Tariff Act of 1930. The purpose of that investigation, the petition for which was filed by the Coalition for Fair Atlantic Salmon Trade, was to determine whether the salmon industry in the United States was being materially injured, or was being threatened with

material injury, by imports from Chile of fresh Atlantic salmon. On July 22, 1998, the Commission reported to the Secretary of Commerce that it had made a determination (pursuant to the anti-dumping investigation) that the industry in the United States was being materially injured or was being threatened with material injury by imports from Chile of fresh Atlantic salmon that were found by the U.S. Department of Commerce to have been sold at below fair value (27). In response, countervailing duties ranging from 0.2% to 11% were imposed on specific exporting companies; exporting companies not identified in the original petition were assessed a countervailing duty equal to 5.9%.

Competition Between Wild and Cultured Salmon. The salmon fishery is one of the most valuable U.S. capture fisheries at dockside, valued at $270 million in 1997 (4). There are five commercially harvested species of Pacific salmon in the United States (28). U.S. landings of high-valued salmon (mainly chinook, coho, and sockeye) in 1997 equaled 108 million kilograms (237 million pounds) worth $221 million at dockside (4). U.S. production of low-valued salmon (such as chum and pink salmon) in 1997 equaled 150 million kilograms (330 million pounds), but the dockside value equaled only $49 million (4). Overall, the average price of the high-valued salmon, $2.05 per kilogram ($0.93 per pound), exceeded the average price of the low-valued salmon, $0.33 per kilogram ($0.15 per pound), by a factor exceeding five.

The differences in prices for the different salmon species reflect distinct characteristics of the different species that fill different niches in the market place (28). The chinook salmon, because of its high fat content, is valued for smoking; it is the preferred salmon species among high-end restaurants in Europe and the United States. Coho salmon, by comparison, are frequently purchased by the European market for smoking, but they are more affordable to U.S. consumers than chinook salmon. U.S. production of sockeye salmon is almost exclusively marketed in the Japanese market, whose consumers favor its flavor and its deep red color. Chum salmon, because of its low ex-vessel value, is often used as a fast-food product; pink salmon is often canned and is consumed both domestically and abroad.

The constant-dollar ex-vessel prices of the three high-valued salmon species harvested in the United States are presented in Figure 12 for the period 1980–1997. As indicated, the constant-dollar prices of all three species fell sharply after 1988. The marked fall in 1989 reflected the sharp increase in farmed production in 1989, which exceeded the 1988 production level by 45% (25) and paralleled the sharp decline in the export price for salmon products (see Fig. 10). The decline in constant-dollar prices since 1989 reflects the continued expansion of farm-raised product as well as increased harvests of wild product. Analysis by Herrmann (29, as cited in 28) indicates that 90% of the decline in the Alaska dockside price of salmon after 1988 and on into the early 1990s was attributable to increased world supplies of salmon rather than to such other factors as changes in exchange rates and worldwide recessions.
Figure 12. U.S. Dockside Price (in constant dollars) of high-value salmon species, 1980–1997. *Source*: (4).

One of the earliest econometric studies that examined the role of cultured salmon was conducted by Herrmann and Lin (30). Using a set of simultaneous equations, the authors estimated the market conditions for Norwegian Atlantic salmon in the United States and in the European Community. Using monthly data covering the period from 1983 through March 1987, the authors estimated that chinook salmon were a weak substitute for Norwegian-produced salmon in the U.S. market. Specifically, the cross-price elasticity between chinook salmon and Norwegian Atlantic salmon in the United States (0.56) suggested that a 10% decrease (increase) in the price of the Norwegian product would result in a 5.6% decrease (increase) in the U.S. demand for chinook salmon. With respect to the European Community market, the authors estimated that European imports of chinook, sockeye, and coho salmon from North America were weak substitutes for Norwegian-produced Atlantic salmon. The authors also concluded that a 1% increase in the U.S. price of the Norwegian product resulted in a long run increase of about 6% in the supply of Norwegian salmon to the U.S. market, and the same percentage increase in the European price resulted in a roughly equivalent percentage decline in product directed to the U.S. market. Finally, the Norwegian product was found to be a luxury good in both the U.S. and European Community markets.

As noted by Herrmann (28), "[s]ince (the 1988 study), several others have found that farmed Atlantic salmon and high-valued Pacific salmon (chinook, coho, and sockeye) are substitutes in the markets of the United States, Europe, and Japan. The substitutional relationship has been expanding in both strength and significance (p. 12)." These studies include ones by Herrmann et al. (31,32) and by DeVoretz and Salavannes (33). More recently, Asche et al. (26) have also provided evidence of substitution between farmed Atlantic and wild Pacific salmon. While substitutability between Norwegian and high-valued Pacific salmon has been found in many of the econometric studies, substitutability of these products in the Japanese market is less well substantiated (32). Given the facts, however, that the U.S. production of coho salmon is destined primarily for the Japanese market, and that Chile is now producing large quantities of cultured coho salmon and targeting the Japanese market, it is likely that the Chilean product will compete with the Pacific coho product in the Japanese market.

These substitutional relationships that have been established for the different species and sources of salmon raise some doubt about whether countervailing duties placed on salmon products entering the U.S. market via trade will provide significant long-term benefits to the capture industry in the United States. Specifically, the countervailing duties cause a decrease in the amount of the cultured product being shipped to the U.S. in the short run, but an increase in shipments of this product to those countries that also tend to import the U.S.-produced wild Pacific product. To the extent that the wild Pacific product tends to compete with the cultured product in those countries, the increase in non-U.S. cultured product will result in a reduced demand for the U.S. Pacific product, if all other things remain unchanged. This reduced demand, in turn, implies a declining dockside price for the wild product.

In addition to the econometric studies that have analyzed substitutability between wild and cultured salmon, several studies, as noted, have been conducted to examine preferences between the two products. Rogness and Lin (34), in a survey of U.S. wholesalers, found that approximately 80% of the surveyed firms considered fresh Atlantic salmon to be a substitute for fresh chinook. In an expanded study of U.S. wholesalers, Herrmann et al. (35) found that the majority of firms considered cultured salmon to be a substitute for fresh chinook, coho, and sockeye in the marketplace. In general, wholesalers considered farmed salmon superior to wild salmon, because it offers more consistent supply, quality, shelf life, and appearance. The primary advantage of the wild salmon, by comparison, was in price.

Finally, conjoint analysis has been used to determine preferences for cultured versus captured salmon (36,37). The results, in general, tend to be mixed. Anderson and Bettencourt found that "expensive" New England restaurants tended to prefer cultured Atlantic product to chum or sockeye salmon, but not necessarily to coho or chinook. The buyers for the "expensive" restaurants, in accordance with their desire to vary their menus according to season, preferred seasonal to year-round salmon products. Buyers for the fish market segment, by comparison, preferred year-round to seasonal salmon, because of their need to maintain a stable supply. Overall, buyers for fish markets tended to be somewhat more indifferent than buyers for "expensive" restaurants with respect to preferred species.

In a recent study of northeastern and mid-Atlantic households, Wessels and Holland found that the average household consumed salmon at home approximately once every six months. More than 60% of respondents were unaware of cultured salmon. Based on conjoint analysis of consumer preferences, the authors concluded that "[t]he salmon industry's strategy of labelling product as to what method of production is used, farm or wild, seems to favor farmed salmon more than wild salmon in the region covered.... This may be the result of the perception that farmed is higher quality and safer than wild, possibly because a farmed product is connected with a product over which the harvester has some degree of control, unlike wild salmon" (p. 57). The authors caution, however, that the results may be specific only for the region considered in the study, and that the preference for wild versus farmed product may be reversed on the west coast, where the wild product dominates.

Crawfish

The production of crawfish or crayfish in ponds represents the largest crustacean aquaculture industry by weight or product, in the United States. Although several dozen species occur in the country, the red swamp crawfish (*Procambarus clarkii*) is the only species farmed. Small amounts of the white river crawfish (*Procambarus zonangulus*) occur in ponds even though it has not been stocked. United States production of crawfish is centered in Louisiana. Texas is the only other domestic producer over the million-pound level annually. Louisiana farmers account for 80% of the country's pond-produced crawfish (38). United States crawfish production from cultured and wild harvests is synonymous with Louisiana. The farmers and fishermen in the state account for more than 90% of the country's total pond and wild crawfish production and for over half of the world production (39).

Farmed production of crawfish occurs in shallow, owner-operated ponds. The pond harvest extends from November through May (as opposed to the batch harvest common in many other aquaculture systems). The wild harvest begins with small amounts in February, followed by a peak in April/May. Because production comes from flooded backwaters of the Atchafalaya River, year-to-year variation in production is significant. The range in wild production between 1990 and 1997 was from 3.2 to 23 million kg (7–51 million lb) (40, 1998). The corresponding farm-raised crawfish production for the period ranged from about 20 to 27.67 million kg (44 to 61 million lb). The advantage of a more reliable and stable supply was in part responsible for the higher producer price for farmed crawfish. A more important factor is the advantage aquaculturists have in supplying the markets earlier in the season. This early part of the season coincides with the Roman Catholic religion's Lenten period, marked by increased consumption of seafood. Farmers generally receive higher prices for their ability to supply crawfish during this period of peak demand. Farm-raised crawfish brought producers from $1.10 to $1.65 per kg ($0.50 to $0.75 per lb) during the period 1990–1997. The weighted average price was $1.28 per kilogram ($0.58 per pound), 11.5% higher than the weighted average price for wild-system crawfish.

The higher average weighted price received by farmers has its foundation in early-season and Lenten-period demand. Farmed and wild crawfish are not differentiated in markets. Each is subject to seasonal availability; farmed crawfish do not have a characteristic of most aquacultured species, year-round availability. This basis for market differentiation to justify higher prices is not available to farmers. When crawfish supply from ponds overlaps the wild-harvest supply, no distinction on the basis of price occurs. The Louisiana Crawfish Promotion and Research Board does not attempt to differentiate the two sources on the basis of price. The only price differentiation is rooted in market grades established on the basis of size.

Mechanical grading of live crawfish was initiated in 1990. The practice involves four grades: jumbo are 15 or fewer live crawfish per pound (0.45 kg); large are 16 to 20 per pound; medium are 21 to 25 per pound; peelers are 26 or more per pound. Ungraded crawfish are marketed as field run. Grading puts larger sizes into the export market and into live retail/restaurant usage. The smaller crawfish are commonly utilized in the processing industry to produce cooked crawfish meat.

Although crawfish from farmed and wild sources are not differentiated on the basis of price, Bell (41) demonstrated a unique linkage. Farmed supply reaches the market earlier in the year than does wild supply. Bell's research found that aquacultured crawfish increases supply and so causes lower prices for wild supply than would occur if no farm industry existed. In terms of natural-resource economics, farm-produced crawfish lowers the price for the wild supply, and that reduction reduces, in turn, the quantity harvested from public waters. It is unique in aquaculture for a farmed supply to be linked to lower price for production from natural areas. The reverse is usually claimed as an interaction between the wild and the aquaculture supplies of various species.

A noteworthy linkage to lower crawfish prices experienced by both farmers and fishermen was low-priced imported crawfish tail meat. An alliance of crawfish processors petitioned the U.S. International Trade Commission for an antidumping investigation of processed crawfish tail meat from China. The 1996 investigation found the domestic industry to have been materially injured by imports because the imported product was being sold at less than fair value (42). Tariffs on processed crawfish meat from China were established. The tariff level varied by exporting company but averaged approximately 115%. This tariff will temporarily insulate U.S. crawfish producers from the deleterious effects of wild supply from China.

Alligator

Alligator (*Alligator mississippiensis*) production comes both from wild harvests and from farm systems. There is often a linkage between failed public management of a species and the development of culture systems. This is undeniably the case with the alligator. The legal hunting of wild alligators gave way to excesses and to poaching when regulations were stiffened. With the exception of the harvesting of nuisance alligators, hunting was banned in the 1960s. The populations were rapidly rebuilt, as a result of effective research and enforcement programs. Controlled harvest was initiated in Louisiana in the fall of 1972. Other states in the south, led by Florida, followed with programs allowing a tightly controlled harvest. The supply (less than 1,500) from harvests was far below the annual alligator harvest of 150,000 in the United States early in the twentieth century (43).

The harvest of wild alligators increased throughout the 1980s and 1990s. However, the approximately 35,000 harvested were an indication wild stocks would not support historical levels. Alligator farming in Louisiana alone grew to such an extent after 1985 that 160,000 animals were produced in 1996. Florida farms produce at about one-third of the Louisiana level; Texas, Georgia,

Mississippi, and Alabama combine for less than 10,000 animals. Collectively, wild harvests and farmed production were projected to be approximately 250,000 in 1997 (44).

The farmed production of alligators may have arisen out of a need to replace reduced harvests of wild animals. Farmed supply is, however, not a perfect substitute for wild alligators. The basic difference stems from the average length and width of wild alligators. Louisiana data reflecting 28,433 wild animals indicated that 76% were from 2 to 2.4 m (6 to 8 ft) in length. The best data on farmed alligators also relates to Louisiana animals. Ninety-seven percent of the production was in the 1–1.3 m (3 to 4 ft) range (45). Farmed alligators seldom bring the same price as wild ones. After 1987, wild animals brought from 33% to 138% more per foot (0.3 m) than did farmed animals (45). The longer and wider wild animals mean more square measure (surface) units for final-product manufacturers. Alligator meat is also a factor in determining the average price. More meat is a feature of the wild alligators, because of their larger size.

The interaction of the wild and the farmed industries occurs domestically and internationally. Markets for alligator skins are overseas, meat is utilized domestically. The dependence on export markets for most United States production puts farmers in competition with foreign producers. Classic species such as American alligators and crocodiles dominate world supply. Data are troublesome to interpret, because trade statistics are often outdated. Also, skins can be stored and sold in another production year. This flexibility can affect producer prices in ways not familiar to aquaculturists producing food species less conducive to long term storage.

Alligator farmers are also subject to interaction with the wild harvest industry via imperfect substitution. Caiman skins from wild sources, once heavily regulated, are gaining market share via improved compliance of exporters and importers. Increasing supplies of these smaller skins will have an impact on farmed alligator production in the United States. Prices to U.S. farmers peaked at 112/m ($36/ft) in 1988. Since then prices have trended into the low teens, and they will be restrained from recovery as supplies continue to increase. The demand side of the market is highly linked to economic conditions in Europe and Asia. France, Italy, Japan and Singapore are among the leading importers. Economic conditions in these countries must be favorable for there to be supply-clearing prices for skins and the goods manufactured from them. Unlike United States aquaculturists of catfish, crawfish, and tilapia, alligator farmers are dependent on export markets. These markets are subject to domestic and international wild-supply competition.

Catfish

Aquaculture of channel catfish (*Ictalurus punctatus*) is concentrated in Mississippi, Arkansas, Alabama, and Louisiana. Pond-culture technologies dominate over raceway and cage-culture approaches. The farm-raised industry, in its formative years of the 1960s, was thought to be constrained by competition by domestic and imported wild catfish (46). In 1965, catfish from the wild accounted for 71% of supply (47). Imports from the Amazon River

system in Brazil were identified as problematical; however, the farmed-catfish industry established a reputation for reliability and quality of production, and so lower-priced wild fish, whether imported or domestic, actually never posed a threat to growth. The aquaculture industry, essentially, produced a product that the market quickly differentiated from wild-source catfish. Year-round supply and relative size uniformity were traits that the U.S. marketing system evidently valued as seafood consumption increased. To date, catfish aquaculture technology has not been successfully utilized overseas to produce competing products. The prediction that foreign-aquaculture catfish supply would compete effectively in U.S. markets was in error (46). Essentially, all catfish product imports originate in Brazil, from river-system sources. The peak of imports from this source during the 1990s occurred in 1991. The equivalent of 5.9 million kg (13 million lb) live weight was imported at a frozen fillet price of $2.42/kg ($1.10/lb). This type of product is clearly serving a lower-valued market in the United States.

The growth in farm-raised supply was also not impeded by domestic wild catfish catches. Pond supply more than doubled from 1985 to 1997, yet producer prices increased. Wild supply of all catfish species has never exceeded 6.8 million kg (15 million lb). There is no market advantage to the 1.10/kg ($.50/lb) received by fishermen versus the farm supply price of approximately $1.50/kg (0.68/lb) (4, 1998). Farm-raised catfish supply exceeded 180 million kg (400 million lb) for the first time in 1992 and has continued to move to the >225 million kg (>500 million lb) level. The industry has correctly shed concern over production competition.

Realization that market expansion was linked to industry organization (to address domestic consumer demand) has yielded results. A farm-raised catfish promotional program began in 1987. Funded by an assessment on catfish feed purchases, the Catfish Institute began efforts to increase consumer awareness and attitudes. Purchase frequencies for at-home and restaurant consumption increased 11–12% (48). Another evaluation of the promotional program estimated a 7% average increase in wholesale sales, attributed to industry-sponsored advertising (49). Catfish farmers are intent on retaining these gains and on further differentiating their products from wild supplies. A Catfish Quality Assurance Program was developed by the Catfish Farmers of America in 1993 (50). This program assures the safety and quality of farm-raised catfish. Gains in favorable consumer perceptions about farm-raised catfish are a significant achievement and an asset to be protected.

Tilapia

Supplies of domestically produced tilapia come from aquaculture businesses and from wild fisheries. The situation is in no way comparable to the wild and cultured supplies of shrimp, salmon, crawfish, or alligators. Aquaculture businesses have produced uninterrupted increases in tilapia supplies ever since government data were first reported in 1991. The beginning report was 2.25 million kilograms (5 million pounds); supplies had risen to 7.7 million kilograms (17 million pounds) by 1997.

Wild supply reached 0.14 million kilograms (0.31 million lb) only once, 1991. Thereafter, wild tilapia levels were between 0.045 and 0.12 million kg (0.1 to 0.26 million lb). This production, primarily from Florida, is a low-value fish: approximately $0.88/kg ($0.40 per pound), compared to the 1997-average farmed price of $3.31/kg (1.49/lb) (4, 1998). Supply from wild sources will not be a determinant of any price, supply, or quality elements associated with domestic tilapia aquaculture.

Domestic tilapia supplies are primarily coming from intensive recirculating systems, not ponds. This situation is likely a result of regulations and economics. Some states allow production only from recirculating systems, to minimize the escapement potential of exotics. Florida and Arkansas do allow tilapia culture from pond systems, but these fish are generally lower-priced than the supply from recirculating systems. Thus, some aquacultured fish have the same effect on others as do wild-caught fish. Intensive recirculating systems accounted for about 70% of domestic supply (51). Expansion of the industry via this technology will reduce, the potential of pond raised tilapia for depressing prices. Recirculating systems are conducive to the efficient marketing of live tilapia. Live fish account for 85% of sales. Projections for 1998 domestic tilapia production 9.45 million kg of (21 million lb) (52) indicate that the live markets historically used will be more price-sensitive in the future. The outlook is for the growth in domestic supply to be increasingly used as processed product.

Imports reached 36.8 million kilograms (81 million pounds) live weight equivalent in 1997. This level was attained after uninterrupted increases since 1993. Approximately half comes from Taiwan, as frozen whole fish valued at less than $1.54 per kilogram ($0.70 per pound). Costa Rica and Ecuador are leading exporters of fresh fillets. A notable aspect of the import situation is that virtually all supply originates from aquaculture. Thus, domestic aquaculturists are minimally influenced by wild supplies from all possible sources. The future growth of the domestic tilapia business depends on competitiveness with imported fresh fillets. These will be the closest product substitute as domestic producers turn to the fillet market form when live-market sales slow.

EEL CULTURE

MARGIE LEE GALLAGHER PH.D.
East Carolina University
Greenville, North Carolina

GAD DEGANI
Galilee Technological Center
Qiryat Shemona, Israel

OUTLINE

Eel culture is probably the first and most long-lived example of intensive aquaculture. The Japanese have successfully practiced intensive eel culture since the 1880s, well over a hundred years. The mainland China fishery (where eels are caught and cultured) is the largest eel fishery at present, with a production of 147,316 tons in 1996. However, significant production of cultured eels also comes from Japan and Taiwan. Throughout the 1990s, cultured eel production in Japan (24,171 tons in 1997, for example) dramatically exceeded the wild catch (860 tons). In Asia, the net worth of cultured eel production is second only to that of yellowfin and makes up 13% of the total value of aquaculture products produced in the region. In addition to Asia, Europe is also an important eel-culturing region of the world, with the highest production being in Italy, where 3,000 tons were grown in 1996 (1). In spite of the importance of cultured eels, however, the industry overall still depends upon wild-caught elvers (young eels) to supply young for culture.

Of the sixteen species of eel in the world, four are currently important in aquaculture production: the Japanese eel (*Anguilla japonica*), the European eel (*A. anguilla*), the American eel (*A. rostrata*), and the Australian eel (*A. australis*). According to Usui (2), these four species are so similar that they may be considered to be the same for marketing purposes. Some investigators believe that *A. anguilla* and *A. rostrata* are, in fact, the same species, because of their similarities in terms of anatomy and life history (3).

Although there has been interest in eel culture in the United States since the early 1980s and some individuals are experimenting with commercial production, there is currently no significant commercial production in the United States. However, a wild fishery for eel culture does exist. Preliminary data from the National Marine Fisheries Service for 1996 indicate that total landings of American eels from the Atlantic and Gulf states were near 646 tons worth approximately US$5 million (4). These figures represent the catch of both market-sized eels, which are generally exported to European markets, and young eels (elvers), which are sold to foreign commercial culture operations. The price of elvers in the United States varies with the demand from out-of-country operations, which has been high for the last several years. For example, in Japan, the so-called "seedling eel" (elver) catch declined from 40.3 tons in 1993 to 22.5 tons in 1997. This decline has increased the market demand for elvers from the United States.

LIFE HISTORY

One of the most striking features of the biology of eels is their catadromous migration, which, in the case of the European eel, covers as much as 7,000 km, from inland European waters to the spawning grounds of the Sargasso Sea. The biology of eels has been thoroughly reviewed by Tesch (5). Tsukamoto (6) and Umezawa and Tsukamoto (7) have reviewed the life history of *A. japonica*. Usui (2), in his practical book on eel culture, records the story of the classic work of the Danish biologist Johannes Schmidt in discovering the elusive life cycle of the European eel.

Adult silver eels migrate from freshwater to the area of the Atlantic Ocean known as the Sargasso Sea for spawning. After spawning, floating eggs hatch in about 24 hours. As the tiny larvae grow into flat, leaf-shaped leptocephali, they are carried along by the currents (of the Gulf Stream in the case of European and American eels) toward land. This journey can take from 10 months to as long as three years, depending on the origin of the larvae and the eventual destination. During this time, the leptocephali metamorphose into unpigmented, cylindrical, "glass" eels. These eels, apparently guided by their olfactory sense to the natural odors of freshwater and/or very specific salinity changes, migrate into inland rivers and lakes. When elvers enter freshwater, they become pigmented. As growth continues and pigmentation is completed, the eels are referred to as brown- or yellow-stage eels (8). This coloration is in contrast to that of the more commercially valuable silver eels, a name that refers to the silver color of large eels that are about to migrate back to sea for spawning. Migrating eels have increased body fat (25–30%) and do not feed during migration. It is assumed that eels that have spawned die, since silvering of the skin, maturation of the gonads, and increases in body fat are also accompanied by degeneration of the gastrointestinal tract (9,10). Although Japanese researchers have had some success in artificially inducing egg production and spawning in eels (11–14), as yet the life cycle of eels has not been closed under captive conditions. Therefore, eel culture depends upon a steady supply of young eels (elvers) from the wild. These populations are highly exploited at present.

TRAINING AND SORTING OF ELVERS

Wild-caught elvers do not feed readily and must be trained to feed. Training is usually accomplished by feeding them minced fish, bivalve flesh, earthworm flesh (in Japan), or *Tubifex* worms and then gradually mixing in increasing amounts of artificial feed. In most commercial operations, feeds are fed as a paste, made by mixing a fishmeal-based powdered diet with water, 5–10% oil, and vitamins. (See Fig. 1.) Elvers may be trained to eat moist feeds, dry crumbles, and pellets just as easily (15,16). Arai (17) noted, however, that eels that are to be fed a dry diet should be trained on a dry diet from the elver stage and that sorting by size must take place more frequently for such eels. In addition, chicken and chicken meal are viable substitutes for fishmeal in artificial diets for elvers (18,19).
Figure 1. Elvers eating an artificial diet. The diet is fed as a paste in a feeding tray that is suspended into the elver tank. (Courtesy of W.L. Rickards.)

High mortality (up to 30%) and widely varying growth rates characterize the initial period of training and growth. Degani and Gallagher (9) have reviewed the phenomenon of widely varying growth rates in American eels. Some elvers do not ever learn to eat the provided diet; they lose weight and eventually die or are cannibalized. Some elvers that do learn to eat grow so slowly and have such poor food conversion ratios that they are of no economic value and must be sorted from those that are growing at appropriate rates (20). Although attractants, such as amino acids, have been shown to be effective in getting eels to eat (21), knowledge of attractants is still too scant to incorporate the technology into culture techniques.

Although cannibalism is not a particularly bad problem in elvers, since only those of little or no economic value tend to be cannibalized, continual sorting of eels must take place during their growth, so that eels in the same pond are of approximately the same size and so that undersized and stunted eels are removed (2). Sorting increases feed efficiency and reduces cannibalism and stress. The eel is a solitary animal in its natural habitat, but exhibits aggressive behavior in culture when there is a size differential, thus causing stress that can affect the health and feeding of all eels (9).

Usui (2) estimated that, given normal mortality rates, careful handling, and continuous sorting, one can expect to harvest 400 kg (880 lb) of eels weighing 150–200 g (5–6.7 oz) each from 1 kg (2.2 lb) of elvers over a 2-year period. If 1 kg (2.2 lb) of elvers contains approximately 3,500 individuals then this harvest rate indicates an overall survival rate of about 60%. It should also be noted that proper training, management, and sorting allow the culturist to bring eels to a marketable size in 2 years, which is much faster than in the wild, where such growth may take from 5 to 10 years.

CULTURE METHODS

Because eel culture has been practiced for so long, much is known about the parameters for successful culture. However, different temperature ranges have been reported as appropriate for eel culture in different *Anguilla* species. Arai (22) reported the optimum range for Japanese eels is 23–30 °C (73–86 °F), while that for European eels is 20–23 °C (68–73 °F). Degani and Gallagher (9) reported the optimum culture temperatures for American and European eels to range from 23 to 25 °C (73 to 77 °F). When the temperature drops below these ranges, the eels consume less food, and they stop eating altogether between 8 and 15 °C (46 and 59 °F).

Eels appear to be less sensitive to low oxygen levels than some other cultured species. Degani et al. (23) found no significant differences in growth rates of European eels within a dissolved-oxygen range of 4–8 mg/L (ppm). Both Arai (22) and Usui (2) reported that the level of dissolved oxygen for Japanese eels must remain above only 1 mg/L (ppm). However, excess oxygen or nitrogen can lead to serious problems with gas embolism in eels under 6 cm (2.4 in.) in size (24).

Current eel culture systems vary from large, extensive static-water ponds to much smaller, highly intensive recirculating systems. Elvers are almost always grown in indoor tanks, where the temperature can be controlled, and as mentioned previously, elvers can be trained to eat artificial diets. When elvers reach 8 to 12 cm (3.2 to 4.8 in.), they are stocked into adult-rearing ponds. The stocking density depends upon the culture method used.

The advantage of recirculating systems, either as tanks or greenhouse-enclosed ponds, is that the water requirement is relatively small, stocking densities can be increased [up to 60 kg/m^3 (0.0037 lb/ft^3)], and the water quality (temperature, oxygen content, pH, and solids content) is controlled. (See Fig. 2.) The ability to heat fingerling ponds in the spring using greenhouses with or without auxiliary heating increases the effective growing season (9). Disadvantages include the need for constant monitoring since oxygen levels can become critical and blockage of filters and build-up of sediment occur with poor feeding practices. These systems must have a biological filter and a source of oxygen. A sedimentation tank or pond is also advisable. Although recirculating systems are becoming more economically viable, more traditional pond culture methods are still the norm.

Figure 2. Poured concrete recirculating tanks used for intensive rearing of eels. (Courtesy of G. Degani.)

The simplest eel ponds in use have no temperature control or water replacement and are essentially static. Stocking densities must be kept much lower in these ponds [1–5 kg/m³ (0.00006–0.0003 lb/ft³)]. However, most commercial pond operations use some variation of a flow-through (running water) or partial-recirculating flow-through system. The stocking densities of these operations are around 10 kg/m³ (0.0006 lb/ft³) (2,9,24).

The basic pond design (earthen or concrete) has one main water inlet and one main outlet, with the bottom sloping toward the outlet sluice. Sluice gates usually have three doors: The board door permits water to be discharged from the bottom or top of the pond; a mesh door prevents the escape of the eels; and a final sluice controls the amount of water leaving the pond. Ponds may have mud bottoms or solid bottoms. Solid bottoms are preferable, since they do not provide eels with hiding places during harvest. Earthen ponds may have solid walls made of concrete slats fitted into grooved concrete posts or boulders cemented together to form a solid wall. These walls support the pond and help prevent elvers and fingerling eels from escaping. In Japan, ponds also have a specific feeding area, which is located on the side of the pond opposite to the source of the prevailing wind. The area is often shaded to facilitate feeding. Larger ponds [>600 m² (71,700 yd²)] in Japan also have specifically constructed "resting areas." "Resting areas" have their own water inlet and outlet, allowing for a limited area of running water. There is also usually a source of aeration, such as a splasher or vertical pump. The concept is that during short periods of poor water quality in the larger pond, eels may enter the resting area, where the water quality is better (2,9).

SEX AND BODY COMPOSITION

Generally, larger eels with higher fat content have a greater market value. Female eels grow to much bigger sizes [60 cm, 300 g (24 in., 10 oz)] and have a higher fat content as compared with males [35 cm, 70 g (14 in., 2.3 oz)]. Thus, females are of greater commercial importance (2), and therefore it is important in aquaculture operations to maximize the number of females that emerge when sexual development begins at around 30 cm (12 in.). Some investigators have suggested that a high population density may lead to a higher proportion of males in wild populations (5,25,26). Degani and Kushnirov (27) found that 77% of communally reared eels became male when injected with human chorionic gonadotropin (hCG), while 60% of eels raised in isolation became female after hCG injection. Hormones can also be used to influence sexual differentiation in eels. Degani and Kushnirov (27) also showed that 70% of eels fed 60 mg/kg (ppm) 17-beta-estradiol (E) for one year became female while of those fed 30 mg/kg (ppm) E or no E, only 32% and 26%, respectively, became female.

In addition, the lipid content of females can significantly influence the marketability of the eels produced. The silver stage of the sexually mature, ready-to-migrate female eel is usually much more desirable than somewhat smaller brown eels, not only because of the difference in size, but also because the lipid content of the silver eel (25–30%) is much higher than that of the brown or yellow eel (5–15%). Size and culture temperature have a profound effect on the total lipid composition of eels. Gallagher et al. (28) found that lipid content was linearly and significantly correlated to weight ($y = 0.09x + 25.99$, $r = 0.62$, where x is weight and y is lipid content). Degani (23) found that eels accumulated higher amounts of body fat at 25 °C (77 °F) and 27 °C (81 °F) than at 23 °C (73 °F).

The amount of effort put into raising eels of a particular sex and the market in which the culturist wishes to sell, since the market size for eels is variable, will determine the lipid content. In Europe, consumers have traditionally preferred eels larger than 0.5 kg (1.1 lb), while in Asia there are markets for both 0.5-kg (1.1-lb) eels and much larger eels, of 1 kg (2.2 lb) or more.

NUTRITION AND FEEDING

Many studies have investigated the nutritional requirements and feeding habits of eels. Arai (17,22) and Lovell (29) reviewed the nutritional requirements and feeding practices of Japanese and European eels, as elucidated in a series of studies by Arai and colleagues. In addition, Cowey and Walton (30) have reviewed the intermediary metabolism of fish, including that of eels. Arai et al. (31) and Nose and Arai (32) investigated the qualitative and quantitative amino acid requirements of Japanese and European eels. The qualitative requirement is similar to that of other species (33,34). However, quantitatively, Japanese eels appear to require higher amounts of many of the 10 essential amino acids — including threonine, tryptophan, and the branched-chain amino acids, leucine, isoleucine and valine — as compared with channel catfish and chinook salmon. Since there is often interaction between branched-chained amino acids, it is likely that an increased requirement for one influences the requirements for the other two (21). In addition, L-cysteine, usually a dispensable amino acid, promotes growth in eels when it is used to replace DL-methionine (35). Therefore, interactions of indispensable amino acids with dispensable amino acids may be of significance in diets for eels.

More recently, Degani and Gallagher (9) reviewed growth and nutrition of *Anguilla* sp. Optimum protein values for eel diets range from 35 to 45% protein, depending upon the energy content of the diet, the source of protein, the age of the fish, and the degree of digestibility of the protein sources used. Elvers may have higher protein requirements. Tibbets (36) reported that the optimum protein requirement for 8-g (0.3-oz) elvers is 48% protein. The protein-to-energy ratio can affect protein use. Gallagher and Matthews (37) and Degani and Gallagher (38) showed that when this ratio is below optimum (140 mg/kcal), there are significant increases in protein catabolism (i.e., the protein is used for energy rather than for protein synthesis). However, as in all fish, this increased use of protein has no significant energy cost. Eels grow best when animal protein sources are used. Gallagher and Degani (39) found that replacing fishmeal with poultry meal did not significantly influence weight

gain in elvers, as long as both diets had a source of fish oil. However, Degani (40) found that replacing fish meal or poultry meal with 10 or 20% soybean meal reduced growth in elvers. On the other hand, Schmitz et al. (41) reported digestibility coefficients for soy protein (0.96) and soybean meal (0.94) that were similar to those for fish meal (0.94) and casein (0.99). Degani and Gallagher (9) reported that protein digestibility varies with size and dietary protein content. When eels (six months from the glass-eel stage) were compared with slow-growing eels that were a year older but of the same size [mean weight of 5 g (0.2 oz)], the protein digestibilities of the two stages of eels were found to be similar (92–94%). But when the former eels were compared to eels of the same age (six months) that were smaller [2.5 g (0.1 oz)], the protein digestibility in the smaller eels was found to be lower (86–94%). Protein digestibility decreased as the protein level of eel diets increased from 30–35% to 40–45%.

Arai et al. (42) reported that eels require both n-6 and n-3 fatty acids and showed that eels grew best on a 2:1 lipid mixture of corn oil to cod liver oil. Takeuchi et al. (43) concluded that the fatty acid requirement for eels can be met with either 0.5% of alpha-linolenic acid and 0.5% of linolenic acid or 1% of alpha-linolenic acid alone. Kanazawa (44) reported that eels can elongate and desaturate alpha-linolenic acid to 20:5 n-3 and 22:6 n-3. In addition, eels are able to use large amounts of fat in their diets, apparently due to their ability to deposit large amounts of fat for their long migrations in the wild. Dosoretz and Degani (45) showed that large eels fed diets with 30% fat grew faster than those fed diets with lower amounts of fat (20%). In addition, the difference in weight gain was due to fat gain. In many cultured species, increased fat gain is not desirable, but in eels, an increased fat content makes the product more marketable. The source of fat in the diet is also important. Gallagher and Degani (9) and Degani et al. (18) showed that (1) some fish oil is necessary in the diet of eels (probably as a source of alpha-linolenic acid) and (2) lipids of plant origin (e.g., soybean oil) are not as effective in achieving weight or lipid gain as compared with lipids of animal origin (e.g., poultry oil).

Eels can also use carbohydrates better than can coldwater species such as trout. With careful formulation, it is possible to replace part of the protein in eel diets with carbohydrates. In a series of studies, Degani and coworkers showed that *A. anguilla* grew better on diets lower in protein (40% vs. 50%) but higher in carbohydrates (38% vs. 20%) (46). Wheat meal was superior to corn starch, sorghum meal, and potato starch as a source of carbohydrates for eels (47). Simple sugars, such as glucose and sucrose, also improved growth when added to diets in levels up to 30% (48). The metabolic role of dietary carbohydrates is unclear. Carbohydrates are stored as glycogen in eels, and they possess glycogenolytic enzymes, but those enzymes do not respond to glucagon. Rather, glucagon increases gluconeogenic enzyme activity in eels, indicating that this is the most important pathway for maintaining blood glucose, at least under normal conditions (21,49). However, glycogen metabolism does respond to acute stress. For example, the amount of liver glycogen decreased when eels were exposed to sublethal doses of pesticides (50).

Lovell (51) summarized the known vitamin requirements of eels. The Japanese eel has been shown to produce deficiency symptoms when fed diets lacking the vitamins required for energy production: niacin, thiamin, riboflavin, and pantothenic acid. A lack of pyridoxine, which is required for metabolism of amino acids and production of neurotransmitters, causes convulsions and nervous disorders in eels. Also required are biotin, folic acid, cyanocobalamine, and ascorbic acid, vitamins that participate in synthesis reactions in the body. Both choline and inositol are also required; these compounds are structural components of cell membranes. Inositol may also play an important regulatory role in the fertilization of eggs during spawning (52). Of the fat-soluble vitamins — A, E, D, and K — only E (alpha-tocopherol) has been studied and found to be essential.

Arai et al. (53) found that eels grew best on artificial diets containing a mineral mix at 2% of the diet. Increasing the level of minerals (to 3–5%) decreased the eels' weight gain. Trace mineral requirements for eels have not yet been determined, but it is likely that eels require all or most of the minerals required by other finfish. Park and Shimizu (54) found that eels grew best when their diets were supplemented with 50–100 µg/g Zn. However, trace mineral supplements should not be added indiscriminately to diet formulations for eels, as excessive levels can suppress growth, and some mineral supplements may be toxic to temperate species of fish.

The feeding rate necessary for good growth is dependent upon the size of the eel. Arai (22) recommended feeding dry commercial feeds at a rate of 6–8% of body weight per day for elvers and small eels, but reducing the feeding rate to 2–3% for larger eels. Matsui (24) estimated that glass elvers should be feed wet feeds at 10–15% of their body weight per day, and larger eels should receive the feed at 7–10% of their body weight per day. The conversion ratios for dry feed to weight gain is about 1.4:1, while for a feed of raw fish, it is around 7–9:1 (2,9).

Knights (55) reviewed the feeding behavior of eels (*A. anguilla*). It is essential to feed eels food of an appropriate particle size, where a 1:1 ratio of particle size to mouth width is appropriate for soft foods. For harder, pelleted foods the ratio must be reduced to 0.4–0.6:1. In elvers, chance encounters with food particles is the way that food is recognized, while in larger eels, vision becomes more important, although eels can also feed in dark or turbid waters. Knights also noted the effects of stressors on appetite and feeding. Most notable among such stressors are temperature shock and intraspecific behaviors. Eels stop or decrease their feeding in response to acute low-temperature stress. The longer the duration of the stress, the longer the recovery period. Also, smaller eels become subordinate to larger eels if size differences become too large. Subordinate eels and elvers may stop eating altogether. As mentioned previously, size grading is crucial to maintaining a homogenous population, and thus reducing aggressive encounters.

DISEASES

Several authors have reviewed diseases of eels (2,5,23,56,57). Because of its intensive nature, disease can be a major problem in eel culture. One of the common bacterial diseases is red spot disease, which affects the intestine and liver and causes red spots to appear on the eel, due to ulceration of the fins and trunk. (See Fig. 3.) It is commonly caused by *Pseudomonas anguilliseptica*. A similar infection, known as red fin disease, is caused by *Aeromonas liquefaciens* and *Paracolobactrum anguillimortiferum*. Other species of *Vibrio*, *Pseudomonas*, and *Aeromonas* have also been implicated in that disease. Columnaris disease is a bacterial disease caused by the myxobacterium *Chondrococcus columnaris*. When the bacteria attack the gills and cause their eventual disintegration, it is called gill disease. But when the bacteria attacks the tail, causing lesions and sloughing of diseased tissue, it is known as tail rot. These common bacterial infections can now be treated effectively by adding antibacterial drugs to feeds.

Cotton cap, or fungus disease, is caused by the aquatic fungus *Saprolegnia parasitica* and often occurs secondarily to a primary bacterial infection. The occurrence of this disease is linked to high or low pH and can be carried over in ponds from year to year. Antibacterial drugs used in conjunction with malachite green are an effective treatment, but the use of malachite green is prohibited in most culture situations. Infected ponds should be drained and disinfected before they are used again.

The parasitic protozoa *Ichthyophthirius multifiliis* also infects eels. The appearance of grey or white spots on the fins and skin of the eel characterize the infection. Since the parasite cannot tolerate saline conditions, the addition of salt water to culture ponds is usually effective in eliminating it. *Myxidium* sp. also infects eels. This protozoal infection is often confused with *Ichthyophthirius* or columnaris infections, because it produces white cysts on the gills, which destroy the gills. The only method for dealing with an outbreak is to isolate or remove infected and dead eels quickly.

Viruses also infect eels. "Cauliflower disease" is characterized by tumors, usually on the jaw, that resemble heads of cauliflower. Mortality is not high from this viral infection, but the eels cannot eat and become emaciated.

A parasitic copepod, *Lernaea cyprinacea*, causes anchor worm disease in Japan. This worm attaches itself inside the mouth of the eel, preventing feeding.

Other organisms have also been shown to infect eels. Those listed previously are presently the most economically important in the culture of eels. In addition, diseases that commonly occur in one species of eel can often readily be introduced into other species. For example, the swimbladder nematode *Anguillicola orassus* was introduced into European eels from Japanese eels (58).

Not all significant diseases of eels are caused by organisms. Gas bubble disease, or gas embolism, (usually occurring in elvers) is caused by supersaturated oxygen or nitrogen levels in the culture water. Bubbles appear on the head of the elver, and it will not eat. Adding new water that is not supersaturated alleviates the problem.

SUMMARY

Eel culture is a strong and viable industry in many parts of the world. However, the life cycle of eels is not closed in captive stocks, and the industry remains dependent upon capture of wild elvers to sustain it. This fact limits exploration into broodstock development and genetic manipulation of wild stocks, which would improve growth rates and disease resistance. Nevertheless, as long as the wild sources of elvers remain plentiful, the industry will prosper.

INTRODUCTION

Aquaculture effluent refers to either a continuous or intermittent discharge of wastewater from an aquaculture facility. All types of aquaculture production systems generate effluents, but the amount of discharge differs significantly between systems. For a unit of fish production, the frequency of discharge, the amount of flow, and the

concentration of pollutants in the effluent determine the effluent load generated by the aquaculture system. In general, systems located in public waters, such as net pens, and systems such as raceways, which discharge continuously, generate more effluent than recirculating or pond systems.

Aquaculture effluents may have adverse environmental impacts because they contain dissolved and suspended pollutants. This entry deals primarily with the dissolved components. Suspended components are covered in the entry entitled "Effluents: sludge."

MAJOR EFFLUENT COMPONENTS AND THEIR ENVIRONMENTAL IMPACTS

The major substances contained in aquaculture effluent, which have potential environmental significance, include phosphorus (P), nitrogen (N), and organic matter. Phosphorus is an essential element for aquatic life and is often regarded as a limiting production factor in freshwater aquatic environments. Biologically available P in aquaculture discharge can stimulate the primary productivity of receiving waters and accelerate the natural eutrophication process. Phosphorus in fish farm discharge water is present as either soluble P, e.g., orthophosphate, or insoluble P. Orthophosphate originates from P excreted in fish urine and from the conversion of insoluble P contained in feces and uneaten feed to soluble P by microbial action.

Nitrogen is another important element supporting aquatic life. Like P, an excess concentration of N increases aquatic productivity and possible eutrophication. The nitrogen compounds of concern to fish health include ammonia and nitrite, which are a concern with respect to receiving waters. Ammonia is a direct product of fish excretion and has high solubility in water. Nitrifying bacteria can biologically oxidize ammonia to nitrite and then to nitrate under aerobic conditions. Both ammonia and nitrate can be used directly by algae and other plants as nutrients. Leaching of nitrate to the groundwater can cause contamination. Ammonia exists in two forms in water: the un-ionized fraction (NH_3) and the ionized fraction (NH_4^+). The ratio of the two fractions is controlled by pH and temperature. The higher the pH and temperature, the higher the un-ionized fraction. The un-ionized fractions of ammonia and nitrite are highly toxic to aquatic life. For example, when the un-ionized ammonia concentration exceeds 0.0125 to 0.025 mg/L (ppm), growth rates of rainbow trout (*Oncorhynchus mykiss*) are reduced and damage to gill, kidney, and liver tissue may occur (1).

Organic substances are also important in evaluating the environmental impacts of aquaculture effluent. Organic decay consumes oxygen and may reduce dissolved oxygen concentration in receiving waters. The impact of organic decay on oxygen concentration can be more directly represented by biochemical oxygen demand (BOD). BOD is the amount of dissolved oxygen necessary to oxidize the readily decomposable organic matter. In the measurement of the standard BOD, a water sample is sealed in a filled bottle, the bottle is incubated in the dark at 20 °C (68 °F) for 5 days, and the measured loss of dissolved oxygen in the bottle can be converted to BOD contained in the water sample in mg/L (ppm).

The primary source of P, N, and organic matter in aquaculture effluent is fish feed. Feed ingredients of animal origin, fish meal, and bone meal are rich sources of P. Phosphorus is also available from cereal grains and other plant protein sources. However, most of the P is present as phytate, which is not well utilized by fish. The concentration and availability of P in the feed have the greatest influence on P retention in the fish and, consequently, on the amount excreted. Nitrogenous compounds, primarily ammonia, are the result of protein catabolism. Quality and quantity of dietary protein and the protein-to-energy ratio of the diet influence nitrogen retention and excretion.

WASTE PRODUCTION

Waste production is typically related to the feeding rate since virtually all of the wastes generated from intensive aquaculture systems originate from fish feed. The majority of the feed will eventually be wasted as fish excretion products, wasted feed, and feces. For instance, in typical salmonid diets, approximately 7.2 to 7.7% of the feed is nitrogen. Of the N in feed, 67 to 75% will be lost to the environment, either as excretion products or as uneaten feed. Nitrogen excretion occurs in two forms, the dissolved form, such as ammonia, and the particulate form, such as organic N in feces. Between 70 and 90% of the nitrogenous catabolites are ammonia with a typical production rate of 3% of the feeding rate.

Phosphorus excretion is also significant. Ketola and Harland (2) reported that the retention of P in several salmonid diets ranged from 14 to 22%, meaning that approximately 80% of dietary P was discharged into the water. Phosphorus is excreted in soluble and particulate forms, and the form of P consumed by the fish will affect the excretion amount of each form. Persson (3) reported 30% of total P from feed was excreted as soluble P.

The amount of feces excreted by fish is typically reported as total suspended solids (TSS), which is defined according to the standard analysis method (4) as particles greater than 2 μm in size. Based on reports of a variety of systems, feces generation values in the range of 0.2 to 0.4 kg of TSS per kg feed appear to be typical (5). The N and P excreted in particulate form can be converted to dissolved form through biological decomposition processes, during which organic nitrogen will be transformed to ammonia and organic P to orthophosphate. In other words, decay of the TSS also contributes to the dissolved components.

Mass balance calculations are a relatively easy method for determining the amount of waste produced through intensive aquaculture. The amount of organic matter, N, and P produced is equal to the difference between the amount added through the feed and the amount is retained by the fish. This approach is applicable to those aquaculture systems based on complete feeding. Data required for a mass balance calculation include feed and fish composition, feed consumed, and fish production. An example of a calculation based on mass balance indicates that 1 kg of trout growing at a rate of 0.007 kg/day (fed dry

feed at about 1.1% of body weight/day) will consume 6.9 g O_2, and produce 4.0 g BOD, 0.63 g N, and 0.07 g P/day (6).

EFFLUENT GENERATION

The amount of effluent generated by an aquaculture operation is largely determined by the type of culture system. Among the principal aquaculture systems, cage culture produces the largest amount of effluent because of the direct water exchange between the culture system and the surrounding environment. Flow through aquaculture systems produce the second highest amount, where typical water flow rates are 8–25 L/s per ton of production (6). Recirculating aquaculture systems greatly reduce effluent volume. Typical systems operate with a water exchange rate less than 10% of the system volume per day. Pond systems generally produce low amounts of effluent. Water discharged from ponds occurs primarily during harvesting, water exchange, or levee repairs.

ENVIRONMENTAL REGULATIONS

In response to concerns about the environmental impact of aquaculture effluents, aquaculture has drawn the attention of regulatory agencies and is facing increased regulatory control. The U.S. Environmental Protection Agency (EPA) issues the National Pollution Discharge Elimination System (NPDES) permit to regulate various pollutants from point sources, including aquaculture. NPDES permits are required for fish hatcheries, fish farms, or other facilities that raise aquatic animals under the following conditions:

1. Coldwater fish species or other coldwater aquatic animals in ponds, raceways, or similar structures that discharge at least 30 days per year, produce more than 9,090 kg (20,000 lb) of aquatic animals per year, or receive more than 2,273 kg (5,000 lb) of food during the month of maximum feeding.

2. Warmwater fish species or other warmwater aquatic animals in ponds, raceways, or similar structures that discharge at least 30 days per year. This does not include closed ponds which discharge only during periods of excess run-off or warmwater facilities which produce less than 45,454.5 kg (100,000 lb) of aquatic animals per year.

3. Facilities determined on a case-by-case basis by the permitting authority to be significant contributors of pollution to waters of the United States. Discharge of pollutants to receiving waters from aquaculture production facilities, except as provided in the permit, is a violation of the Clean Water Act and may be subject to enforcement action by EPA.

NPDES permits for aquaculture operations can set discharge limits on solids, nutrients, and chemical compounds used for water treatments. For example, the current NPDES permit for aquaculture operations in Idaho limits the maximum average net total suspended solids to 5 mg/L (ppm). However, future permits will include nutrient restrictions. The EPA is conducting a preliminary study on water discharged from aquaculture facilities nationwide. Two possible outcomes from that study are the development of national effluent limitation guidelines and standards or the development of technical guidelines for one or more production systems.

Various state agencies also regulate the discharge of aquaculture effluent. Individual states designate beneficial uses for water bodies within their jurisdictions and establish water quality criteria to protect those uses. The state agencies may establish stricter standards than the EPA. Some argue that the current NPDES permit program is adequate, and national effluent guidelines are not necessary. Others feel that several state permit programs are inadequate or inconsistent with the Clean Water Act.

EFFLUENT POLLUTION CONTROL

Controlling the discharge of dissolved compounds from aquaculture effluent presents a challenge, especially in flow through systems. Although typical wastewater treatment technologies for nutrient control and dissolved compound removal are available from other industries, the capital and operational costs of the technologies are often prohibitive. Thus, the technologies are often impractical for aquaculture systems, primarily because of the large effluent volume that requires treatment. The two basic approaches for effluent pollution control are source reduction and interception and removal of the pollutants prior to their discharge into receiving waters.

Source reduction includes the development of more efficient feeds and improved feed management to minimize waste generation. Scientists and the aquaculture industry have made significant progress in fish nutrition, feed formulation, and feed manufacture to reduce the excretion of nutrients. Examples include the selection of ingredients that increase the bioavailability and digestibility of macronutrients such as phosphorus (7), lowering the P content in feeds, and the reduction of urinary excretion of P by fish. Research results have demonstrated that formulating feeds to minimize the excess levels of available nutrients in the fish diets can significantly reduce the excretion of nutrients. However, realizing the benefits of high-performance feeds requires minimizing feed wastage through proper feed management.

Effluent treatment research concerned with pollutant interception and removal has primarily focused on the treatment of suspended solids. Solids need to be removed from systems with continuous discharge as soon as possible to avoid nutrient solubilization. Several filtration processes are available for particle removal that may be feasible in certain aquaculture systems. Other methods include settling basins and constructed wetlands. In pond systems, natural, biological, and chemical processes remove nutrients and organic matter.

One effective method of effluent reduction is recycling the water. In the past two decades, significant research efforts have been devoted to developing recirculating aquaculture systems. The advancements in aeration, biofiltration, and solids removal technology have made it possible

for commercial scale recirculating systems to be profitable under the right conditions. Typical recirculating systems release less than 10% of the total system volume as effluent daily. The effluent can be treated before being discharged to water bodies, or disposed of on land through irrigation.

OUTLINE

INTRODUCTION

Aquacultural effluent refers to either a continuous or intermittent discharge of a liquid stream from an aquaculture facility. Aquaculture effluent can potentially cause adverse environmental impact because of both the dissolved and suspended pollutants it contains. This entry deals primarily with the particulate components of the pollutants. The dissolved compounds are covered under the entry entitled "Effluents: dissolved compounds."

For the purpose of either water conservation or more efficient wastewater handling and treatment, it is desirable in an aquaculture operation to concentrate the particulate waste as much as possible through a solid/liquid separation process. The concentrated waste stream, typically with a solids content greater than 5%, is often called sludge.

Although waste management strategies are likely different for different culture systems, solids removal and sludge management are often the most important components of the strategy because the majority of the pollutants are associated with the particles in the sludge. This entry covers source, production rate, characteristics, regulations, and treatment and disposal of aquacultural sludge.

SOURCES OF PRODUCTION

Waste Excretion

The first step in waste management for an aquacultural facility is to estimate the quantity of waste excreted by fish. Waste excretion rate is typically related to feeding rate since virtually all the wastes generated from an intensive aquacultural system originate from fish feed. Assuming a typical feed conversion ratio (feed input: fish gain) of 1 to 2 and neglecting the impact of uneaten food, 80% of feed (on a dry weight basis) input to an aquacultural system will eventually become waste as fish excretion products (1). Typical waste forms include CO_2, ammonia, feces, and other dissolved substances. The amount of waste produced is often closely related to feeding rate.

The amount of feces excreted by fish is typically reported as total suspended solids (TSS), which is defined according to the standard analysis method (2) as particles greater than 2 μm in size. TSS excretion rates for trout and catfish have been a topic of many studies. The direct TSS excretion rate varied from one report to another, ranging from 0.30 to 0.52 kg per kg feed for trout and from 0.18 to 0.69 kg per kg feed for catfish. Clearly, TSS excretion rate may vary with species, temperature, feeding rate, and management. Based on reports on a variety of systems, however, feces generation values in the range of 0.2 to 0.4 kg TSS per kg feed appear to be typical (3).

One of the major factors that contribute to the differences in reported excretion values is the amount of uneaten feed that ends up in the water. The amount of uneaten feed is usually minimized under laboratory conditions but is less controllable under commercial conditions. Consequently, the actual solids generation rate from commercial aquacultural facilities may be higher than the excretion rates obtained under laboratory conditions. Naturally, effective feeding management can minimize the amount of solids that result from uneaten feed.

Waste Production as Sludge

The amount of solids and the associated sludge volume are two major factors in aquacultural waste management.

The solids mass production rate is determined by the waste excretion rate of the fish within the system, as well as the system's internal waste treatment capability. The volume of sludge generated, on the other hand, is controlled not only by the amount of solids produced but also by the degree to which the TSS is concentrated in the sludge stream. When solids are removed from a system either through backwashing a filter or cleaning a sedimentation tank, the resultant sludge is usually still relatively dilute. Clearly, the disadvantage in dealing with dilute sludge is the large waste volume involved. Thus, it is desirable to design the solids separation and removal system to obtain a sludge that is as highly concentrated as possible. For example, 5% of solids concentration is achievable for sludge thickening using a sedimentation process.

Fish culture produces less waste than large land animals for a unit weight gain because aquatic animals are very efficient at feed conversion. However, if daily waste generation is evaluated on a live weight basis, the amount of waste produced by fish is comparable to that of other animals, but with a much higher sludge volume. The higher sludge volume production is primarily due to the dilute nature of aquaculture waste.

CHARACTERIZATION

Pertinent Environmental Parameters

The potential environmental impact of aquaculture sludge can be described using several key parameters, e.g., concentrations of TSS, biochemical oxygen demand (BOD), and nutrients in the sludge. TSS concentration represents the amount of particulate matter present. In an aquatic environment, elevated TSS concentration increases water turbidity. Additionally, TSS can deposit in the receiving water body causing alteration of habitat conditions. Moreover, because of the organic nature of the TSS from aquacultural operations, the breakdown of TSS creates an oxygen demand that will reduce the concentration of dissolved oxygen in the receiving water.

The second parameter is BOD_5, representing the amount of oxygen consumed by the organics in the waste that biodegrade within five days under standard conditions [20 °C (68 °F)]. BOD_5 excretion rate is also generally expressed as a ratio to the feeding rate. BOD_5 excretion rate varies more widely and is typically lower than that of TSS. Of the BOD_5 excreted, over half is typically in particulate form and the rest is dissolved in water.

Nutrient contents are also important parameters in aquacultural sludge management. The major concerns are nitrogen and phosphorus. The majority of the nutrients are in organic forms when sludge is first discharged from a solids separation and removal process of an aquaculture operation. Mineralization occurs later under a variety of conditions and transforms the organic nitrogen and phosphorous to inorganic forms that are available to plants and are mobile in the environment. Discharge of the nutrients into surface waters can stimulate algae growth, causing eutrophication, while leaching of nitrate nitrogen into groundwater can cause groundwater contamination.

Chemical Characteristics

Aquacultural sludge can be characterized both by the concentration of waste constituents or by the ratios of given constituents to total solids (TS) in the sludge. TS concentration in aquacultural sludge is mainly from TSS. For example, the BOD_5/TS ratio is a measure of the degree of sludge stabilization. A high BOD_5/TS ratio implies a sludge that will rapidly decay and potentially cause oxygen depletion and odor problems if not properly managed. Similarly, the nutrient content of the sludge can be described by total Kjedahl nitrogen (TKN) and total phosphorus (TP) to TS ratios. Higher ratios represent better fertilizer values or strong pollution potential. The characteristics of the aquacultural sludge from a recirculating system using a plastic beads filter are illustrated in Table 1, with reference to domestic sludge.

Compared with typical municipal sludge, most aquacultural sludge has lower solid and BOD_5 concentrations. Of the solids contained in the aquacultural sludge, more than 80% are volatile, 20% higher than those in municipal sludge. Aquacultural sludge also has higher nitrogen and phosphorus contents. Olson (6) found that fish wastes contain a higher percentage of nitrogen than cattle, pig, and sheep wastes. The percentages may change with respect to the stabilization time it will take for sludge as organic nitrogen and phosphorous to convert to ammonia and soluble phosphate, respectively, during the decay processes. The high TP and TKN contents in the fish sludge originate from the feed; most fish feeds contain 7.2 to 7.7% of nitrogen by weight. Of the nitrogen in feeds, 67 to 75% will be lost to the aquatic environment. The phosphorus content of the commercial fish diet ranges from 1.2 to 2.5%, with as much as 80% being lost to the aquatic environment (7).

Table 1. The Chemical Compositions of Aquacultural Sludge

| Parameter | Aquacultural Sludge (4) | | Standard Deviation | Domestic Sludge (5) | |
	Range	Mean		Range	Typical
TS (%)	1.4–2.6	1.8	0.35	2.0–8.0	5.0
BOD_5 [mg/L (ppm)]	1,588–3,867	2756	212	2,000–30,000	6,000
TKN (N, % of TS)	3.7–4.7	4.0	0.5	1.5–4	2.5
TP (P, % of TS)	0.6–2.6	1.3	0.7	0.4–1.2	0.7
pH	6.0–7.2	6.7	0.4	5.0–8.0	6.0

Physical Characteristics

Major physical sludge characteristics that affect the design of a treatment system include particle settling velocity, density, and size distribution. Ning (4) observed that the solids particles in aquacultural sludge from a bead filter settled out fairly quickly with an average zone settling velocity of 1.37×10^{-3} m/s (8 cm/min) (3.1 m/min). The wet density of the sludge was measured as 1.004 g/mL, which is close to the typical value of a municipal sludge. The particle size distribution of the aquacultural sludge showed that particles less than 60 μm and greater than 1,000 μm accounted for 15% and 17% of the total dry weight, while particles ranging from 60 to 105, 105 to 500, and 500 to 1,000 μm represented 8%, 29%, and 31%, respectively.

Biochemical Characteristics

One of the major biochemical characteristics of sludge is the decomposition (or decay) rate constant that represents how fast waste material decays under given conditions. The rate constant referred to here is defined as a first-order reaction ($dC/dt = -kC$, where C is the concentration, t is time, and k is the rate constant). A laboratory study (4) found that oxygen availability and temperature had significant impact upon decay rate constants. From 10 to 30 °C, the anaerobic (without oxygen) decay rate constants of BOD_5 varied from 0.004/d to 0.037/d. For the same temperature range, the aerobic (with oxygen) decay rate constants varied from 0.188/d to 0.329/d. The impact of temperature on digestion rates was more significant for anaerobic digestions than for aerobic digestions. The study also found that aquacultural sludge had digestion rate constants comparable to domestic sludge. For example, the maximum aerobic digestion rate constant of BOD_5 for aquacultural sludge at 20 °C was 0.14 to 0.32/d, whereas the reported value for municipal sludge was 0.05 to 0.3/d (5).

TREATMENT AND DISPOSAL

Environmental Regulations

Federal and state pollution control regulations apply to aquacultural operations. These regulations prohibit direct discharge of aquacultural sludge to receiving water bodies. In most cases, aquaculture facilities are required to obtain permits from the appropriate state agencies for the handling and disposal of aquacultural sludge. Typically, a permit is not going to be issued unless the aquaculture operation has a waste management plan that meets the environmental regulations.

Minimizing the environmental impact of nutrients and solids produced from aquacultural facilities is the primary objective of most aquacultural waste management plans. A typical waste management plan will include, at a minimum, (1) a description of the solids handling and removal systems components, (2) schedules for cleaning frequency of the various waste collection components, (3) a plan including rate and schedule for land application or other approved method of utilization for the waste material, and (4) a monitoring plan that evaluates the effectiveness of the overall system.

It is important during the development of a waste management plan to incorporate best management practices that have been proven effective by the industry and that are acceptable to the regulatory agencies. In fact, the aquaculture industry, with help from the research community, has been making constant efforts to address both pollution reduction and waste management and has developed and demonstrated some best management practices for pollution minimization. Examples include reducing phosphorus through using low phosphorous feed and improving phosphorus digestion efficiency, effluent minimization through the adoption of recirculating systems, effluent treatment through solids separation, land application of fish waste to utilize the fertilizer values, and sludge storage for winter months. A waste management plan should incorporate these practices as much as possible.

Treatment and Disposal

As environmental regulations become more stringent, sludge management becomes one of the major tasks in an aquaculture operation. A proper waste management strategy is now considered critical for maintaining the legality, profitability, and sustainability of an aquaculture facility. Treatment and ultimate disposal are the two major steps in aquacultural waste management. Before the final disposal, two treatment processes (thickening and stabilization) may be necessary for some applications.

Gravity Thickening. The purpose of thickening is to increase solids content. A thickening process is typically employed between the point of effluent discharge from the culture system and the sludge storage and stabilization units. In virtually all applications, it is always desirable to increase solids concentrations to a higher level to improve the economics of treatment and disposal. Clarification, often in settling tanks or ponds, is a common thickening process during which particles settle to the bottom by gravity. When the sediments are removed from the settling unit, solids concentrations are usually at 2 to 5%.

Sludge Stabilization and Storage. A stabilization process is necessary in environmentally sensitive areas where offensive odors need to be minimized. There are typically two major benefits that are related to sludge stabilization: organics decay and volume reduction. Stabilization processes can provide for complete oxidation of readily degraded organics, resulting in a sludge that is unoffensive in nature. Stabilized sludge poses few problems when disposed through land application or landfilling. In addition, stabilization can reduce sludge volumes by 50−75% (8).

Sludge storage is required in cold climates. During wintertime, frozen ground, along with wet winter weather, decreases waste utilization on land and increases surface runoff potential. Therefore, land application of waste in these regions is limited only to certain times of the

year when the vegetation and crops on land are active. As a result, waste has to be stored during the winter months.

Lagoons are the most feasible technology for stabilizing aquacultural sludge. Anaerobic lagoons have been used to treat waste discharges from all phases of the vast agricultural industry and have also been considered suitable treatment processes for aquacultural wastes. In an anaerobic lagoon, organic loading is so high that no appreciable oxygen concentration exists. Sludge introduced into the lagoon ranges from that containing relatively light solids concentrations (approximately 0.1% solids) to slurries containing just enough water to transport the solids into the lagoon. Anaerobic lagoons function successfully over a wide solids-loading range with little maintenance. The major parameters used for anaerobic lagoon design are volatile suspended solids (VSS).

Whenever possible, a two-stage lagoon system should be used for sludge stabilization. A two-stage lagoon system is typically designed in such a way that the first stage is anaerobic, and the second stage is facultative. The main objective of an anaerobic lagoon is BOD reduction through organic decay, while the main objective of a facultative lagoon is nitrogen reduction as well as additional BOD removal. Typical effluent quality from a facultative lagoon is not adequate for direct discharge but is more appropriate for irrigation.

Clearly, a lagoon system can also be used for sludge storage in wintertime. However, the design for the two functions is usually different. Storage capacity is the major design criteria for storage lagoons (or ponds) where sludge and precipitation volume is more important. Organic (VSS) loading rate, on the other hand, is the major design criteria for anaerobic lagoons where the amount of organics and the decomposition rate of the organics are more important.

Sludge Disposal. Currently, the most often used aquacultural sludge disposal process is direct land application. Application methods include using sprinklers and tank trucks. Because high-rate land application of animal manure as a waste has been proven to cause adverse environmental impacts (9), a better approach for aquacultural sludge management is to use the waste only according to its fertilizer value for crops. The high nitrogen content (4 to 6%) of aquacultural waste makes it valuable to crops as a fertilizer, but limitations for such application have also been identified (6). The first is odor, which prohibits this option in populated areas. The second is the propensity for the applied sludge to form a crust. If the sludge is not thoroughly plowed into the soil, some plant seedlings may be unable to push through the crust. The third limitation is the expense of hauling and spreading. The fourth is the slow nitrogen release rate. Since about 90% of the total nitrogen is in organic form, only one-third of the nutrients can be used in the first year (6). This makes application in high rainfall areas questionable, since runoff of the unused nitrogen may cause water quality problems in local surface waters.

The guidelines for application rates of aquacultural sludge on cropland have not yet been established.

However, it would be reasonable to manage aquacultural waste following guidelines similar to those for managing other types of waste. Most animal waste management plans are based on nitrogen. The fundamental premise is that the rate of animal waste applied on land should not provide more plant available N than crops need, in order to avoid contaminating groundwater with nitrate. Studies on animal manure indicate that crops typically remove between 100 to 200 kg of nitrogen/ha (9). Therefore, a similar rate for application may eliminate nitrogen accumulation in the soil and avoid adverse impacts on the environment. The high nitrogen content that makes aquacultural waste valuable to crops as a fertilizer could, of course, also make overapplication of nitrogen more likely. Olson (6) tested three application rates of trout manure in a greenhouse (111, 222, 336 kg N/ha) for growing spring wheat. Satisfactory results were obtained from application rates of both 222 and 336 kg N/ha. Subject to further experimental verifications, Olson (6) recommends 222 kg N/ha as a design criterion for aquacultural sludge application on land. The information presented here would be useful for estimating the amount of land needed for sludge land application for a given operation. The characteristics of aquaculture sludge, however, may vary substantially depending upon waste management systems and many other factors (10,11). Thus, the nutrient values and corresponding rate for land application may be different for aquaculture sludge from different operations.

OUTLINE

Introduction
The Captive Broodstock Concept
Performance of Captive Broodstocks
Conclusions
Bibliography

INTRODUCTION

A major obstacle often facing endangered species recovery programs is overcoming the demographic extinction risks posed by a small population size and limited breeding pairs. Captive rearing of animals to produce adults or offspring to supplement wild populations is a gene maintenance and population amplification technique that has gained worldwide popularity as a component of species enhancement (1–4). Currently, over 105 species of mammals, 40 species of birds, 29 species of fish, 14 species of invertebrates, and 12 species of reptiles are being maintained or enhanced through forms of captive breeding (3,5). Captive broodstocks are an especially attractive alternative for highly fecund animals such as fish. In this entry, we examine the potential use of captive broodstock technology to aid the recovery of depleted stocks of Pacific salmon.

THE CAPTIVE BROODSTOCK CONCEPT

A number of stocks of anadromous salmonids in the Pacific Northwest are currently listed as threatened or endangered under the U.S. Endangered Species Act (ESA) (6–8). In addition, over 200 stocks have been identified as being "of special concern" (9). The ESA recognizes that the conservation of listed species may be facilitated by artificial means, such as captive broodstocks, while factors impeding population recovery are identified and corrected (10).

Captive broodstock programs differ from conventional salmon culture in that fish of wild origin are maintained in captivity throughout their life to produce offspring for the purpose of supplementing wild populations. The relatively short generation time (2–7 years) (11–13) and the potential to produce large numbers of offspring (an average of 1,500–5,000 eggs per female, depending on the species) (11–14) make Pacific salmon ideal for captive broodstock rearing. Survival advantages offered through the protective culture of such large numbers of eggs can be profound. The potential benefits of captive culture over natural production can best be viewed in terms of the two near-independent stages of anadromous Pacific salmon life history: the egg-to-smolt stage and the smolt-to-adult stage.

Wild Pacific salmon generally have high natural mortality through the early life-history stage. For instance, naturally spawned ESA-listed endangered Snake River sockeye salmon generally experienced less than 6% egg-to-smolt survival (15). In contrast, the protective environment of hatcheries can produce many more juveniles than are expected in the wild: egg-to-smolt survival for hatchery-reared sockeye salmon is generally at least 75% and frequently greater (14,16,17). Survival ratios are similar for other Pacific salmon species. Thus, successful hatchery rearing through the juvenile stages alone may provide up to twelvefold survival advantage compared to natural production.

The survival advantages of protective culture offer the greatest benefits during the smolt-to-adult phase. For instance, under current environmental conditions in the Columbia River Basin, wild smolt-to-adult survival of anadromous Snake River sockeye salmon has been estimated at less than 0.2% (16). However, smolt-to-adult survival of Pacific salmon in protective captive culture may easily exceed 50%, more than a 250-fold survival advantage over natural production during these life stages (17). Theoretically, the captive culture of Pacific salmon through both the egg-to-smolt and smolt-to-adult life stages could provide a survival rate more than 3,000 times higher than the rate of natural production of a depleted stock.

Artificial propagation and captive broodstock technologies are not without potential complications and risk. Captive rearing programs have been criticized as "halfway technologies" that address the effects of endangerment but not its underlying causes (18,19). The potential genetic and environmental hazards of using captive culture (inbreeding, genetic drift, domestication, selection, behavioral conditioning, and exposure to disease) and the possible negative interactions of hatchery and wild fish have been well documented (20–24). Some authors argue that the primary course of recovery for depleted populations should be through habitat improvements, after which populations should be left to rebound naturally. Others point out the potential for catastrophic loss of a potentially major portion of the gene pool in captivity through failure of the culture facility or disease outbreak (1–16).

Captive breeding is also widely regarded as less cost-effective in the long-term than in situ preservation (25). However, most fisheries researchers and managers recognize that even aggressive habitat improvements will take several fish generations to complete. Pragmatically, captive broodstocks may offer the best chance for continued existence of endangered populations through the enhanced survival during protective culture (16). As Johnson and Jensen (2) pointed out, "If the gene pool is lost, no amount of habitat protection will help the species." Thus, in many cases, it appears that the risk of extinction in waiting for natural recovery through habitat improvements is greater than the risk to the population from husbandry intervention.

Fish for captive broodstocks can be sourced from all available life stages: eyed eggs, fry, smolts captured from the wild, and prespawning adults, captured and artificially spawned. As a practical matter, the capture of adult Pacific salmon at weirs during their upstream migration and the capture of smolts at weirs during their downstream migration are the easiest to accomplish. However, redd sampling and fry trapping may also be employed. Fish for captive broodstocks should be representative of all portions of the gene pool to avoid artificial amplification of only a portion of a population and subsequent inadvertent reduction in the overall effective population size (10).

Two captive broodstock approaches are being applied to salmon recovery in the Pacific Northwest (17). One strategy involves rearing the populations to maturity in hatcheries. The first or second generation offspring are then stocked into ancestral lakes or streams at one or more juvenile life stages (i.e., fry, parr, smolt). Another strategy involves rearing the broodstock in captivity to adulthood, then releasing the adults back into their natal habitats to spawn naturally. In either case, fish can be reared using simple modifications of standard fish culture practices (16). It is advisable to rear duplicate groups of captive broodstocks at low density in disease free water at two or more secure facilities to avoid potential catastrophic loss of valuable gene pools (16). All fish should be passive integrated transponder (PIT) tagged (26,27) or otherwise marked to allow identification of individuals from each family.

Maintenance of multiple lineages and year classes in culture allows the development of mating strategies that can maintain and potentially increase genetic diversity. Such mating strategies can include random pairing, pairing in as many different combinations as possible, avoidance of pairing between siblings, crossings between different year-classes, and fertilization with cryo-preserved sperm from other generations (10). In any event, each discrete year-class of captive broodstock should be maintained for only a limited number of generations to guard against domestication and to help assure that genetic integrity and adaptability to native habitats are preserved.

PERFORMANCE OF CAPTIVE BROODSTOCKS

The dramatic difference between the natural environments experienced by wild Pacific salmon and the artificial environments experienced by captively reared fish appears to create a number of differences in their relative reproductive potential. Schiewe et al. (17) indicated that egg-to-adult survival during captive broodstock culture has been observed to range from 0 to 88% for sockeye salmon, 2 to 78% for chinook salmon, and 80% or more for coho salmon. Survival may generally be expected to be in the upper range in the absence of disease outbreaks. The size and age of maturity of captively reared adults is generally less than their wild cohorts. For instance, Joyce et al. (28) indicated that captively reared chinook salmon females from the Unuk River in Alaska, matured at 4 years of age and 6.8 kg, while wild cohorts matured at 5 years

and 12.8 kg. Similarly, Schiewe et al. (17) reported that captively reared Redfish Lake sockeye salmon matured at 3 years of age and 1.2 kg compared to 4 years and 2.0–3.0 kg for wild fish. Average viability of eggs from captively reared spawners (30–70%) has also been found to be commonly lower than the 75–95% viability of similar strains of hatchery-spawned wild fish (16,17,29). Captively reared salmon have been shown to demonstrate a full range of reproductive behaviors and the ability to naturally reproduce (29–31). Nevertheless, recent behavioral studies indicate that captively reared Pacific salmon released to spawn in streams may have lower breeding success than comingling wild salmon (32).

The reasons for the poorer reproductive performance of artificially propagated captively reared fish versus ocean-ranched and wild cohorts are not well understood. Most captive broodstock programs we reviewed used spawners collected from a wild population. Therefore, it seems intuitive that much of the poor performance, at least in first-generation offspring, can be attributed to the effects of artificial culture environments. We speculate that the development of nutritionally complete species-specific brood diets would improve the reproductive performance of captive broodstocks by improving gamete quality. However, the effects of genetic change in the captively reared populations as a basis for reduced spawner size, egg viability, and reproductive behavior in fish remain a possibility.

Although in many cases, the average survival and eyed-egg viability of captive broodstocks have not met optimum expectations yet, they still are fulfilling population-amplification goals, at least from the juvenile-production perspective (16,17). For instance, since Snake River sockeye salmon from Redfish Lake (Idaho) were ESA-listed as endangered in 1991, only 16 adults had returned to spawn through 1998. All were captured and spawned, and the eggs were reared as captive broodstock. Those broodstocks have subsequently produced over 800,000 animals that have been released (as either eyed eggs, fry, presmolts, smolts, or prespawning adults) into historic habitats (Flagg, unpublished data). For those Redfish Lake sockeye salmon captive broodstocks, most individual group population amplifications have represented one-to-several thousand times the current estimated natural egg-to-adult survivals of this endangered stock (Flagg, unpublished data). Using captive broodstock techniques, the program has been able to maintain all gene pool segments of Redfish Lake sockeye salmon that existed at the time of listing (6,16,17). A few wild breeding pairs should return in the next few years to augment the population. However, it should be emphasized that for the Redfish Lake sockeye salmon, the major barriers to survival are downstream of the lacustrine rearing habitat. Captive broodstocks alone cannot recover the Redfish Lake sockeye salmon population; habitat improvements must occur for recovery to be a possibility. In addition, it should be noted that captive broodstocking of Pacific salmon is still in the initial stages of development. Years of monitoring and evaluation of adult returns will be necessary to fully evaluate the technology.

CONCLUSIONS

Since a multitude of factors affect both the decline and potential for recovery of a stock, exacting rules cannot presently be defined for the implementation of captive broodstocks. However, knowledge of survival, reproductive success, and offspring fitness is critical to determining levels of risk in implementing a salmonid captive broodstock program. In general, the use of captive broodstocks should be restricted to situations in which the natural population is dangerously close to extinction. Proper precautions should be taken to minimize genetic impacts during the collection, mating, and rearing of captive broodstocks, as any alteration to the original genetic composition of the population in captivity may reduce the efficacy of supplementation in rebuilding the natural population. Furthermore, the liberation of fish from captive broodstocks should be consistent with the known behavior of existing wild fish and with the available knowledge of the life-history characteristics of the wild fish.

In some cases captive broodstocks may provide the only mechanism to prevent extinction of a stock and may be undertaken regardless of prospects for immediate habitat improvement. However, captive broodstocks should be viewed as a short-term measure to aid in population recovery — never as a substitute for reestablishing naturally spawning fish in the ecosystem. Because the benefits and risks have not been established through long-term monitoring and evaluation, captive broodstock development should be considered an experimental approach and used with caution. Salmonid captive broodstocks can provide an egg base to help "jump start" a population, but these efforts must go hand in hand with scientifically sound resource management (e.g., habitat restoration, harvest reform) to fully aid in recovery. The primary consideration should be restoring the fish species to its native habitat.

Hagerman Fish Culture Experiment Station
Hagerman, Idaho

OUTLINE

Energy is not a nutrient; rather, it is the capacity to do work. While most people think of this as mechanical work, in biological systems, energy is the currency driving the chemical reactions of metabolism, including those associated with growth, locomotion, and health.

Energy for biological systems ultimately comes from the sun in the form of radiant energy, which is captured by green plants and used to synthesize glucose from carbon dioxide and water (photosynthesis). Glucose is then used as a source of energy and substrate to manufacture more complex molecules needed for life, including fatty acids, amino acids (protein), and carbohydrate. Animals, of course, cannot obtain energy in this way. They must obtain it through their diet. Thus, animals, including fish, are net consumers of energy to support growth, activity, reproduction, and general metabolism.

The study of the balance between accumulation, consumption, and loss of energy is known as nutritional energetics, or bioenergetics. This entry considers the dietary requirements of energy by aquatic animals and the various dietary sources used to meet those requirements. Several reviews of this topic, as it relates to aquatic animals, are available (1–4) and these should be consulted for more in-depth information.

UNITS OF MEASUREMENT

All forms of energy can be expressed in terms of heat. Until recently, the calorie has been the standard unit for energy. The British thermal unit (BTU) has not been used in nutritional sciences to any great extent. One calorie (cal), also called gram-calorie (gcal), is defined as the amount of energy required to raise the temperature of 1 gram of water from 14.5 to 15.5 °C (58 to 60 °F). In 1960, the Conférence Général de Poids et Mesures formally adopted a Système Internationale d'Unités (SI), which is a refinement of the metric system. In the SI system, the calorie is replaced by the joule (J), which is used for all forms of energy, including chemical, electrical, mechanical, and thermal. The joule is defined as the "work done when the point of application of a force of one newton is displaced a distance of one meter (3 ft) in the direction of the force." One calorie is equivalent to 4.1855 joules. Although the calorie is still widely used by nutritionists, it is increasingly being replaced by the joule as a unit of measure of energy among nutritionists. For convenience,

it is common practice to refer to the energy of a substance in terms of kilocalories (kcal or Cal) or kilojoules (kJ) per gram of feed. A typical trout feed contains 4000 kcal (16,740 kJ) of total (gross) energy per kg (2.2 lb).

ENERGY FLOW

It is useful to consider the energy content of a feed in terms of its relation to the nutrients in the feed. The four proximate principals — crude protein, crude lipid, fiber, and nitrogen-free extract — account for the energy content of the feeds (the minerals, as measured by the ash content, provide negligible energy, although some of them are necessary for its utilization by the animal). Once ingested, the energy of a feed is either absorbed into the body, or it is lost via the feces. Once in the body, a proportion of the energy is lost to the environment via the urine or gills, and the rest is used for metabolism, activity, and tissue growth.

The energy contained in a feed or feedstuff is usually expressed either as the gross energy (GE), the digestible energy (DE), or the metabolizable energy (ME). The GE is defined as the energy released by total combustion of a food into water, carbon dioxide, and other gases. This is known as the heat of combustion, and it is measured as the heat captured by water from the controlled combustion of a known quantity of the substance in pure oxygen. The device commonly used for this measurement is the bomb calorimeter, which consists of a metal chamber that is charged with pure oxygen under elevated pressure and suspended in a known quantity of water. The temperature of the water is then carefully monitored after ignition of the feed.

The GE of substances are additive. That is, if the GE of the individual components of a feed is known, then the GE of the overall mixture can be calculated as the sum of its GEs of constituent ingredients, adjusted for their percentage in a feed. The DE is the proportion of the energy content of the feed that is absorbed by the animal after ingestion. It is generally measured by subtracting the calorie content of food lost via feces from GE. The DE of a feed can also be calculated as the sum of the DE of the constituents, although, under some conditions, the digestibility of constituents can be influenced by the level of the constituent itself, or by the presence of other components of the diet. For example, high levels of carbohydrate may reduce the availability of protein and fats.

The proportion of ingested energy that is available for useful action by the animal (growth, movement, metabolic activity, etc.) is called the metabolic energy (ME). This is measured as the difference between GE and the energy loss via feces, urine, and gill excretions. As with DE, the ME of a mixture can be very much influenced by the relative level of the components. This is so because the efficient utilization of feedstuffs requires that all essential nutrients be present. For example, endogenous protein synthesis requires the presence of suitable levels of each essential amino acid. If there is a deficiency of even one of these, protein synthesis is impaired,

resulting in conversion of the amino acids into energy-yielding compounds and waste products with resulting reduction in ME.

ME includes the energy required for assimilation of food, called the heat increment, which is energy not available for metabolism and growth. Net energy (NE) is defined as the ME minus heat increment. Heat increment manifests itself as heat lost through the body and can be measured directly by using a respiratory calorimeter in terrestrial animals. Only limited data exist for the NE of feeds aquatic animals. The NE of ingested food either is used for growth (NEg), maintenance (NEm), or voluntary activity.

The GE of the energy-yielding proximate principals is not uniform; fat contains more GE per gram than protein or carbohydrates. Research conducted with different animal species and a variety of feedstuffs has provided enough information so that nutritionists can calculate whether or not a particular feed contains sufficient energy without having to resort continually to biological testing. This is less true with aquatic species, however, especially with the recent interest in novel feedstuffs.

The term *physiological fuel value* is generally reserved for use in human nutrition, but is sometimes used in aquatic animal nutrition. The term refers to the portion of the GE that is ultimately available for use in the body. The physiological fuel value is equal to the digestible energy adjusted in the case of protein for the loss of energy in the urine, and is an estimate of the metabolizable energy. The physiological fuel values for humans for carbohydrate, lipid, and protein are, approximately, 16.7, 37.7, and 16.7 J/g (4, 9, and 4 kcal/g), respectively.

The value for protein was based on the energy content of urea, the principal nitrogen containing product of protein degradation in mammals (birds excrete uric acid). In aquatic animals, the principal nitrogenous end product of protein catabolism is ammonia, which requires less energy to excrete than urea requires. The ME value of protein in aquatic species is 21.3 kJ/g of digested protein. Of course, to correctly calculate the ME of feed or feedstuff, the digestibility of the components must be known, and this can be highly variable.

The GE content of the components of crude lipid is not uniform. For example, the energy content of phospholipids is considerably less than that of triglycerides (39.7 kJ/g for triglycerides and 33.5 kJ/g for phospholipids). These values should be used in cases where there is a high level of phospholipids in relation to triglycerides. Also, in general, long-chain fatty acids contain more energy than do short chain ones. The GE of butyric acid (8 carbon chain), for example, is 25.1 kJ/g, compared to 39.3 kJ/g for palmitic acid (16 carbon chain).

The digestibility of different types of carbohydrate is highly variable. Some aquatic animal species are better at digesting complex carbohydrates than others. Not surprisingly, in general, herbivores are better at digesting complex carbohydrates than are carnivores. Many aquatic species are unable to tolerate large influxes of simple carbohydrates, such as glucose. The ME of monosaccharide is 15.9 kJ/g of digestible energy; for disaccharides, it is 16.7 kJ/g and for digestible polysaccharides, it is 17.6 kJ/g.

By making the aforementioned adjustments and by applying the digestibility coefficients for various feed ingredients, it is possible to calculate a fairly accurate ME value for a diet. Direct measurement of ME for aquatic animals requires the use of special chambers to house the animals and quantitatively collect gill excretions. This has been done for some species, notably rainbow trout, but the difficulty of the work and the necessity of specialized equipment has precluded its widespread application.

REQUIREMENTS

The energy requirements of aquatic animals are affected by a variety of factors, including level of metabolic activity, growth rate, and reproductive state. The metabolic rate of fish increases with increasing water temperature. Fish thus require more dietary energy, all other things being equal, when their water temperature is high. Fish adjust their feed intake relative to water temperature; thereby taking in more energy at higher water temperatures. Growth rate is also affected by water temperature, as is feed intake. Maturation in fish results in diversion of dietary energy from somatic (muscle) tissue synthesis to gonadal synthesis. Spawning migrations in wild fish often occur during periods of voluntary starvation. Fish store energy in anticipation of periods of voluntary starvation and food scarcity. Fish raised in hatcheries do not undertake spawning migrations, but do have periods of low feed intake or voluntary starvation as spawning approaches. The energy requirement, expressed in terms of kJ/day, is higher in fish prior to those spawning periods than during regular growth.

Crustacea and finfish differ radically in their tolerance of dietary lipid. Studies with a variety of shrimp species have shown that crustacea fed diets containing lipid at levels in excess of about 10% have reduced growth. For this reason, crustacean feeds derive a greater proportion of their energy from carbohydrate relative to lipid than do finfish feeds. Many species of finfish, e.g., yellowtail (*Seriola quinqueradiata*) and salmonids, grow best under culture conditions when fed diets containing 20−35% lipid. Warmwater species, such as channel catfish (*Ictalurus punctatus*), are intermediate in tolerance of dietary lipid, but tend to acquire lipid deposits in the musculature if fed diets containing more than 10% lipid (5). Farmed marine species, e.g., sea bass (*Dicentrarchus labrax*), sea bream (*Sparus aurata*), and striped bass (*Morone saxatilis*) do not appear to tolerate high dietary lipid levels. Thus, their feeds are limited to 14−16% lipid, with energy being supplied by carbohydrates, similar to channel catfish feeds.

ENERGY BALANCE

Nutrient balance is a widely applied method for assessing nutritional status. To determine nutrient balance, intake is compared with the sum of the losses from the body from all channels. A positive balance occurs when the amount ingested exceeds the amount lost. A negative balance refers to greater loss than intake. A healthy

growing animal will have a positive balance. In some cases, however, where intake is very low or nonexistent, such as occurs for salmon prior to spawning, a negative balance is a normal condition.

Clearly the aquaculturist is interested in maintaining as high an energy balance as economically possible. In animal tissues, the principal repositories of energy are protein and lipid. Carbohydrate, which occurs mostly in the form of glucose or glycogen, accounts for a small proportion of energy stored in the body. Of these, protein accretion is most tightly linked to growth. For a given species and size, the protein content of an animal tends to be less variable than the lipid content, under normal conditions. Protein accretion in animals depends on a variety of factors, including the presence at the sites of protein synthesis of the types, or species, of amino acids required. Twenty-two amino acids are used to make most proteins, and these are obtained either from endogenous sources (catabolism of existing protein, or from de novo production) or from the diet. Amino acids arriving in the body following ingestion are not necessarily available for protein synthesis, but may embark on a variety of competing pathways, including energy production via lipids or carbohydrate. The demands for energy by the body supersede those for protein synthesis, and amino acids are preferentially catabolized to yield energy, when ingested energy from other sources is low. As a consequence, in order to maximize dietary protein retention by aquatic animals, it is important that the nonprotein available energy levels are high.

The improvement in protein retention resulting from increasing the nonprotein energy content of feeds, is referred to as the protein-sparing effect. Modern feeds for several species (including Atlantic and Pacific salmon and yellowtail) are made with very high levels of fat in order to minimize the utilization of dietary protein as an energy source. On the other hand, if the protein to energy ratio is too much tilted toward energy, feeding rate and feed efficiency are impaired. A goal of feed formulators for intensive aquaculture (i.e., where manufactured feed is the principal or exclusive source of nutrients and energy) is to achieve the optimum protein to energy ratio, or more meaningfully, digestible protein to ME ratio, for growth and dietary protein efficiency for various cultured species under specific culture conditions.

The dietary protein to energy ratio that yields the optimum growth and feed efficiency is species dependent and can be affected by a number of factors, including water temperature, swimming level, and source of energy. The current level of knowledge concerning the effect that these factors have on protein and energy utilization is quite rudimentary, as summarized in Table 1. In general, the optimum protein to energy ratio is about two to three times higher than that for swine and poultry. This does not indicate a high protein requirement, but rather a low energy requirement relative to these terrestrial animals. An estimated 3,560 kcals are needed to produce 1 kg of trout, containing 1,910 kcals of energy (6). Thus, trout retain approximately 54% of dietary energy, comparable to 56% reported for channel catfish (7).

Table 1. Optimum Ratio of Dietary Digestible Protein (DP) to Digestible Energy (DE) in Various Species of Fish, Poultry, and Swine (11)

Species	DP/DE (g/MJ)
Channel catfish	19.4–23.2
Red drum	23.4
Hybrid striped bass	26.8
Nile tilapia	24.6
Common carp	25.8
Rainbow trout	22.0–25.1
Swine and poultry	9.6–14.3

SOURCES

As mentioned previously, animals obtain the energy they need from the protein, lipid, and carbohydrate fractions of their food. Each of these components contributes differently to the available dietary energy and has different implications for the overall cost of feed manufacture. Aquatic animal nutritionists must balance the value of the nutrients and energy against the cost of the ingredients when formulating feeds.

Protein

In general, protein is the most costly component of aquatic animal feeds. Strictly speaking, animals do not require protein per se, but instead require a well-balanced supply of amino acids. Ten of the 22 amino acids that are used in the endogenous production of protein cannot be produced by the animal and need to be obtained through the diet (the indispensable amino acids, IAA). The other 12 amino acids can be endogenously manufactured by the animal (the dispensable amino acids, DAA). Most of the DAA are synthesized from compounds that are intermediates in the TCA cycle within each cell. Others are produced from amino acid precursors.

Theoretically, animals could be raised on feeds that supply sufficient levels of all the IAA, but there is an energy cost involved with this. In practice, aquatic animal feeds supply all amino acids, both IAAs and DAAs, thereby reducing the energy required for amino acid manufacture. A feed that supplies all the amino acids (IAA and DAA) at appropriate levels will minimize the energy required to meet the needs of the animal and will optimize protein utilization (assuming that all other nutrients are also present at required levels). Aquatic animals have a higher tendency to use protein for energy than do many terrestrial animals. Amino acids can be used to generate a variety of products, including other amino acids, carbohydrates, and lipids. Some amino acid species can only be used to generate one or the other of these, and some may be used to make all three. In each case, however, all can be used to generate energy.

Lipid

Lipids consist of a variety of substances that are distinguished by their nonpolarity, and thereby their high
Figure 1. Two-dimensional representation of a triacylglyceride (top) and a phospholipid (bottom). The three carbons arranged vertically on the left of both molecules are derived from a glycerol molecule, while the series of serrated line segments on the right are fatty acids. The intersections of the line segments in the fatty acids portions represent the locations of carbons in these molecules. The double lines indicate double bonds between adjacent carbons and are regions of unsaturation. In phospholipids (bottom figure), one of the fatty acids is replaced by a phosphate group, which is further bonded to some other molecule (e.g., choline, inositol, ethanolamine), which is represented in this figure by an "X." None of the bonds in this figure are to scale.

solubility in nonpolar solvents (notably in ether). In the lipid class, the most important energy sources are the fatty acids, which are largely present as triglycerides. Triglycerides are composed of three fatty acids joined to a molecule of glycerol (Fig. 1) and are a prevalent structural component of cell membranes, as well as the principal source of fatty acids in the diet and the principal storage form of energy in the body. On a weight basis, catabolism of fatty acids yields more useful energy than either amino acids or carbohydrate. The digestibility of the lipid sources used in animal feeds is generally high, greater than 90%. Most lipid in commercial feeds is supplied as oil from plants (corn oil, soybean oil), terrestrial animal (tallow, poultry fat), or marine animal sources (fish oil). Marine oils increase feed palatability and are excellent sources of essential fatty acids, e.g., n-3 fatty acids.

Some aquatic animals, such as salmonids and yellowtail, have a high tolerance for dietary lipid, whereas others, such as shrimp do not. This fact has obvious consequences for the feed formulator. Modern commercial salmon diets have very high fat levels (greater than 30%), which spares dietary protein by reducing the use of dietary protein for metabolism energy. Shrimp, on the other hand, cannot tolerate diets containing more than about 10–12% lipid, forcing shrimp feed formulators to look for other sources of dietary energy.

Carbohydrate

Carbohydrates consist of a variety of constituents and are distinguished by their composition of carbon, hydrogen, and oxygen (in a ratio of roughly $1:2:1$) and their lack of solubility in nonpolar solvents. The nitrogen-free extract and fiber proximate fractions are basically measures of different kinds of carbohydrates. The basic structure of carbohydrates are six or five chain carbon sugars, with the most relevant as a source of energy being the six carbon ring of glucose (Fig. 2). Carbohydrates are also present in feedstuffs as double or polymeric sugar (saccharide)
Figure 2. Two-dimensional representation of glucose. The intersections of the line segments are the locations of the carbons in this molecule. The numbers adjacent to the carbon atoms are the conventional numbering of these atoms. None of the bonds in this figure are to scale.

units. In feeds, polysaccharides are the most important carbohydrate component, while mono- and disaccharides are also important sources of energy in animals. The majority of polysaccharides in plant ingredients are made of either starch or cellulose (Fig. 3), which are composed of long chains of glucose connected by α 1–4 linkages (starch) or β 1–4 linkages (cellulose). Both starch and cellulose polysaccharide chains may also contain small proportions of α or β 1–6 linkages. Two forms of starch are amylose, which contains essentially only straight chain 1–4 linkages, and amylopectin, which also contains 1–6 linkages.

Plants use polysaccharides as energy stores (starch) and as structural components (cellulose). Storing glucose in polymeric chains reduces the osmotic pressure of the stored sugar. A polysaccharide consisting of 1,000 glucose units exerts an osmotic pressure that is only 1/1,000 of the pressure that would result if the glucose units were all present as separate molecules. In polymeric form, glucose can be stored compactly until needed. Animals also store glucose in polymeric form as glycogen, a compound related to amylopectin, but with shorter 1–6-linked side chains. Glycogen is primarily stored in the liver and is used to
Figure 3. Two-dimensional representations of starch and cellulose. Starch is a linear series of glucose molecules in identical spatial orientation. Cellulose is similar to starch, except that alternate glucose molecules are inverted. A low percentage of both starch and cellulose of linkages are between carbons 1 and 6 of adjacent glucose molecules (the numbers next to the carbon atoms are the conventional numbering of these atoms). The proportion of these 1–6 linkages in starch or cellulose influences characteristics of the material. None of the bonds in this figure are to scale.

supply short-term demand for energy. Animals (including fish) mainly store energy as lipid and do not use cellulose at all. Some animals utilize carbohydrate as part of their structural components (e.g., chitin, a component of the exoskeleton of insects and crustaceans).

All animals readily absorb simple sugars, like glucose, but in order to utilize the energy contained in the various types of dietary carbohydrates, animals must have the ability to digest the polysaccharides into single glucose units. The glucose contained in cellulose is essentially unavailable to aquatic animals. Carnivorous fish, salmonids for example, produce only small quantities of the enzymes necessary to digest starch (8), and it is recommended that only limited levels of carbohydrates be included in feeds for these animals. Omnivorous or herbivorous animals [e.g., tilapia (*Oreochromis* spp.) and carp (*Cyprinus carpio*)], however, can digest starch and can utilize feeds containing higher levels.

Carbohydrate utilization as an energy source is affected by more than just digestibility. Even highly digestible carbohydrates (i.e., those that are readily absorbed from the digestive tract), may not be effectively utilized. For example, Wilson and Poe (9) compared the ability of channel catfish to utilize six types of carbohydrates, including two monosaccharides (glucose and fructose), two disaccharides (sucrose and maltose), corn starch, and dextrin (a short-chain polysaccharide) as dietary energy sources. Cellulose, which is assumed to be completely unavailable, was used in the control diet. These researchers found that growth, feed efficiency, and proportion of ingested energy retained in the tissues were highest for fish fed the diet containing dextrin, followed by those fed starch. The fish fed mono- or disaccharides as energy sources grew less well than those fed the longer chain polysaccharides (other than cellulose), and, in fact, grew no better than the fish fed the low DE control diet. The fish fed the fructose diet performed significantly worse than the others. The inability of several species of fish to

tolerate rapid influxes of simple sugars is well known, and may, in part, explain the inability of catfish to utilize the simple sugars in this trial. The hormone insulin is released in response to increases in blood glucose levels and is responsible for stimulating the transportation of circulating glucose into cells, where its energy is utilized. The slower rate of intestinal digestion of dextrin and starch into glucose results in an attenuated influx of glucose into the blood stream, with elevated levels coinciding with maximum insulin secretion, facilitating maximum utilization of the dietary energy from glucose.

In plants, starch is contained in granules, which are relatively undigestible. Under conditions of heat and pressure, such as occur during feed manufacture, these granules rupture in a process called gelatinization. Gelatinized starch is more readily digestible to aquatic animals (resulting in higher glucose availability) than is nongelatinized starch and is also important for its binding characteristics. By ensuring that adequate levels of starch are present in a mash, feed manufactures take advantage of the binding characteristics of this gelatinized starch to ensure adequate strength of the pellets.

CHEMICAL FACTORS AFFECTING ENERGY UTILIZATION

Useful energy is derived from carbohydrates, lipids, and amino acids through the action of very specific series of enzyme-controlled reactions. Several of the enzymes involved in these reaction series require the presence of other molecules for their activity; these are known as cofactors. Cofactors include minerals and water-soluble vitamins. Unlike terrestrial animals, aquatic animals can obtain some or all of the minerals they require for the metabolic reactions involved in energy storage or usage from their environment. In common with monogastric animals, however, they need a dietary supply of the vitamins for energy metabolism. In fact, since many of the

B vitamins are closely related to the transfer of energy, animal requirements for them vary in proportion to the intake of energy. Published requirements for vitamins are often best expressed in terms of DE content of the diet. There is some limitation to this principle, however. For example, if a very high proportion of the DE content of a diet is from the lipid fraction, the thiamin (a B vitamin) requirement is actually reduced, because the energy from free fatty acids is obtained via a pathway that does not have a thiamin-dependant step.

As mentioned earlier, insulin is important in utilization of carbohydrates for energy, but the physiology of hormonal action and energy is very complex. For example, insulin secretion in fish species, in contrast to many terrestrial animals, may be even more highly affected by dietary levels of certain amino acids than by glucose (10). Utilization of dietary energy requires the coordinated operation of a great many enzyme systems under hormonal control. The current state of knowledge of the regulation of energy utilization and metabolism is very spare, but recent work in this area has shown promise. A more complete understanding of this field may have profound implications for formulation of future commercial feeds.

ENHANCEMENT

Robert R. Stickney
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

Introduction
Marine Enhancement Reconsidered
A New Model

INTRODUCTION

Enhancement is the stocking of hatchery-reared fish and shellfish into public waters to increase the natural population of the same species inhabiting those waters. One purpose of enhancement is to restore overfished stocks of commercially or recreationally important species. Another is to help recover threatened or endangered species.

The U.S. Fish and Fisheries Commission was created in 1870 and has since evolved into the National Marine Fisheries Service. It was created, in part, to establish hatcheries that produced fish for restocking the nation's inland and marine waters and for introducing new species. Billions and perhaps trillions of fry, fingerling, and larger fishes, along with molluscs and crustaceans, were stocked beginning in 1872. The stocking of marine fishes was largely discontinued after several decades, due to lack of evidence that the stocking programs — which almost exclusively involved stocking newly hatched animals with little chance of survival — were having the desired effect.

State and federal hatcheries continued stocking species that did demonstrate measurable survival, along with producing fish for stocking new bodies of water (e.g., ponds and reservoirs). Most of those programs involved inland water bodies, though hatchery programs, to produce and release Atlantic salmon (*Salmo salar*) and Pacific salmon (*Oncorhynchus* spp.), have continued for over a century and still produce fish that live most of their lives in the ocean.

MARINE ENHANCEMENT RECONSIDERED

Advances in aquaculture over the past few decades, have involved the development of the required technology to bring a variety of marine fishes through the difficult early life stages and to rear them in captivity to sizes where they stand a reasonable chance of survival if released into the natural environment. An important purpose of the research and technology development was to produce animals for captive rearing to market, but a logical alternate use is in conjunction with well-planned enhancement programs.

A well-planned enhancement program should involve determining sufficient information about the environment into which the animals are to be released, and includes a high level of assurance that no significant disruption of the ecosystem will occur. Prior to releasing additional animals into the marine environment, knowledge should be gained about the carrying capacity of that environment and about how the hatchery fish will interact with wild conspecifics. Every effort should be made to ensure that the stocked fish or shellfish have the same genetic profile as the wild ones. Most of the enhancement programs conducted to date were initiated without considering any consequences except meeting the need of increasing the species population size. That is now changing.

The Japanese have been involved with marine fish and invertebrate enhancement for over 30 years. Several dozen species have been involved, though, until recently, few

data were available to show the program's effectiveness. Over 20 years ago in the United States, red drum (*Sciaenops ocellatus*) enhancement was initiated in Texas after the commercial fishery for that species was closed. A private organization has provided funding to the Texas Parks and Wildlife Department to construct and operate hatcheries that release several million fingerlings annually. Due, in part, to the enhancement program, and helped by the commercial fisheries ban, the species has recovered and now provides excellent recreational fishing along the Texas coast.

More recently, along the eastern seaboard of the United States a crash in the population of striped bass (*Morone saxatilis*) led to a total fishing ban and the establishment of an enhancement program. Within a few years, a recreational fishery was once again in place. In Maine and elsewhere, clam-stocking programs have either created new industries or reinvigorated existing ones.

The National Marine Fisheries Service in the United States has, as one of its goals, to build sustainable fisheries. Recovery of overfished stocks to historical levels can be accomplished through regulation, but it may be aided by enhancement stocking programs. Discussions on how such programs might be put into place, and about the types of research that will be required, in conjunction with those programs, are currently underway.

A NEW MODEL

Historically, in the United States, enhancement programs have been operated by government. In Japan, enhancement is conducted, in many cases, through collaboration of Prefectural governments and the private sector. A private-sector role for enhancement of marine species could be an attractive option in the United States.

In the future, an enhancement program might work like this. The organism selected (fish or invertebrate) would be reproduced and reared to release size in a private hatchery. A state or the federal government would determine how many animals should be released and where the releases should occur. Commercial or recreational fishermen would pay access or license fees to participate in the fishery, thereby providing revenue to the commercial aquaculturist who produced the animals for release. Government assistance (perhaps through an up-front fee program) would be required during the period between the establishment of a hatchery and the time the enhanced species recruited into the fishery. Also, the private aquaculturist would have to recognize that, if and when the fishery recovered to the desired sustainable level, further enhancement might be curtailed. That level of recovery may, of course, never occur. However, since many species have been overfished, the private producer could switch from one species to another. Alternatively, the private producer could expand into growout activities or supply stock to other growout aquaculturists.

ENVIRONMENTALLY FRIENDLY FEEDS

OUTLINE

INTRODUCTION

In order to cope with an ever-increasing world human population, it will be necessary to increase world food production. Aquaculture is one of the fastest growing food-producing activities in the world. Aquaculture utilizes water resources but is a nonconsumptive use of these resources. Nevertheless, aquaculture adds nutrients to aquatic resources that can cause environmental pollution. The nutrients added to the aquatic environment originate in the feeds used to raise fish, shrimp, and other farmed aquatic species. Feeds that minimize the nutrient output from aquaculture are called environmentally friendly feeds. Environmentally friendly feed is, therefore, of critical importance for the aquaculture industry, for the aquatic environment, and for the well-being of humankind in the twenty-first century.

METHODS AND TECHNOLOGY

Principal Approaches

Sources of environmental pollution associated with aquaculture are diverse: phosphorus, nitrogen, solid matter, trace metals, chemotherapeutants, and uneaten feeds including fines. Genetic and ecological pollution, such as with net pen escapees and transplantation of nonindigenous species including invertebrates, parasites, and aquatic plants to other locations, are also of serious concern for their unpredictable long-term impacts to local ecosystems (genetic and ecological pollution is not in the

scope of this entry). Aquaculture production, particularly intensive production in raceway ponds and net pens, is increasingly subjected to environmental regulations and waste discharge guidelines. Various regulations, including limitations of production itself, have already been set in many countries. Extensive or semi-intensive aquaculture production in closed systems (e.g., large stagnant-water ponds, indoor water-recycling tanks) may be exempt from environmental regulations. They are, however, more vulnerable to self-pollution and destruction of the internal environment. Waste products that accumulate in a pond deteriorate soil quality by anaerobic fermentation and proliferation of bacteria or pathogens; while in the water column, dissolved wastes not only stress fish directly but also cause an excessive growth of phytoplankton that deplete oxygen at night. Minimizing the excretion of wastes from fish is therefore critical in both intensive and extensive aquaculture systems.

Phosphorus is generally the first limiting nutrient for plants and algae in the freshwater environment, while it is usually nitrogen in seawater and brackish environments. Each can lead to eutrophication of the ecosystem. Solid waste, uneaten feeds, trace metals, and chemical wastes are important in all waters. The amount of uneaten feed in aquaculture production can be reduced by good management practices. Voided fish feces may be collected by settling or screening and can be decomposed in an annexed facility in a manner similar to the treatment of municipal sewage. This, of course, is an effective approach to reducing waste discharge and thus reducing environmental pollution. Feeds are, however, the ultimate source of pollution in most aquaculture operations. Generally, fish excrete all indigestible portions of feeds as feces and the excess portion of absorbed nutrients via urine, gills, or feces. Environmentally friendly feeds must, therefore, be formulated in a way that fish can digest, absorb, and retain as much of the feed nutrients as possible. This implies that increasing the retention of dietary phosphorus (and to a limited extent nitrogen) by improving feed quality is a logical and efficient strategy to reduce environmental impacts of aquaculture.

Data from several studies consistently indicate that approximately 80% of dietary phosphorus in typical commercial salmonid feeds is excreted into water as soluble and fecal forms. The amount of unretained phosphorus is largely influenced by the amount of phosphorus in feeds and its bioavailability. The ultimate source of nitrogen excreted by fish is protein in the diet. Any excess portion of dietary protein not used to synthesize body protein is utilized as an energy source. The nitrogen moiety is excreted as ammonia primarily via the gills, while the carbon moiety enters the Krebs cycle and is metabolized as an energy source. This excess portion of dietary protein is not only wasted as far as fish growth is concerned but it is also environmentally destructive. Reducing the level of dietary (digestible) protein to the minimum required level for fish is, therefore, critical in commercial aquaculture. The digestibility of dry matter and the availability (retention) of trace minerals in the diet involves the same principles as in phosphorus and nitrogen. In summary, the following factors will be critical in formulating environmentally friendly feeds:

1. Reduce nutrient levels in the diet to the minimum requirement levels for fish.
2. Select highly digestible feed ingredients (avoid ingredients of low digestibility).
3. Process feed ingredients to improve the digestibility or availability of nutrients.

Minimum Dietary Requirements of Nutrients for Commercial-Size Fish

In commercial aquaculture, large fish consume predominant portions of feeds and contribute much more waste in the effluent than do small fish. Phosphorus allowances used for commercial fish feeds are, however, based upon data obtained with very small fish reared in laboratories. Nutrient requirements in most animals are known to decrease as they become older or larger because, as they grow larger, the growth rate (retention of dietary nutrients) decreases and increasing portions of dietary nutrients, including phosphorus, are used for maintenance (substantial portions of which can be recycled). For example, the dietary phosphorus requirement of broiler chickens is 50% higher for 0 to 3-week-old birds than for market-size (6–8-week-old) birds (1). Since, in commercial aquaculture, fish are often raised up to 3 kg (6.6 lb) to 5 kg (11.0 lb) in body weight before being harvested, estimates of nutrient requirements made using small fish are unsatisfactory for market-size fish. Obtaining an accurate estimation of the dietary requirement of phosphorus for large fish is, therefore, necessary to minimize phosphorus excretion from fish into the aquatic environment.

Ogino and Takeda (2) reported the dietary phosphorus requirement for optimum growth of rainbow trout (*Oncorhynchus mykiss*) to be 0.7–0.8% of dry diet using juvenile fish of 1.2 g (0.04 oz) in body weight. Numerous researchers have investigated dietary phosphorus requirements for other fish species including channel catfish (*Ictalurus punctatus*), tilapia (*Oreochromis* sp.), Pacific salmon (*Oncorhynchus* sp.), Atlantic salmon (*Salmo salar*), Japanese eel (*Anguilla japonica*), and carp (*Cyprinus carpio*) using young fish of less than 10 g (0.35 oz) in body weight (3). Because young fish are sensitive to nutrient deficiencies, their response to dietary concentrations of nutrients is normally rapid and clear in virtually any response variables, and even the mortality rate may suffice to establish dietary requirement for young fish. The requirement values determined with young fish, however, are not predictive for the requirement for larger fish as mentioned previously. Rodehutscord (4), working on larger trout (initial body weight 53 g or 0.117 lb), found large differences in estimated requirement for phosphorus when weight gain was used and when phosphorus retention was used as the response criteria. For large fish, using an insensitive response variable such as growth to establish the minimum dietary requirement of phosphorus is questionable, especially when the duration of feeding is not sufficient. Large fish can subsist for an extended period without reducing the growth by using body stores unless the level of intake is exceedingly low. The minimum dietary requirement measured using large fish, therefore, tends to be an underestimation and misleading. Eya and Lovell (5), studying post-juvenile catfish (initial

body weight 61 g or 0.135 lb) for their dietary phosphorus requirements, failed to see any effect of dietary phosphorus concentrations on growth of the fish in 140 days of feeding. Numerous other response criteria for estimating the dietary requirement of phosphorus, including plasma, tissue, or body saturation levels, have no rational basis or practical meaning. Changes of enzyme activities could well be a normal adaptive response of the fish to a lowered dietary intake, which do not necessarily imply clinical deficiency for the species.

For estimating dietary requirement of nutrients, the feeding duration must be long enough to obtain legitimate deficiency signs (6). However, because large fish already have substantial body stores (pool) and because their growth rate is low, studying nutrient requirements by means of those conventional approaches requires months of feeding before any response of fish to the dietary treatment can be detected. Also, it is impractical to feed large fish with expensive semipurified research diets for an extended period. With these constraints, there are few data currently available regarding the minimum dietary requirements of nutrients including phosphorus for commercial-size fish. Sugiura (7) used a different approach to estimating the minimum dietary requirement of phosphorus for large fish. The method determines the phosphorus requirement in a few days based upon urinary excretion of phosphorus of fish in a metabolic tank. At low dietary phosphorus concentrations, fish absorb and retain essentially all the available phosphorus contained in the diet (Fig. 1). Once dietary phosphorus concentrations exceed a certain level, fish excrete excess phosphorus via urine. Excretion increases linearly and proportionally to
Figure 1. Estimating the minimum dietary requirement of phosphorus for large rainbow trout (body weight 203 g or 0.45 lb) based on the urinary excretion of phosphorus of fish fed incremental concentrations of P in diets for 3 days. The value remained constant for days 6, 9, and 12. Phosphorus excreted into the urine was indirectly measured by analyzing recirculating tank water. *Source*: Sugiura (7).

the dietary phosphorus concentration. The point where fish start to excrete phosphorus via urine is assumed to be the minimum requirement level of phosphorus in the diet. The rapidity and sensitivity of this method make it possible to estimate the requirement of phosphorus in fish of various nutritional, physiological and environmental conditions. The minimum dietary requirement of available phosphorus determined with large trout (body weight 200 to 400 g or 0.44 to 0.88 lb) using this method has been shown to be variable, ranging between 0.41 and 0.66% of dry diet, depending on the nutritional and physiological status of the fish (unpublished data).

The dietary requirement of a nutrient expressed as a percentage of the diet, however, is not always a reliable value. Growth is the major factor that governs the dietary requirement of many nutrients, especially those constituting muscle and skeletal tissues such as protein (nitrogen), phosphorus, calcium, and several other minerals. Various factors have been shown to influence fish growth (e.g., environmental stresses, cultural conditions, fish strain, life stage, physiological and endocrine factors, energy density, nutrient balance, interactions, digestibility, feed processing and storage conditions, deficiency of trace nutrients, presence of antinutritional factors, feeding frequency, and feeding rate) (8,9). Expression of nutrient requirement per nitrogen retention as representing the growth of fish has been proposed as an accurate way of expressing nutrient requirement (7). Similarly, standardizing (dividing) the measured requirement value (g/g dry diet) by feed efficiency (g fish weight gain/g dry diet) of the diet to obtain Standardized Requirement or Requirement Coefficient (i.e., requirement value when feed efficiency) is a valid procedure to eliminate various confounding factors among different experiments represented by different feed efficiency. Also, it is important to express nutrient requirement in diet on an available nutrient basis rather than as total amount to eliminate differences in nutrient availability (digestibility) among diversified test (basal) diets. Currently, dietary requirements of nutrients are expressed as total amount on a diet basis (without any standardization) or on a digestible energy basis (3). Digestible energy levels are difficult to estimate from the data available in the literature. This is because nutrient content (composition) and the digestibility of an ingredient are variable among manufacturers, and because digestibility of energy sources, especially carbohydrates, varies at different dietary levels and pelleting methods. Also, digestible energy intakes are not always correlated to growth since digested energy is also used for various other ways such as basal metabolism, activity, and heat increment with varied proportions at different feed intakes.

Digestibility and Availability of Nutrients in Feed Ingredients

In order for dietary nutrients to be utilized for various biological functions, including growth, they first need to be absorbed (with or without digestion) from the gastrointestinal tract. Knowing the content of digestible or available nutrients in ingredients (and in the diet) is one of the critical pieces of information for formulating environmentally friendly feeds.

Phosphorus. Many factors are known to influence dietary phosphorus utilization by fish, including the level and the form of phosphorus in the diet and its interaction with other dietary components. Major sources of phosphorus in fish feeds are organic and inorganic forms of phosphorus found in muscle and bone tissues of fish, poultry, or animal by-product meals and inorganic and phytate phosphorus in various plant protein sources. Some fish feeds contain added phosphorus supplements such as di-calcium phosphate. Several investigators have researched the availability of phosphates from various sources to different species of fish (3). In spite of the increasing importance of this subject, however, currently available data are quite limited. Knowing precisely the available phosphorus content in common feed ingredients is essential for selecting feed ingredients based on available phosphorus content, reducing available phosphorus in formulated diets to the minimum required level for fish and eliminating the risk of potential deficiency problems.

The apparent availability of phosphorus in feed ingredients commonly used for fish feeds is highly variable (Table 1). The apparent availability of phosphorus in high-ash ingredients such as meat and bone meal and high-ash fish meal is very low, whereas that of low-ash ingredients such as blood meal and feather meal is high. The low availability of phosphorus in meat meal is presumably due to the bone particle size and the source (animal vs. fish).

The apparent availabilities of calcium, phosphorus, magnesium, and iron in fish bone decrease as the bone content in the diet increases (7). The availability of phosphorus in fish bone was predicted to be above 90% when its concentration is very low, whereas it decreases as the bone content in the diet increases. Although the absorption of phosphorus and many other minerals from diets was significantly and negatively correlated to the concentrations of ash, calcium, phosphorus, and bone in the diet (as the fractional net absorption), the actual net absorption of bone minerals remained fairly stable. This suggests that reducing bone minerals in diets is an essential approach in formulating low-pollution feeds. Once this requirement is met, then the interfering effect of other dietary components having binding properties with minerals, notably phytic acid (discussed later) in plant ingredients, will more likely reveal their nutritionally significant potentials. The use of fish meal replacers that contain less phosphorus is therefore essential to reduce overall phosphorus content in formulated feeds. To replace major portions of fish meal in aquaculture feeds with other protein sources, however, involves several practical problems, including reduction of total protein (and some essential amino acid) content, creation of amino acid imbalance, reduction of palatability, and increases of carbohydrate and fiber contents (i.e., reduction of dry matter digestibility). This is particularly the case when plant protein sources are used in place of fish meal in the feed. Animal byproduct meals, if their ash content is low, offer many advantages over plant sources to offset the previously mentioned shortcomings.

Nitrogen (Protein). Generally, protein digestibility of animal by-products is highly variable depending on the quality of raw materials and processing conditions (Table 1). Apparent digestibility of protein in ring-dried or spray-dried blood meal and deboned whitefish meal are high, while those of feather meal and menhaden meal are relatively low. Blood meal dried in a continuous dryer appears to be very low in protein and energy digestibilities (10). Chilled or ensiled blood are highly digestible (97%), indicating that the poor digestibility of blood meal is due to the processing temperature during the drying process (11). Poultry by-product meals differed markedly in percentages of digestible protein and energy (10,12). Other dietary components, notably gelatinized starch, have been shown to reduce protein digestibility, especially in carnivorous fishes, when the dietary level is too high.

Solid Matter. Apparent digestibility of solid (dry) matter is also highly variable among feed ingredients (Table 1). Animal ingredients of low ash content such as blood meal and deboned whitefish meal are highly digestible. High ash ingredients such as low quality fish meals and high ash animal byproducts have low digestibility of dry matter due to the limited digestibility of the ash portion of the ingredient. Feather meal, despite its low ash content, may not be well digested if the processing condition of the ingredient is not appropriate. Plant ingredients generally have lower digestibility of dry matter than animal ingredients due to their high fiber content and the incomplete digestion of the ingredient, especially when the starch portion is uncooked.

Other Minerals. Apparent digestibility of ash largely differs among ingredients. Animal byproduct meals containing a high percentage of ash have low ash digestibility. Since the ash portion of most ingredients is mainly composed of calcium and phosphorus, reducing the ash content in feed ingredients is essential in reducing phosphorus excretion into feces. Also, the levels of calcium, phosphorus, and ash (and the bone) in diets containing various animal protein sources showed inverse correlations with net absorption (percentage) of calcium, iron, magnesium, manganese, phosphorus, strontium, and zinc (7). Reducing the bone content of fish meals as studied by Babbitt et al. (13) appears to be a rational procedure for increasing availability of dietary minerals in fish meal-based feeds.

Apparent availability of magnesium in fish feed ingredients ranged between 0 and 100%, but most values were between 50 and 70%. Apparent availability of potassium in feed ingredients was high in all ingredients, while that of sodium was lower and more variable than that observed with potassium. Apparent availability (absorption) of iron in fish meals and plant ingredients was very low. In wheat gluten meal, iron absorption was high but the amount of iron in wheat gluten was very low. Blood meal and feather meal contained high levels of iron, and the apparent availability (absorption) was also high, resulting in much higher levels of net absorption than with the other ingredients (7). Net

Table 1. Total and Digestible (available) Crude Protein (CP) and Phosphorus (P) Contents (%) in Feed Ingredients Determined with Rainbow Trout[a]

[a]*Source*: Sugiura (7), Sugiura and Hardy (unpublished data). The digestibility or availability values were expressed as fractional net absorption of nutrients (% per intake). The dietary concentrations of protein and phosphorus (total, digestible or available) were expressed on a dry basis. The fecal samples were collected either by stripping (ingredients indicated with an asterisk) or settling (without asterisk). Dash indicates that the value was not determined. Ingredients of the same trade name but obtained from different suppliers were identified with the letter "A" or "B." The letter does not indicate the grade or quality of the product.
[b]Determined in purified diets (diets low in phosphorus and calcium).
[c]Ingredients were heat extruded.

absorption of copper was significantly correlated to the amount of intake, and the amount of copper absorbed from whole diets was relatively unaffected regardless of source (ingredient). Net absorption of manganese was found to be quite low in all ingredients except for wheat gluten meal, blood meal, and the casein basal diet. This indicates these ingredients or diets contain only minor levels of substances which interfere with the absorption of manganese. Unlike many other elements, net absorption of manganese was not increased by the amount of intake, yet the overall balance of manganese always remained positive in all dietary treatments (7,18). Dabrowski and Schwartz (14) also noted that there was no significant apparent absorption of manganese in the carp digestive tract. In human studies, the percentage absorption of manganese is often below 10% (15). Dietary tri-calcium phosphate reduced the availability of manganese and zinc in carp (16). Availability of manganese in whitefish meal appears to be low in rainbow trout (17).

Apparent availability of zinc was low, especially that from fish meals (18). Rainbow trout fed a whitefish meal-based diet showed growth depression, bone malformation, and cataract incidence, which was suspectedly due to zinc deficiency (19). High bone content in diets has been shown to reduce zinc availability in rainbow trout (20) and Atlantic salmon (21). Also, tri-calcium phosphate reduced bioavailability of zinc in the diet fed to rainbow trout (22–24). Dietary phosphorus has been shown to decrease absorption of zinc in rats (25) and in rainbow trout (26). Menhaden meal, which had higher calcium and phosphorus levels than other fish meals, had lower zinc availability than the others. The availability of zinc in plant sources is generally lower than that in animal sources despite their lower calcium and phosphorus contents (18). Phytate or phytic acid contained in many plant ingredients have been shown to reduce the absorption of zinc in fish (27,28) and higher animals (29–31).

Antibiotics. Apparent digestibility of chloramphenicol was close to 99%, whereas it was in the 7 to 9% range for oxytetracycline (OTC) at two different concentrations (0.1 and 0.5%) in a dry diet fed to rainbow trout. For oxolinic acid, these percentages were 38.1 and 14.3% for the 0.1 and 0.5% doses, respectively (32). They suggested the low digestibility of oxytetracycline (7–9%), compared with the 60% absorption level usually described for OTC in man, may be explained by the great affinity of tetracyclines for calcium and the much higher concentration of calcium in fish feeds than in human diets. Others, however, reported 25% and 30% oral bioavailability of oxytetracycline in seawater chinook salmon (*Oncorhynchus tshawytscha*) and freshwater rainbow trout, respectively (33). The apparent digestibility of virginiamycin fed to rainbow trout at 40 ppm/diet was 98% for factor M and 79% for factor S (34).

Approaches to Increasing Digestibility of Dietary Nutrients

Many feed ingredients having fairly low digestibilities (availabilities) of phosphorus, protein, dry matter, or other nutrients may have other advantages, such as total protein content, amino acid balance, palatability, and price that make them desirable ingredients in aquatic feeds. If this is the case, one might want to use the ingredient but somehow enhance the inherent low digestibility of the feed ingredients. Various methods currently available for this purpose follow.

Dietary Level. Levels of nutrients in diets have an effect on the digestibility or absorption of the nutrient. Notable examples are the digestibility of carbohydrates and the availabilities of many minerals. Dietary phosphorus can be almost completely absorbed regardless of dietary concentration when it is supplied as a water-soluble form except for phytate phosphorus. The excess portion of absorbed phosphorus, however, is subsequently excreted via the urine (7). When dietary phosphorus is supplied in a water-insoluble form such as bone or calcium phosphates, an excess portion of dietary phosphorus that is above the minimum dietary requirement may not be absorbed. Thus, the higher the bone phosphorus in diets, the lower the resulting digestibility of phosphorus. Fish appear to absorb bone (water-insoluble) phosphorus up to their requirement but not in excess, which may be related to gastric acidity and acid output since fish absorb an excess amount of phosphorus when the diet is acidified with organic or inorganic acids (7). Reducing the concentration of phosphorus in diets, therefore, increases the digestibility of phosphorus by fish. Levels of protein have no significant effect on the digestibility of protein in diets; however, any excess portion of protein in diets will be deaminated and the nitrogen moiety excreted as ammonia, while carbon moieties will be utilized as an energy source. This suggests that excess protein in diet, while having no effect on protein digestibility, cannot be justified from either economical and environmental standpoints. Fish, or any other animal species, cannot retain excess amounts of minerals over time. Available minerals in diets, when they are in excess of the dietary requirement, have to be excreted either via urine, gills, or feces, or intestinal absorption has to be regulated. In all cases, reducing the amounts of available minerals in diets is critical to reduce their excretion by the fish.

Phytase. About two-thirds of total phosphorus in soybean meal or most other plant ingredients made from seeds is present as phytate or phytic acid, which is not efficiently utilized by nonruminant animals, including fish (3,35). Besides its low availability, phytate has been shown to interact directly and indirectly with various dietary components to reduce their availability to animals. Calcium compounds, including bone and the dietary supplements, have a strong affinity to phytate to form acid-insoluble precipitates and reduce both calcium and phytate availability. Calcium-bound phytate increases chelation with trace minerals such as zinc to form coprecipitates (36) or with protein to form either phytate–protein or phytate–mineral–protein complexes that are resistant to proteolytic digestion (37). Phytate may decrease endogenous zinc reabsorption as well as affect availability of dietary zinc (38). Increasing the level of phytate from 1.1 to 2.2% in channel catfish diets containing 50 mg zinc/kg (50 ppm) showed decreased weight gain, feed efficiency, and zinc content in the vertebrae (39). With 1.1% phytate in diets, channel catfish require about 200 mg zinc/kg feed (200 ppm), which is 10 times higher than the dietary requirement of available zinc (40). High phytate levels in semipurified diets (2.58%) depressed the growth and feed efficiency of chinook salmon (28).

Phytase is an enzyme specific to phytate hydrolysis. This enzyme is present in the digestive tract of many animals; however, the amount is normally too small to digest dietary phytate to a significant extent. The enzyme present in some plant ingredients, such as wheat bran, is generally inactivated by the processing temperature of feed manufacturing. Development of technology to produce phytase at a low cost offered an opportunity to use this enzyme in commercial animal feeds. Recent studies have shown that supplementing diets with commercially available fungal phytase or

pretreating plant feed ingredients with phytase effectively increase availability of dietary phosphorus in rainbow trout (7,41–43), channel catfish (44–46), carp (47), as well as in higher animals such as pigs and chickens.

Various factors affect the efficiency of supplemental phytase. The rate of phytate hydrolysis by phytase enzyme varies not only with pH, but also with temperature. The optimum temperature varies among different phytases in the range of 45 to 57 °C (48). For homeotherms, body temperature appears to be favorable for the enzyme reaction. For poikilotherms, especially coldwater fishes, however, body temperature could be a limiting factor for the enzyme activity (7), suggesting an economical disadvantage for the use of this enzyme as a dietary supplement in fish feeds. Increasing water temperature increases enzyme activity but also simultaneously increases the rate of food passage through the gastrointestinal tract, offsetting the net effect. Reducing water temperature increases the retention time of foods in the digestive tract; however, the reduction of enzyme activity, feed intake, and fish growth are inevitable at lower temperatures. Alternative methods are those which employ preliminary digestion of phytate in plant ingredients by phytase before mixing with other feed ingredients (41,49,50). Adding water to dry ingredients, which is essential for the enzyme reaction, may be prohibitive as a practical application because of the extra energy and cost required in the succeeding drying process.

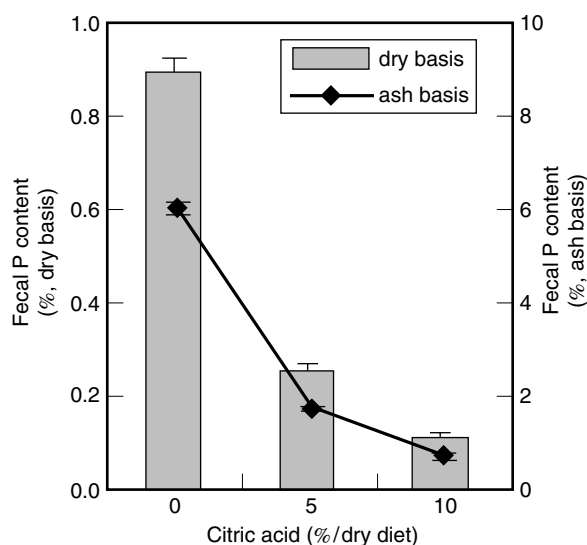
An important consideration for the use of supplemental phytase in commercial fish feeds is that the effect may be negligible when the diet contains phosphorus in an amount more than the dietary requirement (typical in most fish meal-based feeds). Supplemental phytase effectively reduced fecal phytate content in fish meal–soybean meal combined diet, while it increased the fecal non-phytate phosphorus. Total phosphorus levels in feces were, therefore, not significantly reduced. In contrast to this observation, supplemental phytase significantly increased the net absorption (availability) of phosphorus, calcium, magnesium, sodium, iron, copper, zinc, manganese, strontium, and the digestibility of protein, ash, and dry matter when the diet was formulated with soybean meal and low-ash ingredients containing phosphorus near the dietary requirement (7). Apparent availability of phosphorus increased proportionately with the supplemental phytase from 26.6% (no phytase added) up to 90.1% (4,000 units of phytase added per kg or 2.2 lb of dry diet) or 92.5% when soybean meal was pretreated or dephytinized (Fig. 2).

Because of its pH optimum, phytase is active only in the stomach. It should, therefore, be important to increase the stomach retention time to keep added phytase active. It was well recognized before the advent of scientific experimentation that a large single meal stays in the stomach longer than small meals. Researchers demonstrated that small meals could be more rapidly evacuated from the stomach than large meals (51,52). Feeding a single large meal should, therefore, be recommended for phytase-supplemented feeds. This simple practice increased the effect of supplemental phytase about two times (7). Multiple feeding or the use of automatic feeders or demand feeders
Figure 2. Phosphorus content in the feces of rainbow trout fed soybean meal-based diet supplemented with varied levels of phytase with/without citric acid. Error bars indicate standard errors of three replicate tanks. Pretreated (right end columns in the figure) indicates that soybean meal was treated with phytase before mixing with other ingredients (200U phytase/kg soybean meal; equivalent to 100U/kg dry diet, for 24 hours at 50 °C or 122 °F, pH 5.3, soybean meal/water ratio 2:1). The amount of citric acid added was 5% in the diets (dry basis). *Source*: Sugiura (7).

may result in a significant loss of phytase activity. For plant protein feeds, however, not only phytase but also free amino acids may be supplemented to correct amino acid imbalance. In this case, introducing a single feeding practice may not be the best way since frequent feeding is favorable to counteract different absorption rates between supplemented free amino acids and the amino acids in intact protein of feed ingredients (53,54). Another way to increase gastric retention time of feeds, and thus potentially increase hydrolysis of phytate, is to increase the energy density of the feeds (55,56). Also, gastric evacuation time is affected by the size of fish; that is, slower in large fish and faster in small fish (thus small fish require more frequent feeding than large fish). The overall effect of supplemental phytase is, therefore, predicted to be most efficient in large fish fed high-energy feeds in a single feeding per day.

While fungal phytase is now commercially available as a feed supplement, plant phytases inherent in wheat, barley, and rye should be considered as a low-cost alternative when the cost of feeds is one of the limiting factors in feed manufacturing. Stone et al. (50) reduced phytic acid content in canola meal by blending it with acidified fish silage and wheat bran (source of phytase) and keeping the mixture at room temperature for five weeks. During that period, low pH protected the wet material from

bacterial spoilage and also facilitated phytate hydrolysis. Also, if endogenous phytase that is present in some feed ingredients is not heat-inactivated during feed processing, the active enzyme could hydrolyze phytate in the stomach after it is ingested by the animal. The hydrolysis of phytate in this way, however, appears to be less efficient, due to the amount of phytase, limited gastric retention time of food, and the low ambient temperature, particularly in coldwater fish. While microbial phytase produced by intestinal bacterial flora may have a significant effect on the decomposition of phytate in ruminant and other homeotherms, it may have negligible effect in fish species due to low bacterial population in the intestine and their low "body" temperatures.

Acidification. Dietary acidification has long been a common practice in weaning pigs to support their insufficient digestive capacity and to improve their weaning performance (57). Dietary acidification in aquatic animal feed, however, has not drawn deserved attention until recently with regard to the digestibility of dietary nutrients, especially for minerals. Fish meal is one of the main ingredients in commercial feeds for many aquaculture species. The form of phosphorus in fish meal is mostly hydroxyapatite, which is not efficiently utilized by fish (3,35). Several dietary supplements appear to influence the availability of phosphorus and other minerals in fish meal. Supplementing fish meal-based diets with citric acid at a 5% level (dietary pH 4.0) increased the availability of phosphorus, calcium, magnesium, iron, manganese, and strontium in rainbow trout (7,58). Supplementation of fish meal-based diets with citric acid at a 10% level (dietary pH 3.5) further increased the absorption (availability) of phosphorus (Fig. 3), but did not affect feed intake, feed utilization,


protein digestibility, or weight gain of rainbow trout during 35 days of satiation feeding (7). Sulfuric acid and, to a lesser extent, hydrochloric acid were also very effective in increasing the availability of phosphorus in fish meal-based diets when they were added at 38 g and 76 g per kg dry diet (ppt), respectively (the apparent availability of phosphorus was 94.8% and 87.8% with sulfuric and hydrochloric acids, respectively, compared with 71.4% in the control or non-acidified group). The diets supplemented with these inorganic acids, however, had very low dietary pH (2.0–2.4) and had lower feed intakes of the fish than non-acidified diet during 23 days of satiation feeding (7).

Dietary acidification is also effective to increase efficacy of supplemental phytase in diets composed primarily of plant ingredients. Fungal phytases have their pH optima in an acidic range (48). Because of this, supplemental phytase is active only in the stomach of fish. A previous study showed that the pH of the feces was slightly lower when rainbow trout were fed citric acid at 5% in diets than when they were fed nonacidified control diet, suggesting that dietary acidification may preserve phytase activity throughout the digestive tract. In addition, phytate-mineral complexes, which are less soluble at a neutral pH, have increased solubilities at lower pH (59–62). When the diet contained fish meal, however, citric acid strongly disabled the effect of supplemental phytase, and the phytate supplied from soybean meal in the diet was little hydrolyzed. In contrast to this observation, citric acid markedly increased the efficacy of supplemented phytase when the diet was formulated with ingredients of low calcium content and without fish meal. Supplementing a soybean meal-based diet with 500 units of phytase and citric acid amplified the effect of supplemental phytase up to a level equivalent to 4,000 units of phytase even though citric acid per se had no effect on the hydrolysis of phytate (Fig. 2). Dietary acidification might increase the solubility of calcium phosphates in fish meal, which might precipitate phytate as calcium–phytate complex that is known to be resistant to enzymatic hydrolysis (63).

Heating. The digestibility of carbohydrates (and thus that of energy) varies substantially depending on processing temperature and the inclusion level in the feed (64,65). If feeds are processed at relatively low temperatures to conserve endogenous phytase, the carbohydrate portion of feeds may not be well-utilized by fish. This increases gastric passage rate of the chyme and reduces the time available for the digestion of phytate phosphorus as well as other dietary nutrients (66). The low digestibility of carbohydrates also indicates the low digestibility of dry matter (organic matter) and energy. Undigested carbohydrates and other organic matters in feces, instead of stimulating the growth of phytoplankton, will be subjected to bacterial fermentation and mold infestation in a pond sediment and create a noxious, unwholesome environment.

Phytate is resistant to heat treatment. Little decomposition of phytate appears to occur under the processing temperature effective for reducing other anti-nutritional factors (e.g., trypsin inhibitors) in soybean meal. Microwave heating, which was demonstrated effective to reduce phytate in full-fat soybean (67), appears to

Figure 3. Phosphorus content in the feces of rainbow trout fed fish meal-based diet supplemented with citric acid at 0, 5 or 10% in the diet (dry basis). Error bars indicate standard errors of three replicate tanks. The apparent availability of phosphorus in the diet was 70.6% (0% citric acid), 90.9% (5% citric acid), and 96.6% (10% citric acid). *Source*: Sugiura (7).

be ineffective for solvent-extracted soybean meal. Autoclaving at high temperatures has also been reported to reduce phytate but at the expense of some heat labile amino acids (68,69). A high loss of phytate in milled rice by cooking was also reported (70). Little or no loss was recorded for phytate in soybean meal, regardless of the method of heat treatment and the degree of intensity (7).

Heating is also critical to increase digestibility of protein in soybean meals by inactivating trypsin inhibitors and other antinutritional factors in the ingredient or in feather meal by hydrolyzing proteins at appropriate levels of heat treatments. In all cases, excessive heating leads to a reduction of protein digestibility and amino acid availability due to the reaction of amino acids with reducing sugars (known as Maillard browning) or with aldehydes in oxidized lipids. Maillard browning caused an approximately 80% loss in bioavailable lysine in fish protein isolate [incubated at 37 °C (99 °F) for 40 days] in rainbow trout (71). True digestibilities of amino acids in various meat and bone meals varied substantially, depending on the processing systems and temperatures, ranging from 68 to 92% for lysine and from 20 to 71% for cystine (72).

Chelation. An additional benefit of using citric acid and other organic ligands, such as EDTA (ethylenediaminetetraacetate), is that they may prevent precipitation or coprecipitation of minerals at a neutral pH in the presence of calcium and other minerals (73–75). Supplementing diets with EDTA or sodium citrate increased the apparent availability (absorption) of manganese but not other minerals examined (7,58). Hardy and Shearer (22) also reported that supplementing diets with EDTA did not increase availability (retention) of inorganic zinc in the diets for rainbow trout. Chelated zinc (zinc proteinate), however, has been found to be more available than inorganic sources for rainbow trout (22) and channel catfish (76). The apparent availabilities of chelated minerals (copper proteinate, iron proteinate, manganese proteinate, selenium proteinate, zinc proteinate) are all higher than those of the corresponding inorganic sources (copper sulfate, ferrous sulfate, manganese sulfate, sodium selenite, zinc sulfate) in both semipurified diets and soybean meal diets fed to channel catfish (76).

FORMULATION OF THE ENVIRONMENTALLY FRIENDLY FEEDS

Concept of Sustainable Feeds

It is not difficult to prepare environmentally *very* friendly feeds with purified feed ingredients used for laboratory experiments. In order to provide environmentally friendly feeds for commercial aquaculture, however, it will be imperative to meet other standards such as the cost of the feed (economical requirement), fish growth, feed efficiency, disease resistance of the fish (biological requirement), and the final product quality and safety (marketing requirement) (Fig. 4).

Aquaculture of carnivorous fishes, including salmonids and many seawater fishes, relies heavily on the supply of fish meal, which comprises the major portion of the
Figure 4. Concept of sustainable feeds. Environmentally friendly feeds have to meet various other standards.

feed for those species. As a result of the rapid growth of world aquaculture production in the past few decades, there has been a concomitant increase of demand for fish meal (77). The increasing demand, however, cannot be met due to the limited production of fish meal from capture fisheries which are approaching the plateau or maximum sustainable limit (78). Most fish meals contain phosphorus in an amount far excess of the minimum dietary requirement for fish. In order to reduce phosphorus in fish diets, it will be necessary to reduce the fish meal content in the diet by replacing it with other ingredients containing less phosphorus. Also, there has been an increasing contention and skepticism among the general public in regard to the aquaculture of carnivorous fishes since there is a substantial loss of animal protein in this process. Considering the ever-increasing world human population, feeding animal protein sources (fish meal) to fish on any significant scale will not be an affordable or a sustainable practice. Consequently, replacing fish meal with other ingredients that are not directly usable for human consumption should receive increasing priority in formulating aquaculture feeds in the future. This issue is particularly important in developing countries where the use of fish meal in aquaculture feeds is often economically prohibitive (79).

Ingredient Selection

There are numbers of ingredients that may replace a significant portion of fish meal in aquaculture feeds. The availability of alternate protein sources is largely dependent upon the region or country. Since the supply of plant protein sources is more stable and feasible compared with animal by-product materials, the use of plant ingredients should receive high priority, especially when considering the sustainability of aquaculture in terms of the future supply of ingredients for fish feeds. In this regard, Hardy (77) suggested that soybean meal is likely to be the most promising alternate protein source for fish feeds. Also, most plant protein sources contain less phosphorus than fish meal. Replacing major portions of fish meal with plant protein sources, however, encounters several practical problems (e.g., reduction in the growth of fish due to low palatability (low feed intake), low protein

content or amino acid imbalance, and low dry matter digestibility due to high carbohydrate and fiber contents).

Since many animal by-product meals contain high levels of phosphorus, the maximum inclusion level in low-pollution feeds needs to be substantially reduced. The absorption of phosphorus in high-ash (high-phosphorus) ingredients increases as the dietary concentration decreases in terms of the percentage of absorption per intake. The phosphorus content in blood meal is low and the digestibility of protein and the availability of many minerals in it are high. The use of blood meal in practical feeds, however, should be limited because of its amino acid imbalance, which could likely reduce retention of dietary protein and increase nitrogen (ammonia) excretion. Feather meal, deboned fishmeal, and low-ash animal byproducts meals may be feasible alternate protein sources due to their relatively low phosphorus content, high protein content, high digestibility for both phosphorus and protein, and high palatability.

Nonlethal, low phytic acid mutations in corn and barley cause the seed to store most of the phosphorus as inorganic phosphorus instead of as phytate phosphorus (80). Using mutant grains containing lower levels of phytate in fish feeds can reduce phosphorus excretion by the fish (7,81).

Balanced Formula

Protein Levels. Optimum digestible protein (DP)/digestible energy (DE) ratio in rainbow trout feeds has been reported to be 92 mg/kcal (82), 105 mg/kcal (83), or 22.6 g/MJ DE (94.56 mg/kcal) (84). Similar DP/DE values have been found in the literature with other fishes (3,84). Nitrogen excretion in rainbow trout was reported to be 39 to 40% of digestible nitrogen intake for the diet having a DP/DE ratio of 18 mg/kJ (75.31 mg/kcal) and 44% of digestible nitrogen intake for the diet having a DP/DE ratio of 23 mg/kJ (96.23 mg/kcal) (85). Others reported that growth and feed utilization in rainbow trout improved markedly as dietary DP/DE ratio increased from 16.35 to 18.23 g/MJ (68.41 to 76.27 mg/kcal) with no significant effect on nitrogen discharge per kg of weight gain (mean values 29.1 to 29.9 g nitrogen/kg weight gain) (86). These results suggest that rainbow trout require DP in an amount at around 95 mg/kcal DE to support maximum growth, while the requirement of DP to provide maximum nitrogen retention (minimum nitrogen excretion) may be around 75 mg/kcal DE.

Fat Levels. A high fat content is generally preferable in low-polluting feeds. Fish oil and plant seed oils are commonly used for fish feeds. Those sources are highly digestible, essentially free of phosphorus and nitrogen, and supply high energy to the diet. Increasing dietary fat level is, therefore, a simple yet very efficient approach to reduce phosphorus and nitrogen excretions by the fish. Extrusion-processed feeds are generally preferable to compressed pellets for low-polluting feeds. Feeds processed by cooking extrusion can retain higher percentages of fats (25 to 35%) in the pellets due to their high porosity than feeds made by compressed (steam) pelleting (15 to 20%). In addition, carbohydrate digestibility (and also energy and dry matter digestibilities) of extruded feeds is much higher

than that of the compressed pellets due to high moisture and temperature applied in the manufacturing process (although this raises the processing cost). When fish are deficient in phosphorus, however, they appear to increase the retention of dietary fats (87) due to the inhibition of the beta-oxidation of fatty acids. Since high levels of dietary fats and low levels of dietary phosphorus synergistically elevate the fat content of the fish, it appears to be essential to adjust the levels of dietary phosphorus or fats depending on the desired fat content of the final product.

Carbohydrate Levels. Increasing DE value by increasing digestible carbohydrate may reduce feed intake and reduce growth rate of the fish, especially in carnivorous species (65,88). Low-protein (38%) diets containing high levels (30 to 40%) of digestible carbohydrate, however, did not adversely affect overall growth or nutrient retention efficiencies in rainbow trout (89–92). These findings indicate that where fats are unavailable as an energy source for aquaculture feeds, high levels of digestible carbohydrates (often less expensive than fats) can be tolerated even for carnivorous species like rainbow trout. If fish are deficient in phosphorus, however, it may cause glucose intolerance and the high level of digestible carbohydrates in the diet may result in pathological consequences as reported in higher animals (93).

Finishing Feeds

Deficiencies of micronutrients in diets do not cause immediate clinical deficiency of fish. Although it is largely dependent on the nutrient, the degree of deficiency, physiological demand, interactions, and the body store (diet history), it takes at least two weeks with small fish or much longer when fish are large before any signs of clinical deficiency arises. If the nutrient is only marginally deficient, fish can subsist considerable periods using the body store without showing any deficiency signs. Hardy et al. (94) proposed a periodic feeding of low- and high-phosphorus feeds to increase retention of dietary phosphorus and to reduce excretion of phosphorus into water. An extension of this method is the use of low-phosphorus feeds as a finishing diet. It is, of course, imperative to harvest fish before signs of phosphorus deficiency arise. Eya and Lovell (5) reported that year-two channel catfish fed commercial-type feeds containing only 0.2% available phosphorus did not reduce weight gain and feed efficiency in a 140-day feeding period compared with those fed diets containing higher concentrations of available phosphorus.

Commercial trout production feeds generally contain phosphorus at levels much higher than the dietary requirement. The finishing feeds can also be used to dilute phosphorus concentration in the commercial feeds (7). Thus, the finishing feed and the commercial feed need to be mixed in an appropriate ratio to minimize excretion of phosphorus. The ratio needs to be adjusted according to the size of fish in addition to the phosphorus content of both feeds. The ratio may be best determined by actually monitoring the level of phosphorus excreted by the fish and the performance of the fish.

Quality Assurance

Environmentally friendly feeds generally contain high levels of unsaturated fatty acids from fish oil or similar sources. In formulated feeds, varieties of compounds can catalyze the oxidation of fish oil, while others counteract it. Inorganic copper and iron are known to be strong pro-oxidants for unsaturated fatty acids and for certain labile vitamins, to increase rancidity of dietary fats, and to cause a loss of vitamins in feeds during storage. Feeding rancid fats causes undesirable effects; for example, impairment of fish health, increase of vitamin E requirements, decrease in vitamin E stored in tissues and possibly reduction in frozen storage stability of fillets. Since the availability of copper is relatively high in many ingredients and the availability of iron is high in blood meal and feather meal, the redundant supplementation of these metals (as inorganic supplements) should be avoided. Use of chelated minerals may protect labile fatty acids and vitamins in the diet. Phytic acid in plant ingredients may offer similar effects (chelating minerals) and thereby protect labile compounds in the diet, while it also reduces the availability of the mineral to the fish.

Low acceptability of diets containing high levels of soybean meal needs to be further investigated if it is intended to be used as the major protein source in production feeds. Raw (unheated) soybean flour containing high levels of trypsin inhibitor depressed feed intake of rainbow trout at 30% level and completely deterred the feed intake at 60% level in diets. Conversely, heated soy flour and soy protein concentrate containing negligible levels of trypsin inhibitor did not affect the feed intake at either 30 or 60% inclusion levels in diets (unpublished data). This suggests that trypsin inhibitor levels in soybean might have a major effect on the palatability of the ingredient. The diet history of fish, particularly at earlier stages (normally fish meal-based commercial feeds), may be another factor for the preference of feeds (95).

CONCLUSION

Earlier in the twentieth century, when Clive M. McCay pioneered fish nutrition research in the United States, the goals of nutrition in aquaculture were (*1*) to develop feeds that support optimum growth of fish (biological requirement) and (*2*) to use inexpensive feed ingredients whose supply are stable (economical requirement) (96). In the second half of the twentieth century, however, additional needs have emerged: (*1*) to control final product (fish) quality (marketing requirement) and (*2*) to reduce excretion of wastes (environmental requirement). Fish feeds nowadays have to meet all of these requirements: maximizing fish growth and fish quality while minimizing feed cost and waste excretion. These requirements are all endless, yet have critical and direct effects for the sustainability and the development of aquaculture for the future.

EXOTIC INTRODUCTIONS

WILLIAM L. SHELTON
University of Oklahoma
Norman, Oklahoma

OUTLINE

Aquaculture is the farming of aquatic organisms, including fish, invertebrates, and plants. Its objective may be to produce organisms for sport, conservation, ornamental purposes, food, or some specific product. Aquaculture practices range from low-input extensive systems, including ranching, to intensive, highly managed operations. Contemporary aquaculture usually includes artificial propagation, which permits domestication, stock improvement, reproductive manipulation, and, most significantly, assures a supply of animals for stocking. However, the capacity to manage reproduction has greatly increased the opportunity for translocation of species, which can be a double-edged sword: On the one hand, it offers multiple beneficial applications, but on the other hand, it may have associated potential adversities as well. Human-instigated movement of organisms outside their native range is not new. Plants and animals have been moved intentionally or passively with humans during their emigrations throughout the world; in fact, humans are the most widespread exotic species (1). However, our basis for defining an exotic organism is human involvement in the translocation. Food crops have been dispersed throughout suitable climates for their cultivation, and similarly, domesticated animals have had enhanced vagility associated with human resettlement. These companion plants and animals have been greatly modified from their native ancestral types through intentional breeding and passive selection. Consequently, nonnative domesticated organisms, even though they are not indigenous to their contemporary locale, are no longer generally perceived as exotic.

Fish have been moved outside their native ranges, but only a few are greatly changed from ancestral types. The common carp, *Cyprinus carpio*, and goldfish, *Carassius auratus*, probably have had the longest controlled association with humans. The common carp may have been the earliest fish that was transplanted (2,3); both the common carp and goldfish have distinct varieties that

differ significantly from the wild type (4), and rainbow trout, *Oncorhynchus mykiss*, has over 200 different stocks. Nonnative fish are a part of aquaculture to different degrees in various countries, although not to the extent that other cultivars and breeds are used in agriculture and animal husbandry. Actually, limiting fish farming to indigenous species or culturing native fishes only within their historic range can be a serious constraint on aquatic food production. Agriculture practices have evolved over centuries and have been modified to adapt to various climates and economies, and nonnative organisms have been fully accepted.

Aquaculture is a practice dating back at least 30 centuries (see the entry "History of aquaculture"), but the scientific bases for modern activities are relatively recent developments (5,6). Most of the adaptive practices in the United States for economically important species have been incorporated within the past four to five decades, but concomitantly, there also has been a growing environmental sensitivity. Thus, aquaculture has been compelled to develop under the scrutiny of many ethical and environmental considerations that were not applied during the formative period of agriculture.

While the goals of an unmodified environment are laudable, it is not realistic to aspire to return the faunistic distribution in North America to that of pre-European arrival. We can be custodians of natural systems without halting appropriate development. If aquaculture is to meet the expanding aquatic food deficit associated with the current capture-fisheries shortfall, if it is to provide biocontrol options in natural-resource management, and if it is to reduce overexploitation of ornamental fish in their native range, then introduced species must be recognized as a necessary option of managed production in aquatic systems. Yet, we cannot ignore the potential adverse impact of exotics on aquatic habitats and the native fauna; rather, we should assess and evaluate introductions using controls and safeguards and, if indicated, proceed responsibly. This contribution addresses exotics largely from the perspective of the United States, but since aquaculture is a global issue and the definition of "exotic" is from a relative perspective, a thorough understanding of exotics in aquaculture must include information for other countries as well.

BACKGROUND

A general understanding of aquaculture is somewhat intuitive as a parallel to agriculture, since aquatic culture is usually associated with foodfish production, which is essentially aquatic-animal husbandry. Historically, eggs or larvae were collected from natural spawning areas and transferred to culture systems for growout, but as propagation techniques were developed, all phases of the life history became controlled (7–10). Today, aquaculture includes management of broodstock, controlled propagation, nursing, growout, processing, and marketing, as well as genetic manipulation (11). A nonfood commercial application of the culture of fish is the production of ornamentals, which is also a positive development for the conservation of species within their

native ranges. In a slightly different application of the culture of fish, juveniles are produced for stocking into sport fisheries, although the growout phase is usually in public waters and harvest is through angling. The cultivation of endangered species for restocking into open systems is similar to the culture of sportfishes in that it encompasses only spawning and the early phases of life history.

The facilities where aquaculture activities are conducted generally characterize the focus of the operations. Commercial aquaculture is associated with fish farms, while the facilities dedicated to the culture of sportfish or for conservation programs are usually called hatcheries. The latter are most often operated by government organizations, while the former are managed by owners and operators in the private sector. Huet (7) has distinguished between fish culture for restocking and fish culture for food, while Bardach et al. (8) have defined aquaculture to be the rearing of aquatic organisms for human food. Stickney (9) and Pillay (10) have incorporated a broader interpretation of aquaculture, stating that it is not limited to vertebrates, finfishes, food fishes, or even animals, but also includes plants and "byproducts," such as pearls. All of these activities include introductions, either exotic or transplanted.

The concept of exotic organisms must be defined, especially within the context of aquaculture. The terminology used in this chapter is based on the standardized system proposed by the introduced fish section (the exotic fish section, before 1985) of the American Fisheries Society (12). A fish or organism that has been intentionally or accidentally moved outside its natural range by humans is defined as introduced. A species is considered native or indigenous in its historically natural range (13). Introductions can be made either within a country (the organism is considered a transplant) or between countries (the organism is considered an exotic). Thus, a transplanted aquatic organism has been moved by man between watersheds within the country of origin (14). Further, an introduction is considered to include the release, escape (15), or establishment of an exotic species into a natural ecosystem—i.e., one in which the species does not naturally occur, either presently or historically (16). Since the introduction of an exotic species from another country and the movement of a species into a new drainage or range can have comparable ecological effects, even the formerly widely accepted practice of managers transplanting fish in stocking programs is becoming increasingly scrutinized (17). Definition of an introduction as established or naturalized is based on successful reproduction and recruitment and provides some concept of long-term considerations.

It is important to understand that even though the terms under which an introduction is defined as established or naturalized may seem biologically illogical, they carry ecological implications and determine legal issues for the regulation of translocations. Despite the best of intentions and concerted efforts, escape of transplanted or exotic organisms from research or commercial facilities must be anticipated (18,19); consequently, confinement under such conditions is still considered an introduction. The potential impact of fish introductions into a new environment are speculative at best, and while an assessment requires detailed studies, even the results of such studies are usually inconclusive (20,21). Nevertheless, appropriate dialogue should precede an introduction, and if an assessment is considered, it should be done in an ecologically responsible way, using fish that are reproductively limited (22,23). A period of observation within a particular aquatic habitat is the only realistic means of accurately evaluating an introduction. Management of reproduction through artificial propagation has been the foundation for commercial culture (24), but now the capability to manipulate phenotypic sex, chromosome composition, and the genome itself have provided a quantum leap forward (25,26).

MANAGEMENT OF REPRODUCTION

Management of reproduction has been critical to the development of contemporary aquaculture, and it has also been a major factor in the increasing number of introductions. On the other hand, manipulation of organisms' reproductive systems can offer new tools for using the organisms in an ecologically responsible manner. Thus, management of fish reproduction can be considered from two perspectives: One involves the production of seedstock under controlled conditions, while the other limits reproductive success. Both approaches are valuable for aquaculture. The control of fish reproduction through artificial propagation has provided tremendous opportunities. The capability to spawn fish under controlled conditions assures an adequate supply of young for growout, whether for food or stocking, and removes the constraints of limiting culture to the geographic proximity of the native range of the fish (27). Artificial propagation also has been one of the most important milestones in catholic aquaculture, in that it has facilitated the capability to move fish to new areas and to establish culture for these species far outside of their natural range, such as is the case for Chinese carps (28). Traditional culture of Chinese and Indian carps, as well as of milkfish, was dependent on capturing wild-spawned fry or fingerlings. Artificial propagation also opens new vistas for the culture of species formerly available only from capture fisheries, such as penaeid shrimps, various characins, and many marine species (29–31). Further, even for species that reproduce under culture conditions, such as common carp, induced ovulation has permitted more efficient management and has provided a greatly enhanced capacity to conduct breeding programs (4,32–38).

Development of reproductive controls has direct applications to aquaculture in cases for which management of recruitment is desirable or for quality considerations (39), as well as for introduced fish for which no reproduction is wanted (40,41). Reproductively limited populations have been instrumental in efficient culture of several species, and while limitation of reproduction is not commonly used as a component of introduction protocol, the capability for it is already developed (42).

Artificial Propagation

Reproduction of fish represents one of the most diverse assemblages of modalities and strategies among vertebrates (43–45). Artificial propagation can be considered across the spectrum, from simple environmental manipulation to more sophisticated physiological control (24,25). Photoperiod and temperature programming have been effective for inducing spawning in a variety of marine species. Hormonal therapy was started in the 1930s and was initially restricted to the use of homologous or heterologous injection of pituitary glands. Today, gonadotropins, such as salmon and carp gonadotropic hormone (GtH), have been extracted, purified, and packaged for more convenient use. They are calibrated and bioassayed for efficacy (27,35). Pituitary extracts and simple dried glands are currently still in wide use for artificial propagation. Time-release carrier systems, which greatly enhance the treatment of fish that are sensitive to handling or that need multiple injections (32,46), are also being perfected for long-term hormone delivery. Various mammalian hormones such as luteinizing hormone (LH), follicle-stimulating hormone (FSH), and human chorionic gonadotropin (HCG), were tried in the 1950s and 1960s, but only the latter is still in common use, and it is not as broadly effective as GtH. Gonadotropin-releasing hormone (GnRH), the hormone produced by the hypothalamus, regulates the production and release of GtH from the pituitary gland; it was purified in the 1970s and reported as luteinizing hormone-releasing hormone (LH-RH), which is a mammalian term. For fish, GnRH is the more appropriate descriptor. Superactive analogues (GnRHa and LH-RHa) now have been synthesized and are increasingly being used (27).

Artificial propagation through controlled final maturation, ovulation, and spermiation permit genetic selection to improve stocks for various desirable traits in animal breeding programs (5). Genetic improvement of fish growth in aquaculture is the primary focus, but factors such as disease resistance, color selection, and others may also be the object of selection. Fish have a few biological characteristics that are conducive to selective breeding: external fertilization, high fecundity, and potential for hybridization.

Domestication is the transfer of an organism from its natural area to a captive environment, and its genetic adaptation to the new environment. Common carp have been the most intensively domesticated fish, but many strains of channel catfish, *Ictalurus punctatus*, and rainbow trout have been developed by multiple hatcheries, farms, and research institutes as well. Carp have been cultured for centuries, while most domesticated strains of channel catfish originated from the wild only in 1949. Culture of tilapia may date back to ancient Egypt, but little stock selection has occurred. Artificial reproduction of naturally ripened broodstock of rainbow trout originated in the 18th and 19th centuries, and there are over 200 different stocks of the trout species.

Artificial propagation of foodfish has been instrumental in enlarging the geographic range for the culture of exotic species, such as Chinese carps, and also of native species.

This technology has greatly expanded the culture of species used in sport fisheries and for conservation-oriented reintroductions. The effectiveness of induced spawning in culture for sport fisheries is exemplified by the widespread introduction of the striped bass, *Morone saxatilis* (47). The primary impetus of using artificial propagation on striped bass was to develop inland fisheries, but in the interim, this species and its hybrid with the white bass have become increasingly important in foodfish culture (see the entry "Striped bass and hybrid striped bass culture"). Native to the Atlantic and Gulf coasts of the United States, the striped bass has been widely disseminated into inland waters. The current sport fisheries and foodfish producers are totally dependent on artificial propagation, with the exception of about 10 naturally reproducing reservoir populations. This example also illustrates the contrasting attitudes of transplanting sport fish and using an exotic species. Widespread stocking of striped bass was possible only after the techniques for induced spawning were developed (48). Beginning in the 1960s, reservoirs throughout the United States were stocked with striped bass, which have provided countless hours of recreational fishing and millions of dollars of increased revenues for sport fisheries (49). However, even though reservoirs are artificial systems, little consideration was given to the potential impact that the introductions might have on resident piscivores. Although there was little opposition to these earlier transplants, this type of action in the future probably will be as thoroughly scrutinized as exotic introductions.

Introduction of an exotic fish during the same period of time did not benefit from a similar "honeymoon." The grass carp, *Ctenopharyngodon idella*, was imported in 1963 as a potential biocontrol for nuisance aquatic plants, but opposition to its introduction developed immediately. The importance of artificial propagation again was the key factor that made the introduction possible, as grass carp culture had been restricted to China until induced spawning techniques were developed in 1961 (28,50). The dichotomy in opinion concerning this introduction presented little negotiable middle ground. The controversy that ensued epitomizes the adversarial atmosphere that can develop between proponents and opponents in such a conflict and that interferes with a rational evaluation. However, the controversy did add impetus to investigations of techniques for the control of unwanted reproduction. The results from some of these studies have contributed to the potential for an orderly system of assessment. Thus, the quandary that can result from the advances in artificial propagation may also be the source of solutions to rectify conflicts and provide a basis for effective assessment.

Manipulation of Reproduction

Early efforts to manage unwanted reproduction in fish were initiated as a means of controlling recruitment of tilapia for aquaculture (5,24,25,36,51). These techniques include monosexing, sterility, hybridization, and various combinations (see the entry "Tilapia culture"). The proposition of using reproductively limited fish in aquaculture was the stimulus to apply these techniques

to exotic introductions (18,22,23,25,40,41); some of these control measures were developed and practiced only after the introduction, as for grass carp (42). The effectiveness of these techniques was obviously compromised in these cases, but the debate was instrumental in stimulating research on the protocols. While most of the techniques have been most widely applied to grass carp, they have also been tested with several other species (52,53).

Reproductively limited fish can be developed by a number of techniques, with differing complexities, and thus the techniques involve various time constraints and/or degrees of security against possible reproduction. Direct induction of monosex or sterile fish can be applied after the specific details of the technique are developed for the species of concern. Although these direct methods are rapid, their disadvantages include the fact that the treatment must be applied to each individual and that innate biological variability prevents uniform attainment of 100% efficacy. On the other hand, if induction is used as a means to develop broodstock, then absolute efficacy is not necessary. The fish developed with the successful treatment will be the agents for production of the reproductively limited progeny. Only the offspring will be used in environmentally sensitive situations. In fact, reproductively limited progeny can be used in stocking, or reproductive control can be limited to the actual assessment.

The sex-determining mechanism is not important in direct steroid monosexing, unless the breeding approach is to be used, in which case it becomes pivotal to success. Sex determination is not a defined issue, particularly in tilapia, although it is generally considered to be monofactorial (5,54–59). Trombka and Avtalion (60) indicated a high degree of crossing over where sex genes may be transposed, and Muller-Belecke and Horstgen-Schwark (61) reported that two or more sex-determining factors may override the XX–XY mechanism. Sex determination was considered to be more predictable among cyprinids (42), but Komen et al. (62) identified a masculinizing gene in common carp that modifies sex determination in XX females. The following option chart summarizes categories of reproductively limited fish that can be developed and is based on a model in which sex determination is considered to be controlled by homogametic (XX) females and heterogametic (XY) males.

I. MONOSEX
   (1) Hybridization (tilapia)
   (2) Direct
      (a) Sex reversal (hormone)
      (b) Gynogenesis (all females)
   (3) Breeding
      (a) Sex-reversed males (all females)
      (b) Androgenesis (YY males)
II. STERILE
   (1) Most fish hybrids are fertile
   (2) Direct

      (a) Triploidization (3N)[1]
      (b) Tetraploidization (4N is fertile)
   (3) Breeding: Tetraploids (4N) $\times$ (2N) = 3N

Hybridization. Hybridization has been used in aquaculture and stocking programs for a number of reasons, such as to modify an organism for particular culture situations or to meet alternative sport fishery needs. Interspecific hybridization among fish within the context of fish culture has been reviewed broadly (63–66) and for coldwater fish (67,68), warmwater species (69,70), molluscs (71), and crustacea (72). Specific families have been the focus of more intensive investigations, including salmonids (73), ictalurids (74), cyprinids (75), cichlids (55,76), esocids (77), centrarchids (78), and percichtheids (79,80). The application for the latter three groups has been primarily in sport fisheries.

Monosexing for reproductive control was not the primary objective among the majority of interspecific hybrid crosses, but has been extremely valuable with reference to aquaculture, monosex, and sterile progeny. The triploid hybrid grass carp was a particular application in the United States (81,82), and monosexing of cichlids by hybridization was a major advancement in tilapia aquaculture. Hickling (83) discovered that hybridization between particular cichlid species yields all-male progeny. Without management of excessive recruitment, the culture of tilapia would be reduced to a low-quality, subsistence activity. However, when unwanted reproduction is controlled, tilapia are among the most desirable culture species. Interspecific hybridization of tilapia has been studied further, and numerous other crosses of interest have been identified (55,76,84–86). Eight interspecific crosses yield all-male, or nearly all-male, progeny (5). Hybridization was the primary means of monosexing for tilapia until hormone-induced sex reversal was developed, which today has become the primary means of reproductive management in most tilapia culture systems. However, hybridization is still a primary tool in Israeli aquaculture, although sex reversal is used in combination with the interspecific crosses (87,88).

Hormone-Induced Sex Reversal. Sex reversal through administration of exogenous steroids has been developed most extensively for tilapia culture. The assumptions of this technique are that (*1*) steroids (androgens and estrogens) mimic natural induction by genetic sex-determining factors to alter development of the phenotypic or gonadal sex; (*2*) the exogenous steroid must be efficacious, adequately concentrated, and efficiently delivered, so as to provide the physiological or pharmacological effect; (*3*) treatment must proceed during a critical period of gonadal differentiation; and (*4*) steroid-induced development of the gonadal sex does not spontaneously revert. While the details deviate for particular species or under certain circumstances, these generalized guidelines have resulted in the development of effective programs for sex control (25,36).

---

[1] The normal, or diploid, chromosome number is designated by 2N.

Studies of sex reversal in tilapia were initiated in the mid-1960s, underwent rapid experimental development in the 1970s, and attained commercialized application during the 1980s (41,87,89). Major control factors have included the selection of the steroid, the concentration of steroid, the mode of the steroid's delivery, treatment initiation, treatment duration, and treatment conditions (90–92). Given the selection of an efficacious steroid and the appropriate concentration for the delivery mode, one of the major considerations is the temporal relationship of the treatment. Under the assumption that a physiological or pharmacological level of the steroid must be administered throughout the period of gonadal differentiation, the length of that period must be determined either histologically or by way of a range of empirical treatments. Furthermore, factors that affect growth are considered pertinent to sex reversal, since physiological processes such as gonadal differentiation are altered by a balance between chronological age (time) and growth (size) (93). Therefore, the period of treatment must consider age and growth; this window of opportunity for treatment optimization has been conceptualized for tilapia (51) and expanded for common carp (93–95) and grass carp (96,97). The genetic basis for the development of phenotypic sex is determined at fertilization, which usually translates gonadal sex with fidelity, but because of the sexual bipotentiality of premeiotic germ cells, the gonadal sex can be exogenously influenced (25).

Functional sex reversal can be considered as a programmatic component, rather than a direct means of producing monosex fish. Postulated breeding programs for tilapia (51,98,99) have been demonstrated (59,100,101). All-female rainbow trout culture has been similarly developed through sex reversal and breeding and is being practiced on a commercial scale in Europe (102,103). Treatments for tilapia through oral delivery can be 100% effective, but frequently are somewhat lower, and treatments for grass carp via hormone implants have been over 90% effective. Thus, these protocols can be used in developing broodstock for breeding monosex progeny (42,51).

Chromosome Manipulations

Gynogenesis. Chromosome manipulation, including gynogenesis, androgenesis, and polyploid induction, provides numerous options for genetic selection, sterility induction, and sex control (25,37,40,41,104–107). Gynogenesis is the development of ova without paternal genetic contribution (see the entry "Gynogenesis"). Sex control for monosexing is dependent on the mechanism of sex determination and permits all-female production for homogametic female species through gynogenesis and, indirectly, all-male populations through androgenesis by producing YY males. In contrast, induced sterility by ploidy manipulation is based on odd chromosome sets (3N), and its effectiveness is not dependent on genetic sex. While our understanding of sex determination is far from complete, we can consider certain aspects as somewhat basic. Heteromorphic sex chromosomes in fish are rare, but

functional heterogametic sex appears relatively well established, despite evidence for autosomal influence in tilapia (5,54,57–61,108) and common carp (62,95,109).

Induced gynogenesis and polyploidy are based on optimized manipulation of at least four variables: shock type (cold, hot, or pressure), intensity of shock, time of application postinsemination, and duration of shock (104,110,111). Shock must be applied either early (polar body), to retain the chromosome set usually lost with the second meiotic polar body, or late (endomitotic), to interfere with first mitosis. Further, improved standardization of treatment can result by referencing time of shock to biological age (tau), thereby incorporating temperature-affected changes into the rate of development (111,112). Artificial gynogenesis and polyploidization have been accomplished in tilapia (113,114), common carp (62,115–117), and Chinese carp, with no shock (42,118), heat shock (52,53,119), cold shock, and pressure shock (120,121).

Gynogenesis can be an end or a means. All-female progeny can be directly produced by gynogenesis, which was the basis of one of the first biological assessments using reproductively limited fish. Stanley (118,122,123) used gynogenesis to supply monosex grass carp for a large-scale study in Lake Conway, Florida. No shocking was used in the induction, and only about 45,000 diploids were produced from over 58 million eggs. While this effort was inefficient, the reproductive limitation was sufficient to overcome opposition for testing. Shock techniques would have greatly enhanced the efficiency, but were not well studied at the time. With the monosex breeding system for grass carp (42), the total number of monosex fish needed for the Lake Conway study were produced 10 times over by using a single XX male to fertilize eggs from only one female; unfortunately, this program of induction was developed a couple of years too late.

Gynogenesis also can be a valuable means of estimating an optimum treatment protocol for induction of polyploidy (22,107,124). Early-shock gynogenesis optimization provides a protocol for optimum triploid production, while a late-shock protocol will estimate the best treatment for tetraploidization. The evaluation of optimal treatment relationships is facilitated, since assessment is based only on the hatch of viable diploid larvae, whereas polyploidy (3N or 4N) must be verified by more involved methods. Haploids may survive to hatch, but they die before swim-up; therefore, a direct count of viable larvae indicates the best treatment. Several features are conveniently incorporated into most gynogenetic studies, to permit verification that diploids are gynogens and not progeny from normal fertilization. First, heterologous sperm are usually used. Second, these gametes are treated to inactivate the paternal DNA; this feature assumes thorough elimination of the male genome. Ultraviolet irradiation is the most convenient and safest means of sperm treatment. As a third level of assurance, a genetic marker is used, if available, during protocol development. For example, using a female with a homozygous recessive trait, such as the scattered-scale pattern in common carp, or one of the color mutations provides a visual confirmation of progeny with only maternal inheritance. Gynogenetic progeny of a

light-color koi carp female lack pigmentation at hatching, while any diploids that might result from normal fertilization by a nonkoi male have dark pigmentation at hatching. Albinism is an excellent genetic marker and is available for several species, including the grass carp (125). The recessive marker is used in the parent for which the genome will be represented in the progeny — i.e., female albino for gynogenetic studies and male albino for androgenetic studies.

Triploidization. The induction of polyploidy is analogous to gynogenesis, except that untreated sperm from conspecifics is used for fertilization, and a genomic contribution, rather than a heterologous DNA-deactivated spermatozoa, is employed. Triploids are produced by early shock for polar-body retention, while tetraploids can be induced by interference with first mitosis by late shock. Evaluation of polyploid induction requires determining the ploidy by karyotyping, red-blood cell nuclear analysis, or quantitative DNA determination (126,127). Triploidization has tremendous potential in the production of sterile fishes for water resource management or for assessment studies. The level of gonadal development of triploid fish differs from that of diploids. In general, triploid fish have smaller gonads than diploids; males may have near-normal size testes, but with limited spermatogenesis, while the ovaries of 3N fish are poorly developed and typically have few ova (128).

Tetraploidization. Another means of producing triploids is through the initial induction of tetraploidy and the subsequent use of the 4N fish in a breeding program with diploids. Progeny from a 4N-by-2N cross all will be triploids. The induction of tetraploidy follows the protocol characterized by endomitotic gynogenesis. Normal fertilization is accomplished, and development proceeds, but first mitosis is interrupted by shocking. Tetraploid males and females are produced and develop as fertile adults; therefore, theoretically, a 4N line can be produced (104,107,110). Further, and perhaps more significantly, all-triploid progeny can be faithfully produced by breeding a tetraploid (male or female) with a diploid (female or male, respectively). Thus, production of tetraploids has its greatest potential in the development of broodstock for production of all-triploid progeny. Tetraploidy has been induced in relatively few fish — for example, various salmonids (129), channel catfish (130), common carp (62), grass carp (121), and tilapia (131,132). Chourrout et al. (129) and Thorgaard et al. (110) produced triploid rainbow trout by breeding tetraploids with diploids.

Androgenesis. Androgenesis generally can be considered as the reciprocal of gynogenesis: It is the production of progeny with only the paternal genome; the female genome must be eliminated in order to induce androgenesis. In this process, non-genome-bearing ova are activated with normal spermatozoa, and diploidization is accomplished by shocking prior to first mitosis. A late-shock gynogenesis protocol can be used to estimate the treatment to produce diploid androgenotes. However, elimination of the female genome is more difficult than in sperm treatment, since the egg is larger, and penetration of UV radiation is limited. Thus, while gynogenesis required the appropriate treatment of spermatozoa, androgenesis depends first on effective ova treatment. As the viability of eggs is reduced during storage, treatment must proceed soon after ovulation. Despite these complications, there are several advantages for ploidy manipulations that result in progeny with paternal inheritance. The expected production of progeny with a 1 : 1 sex ratio is based on segregation of X- and Y-bearing sperm. Diploid induction results in XX females and YY males. The latter will be functional as broodstock and produce only male (XY) offspring. Also, androgenesis has potential for restoration of endangered species, through the induction of diploid progeny from cryopreserved sperm.

Androgenesis and the resulting production and viability of YY male progeny have been verified in several coldwater fish (133–135). Androgenesis has been demonstrated in tilapia (136) and common carp (137–140) and all-male progeny have been produced by breeding YY males of common carp, loach, and sturgeon.

HISTORY AND STATUS OF AQUACULTURE WITH REGARD TO EXOTIC SPECIES

Fish culture is an ancient practice. It originated in China about 3,000 years ago and then developed in Europe somewhat later. In North America, fish culture can be traced to the mid- to late 19th century (141,142). Aquatic resources are an important source of animal protein for human nutrition; the worldwide commercial harvest of aquatic animals was about 97 million metric tons (MMT; 1 metric ton = 2,200 lb = 1 long ton) in 1991, with about 71% being directly used for human consumption (143). The potential world wide production from all sources is estimated to be 100–150 MMT, of which about 27 MMT is discarded bycatch. At present, the growth of capture fisheries is insufficient to maintain the needed food supply sustainably, in fact, the harvest has already entered into a period of decline (144,145).

Fish culture must meet the future growing needs for aquatic products, since the capture fishery supply is overexploited and the harvest is currently static at best, despite increased effort to expand it. Worldwide aquaculture production has steadily increased in recent years, at about 15% per annum; in 1992, 84% of production was in developing countries. Aquaculture production in 1994 was 18.5 MMT, 42% of which was from the production of carp (146). Much of the increasing production has been due to worldwide transplants of carp, tilapia, catfish, and salmonids into areas where they are now cultured (144). After centuries of development, animal husbandry has generally focused on four herbivorous mammals and four omnivorous birds, while in aquaculture, about 300 species are produced in large quantities. Yet, limited scientific data on indigenous species generally has discouraged the use of these species, in favor of accepting the more tested nonnative species that have well-developed culture systems. Two groups of fish — carp and tilapia — have been most important globally in fish culture (147). These fish are widely cultivated outside of their historic native ranges. The rate of exotic transfers has increased since about 1945, somewhat in conjunction with expanded developments in techniques for artificial propagation (148).

Exotic transfers have occurred worldwide in four general waves. Prior to 1900, movements were made primarily by salmonids; then common carp was disseminated in the early part of the 20th century. Tilapia were commonly transferred during the early part of the second half of the 20th century. Finally, the most recent trend has been the movement of Chinese carp, during the 1960s and 1970s (149). A total of 1,354 introductions of 237 species into 140 countries have been recorded; only 98 species have been introduced for aquaculture, however. Also, relatively few of the transferred species have been widely distributed; only 10 species have been introduced into more than 10 countries. Seventy-eight exotic species have been introduced for sport fishing, but this figure does not include intranational transplants. Over 298 (22%) of the introductions did not result in establishment of the species, and 246 (18%) of the introductions did not breed under natural conditions. A total of 321 (24%) of the introductions resulted in established populations, but only 89 had sufficient impact to cause serious concern, while the other 232 have been judged to be neutral or beneficial to the area (149).

The first half of the 1800s was an active period for fish transfer in the United States. During that time, fish were being cultured largely for restocking, due to depletion of natural populations from overfishing. Native fish were also being transplanted outside of their natural range by government agencies; for example, striped bass were moved to California and rainbow trout and Pacific salmon to the east. The common carp was the first recorded introduction into the United States, followed by the brown trout, *Salmo trutta*. During the same period of time, rainbow trout were being exported from the United States to other countries. Today, rainbow trout have been introduced into 44 countries, which is nearly as widespread a range as that of carp and tilapia. Also, many centrarchids have been exported to numerous countries, and, more recently, paddlefish, buffalofish, and channel catfish have been introduced into Russia and China, as well as 10 other countries. Thus, exotic fish transfers have not been a one-way street. Tilapia were imported into the United States in the 1950s and 1960s, and Chinese carp were brought in the early 1960s. The brown trout of Europe has been introduced into 33 states as a sportfish and is generally considered a positive addition; there is virtually no contemporary foodfish culture for this species in the United States (150). Forty-six species have been transferred into North America, 39 of which were considered established in the early 1980s (151); the United States now has at least 70 established exotic species (21), 42 of which were considered to have reproducing populations in the mid-1960s (150). Well over half of the these 42 species (23) are established in Florida, and all but 3 were related to the aquarium trade (152).

Foodfish

Exotic. World aquaculture production was about 13.9 MMT in 1992, 51% of which was finfish, 20% molluscs, and 4% crustaceans; the rest was plants and various other products (143,153). In 1994, the total production was estimated to be 18.5 MMT (146). Culture of the Pacific oyster,

Crassostrea gigas, in the United States takes place primarily in the northwest, where the Pacific oyster was imported early in the 1900s, to supplement dwindling stocks of native species (154). The Pacific oyster makes up about 40% of the 20,000 MT of oysters marketed in the United States (155) and about 56% of the world production of oysters (156). The Pacific oyster was introduced to Britain from the United States in 1965, again because overexploitation had depleted the native fishery; today, a commercial industry has developed around the species. The most widely cultured freshwater shrimp in the world is the giant freshwater prawn, *Macrobrachium rosenbergii*. Most of its culture occurs in the Indopacific, but it was introduced into Hawaii in the mid-1960s and by 1988 was a $18.2 million crop (157).

Tilapia production in 1995 was 700,000 MT worldwide, and over half (473,000 MT) of the tilapia were farm raised. The natural distribution in Africa of aquaculturally important species has been described by Philippart and Ruwet (158). Despite introduction worldwide, tilapia production is only about 5% of the total production of farmed fishes, but because of the management of reproduction through hand sexing, hybridization, and sex reversal, they are becoming increasingly used (159). The Nile tilapia, *Oreochromis niloticus*, is the most popular species, making up 64% of the world production of tilapia, and *O. mossambicus* makes up about 10% of the worldwide production (160–162). Tilapia are cultured in about 70 countries; China has the greatest production (157,000 MT) and the Philippines the next greatest (63,000 MT). The United States ranks third in world production of tilapia (6,800 MT), with California culturing more than any other state.

Tilapia culture is one of the most rapidly growing foodfish components in the United States, but imports currently far exceed production on domestic farms. Although domestic production doubled between 1986 and 1992, only 20% of the demand for tilapia was satisfied; 24,000 MT were imported in 1995, making tilapia the third largest imported aquatic product, behind salmon and shrimp (163,164). About US$1 million worth of tilapia were imported from Honduras in 1996 alone. In 1989, about 3,000 MT of tilapia were produced in Jamaica, all of which were sex-reversed monosex males (165). Farmed tilapia are almost exclusively monosex, either through hybridization, hormone-induced sex reversal, or both. Israel produced about 15 million monosex fry in 1996 (166). While some concern has been raised over human consumption of steroid-treated tilapia and although the Food, and Drug Administration (FDA) is presently regulating the use of hormone treatment in the United States, there is no evidence of any human health hazard. Studies have demonstrated rapid posttreatment tissue clearance in fry, which are only a few grams (28 g = 1 oz) in weight, and that no residual hormones can be detected within one month of the termination of monosexing treatment (167,168).

Common carp was the first fish known to be cultured for food, the first fish to be transported outside its native range, and the first exotic species to be introduced into the United States. It is farmed in 60–70 countries, but in

only 11 of them is production in excess of 10,000 MT/year (35). The total worldwide carp production in 1991 was in excess of 987,000 MT (6,169). Carp as a group is the most widely cultured fish, and tilapia culture is nearly as widespread. Exotic finfish production in the United States during the 1980s has been summarized by Shelton and Smitherman (18). During that period, chinese carp were cultured in eight states by more than 30 producers, but grass carp were used primarily to stock culture areas for aquatic vegetation control; tilapia were grown on 24 farms in 13 states for the food market. Current commercial production of exotic aquatic organisms in the United States includes shrimp, Pacific oyster, tilapia, common carp, and Chinese carp. Foodfish production for the latter two groups is mainly for ethnic markets, but a primary focus in the culture of common carp is the koi variety, for the ornamental market.

Transplants. Some critics of exotic species in aquaculture have suggested that native species should be used preferentially (170). In fact, the primary basis for U.S. aquaculture is endemic channel catfish and rainbow trout; however, much production is outside their native ranges. Production from the culture of exotic species in the United States is relatively little compared with that of the culture of native species. In 1985, over 200,000 MT of catfish were produced in 50,000 ha (123,500 acres) of water. During that year, about 2% of the channel catfish grown in the United States were cultured in California (171), where it is a transplanted species (21). About 30% of the rainbow trout farmed in the United States are outside their natural range, but the majority are cultured in the Snake River Valley (141), which is within their native range. The development of artificial propagation for salmonids in the mid-1800s initiated a period of movement, both as transplants in the United States and as introductions into other countries. Denmark received rainbow trout in 1870 and soon established a commercial facility for them. Rainbow trout are currently produced in 40–55 countries and are the major freshwater salmonid produced for food. In 1994, production of rainbow trout was 300,000 MT; Denmark led the production, with 41,000 MT, while production in the United States and Chile was about 15,000 MT each (172).

Another endemic species that has had major advances in its culture is the striped bass. Striped bass were first transplanted to the west coast of the United States between 1871 and 1881, and a naturalized sport fishery was established during that time. The species has been exploited in both a sport and a commercial capture fishery within its natural range on the east coast. In the 1940s, a landlocked population was discovered that was reproducing in the newly impounded Santee-Cooper reservoir system. Investigation of artificial propagation techniques followed, and in the early 1960s, a successful protocol was reported. During the period that the propagation techniques were being developed, the natural populations of striped bass on the Atlantic and Gulf coasts were declining. Curtailment of harvest created a deficit in the ongoing demand, and commercial farming developed rapidly. The hybrid striped bass × white bass, *Morone chrysops*, has emerged as the primary culture organism,

favored over either parental species. U.S. production of the hybrid in 1989 was estimated at 450 MT and was projected to be about 1,350 MT by 1995; 152 MT were produced in California in 1987, an area not within the natural range of either species (173,174). Concern for maintaining genetic purity in natural waters has stimulated the production of sterile triploid hybrids for culture, so that no escapees will contaminate the gene pool of the wild population (175).

Exotic Foodfish in Other Countries. The culture of exotic fish outside the United States is an even larger proportion of the total production. Rainbow trout, as previously mentioned, were exported from the United States beginning in the latter half of the 19th century; today, rainbow trout is cultured in over 40 countries, and, with the exception of rainbow trout cultured in the United States, all represent the farming of an exotic species. Chile is second to Denmark in the production of farmed salmonids, including coho, *Oncorhynchus kisutch*, and Atlantic salmon, *Salmo salar* (176).

Tilapia are cultured worldwide and are exotic in all countries outside the African continent. Transplanting tilapia around the African continent has also been a common practice (76). The numerous introductions worldwide and subsequent redistributions have resulted in several genetic bottlenecks, with the resultant loss of genotypic variability (177,178). The total world production of tilapia is second only to that of carp.

In China, 109 species of fish have been introduced, and 16–18 of the 40 freshwater species cultivated in China are exotic, including rainbow trout, channel catfish, and paddlefish — all from the United States — and common carp and tilapia (179–181). In addition, 88 tropical exotic fish are cultured for the ornamental trade. Pond culture in China has been developed to a virtual art form, but it is also common for fish to be stocked into more extensive reservoir ranching systems (182,183). Ocean ranching of transplanted sturgeon in the Black Sea and the Caspian Sea has maintained the caviar industry for decades (184), although the fisheries are now in a rapid state of collapse, due to the breakup of the Soviet Union (185).

In the 1960s, India imported grass carp and silver carp, *Hypopthalmichthys molitrix*, from China; these plus common carp, in the polyculture of its native carp, is now called "composite culture" (186–188). This combination is used in traditional pond culture, but also to supplement reservoir capture fisheries (189). Introduction into Sri Lanka of *O. mossambicus* in the 1950s and *O. niloticus* in the 1970s has also been the basis of a major capture fishery in reservoirs (190). Balayut (191) has discussed some of the failures to establish fisheries by stocking exotics in reservoirs of southeast Asia.

Israel introduced common carp from Europe in the 1930s. Common carp was the basis for fish culture until tilapia was introduced in the 1950s, which developed into polyculture by the 1960s (192). The production of common carp in Israel has been stable over the past couple of decades, but the production of tilapia has been increasing; in the mid-1990s, the amounts produced of the two species were nearly equivalent (193,194). *Oreochromis aureus* is native to the Jordan Valley, but *O. niloticus* is exotic, and

about 60% of the tilapia cultured are hybrids between those species (166). In 1996, 15,000 MT of five groups of freshwater finfish were produced in Israel [common and Chinese carp (38%), tilapia (45%), rainbow trout, and hybrid striped bass]; all of the species are exotic (195). The total production of farmed fish in Israel occurs almost exclusively on *kibbutzim*; the 55 farms in Israel, with about 3,000 ha of water area, had an average annual yield of 4.5 MT/ha (1 ha = 2.47a; 1 MT/ha = 1.12 T/a). Foodfish production has intensified through polyculture, improved diets, and aeration; the yield has increased from about 2 MT/ha in the 1950s to an average of about 5 MT/ha in the 1990s (195). Annual fish consumption in Israel is about 10 kg/person (22 lb/person), for an annual consumption of about 60,000 MT (196). Approximately 5,000 MT come from capture fisheries in marine and freshwaters, and about 15,000 MT (25%) is from culture; however, 40,000 MT (67%) must still be imported.

Sportfish

Sport fishing in the United States is important recreationally and economically; 50 million Americans fish each year and generate US$69 billion in economic output (197). Stocking has been an important component of sport fishery management, and fish culture is the foundation that supports the entire infrastructure: Stocking programs would cease without artificial propagation and culture. In the early days of fish culture in the United States, hundreds of millions of fry were produced, and the public accepted stocking as the answer to management.

Exotic fish have been a significant, although comparatively small, segment of the aforementioned stocking programs. Most of the exotic species that have been used for sport fishing in the United States have been experimental, and virtually none have developed into lasting fisheries (198). On the other hand, some of the fisheries based on transplants have been spectacularly successful. The vast majority of stocked sportfish are native, but not necessarily to the area to which they have been released. Thus, introductions through transplanting endemic species have been by far the primary focus of culture for sport fishing. Supplemental stocking of native species has proven largely ineffectual, but transplanting native fish into new areas has produced good results, as well as disastrous ones. The Colorado River reservoirs provide a particularly poignant example of the latter. Rainbow trout, red shiner (*Cyprinella lutrensis*), threadfin shad, (*Dorosoma petenense*), channel catfish, striped bass, bluegill (*Lepomis macrochirus*), largemouth bass, smallmouth bass, (*Micropterus dolomieu*), black crappie, (*Pomoxis nigromaculatus*), walleye (*Stizostedion vitreum*), and yellow perch, (*Perca flavescens*) are among the fish that have been transplanted outside their native ranges into this system. The positive outcomes are generally well known, while the disastrous consequences of these actions may be generally less familiar, even though they have been effectively articulated (199). The closure of the Hoover Dam in 1935 initiated drastic changes in habitat that affected the fish of the Colorado River; however, the introduction of the aforementioned array of predatory and prey species into the

newly created reservoirs further limited the survival of native fish and subsequently complicated recovery efforts for the unique species that were recognized as near extinction.

More than 206 species in the United States occupy waters beyond their native range (21), 75% of which were introduced as sportfish. Thirty-six percent of the states have fewer native than nonnative sportfish species; on the average, nonnative fish make up about 38% of the fish that go into state recreational fisheries (200). Forty-nine of the 50 states use nonnative sportfish in their management programs. California epitomizes the significance of transplanted fish in sport fishery management: Most of the important North-American sport species are not native to California, including centrarchids, ictalurids, and percichtheids. Only 10 inland species native to California are considered sportfish; during the past 125 years, 30 nonnative fishes have been introduced for recreational purposes (201). Fishing for nonnative species has supplied between 40 and 75% of the angling effort over the past 50 years.

Coho and chinook salmon, *Oncorhynchus tshawytscha*, were introduced into Lake Michigan after the decline of the lake trout, *Salvelinus namaycush*, fishery, and sport fisheries for the two types of salmon were established. In some warmwater reservoirs, rainbow trout have supported two-story fisheries far outside of the trout's natural range, both geographically and climatologically, and unique tailwater fisheries also have been maintained. The success of the striped bass in this regard is legendary. Dispersal of striped bass into 456 inland reservoirs in 36 states has established viable sport fisheries. Hybrid culture was developed simultaneously with these fisheries programs, and hybrids were introduced into 264 reservoirs (47,141); about 2.3 million ha (5.7 million acres) have been stocked with hybrids (79). These stocking programs have been an unprecedented success. It is significant that in all but 10 reservoirs, the fisheries must be maintained by annual stocking from hatchery production. Each state is responsible for perpetuating its own stocking program and must cultivate the expertise and maintain the facilities to propagate striped bass and/or hybrids. One of the primary reasons for the success of the program has been the strong support of governmental agencies and the dissemination of developed technology through production manuals (48). The programs represent significant transplanting activity and total commitment to the culture for continuance.

A component that is vital to sport fisheries, but which is often overlooked in the context of fish culture, is the production of baitfish. About 11,000 MT of baitfish were cultured in the mid-1980s, ranking third in value, behind catfish and trout (141). The annual farm-level sales for baitfish were about US$71 million in the mid-1980s (202). While this culture activity is supportive of sport fisheries, the use of live baitfish itself can be a source of transplanting. On the downside, bait bucket introductions have been indicated for 58 species transplants (21).

Resource Management

Introductions of fish as agents for biological control have not been great in terms of the number of species that have

been introduced, but perhaps no other activity has elicited such conflict among various stakeholders. The National Academy of Science (NAS) has proposed that biological control become the primary pest-control method in the United States (203). Biological control is considered to be a more environmentally friendly alternative than chemical controls. However, most of the introductions have involved exotics, and proposals for their use in varying degrees to open waters have resulted in extreme opposition. Biological control of nuisance aquatic plants has been the primary target, although other aquatic management aspects have also been considered.

Several species of tilapias were introduced for plant control, most notably *O. mossambicus* and *Tilapia zillii* (50,204). Those two species have been effective in some situations, but they are infrequently used today for this purpose. The grass carp is the primary species used for control of nuisance aquatic plants. Its introduction in 1963 for investigative purposes was soon followed by its employment for pest control. A special session at the 1977 American Fisheries Society (AFS) meeting discussed the status of the grass carp in the United States (205). The AFS sponsored another, more general symposium in 1985, called "Strategies for Reducing Risks from Introduction of Aquatic Organisms," the contributions of which were published in a 1996 issue of *Fisheries*. The cover of the issue depicted three exotic fish and the movie title "The Good, the Bad, and the Ugly." This expression and the perspectives in the papers illustrate the polarity that had developed over the use of exotic fish for pest control. The proponents and opponents of this method are probably no closer to meeting at some midground today than in the 1960s and if anything, the chasm is widening. Several symposia have been convened in the intervening years, and the result to date is the creation of a set of literature on grass carp that is probably unrivaled by the literature on any other species. This information is best accessed by starting with the biological synopsis (206). For more details on the biology, culture, and efficacy of grass carp as a biocontrol, consult other major contributions (8,207–209). The single most significant outcome of this exotic introduction was the stimulus to examine reproductive controls.

Original stockings of diploid grass carp involved about 40 states in the United States by 1972. During the 1970s, controversy over potential natural reproduction stimulated the development of techniques to produce monosex grass carp (42,118) and a triploid hybrid (female grass carp × male bighead carp, *Aristichthys nobilis*) (210), and then, in 1982, an Arkansas fish farmer produced triploid grass carp. Direct induction of triploidy has been accomplished for various cold- and warmwater species, including salmonids, catfish, cyprinids, and cichlids, by thermal and/or pressure shock (25,32,113).

In 1984, the U.S. Fish and Wildlife Service issued an opinion that female triploid grass carp are functionally sterile and that sperm from triploids are probably nonfunctional (211). The triploid reproductive potential is characterized by extremely low development of viable spermatozoa, low fertilization success, and extremely low survival of embryos (212,213). The production of

triploid grass carp in the United States has greatly expanded in the last five years to meet the demands for biological control of nuisance aquatic plants; triploids are sanctioned by most state governments and are considered ecologically safe (28). Stocking has encompassed farm or watershed ponds as well as large water bodies [i.e., >50,000 ha (123,500 acres)], with one-time stockings of over 400,000 triploids. Verification of triploidy is necessary, since some diploids are also produced via direct induction, and some states permit only triploids to be stocked. Consequently, each individual fish is tested by the producer, then independently verified through subsampling before shipment (214), and a subsample is usually rechecked at the destination. The system of verification, certification, and use of the triploids has been described (215). Despite the problem of diploid contamination and the need to cull the progeny, direct 3N production of grass carp developed commercially in the United States following the shortfall of expectations for the spontaneous triploid–hybrid grass carp (214,215). Most triploid grass carp used in the United States are produced in Arkansas, where the direct value to fish farmers is about US$1 million annually (216). Optimization of triploid induction has been studied by scientists (119,120), although the specific protocols used by commercial producers are proprietary information.

The collection of eggs and larvae of grass carp in open systems since the 1980s (28,217,218) has documented that natural reproduction is occurring in North America as predicted (219); however, it is important to emphasize that this spawning is related to the use of diploid fish in open systems for nearly two decades before reproductively limited stocks were produced. This fact stresses the need to use reproductive controls before testing or stocking exotics; had this process been undertaken with grass carp prior to their release, naturalization would not have occurred in U.S. waters.

Chemical and mechanical controls are more than twice, and up to 20 times, more expensive than biological controls (209). Further, the environmental impacts attributable to grass carp would have occurred even if the vegetation were removed mechanically, since the primary biological effect is due to the removal of cover. Stocking for nuisance aquatic plant control is related to weed biomass and type, and to the growth of fish. In a large-scale stocking test in Lake Conroe, Texas, triploids were stocked at 74/ha (30/acre) of vegetated area. Submersed vegetation was eliminated in two years, and the sport fishery changed, as would be expected, to less cover-dependent species and a more open-water fishery. A thorough analysis of weed control effectiveness and reported impacts for this case has been performed (28,209).

In addition to grass carp, other Chinese carp have been considered for water quality management. For example, silver carp and bighead carp have been investigated for use in systems to manage plankton, as reported by various workers (14,28,220–224). Black (snail) carp, (*Mylopharyngodon piceus*) introduction has been erroneously linked to importation for control of the zebra mussel (*Dreissena polymorpha*) (225). In fact, the

black carp was imported in the early 1980s as a biocontrol for snails (M. Freeze, Keo Fish Farm, AR, personal communication, 30 September, 1994), as certain snails are intermediate hosts for some parasites of wading birds; the parasites subsequently infest fish muscles as yellow or white grubs. Some processors have rejected catfish because of heavy grub infestations. Triploid black carp stocked at 5−10/ha (2−4/acre) successfully eliminated yellow grubs from a North Carolina hybrid striped bass culture (226). Commercial producers have already developed induction techniques for producing sterile triploid black carp, and gynogenesis has also been reported for this species (53).

The black carp is the first fish species to be considered under the Generic Nonindigenous Aquatic Organism Risk Analysis Review Process, which was authorized by the U.S. Congress in the Nonindigenous Aquatic Nuisance Control and Prevention Act of 1990 (15). The recommendation of this process was that the black carp should not be used for controlling zebra mussels in open waters unless research demonstrated the effectiveness of the method, but its use as a biocontrol of yellow grubs in fish farm facilities should be allowed (227). The primary concern with the use of the black carp in open systems in the United States is the vulnerability of endangered molluscs. Black carp also have been suggested as a potential biocontrol of snails in areas of bilharzia endemicity, but only preliminary studies on this use have been completed (228). Again, consideration in this case was also with the proviso that reproductively limited fish be developed prior to use.

Ornamental Fish

About 6,000 freshwater species are in the world trade for ornamental fish, and 59 of the most popular species are currently commercially reared in the United States (229). Ornamental fish culture is the most profitable aquacultural enterprise. Worldwide, it is farm valued at about US$400 million per year. A very positive aspect involving conservation is that fish from breeding farms are replacing fish from wild-caught sources (144). Ornamental fish production is among the leading cash crops in U.S. aquaculture, with a retail value of approximately US$1 billion (230). There were 193 tropical fish growers in Florida in 1987, with sales of about US$21 million (50).

Twenty-eight species of ornamental fish have escaped and established breeding populations in Florida (229,231) 10 of which have since been extirpated (152). While ornamental fish are often considered tropical species, considerable culture is directed toward two temperate species: goldfish and the fancy carp, or koi ("the living rainbows"). The estimated farm-level value of goldfish alone is US$10−20 million annually, a figure that includes aquarium fish as well as feeder and bait fish (232). More recently, backyard water gardens have increased in popularity with the growing interest in koi and fancy goldfish. Local garden clubs have further enhanced participation in this leisure activity. In Israel, production of ornamental fish does not appear in statistics for foodfish, but this component of fish culture is important economically. MagNoy, a marketing cooperative among four kibbutzim, exports goldfish and koi and accounts for about 30% of the European market, or about US$20 million per year.

ENVIRONMENTAL IMPACT

Many forms of human activity, including food production, whether terrestrial or aquatic, affect the environment (19). Human perturbation has had the effect that few freshwater habitats are undisturbed (21). This scenario is forcefully summarized by Warren and Burr as follows:

> . . .nearly all major streams in the East are dammed and regulated. Groundwaters across much of the country are being pumped at rates exceeding those at which aquifers can be recharged. Problems of point source and general pollution continue in the Great Lakes, Midwest, South and Northeast. Acid rain is destroying northern lakes, and poor land-use practices in the agricultural states of the Midwest and South have doubled sedimentation rates in the past 20 years. Drainage of wetlands, primarily for agriculture and urban expansion, throughout the eastern United States continues at unabated rates in many regions. Predation and competition for resources with nonnative species are increasingly recognized problems in the West and subtropical states such as Florida (233)

While this summary is appalling, it is not possible to completely avoid environmental damage or resource exploitation (19).

If we consider aquatic extinctions as a measure of environmental impact, then habitat alteration has been a contributing factor to the extinction of 73% of the 40 extirpated North American fish (234). It should be noted that one of the factors of aquatic ecosystem degeneration mentioned by Warren and Burr (233) was nonnative species, which has also been identified as contributing factor in 68% of the species extirpations (234). An important point to remember, however, is that nonnative fish have been considered as a *contributing factor to*, not the *cause of*, extinctions. As has been described for the case of aquarium fish in Florida, the impacts of exotic fish are more symptomatic of environmental problems than they are the primary cause of the problems (235). There are numerous examples in which invading species have become established and integrated into local biota without an associated extinction of native species (236). Warren and Burr further state that few successful invaders have become pests or have caused major changes in the receiving system. Most invasions do not cause extirpation of organisms directly. However, predicting whether a species will be benign or become a pest is not possible; it is in a large part conjecture (50,170) or speculation (20). However, paucity of ecological damage cannot be considered proof of general safety (203).

Courtenay (21) has stated that any introduction is a risk and will result in impacts on native biota; however, an impact may be negligible or it may be major, and predicting its magnitude is nearly impossible. Seventy percent of 31 studies conducted by Ross (237) have documented a decline in the population of native fish

following the introduction of an exotic or transplanted species, but most introductions lack adequate prestocking data. Introduced forms impact native ecosystems through (*1*) habitat alteration, (*2*) introduction of disease or parasites, (*3*) hybridization with native species, (*4*) trophic alteration, and (*5*) spatial alteration (238). Many examples of fish-introduction "cause and effect" may be, in reality, correlative events related to habitat perturbation or overexploitation of a fishery, rather than causation. For example, rainbow trout introduction to Lake Titicaca, Peru, has been considered negative (239), but concurrent changes were not adequately documented and may have been contributing causal factors as well (143). Also, regarding the environmental effects attributed to fish introductions into Colorado River impoundments (199,240), while the numerous introductions may have been misguided, the effects on the native fauna were certainly first precipitated by the ecological shift from a riverine habitat to the semilacustrine system of reservoirs.

Despite the potential of farmed fish to escape, hatchery-reared individuals generally have lower survival rates and a lesser ability to compete with native species in open systems. Hybridization potential is a greater risk with transplanted native species than with introduced exotic species (143). Statistics for worldwide introductions suggest a very low success rate for naturalization and an even lower level of pest status for introduced species (149,241).

Why introduce a species and thus run the risk of adversity? There are several reasons. First, humans have created numerous altered habitats (e.g., reservoirs), and it is reasonable to use exotic or nonnative species in such systems (143). Second, in aquaculture, introducing or transplanting nonnative species is justifiable, because relatively few of the vast number of species with potential for aquaculture have a developed biological technology adequate to assure success in culture. Also, aquaculture is not a recreation, nor an avocation; it is a business with financial success at risk. Without the introduction of transplanted channel catfish, striped bass, and exotic tilapias, what would be the aquaculture profile in California? Also in California, without the introduction of centrarchids, what would be the sport fishery?

Much of the published criticism of exotic introductions has not been repeated here; such sources are harbingers of the drastic mistakes made by introductions and repeatedly warn of the likelihood of a "Frankenstein effect." Yet, most of those sources indicate that examples of damage or pest status are not common, and are even rare, considering worldwide statistics. While the total number of species that have become established is relatively small, the number that has become problematic is much smaller. Opposition to stocking exotics is usually on the basis of their potential to cause environmental degradation or to compete with native fauna (238). These concerns can be addressed for nonnative fishes using reproductively limited populations, so as to retain the option of terminating continued population support if further stocking is contraindicated.

CONTROL MEASURES AND RISK ASSESSMENT

Many species transfers are related to utilitarian motivation. For fish, such motivations may include sport fishing interests; biological control applications; aquaculture considerations; or simply aesthetics, as with ornamentals (242). The potential environmental effects of introductions are not altered by whether access to natural aquatic habitats is by way of purposeful stocking or through escape from controlled environments, since the impact can be similar. "Assessment" implies an *a posteriori* situation, whereas "risk assessment" attempts to predict or evaluate the likelihood of damage (243). Therefore the evaluation process becomes basically a modeling exercise for risk assessments. If we subscribe to the concept of "environmental roulette" proposed by opponents of exotic fish, and if the risk assessment process takes into account previous statistics on introductions, the odds are greatly in favor of predicting that an introduction will cause no adverse impact. Obviously, however, the process of risk assessment cannot depend simply on the odds. Assessment further implies that a commitment for an introduction may have been made, or that an unintentional introduction has occurred. In either case, the evaluation process may be affected by the potential for serious environmental or professional repercussions. However, this need not be the case if a system of reproductive limitation is developed before the introduction takes place.

Species transplants can have adverse ecological effects, and it may be impossible to eliminate the species from the area. However, if the introduction does not result in naturalization — that is, reproduction and recruitment are prevented — then any adverse impact will be temporary. Assessment using reproductively limited fish is a means of evaluating the impact of an introduction without making an irrevocable commitment. Fish with reproductive limitations cannot spawn, even if a suitable habitat is present: They are sterile or monosex. Both of the restrictions can be induced directly, or may be developed through a breeding program that produces only offspring with the reproductive limitation, as described in previous sections. The direct means of inducing monosex or sterile fish can be developed quickly and used in a preliminary assessment, but with some constraints, while a breeding system requires more time to develop, but can be perpetuated and accomplished on a commercial scale.

The outcome of introductions is not precisely predictable. If none of the introduced individuals survive, there should be no impact on the environment, while on the other hand, naturalization can result if reproduction and recruitment occur. Colonization may involve competition with natives or various other interactions within the local community, some of which can be catastrophic. Thus, purposeful animal transfers are fraught with uncertainties, and consequently, anticipation of the myriad of potential biotic interactions is nearly impossible.

Introduction of genetically modified organisms (GMOs) has been considered in the same environmental context as introduction of an exotic or a transplant. Depending on the degree of change and the phenotypic effect in a GMO, the same range of potential environmental impacts might be anticipated as would be hypothesized for exotic species

(244,245). However, in the US guidelines for engineering GMOs, ploidy manipulated fish are considered to be GMOs, which contradicts the use of the proposed system (246). On the other hand, Thorgaard and Allen (247) indicate that the use of sterile organisms has little negative impact on native populations; therefore, using monosex or triploid populations would seem to be logical means of evaluating the impact of GMOs.

Radonski and Loftus (17) and Horak (248) have indicated that the U.S. Nonindigenous Aquatic Nuisance Prevention and Control Act of 1990 generally ignores or minimizes the benefits of introductions, while emphasizing or exaggerating the risks, which is typical of much of the literature on introductions. A program that can functionally encompass the assessment of the introduction of either a GMO or an exotic fish would be useful. Presently, exotic-fish introductions are being considered under the umbrella of various guidelines that are recommended for use, most of which incorporate a series of decision boxes (249) or codes of practice (250,251). These processess are literature-review driven and also may include a survey of experts opinions, called "opinionnaires." The ICES (International Council for the Exploration of the Sea) guidelines are perceived as idealistic and restrictive, and they do not bind the signatories; therefore, they might even be ignored (15,252). The U.S. Nonindigenous Aquatic Nuisance Prevention and Control Act of 1990 (15) provides for a slightly more proactive risk assessment process and has been used in a first-case consideration for a fish, the black carp, by an aquatic nuisance species task force (227). The process is modeled after experience in agriculture pest assessment, which still consists primarily of basically literature review and panel hearings.

Selecting a course of action without an option to reverse the decision is not logical, but essentially has been the modus operandi for introducing species. Accidental escapes will continue to happen, but this eventuality, as well as purposeful introductions, can be approached pragmatically, scientifically, and realistically. In the final analysis, an introduction can be assessed only within the actual habitat or community under consideration. The binary decision either to forgo making the introduction or to try it out does not need to be such a decisive dichotomy; assessment can be done in an ecologically safe manner. Since colonization depends on reproduction and recruitment, evaluation of a fish introduction (transplant, exotic, or GMO) can be made in a real context without making a permanent, irretrievable commitment. If tests are conducted using reproductively limited fish, then effects can be documented without concern for recruitment. Further, if the reproductively limited fish are developed outside of the United States—for example, in the country of their origin—then the threat of accidental escape of nonlimited fish is also eliminated.

The level of security associated with various approaches to sex control can be considered in the context of acceptable risk. Stocking into a habitat that lacks some essential environmental element for spawning may be considered to provide adequate security; however, this safeguard is minimal, considering the capability of the fish to emigrate and gain access to conditions that meet reproductive requirements. This fallacious premise was posed in the original grass carp introduction into the United States. Additionally, recruitment may be limited by predation or other factors (219), but such factors should not be perceived as primary security measures on which to base an introduction. On the other hand, we can consider monosexing or sterilization as primary means of reproductive control (38,39,123).

Stocking only one sex can provide considerable security against reproduction, but the monosexing effort must be totally effective. Monosexing can be accomplished through a combination of gynogenesis, sex reversal and breeding for the production of single-sex progeny, or through androgenesis and subsequent breeding for the production of (all-male) progeny. Direct steroid induction by sex reversal is not recommended as a reproductive limitation for an assessment process, only as a means of developing a breeding program. In stocking monosex fish, we must consider that no prior introduction of mixed-sex populations has occurred. Monosexing may be appropriate for exotic fish, but is of limited value for transplanting native species into a new watershed, depending on the resident fauna, as closely related species with similar reproductive biology present the opportunity for hybridization. However, considering the selective disadvantage for successful reproduction of hybrids in a natural community (64), this method may still have some value.

Genetic-based sterility involves polyploidization, specifically triploidy, which has been achieved through some intergeneric hybridizations, resulting in triploid hybrids, or by induced chromosome manipulation (123,253). Hybrid reproductive potential may vary from complete sterility in triploids to apparently normal fertility (64). However, there may still be cause for concern regarding the basis of differential effects between sexes: Triploid females usually have poorly developed ovaries, while males have more extensive morphological development, but still with general gametic inviability (212,254,255). The specific mechanism for producing triploidy might occur by direct induction, as has been and still is being applied for grass carp, or through a breeding system (tetraploid × diploids) developed with polyploid induction.

We must consider introduction protocol when determining the appropriate time for applying a selected technique. The codes of practice and guidelines for the transfer of exotic fish (249–251) all have one basic shortcoming: No provision is made for actually assessing the effects of the transfer within the habitat of consideration. However, this deficiency can be rectified by incorporating the use of reproductive limitations in the process. To be most effective, the sex control mechanism should be developed prior to the introduction. Then only reproductively limited fish need be imported for assessment, or alternatively, broodstock that produce the reproductively limited progeny can be developed overseas and imported for breeding. At slightly lower levels of security, reproductive limitations can be induced directly in fish to be tested. Techniques for induction of triploidy were not developed for use with grass carp until after their introduction to the United States, but the methods have been successfully applied to black

carp so as to reduce the risk associated with any proposed introduction. This may avert some of the controversy that occurred with the grass carp. Methods to produce reproductively limited fish can be used to test introductions, as they have been developed sufficiently to be considered operational and available for incorporation into a functional assessment protocol. Additional techniques still await refinement or development, after which they can be added to our repertoire of options. Tetraploid induction is potentially one of the most logical systems to be refined in the future. However, this process will require several years to optimize, as will efforts to develop processes for androgenesis.

EYESTALK ABLATION

Joe Fox

Granvil D. Treece
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

The use of eyestalk ablation for induction of maturation in crustacean-rearing facilities is considered by most aquaculturists to be essential for predictable hatchery operation. Recent efforts at achieving maturation via naturally induced manipulation of physiochemical and nutritional parameters have also shown signs of success in some species. In female penaeid shrimp and female crabs, the production and storage sites of the gonad-inhibiting hormone (GIH) are located in the eyestalks. This hormone inhibits the maturation of the ovaries. In nature, some environmental factor or factors cause the decrease of this substance as the shrimp migrate from the estuaries to offshore areas, where they normally spawn. Eyestalk ablation, removal, or extirpation eliminates, or at least reduces, this inhibitory hormone to a level where full and accelerated maturation of the ovaries can take place. Ablation is the preferred methodology for captive maturation of penaeid shrimp due to (1) inhibitions inherent to most culture situations, (2) increased fecundity of ablated females, and (3) enhanced spawning frequency. The ablation process is discussed in this entry.

BACKGROUND

The stimulating effect of eyestalk ablation on reproduction of decapod crustacea was first evaluated for penaeid aquaculture in the early 1970s, when bilateral eyestalk ablation (both eyes) was attempted by French researchers (1). This methodology was found to stimulate rapid ovarian maturation; however, ablated females suffered high mortality (probably due to hormone desynchronization), and ova were typically reabsorbed without subsequent spawning (2–4). Those problems were alleviated by the ablation of only one eyestalk (unilateral eyestalk ablation), which provided moderate hormonal stimulus without reabsorption of ova or excessive mortality (3,5,6). Consequently, unilateral eyestalk ablation rapidly emerged worldwide as a simple procedure for inducing reproduction of numerous species of penaeid shrimp reared in captivity. Some researchers have even used ablation to improve growth rate of shrimp (7).

THE ABLATION PROCESS

The ablation process requires that only hard-shelled (intermolt) shrimp be used. Postmolt (Stage V) females are not recommended for ablation, due to increased potential for handling mortality associated with the softened exoskeleton. Premolt (Stage IV) individuals are also not used because of potential for molting during recovery from the ablation process. One study of note (8) has shown that ablation undertaken between 8 and 10 days postmolt resulted in significantly greater egg production versus ablation at 13–15 days postmolt.

Eyestalk ablation has been performed using a variety of methods, including simple severing with scissors, enucleation (9), cautery (4), and ligation (10). Each of these methods has been effective in removing or destroying the X organ/sinus gland complex. Stress can be reduced and losses minimized if shrimp are held in chilled water before and after ablation (2). To minimize stress, the ablation should be performed as quickly as possible and can be done under chilled water, but this is not always necessary or practical. However, in commercial hatcheries ablation is usually done in the early mornings, when temperatures are lowest. Female mortality due to ablation should be very low, but some mortality should be expected. The effects of eyestalk ablation vary with season of the year and stage in the molt cycle. Shrimp that are ablated as they prepare to enter their reproductive peak are more conditioned to yield a reproductive (as opposed to molting) response than those entering a reproductively dormant period (11,12). Within a molt cycle, ablation performed during premolt leads to molting, ablation immediately after molting causes death, and ablation during intermolt leads to maturation (13).

Ablation is performed on either the left or right compound eyestalk. The eyestalk chosen for ablation can, if possible, be one that is obviously infected or otherwise damaged. The damaged eye should be ablated in order to leave the shrimp with one unablated functional eye.

There are various methodologies used to accomplish the ablation procedure. All procedures require holding the female shrimp gently, yet firmly, and partially submerged in a separate ablation tank. The following methods are typically employed:

(a) **Enucleation** — Grasp the eyestalk just behind the eyeball, using the thumb and index finger. Squeeze hard and roll the thumb and finger outwards away from the body, thus crushing the eyestalk and squeezing out the contents of both it and the eye. The objective is to squeeze the contents outwards and not let them follow the eyestalk back into the head region. To aid in the removal of eyestalk contents, an incision on the front of the eye with a sharp blade may be made. Many penaeid aquaculturists prefer this method, however, it is simply a matter of preference. The authors have found incision of the compound eye to

be unnecessary. Enucleation has the advantages of simplicity and rapid clotting of hemolymph within the empty eyestalk. The main objective of any ablation methodology should be speed and reduced stress. The only detrimental aspect of enucleation is that it results in an open wound, which increases the potential for subsequent infection.

(b) **Ligation** — By this method, a string is tied around the base of the eyestalk as close to the carapace as possible. The string should be drawn fairly tight, causing the eyestalk to fall off in a few days (14). The procedure does not leave the shrimp with an open wound; however, successful ablation is often unpredictable.

(c) **Cautery** — This method calls for severing the eyestalk, followed by sealing of the wound via electrocauterization, heated forceps, or the application of a silver nitrate bar. Some practitioners simply cauterize the compound eye itself. In either case, the wound is rapidly sealed by scar tissue.

Pinching is considered the most readily applicable method of ablation. It can be undertaken by one person, and the wound should heal rapidly, without application of antibiotics. Ligation requires two persons, one to hold the shrimp and the other to tie the eyestalk. Cautery requires either a cauterizer or silver nitrate bar, either of which is often unavailable. Ultimately, the latter methods involve increased handling of subject animals.

FECUNDITY AND VIABILITY OF SPAWNS

Ovarian development in sexually mature females can commence within three days postablation, followed by a first spawn within approximately one week. The ablated population should be in full production three weeks after ablation. If ablated during the intermolt stage, the females will mature and spawn immediately. However, if ablated during early premolt, they will molt before maturing.

The fecundity and viability of spawns from ablated females have sometimes been inferior to spawns from females matured in the wild (13,15–17). Furthermore, commercial producers prefer postlarvae produced from wild, rather than captive spawns, which suggests that embryonic characteristics may influence juvenile survival and growth. For example, researchers found that eyestalk ablation of the crab *Paratelphusa hydrodromous* during the prebreeding season resulted in precocious ovarian growth (18). However, in comparison to normal mature ovaries, the ovaries from ablated females were smaller, higher in lipid composition, and more variable in distribution of yolk among oocytes. These differences presumably are consequences of hormonal insensitivity of ablated shrimp to physiological or environmental limitations, such as improper oocyte differentiation, nutrient storage, food supply, or temperature.

After spawning, unilaterally ablated females immediately reinitiate ovarian maturation and consequently spawn more frequently under nonnatural conditions than unablated females. This increased frequency can deplete female nutrient stores and is probably partially responsible for the lower survival rates of ablated to unablated females: Emmerson (16) reported that ablated *Fenneropenaeus indicus*, having a spawning frequency of five days, eventually spawned fewer eggs and died; however, it was suggested that this problem could be alleviated by proper nutrition.

ABLATION OF MALE PENAEID SHRIMP

Male ablation causes precocious maturation of *Marsupenaeus monodon* and *Fenneropenaeus merguiensis* (19); however, it has also been shown to increase gonad size and to double the mating frequency of smaller (25–30 g; 2–10.5 oz) *Litopenaeus vannamei* in comparison to similar-sized, unablated control shrimp (20). Eyestalk ablation of male shrimp has rarely been considered useful, and the authors do not recommend its use under practical culture conditions.

Further information on ablation and shrimp reproductive physiology can be found in References 21 and 22.

MATURATION WITHOUT ABLATION

A few researchers and one commercial hatchery in Venezuela have been able to achieve egg development, mating, and spawning of captive penaeids without ablation, utilizing temperature and photoperiod manipulation. However, as a rule, hatcheries have not been able to base a long-lasting, profitable, highly productive commercial operation on this approach to maturation.

MATURATION RESEARCH INTO HORMONAL CONTROL

Researchers in the 1980s were able to isolate and characterize hormonal systems involved in maturation and reproduction of the spiny lobster (*Panulirus* sp.) (23). Those same researchers later undertook the same study with penaeid shrimp (24–29). The only penaeid shrimp investigated was the pink shrimp, *Farfantepenaeus duorarum*. Progress with respect to elimination of some of the husbandry problems associated with maturation (egg fertility, decreased spawning rate over time) appears slow in coming. Unilateral eyestalk ablation is still the method of choice for maturation of penaeid shrimp. Until ablation can be eliminated successfully and replaced with a superior method, hatcheries must depend on it to sustain production.

Other important works dealing with crustacean hormonal control, ablation, and crustacean reproduction can be found in Refs. 30–67.

FEE FISHING

ROBERT R. STICKNEY
Texas Sea Grant College Program
Bryan, Texas

OUTLINE

In many parts of the United States and some other countries, it is possible to find privately owned ponds and lakes that have been stocked with fish and to which access can be gained by anglers. Charges for recreational fishing are usually assessed on the basis of the weight of fish caught; this type of fishing is called "Fee Fishing." Many fee fishing operators are also fish culturists. They may produce fish only for stocking their facilities, or they may both stock their own water bodies and sell excess fish to other culturists or fee fishing operations. Fee fishing has been present in the United States for at least a few decades (1). In Brazil, fee fishing is a more recent development—one that absorbs a large percentage of the fish produced by commercial aquaculturists in that nation.

PROVIDING A GOOD FISHING EXPERIENCE

While the majority of anglers may consider taking a boat or hiking to some place on their favorite stream, lake, or reservoir to be one of the most satisfying parts of the fishing experience, merely getting away from a hectic life for a few hours also has appeal for an increasing number of people. That may be why many of the fee fishing operations established in the United States are within short drives of large urban areas. Fee fishing can provide an angling opportunity without requiring a major expenditure in time for preparation or money for travel and gear. As important, perhaps, is that persons who frequent fee fishing operations can almost be guaranteed that they will catch fish.

The quality of fee fishing operations varies widely. (See Fig. 1.) The more successful ones have well-maintained facilities and offer a variety of amenities, in addition to well-stocked bodies of water filled with hungry fish. Fee fishing operations do not have to be located on expansive sites or even outside of city limits. Small earthen or concrete ponds, circular tanks, and raceways constructed on large lots within a city have been used successfully for fee fishing in some instances. More serious anglers may not be as much interested in such facilities as in larger ones located in more pastoral settings, but local, virtually backyard operations have some appeal, particularly to children's groups.

It is often not possible to obtain permits to establish a fee fishing operation on a stream, because such waters are considered to be public in many countries. Thus, fee fishing is typically restricted to small ponds and reservoirs on private land. A fee fishing operation may have from one to several bodies of water associated with it. Successful operations may rotate ponds, allowing fishing in some parts of the facility while closing others. The parts of the facility open for fishing may be altered periodically. Ponds or reservoirs might undergo renovation and restocking or just be closed, in order to move fishing pressure around and provide anglers with new surroundings.

Ponds or reservoirs may be square or rectangular in shape (see the entry "Pond culture"), or, to make them more aesthetically appealing, they may have irregular shapes. Pond banks are often landscaped to provide at least the impression of being far removed from the urban environment, even when they are located in or very close to a major city. Grassy, well maintained sites, with trees to provide shade and additional beauty, are common features.

SPECIES OF FISH

Fishes commonly found at fee fishing operations in the United States are channel catfish (*Ictalurus punctatus*), largemouth bass (*Micropterus salmoides*), and trout (rainbow trout, *Oncorhynchus mykiss*, being perhaps the most popular). Historically, some crawfish (*Procambarus* spp.) producers in Louisiana have opened their ponds to those willing to pay for the privilege of trapping the desirable crustaceans (2).

Catfish and bass fee fishing operations exist in most states, while trout operations are seen only at altitudes and latitudes where the water is sufficiently cold to allow the fish to survive throughout the year. Some state fish

Figure 1. A rural fee fishing operation in Brazil provides a restful setting.

and game agencies stock public waters with trout in the spring and sell special licenses that allow anglers to fish for them, with the idea that by the time the water temperature becomes too warm to support the trout, most of the fish will have been caught. It would be possible for fee fishing operations to do the same thing, but most depend on having year-round fishing for one or two primary species, so one would rarely find trout in a facility that is better suited for the maintenance of bass or catfish.

In Brazil, various native species, including some of the Amazon River region catfish, have been stocked in fee fishing ponds. Tilapias (*Oreochromis* spp.), which are exotic to Brazil, can also be found. Fishing for tilapias involves attaching a feed pellet to a hook, since the fish consume plankton in nature. Cheese and some other types of bait have also been successfully employed, but tilapias, which readily accept prepared feeds, find feed pellets to be a familiar dietary item. An individual Brazilian fee fishing pond may contain a mixture of species, or each species might be stocked exclusively in its own ponds, thereby allowing the angler to select the particular fish he or she wishes to catch. (See Figs. 2 and 3.)

HOW IT WORKS

For small operations, it makes sense to purchase fish for stocking. Small facilities may not have the physical space to maintain broodstock, hatch eggs, and rear fish to catchable size. If the operator is sufficiently trained and has the space and personnel, maintaining spawning and rearing facilities may be the most desirable approach. Having the complete life cycle under control of the culturist helps ensure a good supply of fish of known quality and,

Figure 2. This Brazilian fee fishing operation features an array of native and exotic species.

Figure 3. Ponds may contain multiple species or, as in this case, be stocked with only one species (in this case, red tilapia).

in large facilities, may provide significant cost savings relative to purchasing fish of catchable size. A third option is to purchase fingerlings and rear them for whatever period is required for them to reach a size at which they can be stocked into fee fishing ponds.

While the fish within a fee fishing pond vary in size, any that are caught should all be considered "keepers" by the anglers who fish for them. This is because, in most instances, fees are assessed based on the weight of the fish caught. At most fee fishing locations, anglers are required to keep all fish landed, a practice that could become contentious if the fish were considered too small to take home. Another alternative is to charge a set rate and allow anglers to take home a specified maximum number of fish.

By stocking heavily and limiting the amount of supplemental food provided in fee fishing ponds, the fee fishing operator can ensure that most anglers will catch fish relatively quickly and easily. As an incentive to keep anglers fishing once they have put a number of fish in the creel, as well as to keep the anglers returning for more, fee fishing operators may tag one or more fish that, if caught, will carry a reward rather than a cost to the angler.

As time passes, fish that have been caught and surreptitiously released or hooked only to escape, will learn to avoid a lure or baited hook. As a result, over a period of time, angler success may decline, even though there are plenty of fish in the pond. Removing fishing pressure by rotating ponds open to anglers may help reduce the problem by allowing time for the fish to "forget" what they have learned about lures and bait, but in some cases, it is best to drain the pond and remove all of the fish prior to restocking. The fish that carry reward tags, however, would probably be retained and restocked, since the operator is not particularly interested in having them landed; the more wary those fish are, the better.

AMENITIES

The wise fee fishing operator should cater to all of the needs of the anglers who frequent the facility. (See Fig. 4.) A snack bar can provide food and drink, while a bait shop

Figure 4. Amenities may be fancy or modest. Stools placed around this pond provide an extra touch of comfort for anglers.

should supply not only live bait, if used, but also fishing tackle for purchase or rent. Ice and coolers, sunscreen, first-aid supplies, and a number of other products that anglers might need are often available. Fishing licenses should also be available for sale to customers. Tours of hatchery facilities may or may not be made available.

Picnic tables and fire pits or barbecue grills can provide an added attraction for family outings. Toilet facilities, typically in the form of portable outhouses, should be readily available to customers. Coin-operated fish-feed dispensers may also be provided near rearing ponds, so that, for a cost, anglers also have the opportunity to feed fish that are being grown for future stocking.

Once the anglers decide to depart, they have their catch weighed, and the fee is assessed. Many operators will also clean the catch for an additional charge.

The success of fee fishing operations depends not only on providing anglers with a successful fishing experience, but also on location and expectations of anglers. Careful study of angler preferences, in terms of the species available for capture and the amenities considered desirable or indispensable, along with the level of interest, the willingness of potential customers to use the facility, and the frequency of use, help ensure success.

USFWS, Fish Technology Center
Bozeman, Montana

RONALD W. HARDY
Hagerman Fish Culture Experiment Station
Hagerman, Idaho

OUTLINE

INTRODUCTION

Feed additives are nonnutritive ingredients or nonnutritive components of ingredients that are included in feed formulations. Since the goal in formulating and manufacturing feeds is to supply nutrition to the animal, it appears to be contradictory to include nonnutritive ingredients in feeds. However, feed additives are necessary to stabilize feeds to prevent deterioration during storage, or to improve fish health, nutrition, or product quality. Feed additives augment the nutritional value of feeds or otherwise increase feed efficiency or fish production.

COMPONENTS OF INGREDIENTS

Water and fiber are constituents of many feed ingredients and their levels in feeds need to be considered during feed formulation. Water is an essential substance for terrestrial animals, since intake of water is necessary for life and for nutrient metabolism to occur. Fish live in water, so it is not necessary to supply water in the diet. Natural food for fish contains 65–85% water. However, fish must drink water to hydrate and dissolve manufactured feed particles in the gut. In addition, some fish species consume moist feeds more readily than dry feeds. Newly hatched salmon are a noteworthy example (1,2). Whether this difference is associated with feed texture or a physiological response in the digestive tract is unknown. Growth rates of brown trout (*Salmo trutta*) and turbot fingerlings were not affected by dietary moisture content (3,4). The need for dietary water may be related to species and the salinity of the environment. Fish must swallow water to hydrate dry feeds, and fish living in saltwater must excrete the salt. More research is needed to determine the relationship between water in the feed and salinity of the rearing environment. Regardless of the nutritional or feed consumption effects of feed moisture level, high levels of water in feeds necessitates special storage methods

(e.g., freezing) or the addition of antimicrobial or fungal compounds to prevent mold growth.

Fiber is a component of feed ingredients that is nonnutritive to most fish, has some beneficial effects at moderate inclusion levels, and can be detrimental to both feed quality and fish performance at high dietary levels. Fiber is indigestible to salmonids and other carnivorous fish and is highest in ingredients from plant origin because plants contain cellulose, hemicellulose, and lignins. Digestibility of fiber occurs as a result of enzymes produced by intestinal microflora in the digestive tract of species such as channel catfish (5). Digestive enzymes such as cellulase, which are needed to utilize the energy from fiber, are not produced by fish.

The beneficial effects of fiber are associated with its ability to stabilize or blend pellets. Low levels of fiber increase the stability of pellets produced by some processing methods. Fiber is added to semipurified diets used in research. Some types of fiber are added to practical diets, such as those manufactured by compression pelleting, which enhance pellet hardness and durability. However, high levels of fiber in a feed lower pellet stability, causing the feed to disintegrate quickly in water or fracture during handling.

ADDITIVES THAT AFFECT FEED QUALITY

Binders

A variety of substances are added to feeds to facilitate the binding of ingredients into a feed particle. Increasing the strength of the pellet increases feed efficiency by reducing the production of fines during shipping, handling, and after the feed is put in the water. Also, for species that require high feeding rates, or when feed is supplied improperly, a water-stable pellet will not disintegrate and foul the water. Some binders act as a lubricant during processing, thereby increasing production rates and decreasing horsepower requirements and wear on pellet dies.

Binders should be selected to match the requirements of the species fed, type of feed, and manufacturing method used to make pellets. Some binders are activated by heat and pressure while others require only moisture. Some binders provide additional nutritional value to the feed. Inclusion rates of binders vary; nonnutritive binders are limited to only 2–5% of the feed, while nutritive binders may be included up to 20–30%. Higher inclusion rates are appropriate for nutritive ingredients that have binding properties, such as fish hydrolysates.

The primary ingredients used in aquatic feeds vary in their ability to form a pellet, or pelletability. Inclusion of cereal grains (e.g., wheat flour and soybean meal) facilitates pellet formation. Other ingredients (e.g., wheat gluten, krill meal, and liver meal) also have high pelletability, but they are relatively expensive and are generally used only in larval, starter, or specialty feeds. Fish meal is the main protein source used in many aquatic feeds and has neutral to negative effects on feed pelletability. Use of low-ash fish meals (e.g., products with the bones removed either before or after drying) seem to make feed mixtures more difficult to pellet. Higher

moisture levels can overcome this problem, but require more energy to dry the pellet, thus increasing processing costs.

Many types of materials have been used for binding pellets and more are being developed. Aquatic feeds are just one of dozens of uses where pelleting is necessary. Other industries requiring pelleted products include terrestrial animal feeds, pharmaceuticals, human nutritional supplements, plastics, agricultural chemicals, fertilizers, and others. Binders used in aquatic feeds can be classified as plant extracts, animal extracts, minerals, polymers, and wood processing by-products. Carrageenan, alginates, and agar are extracts from marine plants and are used as binders in aquatic feeds. They are particularly useful in larval feeds and moist feeds. Products from plants include starches, pectins, molasses, and a wide variety of gums. Again the type of manufacturing used in pellet production must be considered when choosing a binder. Starches are the primary binder used for pellets produced by cooking extrusion, and molasses is most effective binder in compression pellets. Purified and semipurified diets used in nutritional research often use gelatin (extracted from terrestrial animal by-products) as a binder. Gelatin is also used in many specialty feeds. Collagen, also a by-product of terrestrial animal farming, is an effective binder in some applications. Urea formaldehyde condensation polymer is a pellet binder used in animal feeds at low levels (0.5–2%). It is not currently approved for use in feeds for aquatic species in the United States. However, the polymer is used in shrimp feeds in many parts of the world and is very effective.

Wood-processing by-products used in aquatic feeds include lignin sulfonate (Permapel), hemicellulose, and carboxymethylcellulose. These binders are used only with compression pelleting and are indigestible to fish. Besides contributing the binding of the feed pellet, lignin sulfonate allows more steam to be added during processing. The additional steam increases gelatinization of the starch, increasing the energy value to most species. Lignin sulfonate is added at levels of 2–4% of the feed. Spray-drying of the soluble by-product from pressed wood manufacturing produces a dry hemicellulose product. It is not used as often in fish feeds as lignin sulfonate and is limited to 2% of the feed. Carboxymethylcellulose is used more widely in applications other than in aquatic feeds, and its upper inclusion level is 2–3%.

Bentonite is a mineral (clay) that is mined for many purposes, and has been used in commercial aquaculture feeds for some time. It consists of trilayered aluminum silicate and is supplied in either a sodium or calcium salt form. Inclusion levels for both products are typically 1–2%. Sodium bentonite swells when water is added but calcium bentonite does not. These characteristics can affect final pellet quality and performance. Bentonite is also reported to bind with aflatoxins in the gut, thus carrying them through the digestion tract and preventing their absorption and subsequent toxic effects (6).

Moist and semimoist feeds require different binders than do dry feeds (<10% moisture). Moist feeds contain 25–70% water. For example, the H440 semipurified research diet and other such diets use gelatin as a

binder, usually at 4–10% of the diet, depending on the specific feed formulation (7). Moist diets containing a mixture of dry meals and a wet-fish component sometimes use alginates to hold pellets together. A comparison of binders using a 41% moisture feed showed that calcium and alginate were more effective than corn starch, gum, agar, carboxymethylcellulose, chitosan, carragenaan, and collagen (8). Alginates require calcium ions to be activated. Calcium can be provided by fish bones or inorganic calcium sources added to the feed.

Antimicrobial Compounds

Mold, yeast, and bacteria can grow in feeds containing more than 12% moisture, unless the feed is frozen or the water activity of the feed is lowered by the addition of sugar, salt, glycerol, or propylene glycol. Water (i.e., steam) is added to feed mixtures during pelleting, and the resulting pellets are dried before being sold. Pellets generally are dried to 8–9% moisture, but exposure to humid conditions or rain can increase pellet moisture levels sufficiently to support mold growth. If mold is visible in a sack of feed, it should be discarded. Before mold is visible, it is well established. Many molds produce compounds that are toxic to fish (9) and, at the very least, will decrease feed consumption.

Mold inhibitors are routinely added to fish and animal feeds. Many proprietary products containing a combination of mold inhibitors are available. A list of antimicrobial compounds used in feeds is presented in Table 1.

Some fish feeds contain moisture levels in excess of 12%. The Oregon moist pellet (OMP) contains 28–32% moisture and must be stored frozen to prevent spoilage. Semimoist feeds containing 17–25% moisture are used as starter feeds for a variety of fish fry. In these feeds, microbial spoilage is controlled by a combination of approaches. The first element of microbial control is to begin with a feed

Table 1. Antimicrobial Compounds Used in Feeds[a]

Compound	Limit
Benzoic acid	0.1%
Calcium propionate	None
Calcium sorbate	None
Distearyl thiodipropionate	0.005%
Formic acid	2.5%
Methylparaben	0.1%
Potassium bisulfate	Not for use in B_1 sources
Potassium metabisulfite	Not for use in B_1 sources
Potassium sorbate	None
Propionic acid	None
Propylparaben	0.1%
Sodium benzoate	0.1%
Sodium bisulfite	Not for use in B_1 sources
Sodium metabisulfite	Not for use in B_1 sources
Sodium nitrite	0.002%
Sodium propionate	None
Sodium sorbate	None
Sodium sulfite	Not for use in B_1 sources
Sorbic acid	None

[a]From Reference 10.

mixture that has a low microbial load. Pasteurizing wet fish ingredients accomplishes this. A second element of microbial control is to add antimicrobial compounds to the feed. Naturally, the antimicrobial compounds must be ones that do not lower feed palatability or otherwise affect fish health or performance. The third element of control is to lower water activity, as mentioned earlier. This is the same principle used to preserve jam and jelly; sugar lowers water activity in these products, reducing the available or unbound water below levels sufficient to support microbial growth. The final element of microbial control is to package feed in a modified atmosphere of inert gases, such as nitrogen or carbon dioxide. Aerobic microorganisms cannot grow in an atmosphere lacking oxygen. Once the feed package is opened, it must be used rapidly or frozen.

Antioxidants

Feeds for many fish species contain very high levels of polyunsaturated fatty acids relative to terrestrial animal feeds. Unsaturated oils are susceptible to oxidation, and oxidizing lipids decrease feed quality by forming harmful free radicals and other compounds and by destroying other nutrients. Once polyunsaturated fatty acids begin to oxidize, the oxidation process is self-sustaining (autoxidation). Antioxidants are chemical compounds that prevent or interrupt autoxidation.

The occurrence of autoxidation requires a substrate (e.g., polyunsaturated fatty acids), but is accelerated by a variety of environmental factors, including increased temperature and exposure to pro-oxidants e.g., copper and iron, light, UV radiation, and oxygen (10). Antioxidants protect the feeds from autoxidation, but an abusive feed storage condition will eventually result in autoxidation, regardless of antioxidant content of feeds.

Autoxidation consists of three steps that result in an autocatalytic reaction that will continue as long as substrate is available and no antioxidants are present. The initiation step requires oxygen, a substrate, and a catalyst and results in free radical production (10). The propagation step itself forms more free radicals, which is why the process is described as autocatalytic. The quantity of free radicals produced by the oxidation of one fatty acid increases with the number of double bonds possessed by the fatty acid. Free radicals and peroxyradicals combine to form stable products in the third step of the reaction, known as termination.

There are two types of antioxidants, hydrogen donors and chelates, that tie up metallic pro-oxidants, (e.g., copper and iron). Thus, by preventing the formation of free radicals (chelation) or by quickly making the free radicals unreactive (hydrogen donors), the antioxidants prevent oxidation from continuing. After antioxidants donate hydrogen atoms, they no longer have antioxidant properties, which is why they are called sacrificial antioxidants. When all of the sacrificial antioxidants in a feed are used up, oxidation proceeds rapidly.

Sacrificial antioxidants commonly used in aquatic feeds include ethoxyquin (santoquin), butylated hydroxytoluene (BHT), and butylatede hydroxyanisole (BHA) (11). Other antioxidants of this type include thiodipropionate, propyl

gallate, and thiodipropionate, but those are not commonly used in commercial aquatic feeds. Ethoxyquin is an amine antioxidant and is usually added directly to oils, whereas BHT and BHA are added to mixed feed ingredients. Legal limits have been established for these additives in oils and feeds, but since these antioxidants are sacrificial, their detectable levels diminish as they react. Inclusion levels in finished feeds are typically 0.1% for BHA and BHT, and slightly lower for ethoxyquin. Tocopherols are natural antioxidants found mainly in plant oils, and alpha-tocopherol is a primary source of vitamin E. Beta, delta, and gamma tocopherols are effective antioxidants, but have less vitamin E activity than alpha-tocopherol.

Chelating antioxidants include both natural and synthetic compounds. Ethlyenediaminetetraacetic acid (EDTA) is a synthetic compound that chelates pro-oxidant metals and is commonly used to prevent oxidation. Ascorbic acid also functions as a chelate. A synergistic effect has been observed when phenolic or amine (sacrificial) antioxidants are combined with antioxidants that chelate pro-oxidants. This combination helps prevent oxidative damage by inhibiting participation of the pro-oxidant in the reaction and by reacting with any free radicals that are formed.

Some nutrients commonly founds in feeds also have antioxidant activity including, ascorbic acid, phytic acid, lecithin, and selenium (11). These sources can be expensive to add as antioxidants, and depletion in the feed over time may indicate that oxidation is in progress.

Feeding Stimulants

Circumstances are encountered in aquaculture whereby fish will not readily consume formulated feeds. These situations include, but are not limited to, first-feeding larvae, fry, or fingerlings being weaned from live food to formulated feed, low water temperatures, disease, culture of wild-strain fish, and addition of ingredients that reduce the palatability of feeds. Feed consumption is influenced by several factors, with flavor, taste, or smell of the feed being very important. Flavorings to enhance feed palatability have been used extensively in the pet food industry for many years and their use in aquaculture is increasing. Feeds for farmed fish species do not often use flavoring except in specific situations.

Single compounds and synthetic ingredients that increase fish feed consumption have been identified. Not all species of fish respond to all ingredients. Many natural ingredients are highly palatable and can increase feeding response and feed intake. Several feeding stimulants work synergistically. Fish meal and fish hydrolysates, krill meal and krill hydrolysates, shrimp meal, liver meal, fish solubles, and fish oils all have a positive response on the feeding behavior of many species of fish. Very high inclusion levels of the hydrolysates can decrease palatability and feed pH. High levels of liver meal can interfere with pellet formation depending on the processing method used. Thus, the use of these ingredients must be matched with feed pelleting constraints and fish feeding response.

ADDITIVES THAT AFFECT FISH PERFORMANCE AND QUALITY

Fish performance can be affected by feed additives in a number of ways. Metabolic reactions can be stimulated and directed by feeding enzymes and hormones. Pathogenic organisms in the gut can be controlled by feeding chemotherapeutants. Probiotics can enhance the immune response of fish. The addition of pigments to the feed results in flesh with appropriate color to meet consumer expectations, as is the case with salmon. In addition, pigment supplementation to feeds can alter external coloration of fish.

Enzymes

Increased growth, improved nutrient utilization, and pollution reduction are all reasons for adding enzymes to formulated feeds. If feeds only contained the ingredients that fish consume in the natural environment, enzyme supplementation would not be necessary. However, natural foods are expensive and not practical for most aquaculture operations.

Young animals typically feed on a variety of zooplankton, and it is thought that the endogenous enzymes of the zooplankton aid digestion. The growth rate of *Marsupenaeus japonicus* (shrimp) larvae was improved with the addition of microencapsulated bovine trypsin to a formulated feed (12). This observation alone was significant, but an increase in total endogenous protease activity was also observed. The supplemented enzymes seemed to initiate the metabolic process in the digestive system. Microencapsulated amylase, a starch digesting enzyme, also increased growth of shrimp larvae (12).

Enzymes can also be beneficial in adult animals with fully functional digestive systems. Phytate is the storage form of phosphorus in seeds, such as corn and wheat, can bind minerals making them unavailable to fish. Phytase is an enzyme that releases phosphorus from phytate, thus increasing its availability to monogastric animals (e.g., poultry, swine, and fish). Phytase is heat sensitive, and its activity is lost if it is added to feeds before extrusion pelleting. When it is added to fish feeds after pelleting by topdressing, it increases phosphorus availability, especially in catfish (13–17).

Hormones

Some feed ingredients contain anabolic steroids and others contain phytoestrogens, compounds that mimic the activity of estrogen. Fish meal produced from mature fish contains biologically significant quantities of testosterone compounds that stimulate muscle growth (18). Adding testes to fish carcasses increases the growth rate of salmon fed diets containing fish meal produced from the fish carcasses (19). The effects of phytoestrogens on fish growth or maturation is not well known. Phytoestrogens are present in several grains (9).

Hormones have been studied as feed additives and their use in fish production has been reviewed (20,21). Hormones are used to influence fish growth rates, sexual development, and osmoregulation. Sex reversal is the main

use of hormones added to fish feeds at the present time, particularly for species such as tilapia where one sex grows faster than the other (11).

Recently, researchers have been investigating the effects of growth hormone on fish growth. Injections of recombinant bovine somatotrophin (bST) dramatically increases growth in rainbow trout, catfish, and sturgeon (*Acipenser* sp.) (22,23). An oral form of bST has not yet been developed. In the future, it may be feasible to add growth hormone to feed to influence growth and reduce the time required to raise long-lived fish, such as sturgeon, to maturation. Growth hormone is unlikely to be used in food fish production but might have application in stock restoration and reintroduction efforts.

Pigments

The color of flesh, skin, or eggs of farm-reared fish has often been used as a measurement of quality. Pigments found in salmon and other fishes are not synthesized but must be provided in the diet. A variety of natural pigments is found in both plant and animal feedstuffs. Some of these pigments improve product quality, but other pigments have a negative influence on product quality. Yellow pigment from xanthophyll in corn is undesirable in channel catfish (24) and trout (25), but is desirable for yellowtail (*Seriola quinqueradiata*), red sea bream, (7) and muskellunge (*Esox masquinongy*) (26). Differences among species have been observed in utilization of pigments (27–29).

Because of the relationship of color to perceived quality, pigmentation in farm-reared salmonids has been extensively studied (7,30,31). Carotenoid pigments are responsible for coloration in salmonids, and they must be added to feeds. Besides being important for consumer acceptance, carophylls (i.e., B-carotene) may serve as a precursor to vitamin A. Both canthaxanthin and astaxanthin are carotenoid pigments that provide a reddish-orange color to salmonids. Astaxanthin is the primary carotenoid consumed by wild salmon, and is available either in synthetic form or from natural sources.

Chemotherapeutants

Antibiotics can be effectively administered through the feed to combat pathogens. Prophylactic use of antibiotics, and their use to increase growth and feed efficiency is very controversial. Concerns for stimulating resistant strains of pathogens to antibiotics and introducing the drugs or their metabolites into human foods are the primary concerns. Because of these concerns and the economic cost, antibiotics are not frequently used in aquaculture to increase animal performance. Feed-borne therapeutants are often effective in treating disease. Currently, only oxytetracycline is approved for use in the United States, but efforts are underway to gain approval for florfenicol and there is some interest in pursuing approval for amoxycillin. In the United States, medicated feeds for both aquatic and terrestrial animal production have specific labeling requirements, withdrawal periods, and other restrictions required by the Food and Drug Administration of the U.S. Department of Agriculture. The aquaculture industry has a very limited number of antibiotics available for use, relative to terrestrial animals, due to regulatory restrictions and the cost of obtaining regulatory approval for minor use species.

Hagerman, Idaho

OUTLINE

It is evident that the quality of fish feeds is determined in large part by the quality of the feed ingredients used to make the feed. High-quality fish feed cannot be produced from low-quality ingredients. The challenge for fish-feed manufacturers is to determine which measurable characteristics contribute to high-quality feed ingredients. Feed ingredients are complex mixtures of organic and inorganic compounds that are subjected to a variety of cooking, extracting, and drying processes, each of which can vary between manufacturers and between individual batches. Variation in plant products (from crop to crop), in animal or fish products (from species to species), and in the components of the raw primary material (plant or animal) that make up the utilizable by-product further complicate the task of making consistent the properties, composition,

and quality of feed ingredients. Superimposed upon these variables are the potential changes that can occur during storage, first after a feed ingredient is produced but before it is used in feed manufacture, and then after a feed has been produced. Enumerating all of the possible factors that affect the quality of feed ingredients is an imposing task, but limiting our concerns to the major factors affecting the quality of principal feed ingredients is generally sufficient for the needs of the aquaculture feed industry.

It is also evident that the aquaculture feed industry needs to have rapid, simple, inexpensive chemical tests that accurately predict the nutritional quality of feed ingredients for fish and shrimp. For simple feed ingredients (e.g., fats and oils) that are subject to just a few major quality problems, such tests exist. At the other end of the spectrum is fish meal, which is subject to nearly all the conceivable quality problems. For decades, scientists have devised chemical tests to predict the nutritional quality of fish meal, and, while these tests have proven useful, no single test has been developed that measures all of the quality parameters of fish meal. Between these two extremes lie most other feed ingredients; they often have relatively complicated quality problems, ones that nonetheless are well-defined and are detectable with appropriate testing.

This entry covers the main factors that govern the quality of the major feed ingredients used in aquatic feeds, and the various ways in which specific problems can be identified and, if possible, quantified. The quantification is important, because no feed ingredient is perfect with respect to quality, and price should correlate with quality. As the sensitivity of analytical methods improves, and as new tests for measuring quality are developed, the aquatic feed industry must learn what limits are acceptable in feed ingredient quality testing, and which test results most accurately predict nutritional quality and enable the buyer to avoid poor-quality or potentially lethal batches of feed ingredients.

GENERAL CONSIDERATIONS

Feed Ingredient Definitions

Feed ingredients all have standard definitions that follow the International Feed Vocabulary, which is designed to give a comprehensive and concise name for each ingredient (1). Each name is based on six components: (a) the origin, including scientific name, common name, and chemical formula (if appropriate); (b) the part fed to animals, as affected by process(es); (c) the process(es) and treatment(s) to which the part has been subjected; (d) the stage of maturity or development; (e) cutting (applicable to forages), and (f) grade. An international feed name for each ingredient is based upon these components. For example, anchovy meal is named as follows:

> Fish, Anchovy, *Engraulis ringen*, meal, mechanically extruded.

Soybean meal is named as follows:

> Soybean, *Glycine max*, seeds without hulls, meal, solvent extracted.

Each feed ingredient also has been assigned an international feed number, which is a six-digit number used as identification, especially in computer databases. The feed identification numbers for the anchovy meal and soybean meal are 5–01–985 and 5–04–612. These feed ingredient names and numbers and the nutritional data can be found in a number of publications (2,3). In the United States, the Association of Feed Control Officials (AAFCO) provides definitions of feed ingredients that are more descriptive, having been developed over many years. The AAFCO utilizes international feed names and numbers in its ingredient identification systems. This information is available through the Feed Composition Data Bank, National Agricultural Library, 5th Floor, 10301 Baltimore Blvd., Beltsville, MD, 20705, USA.

Chemical Tests: Limits and Value

The results of chemical tests are used to evaluate and rank feed ingredient quality. The aims of the tests are to determine whether batches of feed ingredients meet the specifications associated with high quality. For the most part, the results of these tests enable ingredient buyers to avoid poor-quality feed ingredients: those that do not meet specifications because of adulteration, poor-quality raw material, inadequate or excessive processing, deterioration associated with storage, or microbial contamination. The value of these tests may be compromised by a number of factors, including improper or non-representative sampling of the feed ingredient, mistakes made in the laboratory while conducting the tests, inadequate replication of measurements, imprecise lab technique, errors in calculations, and lack of understanding of the value and limits of the results. What follows are descriptions of the major chemical tests conducted on aquatic feed ingredients, with emphasis on why each test is done, what it is intended to measure, and what the results mean with respect to ingredient quality, all as they pertain to feeds for aquatic species.

FISH MEAL

Steps in Manufacturing that Affect Quality

World production of fish meal has remained relatively constant in recent years, at an annual production level of 6–7 million metric tons, and it is not expected to increase significantly in the future (4). Currently, aquaculture uses about 15% of the world supply of fish meal each year, while 50% is used for poultry, 25% for swine, and 10% for all other uses. Fish meal remains the principal protein source in feeds for the salmonids, for shrimp, and for most marine species, constituting between 35 and 50% of most feed formulations (5). Because of its high proportion in aquatic feeds, its relatively high cost, and its importance in supplying amino acids for tissue synthesis, fish meal is the feed ingredient most closely scrutinized. Despite this scrutiny, defining high quality in fish meal remains a complex undertaking.

"Fish meal" is actually a generic term for a range of protein meals prepared from numerous species of fish and fish offal. Most fish meal is produced from whole fish of species not generally used directly for human consumption. The major species of fish used to produce fish meal and the countries in which various fish meals are produced are listed in Table 1. Because the species of fish used to produce fish meal determines many of its quality characteristics, fish meals are generally defined by species. Proximate composition of fish meal varies with species, primarily in the proportion of protein and ash in the final meal (Table 2). Fish meals produced from bony fish, such as mackerel or menhaden, contain a higher percentage of ash (minerals) and lower percentage of protein than do meals produced from less bony fish, such as herring, capelin, pilchard, and anchovy. The percentage of crude lipid is usually in the range 7–10% for herring, anchovy, and menhaden meals, and around 5% for white fish meal (Table 2). Another defining quality characteristic that depends upon the species of fish used to produce the meals is the color of the meal. Fish meals are sometimes categorized as either "white" fish meals or "brown" fish meals. White fish meals are produced from white-fleshed fish, such as pollock and whiting, while brown fish meals are produced from mackerel, menhaden, and anchovy. White fish meals are usually produced on fishing vessels from very fresh, cold-water fish; brown fish meals are produced in tropical or subtropical areas, where fish spoilage is rapid. In the past, white fish meals were considered superior to brown fish meals for use in aquatic feeds, most likely because of differences in quality associated with raw material freshness and/or conditions of manufacture. Because brown fish meals were typically transported by ship in bulk, the meals were allowed to age (oxidize) outdoors, to prevent combustion caused by

Table 1. The Types of Fish Meal Produced by Countries that Export It[a]

Country	Type(s) of Meals
USA	Menhaden (FD and SD)
	Pollock (white fish meal) (SD)
Canada	Herring (SD)
Peru	Anchovy (FD and SD)
Chile	Anchovy and horse mackerel (FD and SD)
South Africa	Pilchard
Norway, Iceland	Herring and capelin (LT)
Denmark	Sand eel, pout, and sprat (LT)
Japan	Sardine

[a]FD = flame-dried, SD = steam-dried, LT = low-temperature dried.

Table 2. Average Percentage of Protein and Ash (on an as-fed basis) in Various Fish Meals[a]

Type of Fish	Crude Protein (%)	Crude Lipid (%)	Ash (%)
Herring, capelin, sand eel	70–72	8–9	10–11
Anchovy, horse mackerel	65	7–8	14–15
Menhaden	64–65	9–10	17–19
White fish meal	62–63	5	21–22
Fish processing waste	55–60	9–10	18–24

[a]It is reasonable to expect that values for crude protein and ash should be within 1% of the published values.

heat production during shipping. Thus, the quality of the lipids in brown fish meals produced in South America was lower than that in white fish meals. The addition of antioxidants has reduced that problem. Recent studies indicate that there is little or no difference in nutritional quality between white fish meal and brown fish meal, provided that the freshness of the raw material and the conditions of manufacture are similar (6).

To understand the factors that determine the quality of fish meals and the rationale behind the chemical tests used to measure fish meal quality, one needs to be familiar with the manufacturing processes used in fish meal production. Fish are caught, then held onboard the catcher boats for various periods, before being delivered to fish meal factories. The choice of the net used to catch the fish and the way in which the fish are brought on board the fishing boat are the first steps in which quality can be affected. Large nets that allow fish to be crushed and net unloading practices that further physically damage the fish can reduce quality by rupturing cells and releasing proteolytic enzymes that begin to hydrolyze cellular and structural proteins in the fish. Enzymatic protein hydrolysis is accelerated by warm temperatures, meaning that the longer the fish remain in the hold of the fishing boat, especially without refrigeration or ice, the more hydrolysis will occur. The fish are then delivered to the fish meal factory, where they are unloaded into large pits prior to being processed. Again, thermal and physical abuse of fish at the bottom of pits increase the likelihood and extent of protein hydrolysis.

Once the fish are taken into the factory, they are rendered and dried to produce fish meal (Fig. 1). First, the fish are cooked, to release fish oil and to denature protein. Cooking is a continuous process, beginning with heaters and ending in a cooking vessel when the fish reach about 90 °C (194 °F). This thermal pressing is sufficient to denature and inactivate proteolytic enzymes in the fish, so there is no further enzymatic hydrolysis of the protein. No solid material, oil, or water is lost during this stage, because the cooking takes place in a closed system. After cooking, the fish is pressed on a screen to remove water and oil. The residue, or presscake, then moves to a dryer, where more water is removed by heat in the form of a flame, hot air, or steam-jacketed surfaces, the latter with or without vacuum. The liquid fraction removed by pressing is separated by centrifugation into water and oil fractions. The water fraction (stickwater), which contains soluble protein, is concentrated by heating. After concentration to about 50% moisture, the stickwater, now called "solubles," is generally added to the dryer where presscake material is being dried. Fish meal containing both presscake and solubles is called "whole fish meal"; fish meal made from dried presscake only is called "presscake meal." On some fish processing vessels containing fish meal factories, there is no room for the equipment for recovering and concentrating the stickwater. On these vessels, the stickwater is discarded. Most white fish meals made in the past were actually presscake meals.

From this brief description of fish meal production, one can identify critical steps or stages where quality can be influenced by variability in the freshness of the raw material or by differences in processing. Chemical tests for fish meal quality yield results that relate to one or more of the critical steps in the process. The first stage affecting quality is raw material freshness, which is judged by the levels of volatile and biogenic amines both in the raw material and in the finished fish meal. The second stage affecting quality is presscake drying, which involves drying temperature and time. The third stage affecting quality involves the solubles: specifically, the conditions (time and temperature) of heating during concentration. The final stage of fish meal manufacturing affecting quality is whether or not solubles are added back to presscake (either from the same or from a different batch of raw material). This last point is often overlooked, and it can explain contradictory results with respect to fish meal quality that are sometimes obtained from different chemical tests on a single batch of fish meal, because some tests measure changes associated with the soluble fraction, others those with the presscake fraction.

Freshness Indices for Fishery Products

Degree of freshness of the starting material is an important factor contributing to the quality of the finished fish meal. The scale of degree of freshness runs from "fresh" (meaning a product having a chemical composition nearly identical to that of the live fish) to "deteriorated" or "spoiled" (meaning that chemical and microbial changes postmortem have proceeded significantly). While there are many factors that contribute to the rate of decomposition and to the chemical changes characteristic of spoilage (e.g., species of fish, handling, sorting of the product), the most important factor affecting quality is the postcapture, preprocessing holding temperature (7,8).

"Fresh vs. spoiled" should be distinguished from "frozen vs. not frozen," because it is a common practice to equate "frozen" with "not fresh." Proper freezing of fish postcapture includes having the fish muscle temperature
Figure 1. Simplified schematic presentation of the steps in the manufacturing of fish meal.

pass through the critical freezing zone (0 to $-5\,°C$, 32 to $23\,°F$) as rapidly as possible, to minimize (i) the formation of large ice crystals within tissue cells, (ii) the residence time of concentrated salt solutions with the proteins, and (iii) effects on intracellular pH changes (9). Proper freezing and storage of fish at $-20\,°C$ ($-4\,°F$) or lower can help keep a product fresh. Therefore, a fresh product that has been properly frozen will still have many of the characteristics (chemical especially, and usually — depending on species — textural) of the freshly caught product; conversely, a spoiled product that has never been frozen should not be called "fresh."

The ideal test for fish freshness should be accurate, sensitive to the early stages of product decomposition, repeatable, rapid, relatively inexpensive, and applicable to a large number of species. The tests that have been developed and applied historically are the following: for microbial decomposition — total volatile nitrogen (TVN), total volatile bases (TVB), biogenic amines (e.g., histamine), and microbial profiles; for reduction of raw food fish freshness — nucleotides formed from the breakdown of adenosine triphosphate (ATP), principally inosine monophosphate and hypoxanthine (K_1 value); for overall microbial proliferation — microbial identification and numeration; and for general reduction of product freshness — degree of lipid oxidation. Although the K_1 value is the only truly sensitive index of early product freshness, it is typically used to assess fish for the sashimi market rather than fish destined to be processed for fish meal.

Total Volatile Nitrogen, and K_1 Value. There have been several tests used in the seafood industry to estimate the freshness of fish and shellfish. Several of these rely on the measurement of nitrogenous compounds; others attempt to estimate the level of lipid oxidation (discussed elsewhere in this volume) or degradation products of adenosine triphosphate (ATP). Total volatile nitrogen (TVN) can be measured; it includes both total volatile bases (TVB) and total volatile acids (TVA). TVB analysis measures low-molecular-weight volatile bases and amine compounds produced by microbial decarboxylation of amino acids; this test is commonly used as a microbial spoilage indicator. TVB also includes trimethylamineoxide (TMAO), which is a molecule in marine fish and shellfish associated with osmoregulation. In frozen fish, TMAO is reduced by endogenous enzymes to dimethylamine (DMA) and formaldehyde, whereas in fresh or iced fish, it is reduced by bacterial enzymes to trimethylamine (TMA) (10,11).

Although the various fractions of TVN can be measured by methods such as distillation/titration (12), flow injection analysis with gas diffusion (13), and gas chromatography (14), the volatility of these compounds affects their levels in products (e.g., fish meal) that have undergone thermal processing, or in pelleted feeds. In fish meal production, for example, the TVN compounds can evaporate during the drying stage. Pike (15) held herring at about $7\,°C$ for up to seven days before processing into fish meal. TVN values in the raw material increased from 22 to 143 mg N per 100 g fish during this period. Norwegian LT-94 fish meal specifies TVN values no higher than 40 mg N per 100 g fish at the time of processing, compared to allowable levels for lower grade fish meal no higher than 90 mg N per 100 g fish (16). If there were no loss of TVN during the fish meal drying process, TVN values should be concentrated by four to five times in dried meal. However, TVN values in herring, menhaden, anchovy and LT-94 fish meals typically range from about 28 to 155 mg per 100 g sample (17), because of the loss of TVN compounds during drying. In frozen herring, TVN values measured in the fish before drying increased, from 83.5 mg N per 100 g after thawing to between 337 and 412 mg N per 100 g, after 12 days of storage at $2–5\,°C$ ($35.6–41\,°F$) (15). Values in dried presscake meal ranged from 82 to 100 mg N per 100 g, far below the theoretical range of 1350 to 2060 mg N per 100 g another demonstration that TVN compounds are lost during drying.

Biogenic Amines. Conditions that favor the formation of biogenic amines and the analytical methods to measure them are discussed in the section "Tests for fish meal quality performed on dried meal."

Nucleotide Degradation in Fresh Fish. The K_1 value is an index that is widely used in Japan for estimating the freshness of fish (18). The K_1 value is a ratio of the concentration of ATP to that of its degradation products (Fig. 2); it provides an assessment of freshness prior to bacterial spoilage. The assay of nucleotide degradation products required for the calculation of the K_1 value can be performed with high pressure liquid chromatography or by polarographic methods using immobilized enzymes (19). For fresh fish, K_1 values range from $<0.2–0.4$. The reactions that degrade ATP occur rapidly after harvest, especially if the fish are stressed during capture. The little ATP that is left is usually degraded during the first few days of refrigerated storage. Therefore, the K_1 value can be simplified by eliminating the adenosine nucleotide compounds from the calculation:

$$K_1 = 100 * ([HxR] + [Hx])/([HxR] + [Hx] + [IMP])$$

where HxR = inosine, Hx = hypoxanthine, and IMP = inosine $5'$ − monophosphate (20).

Degree of Lipid Oxidation. Methods for measuring the degree of lipid oxidation are discussed in the entry "Lipid oxidation and antioxidants."

$$ATP \longrightarrow ADP \longrightarrow AMP \longrightarrow IMP \longrightarrow Inosine\ (HxR) \longrightarrow$$

$$Hypoxanthine\ (Hx) \longrightarrow Xanthine\ (Xa) \longrightarrow Uric\ acid$$
where:

   ATP = adenosine triphosphate

   ADP = adenosine diphosphate

   AMP = adenosine monophosphate

   IMP = inosine-5-monophosphate

Figure 2. Degradation pathway of ATP.

Tests for Fish Meal Quality Performed on Dried Meal

Proximate and Amino Acid Composition. The proximate composition of fish meal is the first characteristic upon which fish meal quality is judged. The composition depends upon the species of fish used as raw material, upon the amount of solubles added during drying, and upon whether fish processing waste (very high in ash) was used to produce the meal. The proximate composition of fish meals should be compared to published values (3), and meals having either protein levels lower than expected (by ≥1%) or ash levels higher than expected (by ≥1%) should be avoided (or else purchased at a discount).

The amino acid composition of fish meal can vary with the degree of thermal abuse during drying and with the proportion of processing by-product included in the raw material. Thermal abuse can reduce the protein digestibility of fish meal, and such a reduction is usually associated with decreased bioavailability of essential amino acids such as lysine and methionine (20a); thus, the nutritional value of the meal will be reduced by thermal abuse. The amino acid composition of fish meals produced from fish processing by-products, such as the by-products of filleting or surimi, can vary substantially, depending upon the proportions of muscle, viscera, skin, and bones in the raw material. In both cases, examination of the amino acid profiles can be useful. The concentrations of individual amino acids can be determined by acid or alkaline hydrolysis of the protein, followed by separation and quantification of the amino acids by ion-exchange, gas-liquid, or high-performance-liquid chromatography (20b). It is important to remember, however, that although the total amino acid compositions may be similar between two different fish meals, the *in vitro* digestibilities of their specific amino acids may differ (Table 3).

Water-Soluble Protein Test. The water-soluble protein test is sometimes used to provide insight into the extent of enzymatic hydrolysis (decomposition) in the raw material before processing, the assumption being that the products of hydrolysis (e.g., peptides and free amino acids) are soluble compounds. In practice, however, this test is not an accurate measure of the freshness of the raw material. In the fish meal manufacturing process, water-soluble protein is removed from the cooked fish during the pressing process, along with fish oil. After oil removal and

concentration of the water fraction, the solubles may or may not be added back to the presscake in the dryer. Thus, applying the water-soluble protein test to fish meal will indicate whether the fish meal contains solubles, rather than indicate the freshness of the raw material. If solubles have been added back in order to produce whole fish meal, then the value for water-soluble protein should be around 30–35% of total protein. If the value is significantly higher, either more solubles were added than normal, or the raw material had undergone significant enzymatic hydrolysis before processing. If the value is very low (<5%), the fish meal is not whole meal, but rather presscake meal (without solubles). If the value is between 5 and 30%, the most likely cause is that a low proportion of solubles was added to the presscake during the drying process. This test is affected by the amount of fish solubles contained by the fish meal, so it does not necessarily measure the degree of enzymatic hydrolysis of the raw material or predict the nutritional quality of the fish meal.

Biogenic Amines. Biogenic amines are compounds produced from amino acids by spoilage bacteria (Table 4). Their levels in a fish meal reflect both the extent of the enzymatic hydrolysis of the raw material and the conditions of processing. Although all fish meals likely contain biogenic amines at low levels that vary according to the species of fish used to produce the fish meal, elevated levels suggest that the raw material used to make the fish meal had undergone proteolytic and/or microbial degradation. Unlike TVN compounds, biogenic amines are heat-stable and do not volatilize or evaporate during the typical drying process of fish meal. Biogenic amines are water-soluble; they separate from presscake along with the soluble fraction and remain with the solubles. Typical levels of biogenic amines in fish meal produced from fresh, from moderately fresh, and from spoiled fish show a dramatic upward trend (Table 5). High levels of added histamine in fish feeds have been reported to cause abnormalities in the digestive tract of rainbow trout (21,22). These changes are not necessarily associated with reduced growth rates or mortality in fish, in contrast to findings with poultry. Of particular interest is the biogenic amine gizzerosine, so named because it causes gizzard erosion and death in chicks when present in their feed. Gizzerosine is a concern in fish meals made from scombroid fish such as mackerel, albacore, and tuna. Fish meal produced from stale scombroid fish contains high levels of histamine, which can combine with lysine during processing to form gizzerosine. Gizzerosine exerts its toxicity on chicks by stimulating excessive gastric

Table 3. The Digestibility, by Catfish (C) and Atlantic Salmon (AS), of Several Amino Acids in Various Protein Ingredients (in %)[a]

Ingredient	ARG	LYS	MET	VAL
Canola meal (AS)	91.4	92.0	99.9	83.8

[b]As measured in the raw material at the time of processing.

acid secretion. Because gizzerosine is difficult to measure chemically, bioassays using young chicks are conducted to identify fish meals containing gizzerosine (23). While the effects of gizzerosine on salmonids and other farmed fishes are unknown, the morphological changes in the stomachs of fish resulting from histamine addition to fish feeds are identical to those observed when fish meal containing high levels of biogenic amines, as determined by chick bioassay, are included in fish feed (22).

Methods available for the assay of biogenic amines include high-pressure-liquid chromatography (HPLC), gas-liquid chromatography, flow-injection analysis (24), and enzyme biosensors (24a). The HPLC method is becoming the method of choice for the quantification of histamine and the other biogenic amines. Conventional amino acid analysis has also been used for histamine analysis. For fish meals produced from scombroid fishes, histamine levels clearly reflect the freshness of the raw material. For other species, such as herring, reports in the literature are not in agreement. Some researchers report that histamine levels increase dramatically as the fish spoils (15); other researchers report that levels of cadaverine increase more dramatically than those of histamine (8).

***In Vitro* Digestibility (Pepsin and pH-stat. Digestibility).** Exposure of fish meal to high temperatures for long periods during the drying process can reduce the nutritional quality, by causing chemical linkages to form between amino acids that make them indigestible by fish and other animals (25,26). For years, the animal and fish feed industries have relied upon the pepsin digestibility test, performed in the laboratory to detect fish meals that have been subjected to thermal abuse during manufacture. This test relies upon the enzyme pepsin, usually obtained from pig stomachs, to digest the protein in the fish meal. If the protein has been damaged by thermal abuse during drying, then the pepsin digestibility value will be lower than the values typically obtained from high-quality fish meal (not thermally abused). The original pepsin digestibility test (27) was modified, by diluting the concentration of pepsin to increase the accuracy of the test, so that fish meals of average and high quality could be distinguished from each other (28). This modification is known as the Torry method. The original method could detect differences only between high- and low-quality fish

meals; comparisons between average and high-quality fish meals gave pepsin-digestibility values of 97.7, 96.8 and 98.5% for menhaden, anchovy, and Norse LT-94 fish meals, respectively (17). By the Torry method, however, pepsin-digestibility values for the same fish meals were 84.0, 87.4, and 96.8%. No correlation was found between the AOAC pepsin-digestibility test and biological tests of fish meal quality, but a significant positive correlation was found between the results of the Torry pepsin-digestibility method and the protein quality of the fish meals as determined by biological tests (17).

A similar method for measuring the *in vitro* digestibility of fish meals and other protein sources is the multienzyme pH-stat method. This method uses a combination of proteolytic enzymes rather than a single enzyme (pepsin) to digest the sample, and it maintains a constant pH in the test solution during digestion. Recently, this method has been applied to aquaculture feed ingredients for salmonids, by substituting proteolytic enzymes extracted from the pyloric cacae of rainbow trout in place of enzymes from land animals (29). The use of digestive enzymes from shrimp hepatopancreas to perform an *in vitro* evaluation of protein in feeds for white shrimp also has been reported (29a). Several studies suggest that multienzyme tests accurately predict the biological value of fish meals (17,30).

Other Chemical Tests. Beside the recommended values of chemical tests discussed previously (Table 6), several other chemical tests designed to measure the effects of overheating of fish meal are usually listed as predictive of nutritional quality; however, recent research has not found them to be particularly accurate for fish. These are the available lysine test and the measurement of sulfhydryl groups and disulfide bonds in fish meals. Lysine is a reactive amino acid; under conditions of overheating and in the presence of suitable reactive compounds, such as glucose, lysine can form undigestible chemical linkages, which can be indirectly measured by a chemical assay (31). Similarly, overheating of fish meals causes the number of SH groups to decrease and the number of S−S bonds to increase (32). Anderson et al. (17) compared 10 fish meals and found differences in available lysine level, sulfhydryl groups, and disulfide bonds among the fish meals. Percentage available lysine in the fish meals was correlated with fish performance in feeding trials, but the test did not rank the fish meals in the exact order of nutritional value — that is, levels of sulfhydryl groups and

Table 6. Summary of Chemical Tests to Measure Fish Meal Quality for Aquatic Feeds

Chemical Test	Recommended Values
Total volatile nitrogen (TVN)	<60 mg N/100 g sample (raw material)
Total volatile nitrogen (TVN)	<150 mg N/100 g sample (meal)
Pepsin digestibility (Torry)	>87.5%
Histamine	<800 µg/g
In vivo "apparent digestibility" coefficient (protein)	>90% (>94%, with "feces settling" method)

disulfide bonds in the fish meals did not appear to be strongly correlated with fish performance. In summary, these tests are useful in characterizing fish meals for aquatic feeds, but they do not appear to provide any information on the nutritional quality of fish meals beyond that provided by the Torry pepsin digestibility test and by multienzyme digestibility tests.

MEALS MADE FROM ANIMAL BY-PRODUCT

General Considerations

Blood meal, poultry by-product meal, feather meal, and meat-and-bone meal are protein ingredients that have been used in fish feed formulations for many species. Each of these protein sources has at least one undesirable characteristic that has limited its use (Table 7). For example, poultry by-product meals from different manufacturers vary widely in ash content and in apparent protein digestibility (33). Meat-and-bone meal also varies in ash content between producers, depending upon the proportion of bone in the raw material used to make the meal (34). Variability in ash content makes it difficult to formulate a low-ash, low-phosphorus (environmentally friendly) fish feed from these ingredients. Feather meal, produced by hydrolysis of chicken feathers in a strong base under pressure, is a high-protein feed ingredient containing a relatively low ash content. Its use in fish feeds is, nevertheless, limited by variability in its amino acid profile and in its apparent protein digestibility among product from different manufacturers (35,36). Blood meal is another high-protein feed ingredient that has historically been used at levels up to 10% in many salmonid diets. Again, variability in apparent protein digestibility among products from different manufacturers (and occasional contamination with salmonella) limit its use in aquatic feeds (35).

Tests for Quality

For animal by-product meals, the proximate composition and the appearance are the first characteristics upon which quality assessment can be based. Meals having crude protein and ash values different from tabled values (3) should be avoided. The color and odor of

Table 7. Disadvantages of Some Alternate Protein Sources Potentially Suitable for Aquatic Feeds

Ingredient	Negative Qualities
Blood meal	Variable digestibility coefficients
Canola meal	High in fiber and in phytic acid
Corn gluten meal	Adds fiber; colors fish flesh yellow
Feather meal	Variable digestibility coefficients
Meat and bone meal	High ash level
Poultry by-product meal	Variable in quality; high ash
Rapeseed/soy protein conc.	High level of phytic acid
Soybean meal	Poor palatability, antinutritional factors
Wheat gluten meal	Too expensive

animal by-product meals both suggest the degree of heating used during processing. Dark meals have likely been overheated; they will generally have lower apparent protein digestibility values than lighter meals. A burned odor can sometimes be detected in dark meals — another suggestion that the product has been overheated. Pepsin digestibility should be measured on animal by-product meals, and batches with substandard values should be avoided. Rendered products are available in various grades (e.g., regular, pet-food, and low-ash). The pet-food and low-ash grades are value-added products, produced by a combination of ash removal with blending to a specified protein and ash percentage. These specifications are important for pet-food manufacturers, but they are not predictive of ingredient quality for fish.

Other Animal/Fish Protein Sources

Molluscan and crustacean meals are often used in feeds for shrimp and marine fish. These specialty meals are produced, in relatively small amounts, by a variety of producers. One potential nutritional problem is the very high ash content of crustacean meals — especially shrimp and crab meals ($\sim$40% ash; Refs. 3,36a), if used at high substitution levels. Another problem is that variability in quality, especially in squid meal, can be very high. Most variation in quality results from the type of processing, mainly drying, used in meal production. Drying methods range from those used in food production (e.g., spray drying, freeze drying), through those used in fish meal production, to primitive methods such as sun-drying. There are no well-defined standards for these molluscan and crustacean meals; therefore, buyers must judge the quality of products by appearance, odor, proximate composition, and, possibly, pepsin digestibility. These ingredients are, however, usually used in feeds only at low substitution levels: as a source of trace minerals and carotenoid pigments (36a), to improve palatability and feed intake, and to supply specific essential nutrients (e.g., sterols for shrimp). They are less important in feeds as protein sources supplying amino acids for growth.

OILSEED MEALS AND CONCENTRATES

Manufacturing Considerations

Oilseed meals are produced from the residue or presscake of oilseeds grown and processed for their oil. The most common oilseed meals are soybean meal, canola (rapeseed) meal, sunflower meal, peanut meal, and cottonseed meal; soybeans constitute 50% of the world oilseed production (37). After the seeds are crushed, oil is extracted from the seed and the residue is dried. In some products, the hull of the seed is removed. The hull contains fiber; removing the hulls increases the percentage of protein in dried oilseed meal. Oilseed protein concentrates are products made from the de-oiled presscake by removing the soluble carbohydrate fraction and concentrating the protein fraction by a series of extractions (38). The proximate composition, nutritional value, and functional properties of oilseed protein concentrates vary with the method of production.

Generally speaking, the apparent protein digestibilities of oilseed protein concentrates are higher than those of oilseed meals. Typical apparent protein digestibility values for oilseed meals and concentrates, as measured in salmonids, are shown in Table 8.

Soybean Products: Quality Problems and Detection

Soybean meal, like many oilseed meals, contains antinutritional compounds that must be removed or inactivated by processing before the meal can be used in animal or fish feeds. The principal antinutritional components in soybean meal are trypsin inhibitors, which reduce protein digestibility by binding with the digestive enzyme trypsin in the intestine of the animal. Trypsin inhibitors are sensitive to heat, and ordinary presscake drying lowers the level of trypsin inhibitors in the dried meal to levels that do not affect the growth of most domestic animals and of some species of fish (e.g., catfish). Salmonids, particularly juveniles, are more sensitive than catfish to trypsin inhibitor level, and thus more extensive heat treatment is necessary to reduce residual trypsin inhibitor levels in soybean meal for salmon and trout (39). Overheating soybean meal, however, may reduce protein quality by causing reactions between amino acid residues, such as lysine, and portions of the carbohydrate fraction in soybeans, a process often leading to the Maillard reaction (40). The products of these reactions are generally indigestible. In soy protein concentrates, where the levels of trypsin inhibitor are usually low, the major concern is the level of phytic acid, which can form strong bonds with divalent cations.

Vohra and Kratzer (37) summarized the various chemical tests used to determine the adequacy of heat treatment of soybean meal. They divided the chemical tests into two groups: those that detect underheated soybean meal, and those that detect overheated meal.

Chemical Tests for Detecting Underheated Soybean Meal. Chemical tests to detect underheated soybean meal mentioned by Vohra and Kratzer (37) were the measurement of urease activity, of trypsin activity, and of protein solubility. Urease is an enzyme naturally present in soybeans; it does not have any known substantial nutritional relevance, but it is heat-sensitive, and its activity correlates positively with the activity of residual trypsin in dried soybean meal. It is also relatively easy to measure (27). Urease activity in commercial soybean meal ranges from 0.02 to 0.1 increase in pH (37); values over 0.5 increase in pH indicate insufficient heat treatment of the soybean meal. If no increase in pH is detected with the urease test, then this result might mean that

the soybean meal has instead been over-heated, so some residual urease activity in the meal is preferred, at least for soybean meal intended for use in poultry feeds. Unheated soybean meal has a urease activity of >2.25 pH rise (41).

As mentioned, trypsin inhibitor activity in soybean meal decreases with heat treatment, in proportion to urease activity. Unheated, solvent-extracted soybean meal can contain more than 21 trypsin inhibitor units/mg sample (42), but commercial soybean meal subjected to normal heating during the presscake drying process generally contains about half the trypsin inhibitor activity of unheated meal. Additional heating further reduces trypsin inhibitor activity; the amount of reduction depends upon the temperature and the duration of heat treatment (Table 9). For salmonids, additional heat treatment increases fish growth rates when the treated meal is added to feeds, as compared to no heat treatment (45). The heat generated by steam extrusion is sufficient to lower trypsin inhibitor levels, at least in full-fat soybeans (44). Wilson (45) extruded full-fat soybeans having an initial trypsin inhibitor activity of 46.5 (in trypsin units inhibited per mg sample) and succeeded in reducing it to 8.1 after steam extrusion.

A third method for measuring the extent of heat treatment of soybean meal is the water solubility test; this test involves measuring Kjeldahl nitrogen levels in the soybean meal and in a water extract of the soybean meal (37). The method has been slightly modified by performing the extraction in 0.2% KOH (42). Heating decreases the percentage of 0.2% KOH-extractable protein, from about 99% in raw soybean meal to about 72% after 20 minutes of autoclaving; this decrease corresponds to a decrease in trypsin inhibitor units from 21.1 to 1.0 (42).

Chemical Tests for Detecting Overheated Soybean Meal. Excessive heat treatment of soybean meal is thought to reduce protein digestibility by causing the creation of protein-carbohydrate linkages that are indigestible by most animals. Tests for detecting overheated soybean meal are based upon the number of free functional groups in the protein fraction of the soybean meal; these groups can be detected by several dye-binding tests, by formaldehyde titration, or by a fluorescent derivative (37). Cresol Red dye binding is a relatively simple, rapid test requiring

Table 8. Digestibility by Salmonids of Oilseed Meals and Concentrates (in %)[a]

Ingredient	Dry Matter	Protein
Canola meal	53.5	83.5

only a spectrophotometer. Olomucki and Bornstein (44) reported that values in the range 3.8–4.3 mg Cresol Red absorbed per g meal indicate properly heated soybean meal, and that values over 4.3 indicate that overheating has occurred. Orange G dye binding and Commassie Blue are two other rapid, simple tests to detect overheated soybean meal; of the two, the Commassie Blue test is preferred, because it is more rapid and sensitive (Table 10) (46).

Other Oilseed Products: Quality Problems and Detection

The two major quality problems associated with other oilseed meals are glucosinolates in canola/rapeseed meals and gossypol in cottonseed meal. Glucosinolates interfere with the function of the thyroid gland in fish, and so pose problems during metamorphosis and maturation. The use of rapeseed/canola protein products in fish feeds has been thoroughly reviewed (47). Gossypol causes a number of problems in fish, including anorexia and increased lipid deposition in the liver. The use of cottonseed meal in fish feeds has also been thoroughly reviewed (48).

FATS AND OILS

Fish oils contain higher levels of polyunsaturated fatty acids than do oils extracted from oilseeds and other plants; therefore, they are more susceptible to oxidation. The use of high-energy feeds in salmon farming requires the addition of over 20% fish oil; that supplementation level increases the potential for oxidative problems, both during lipid storage in the feed manufacturing plant and after pelleting, before the feed is used. Oxidation of polyunsaturated oils produces free radicals, peroxides, and other potentially toxic or reactive compounds, and feeding fish a diet containing oil that is in the process of oxidizing may cause signs of vitamin E deficiency in fish of previously marginal vitamin E status (3). Most fish and plant oils contain naturally occurring antioxidants that, up to a point, prevent oxidation of fatty acids; beyond that point, oxidation occurs very rapidly. The antioxidants ethoxyquin, BHA, BHT, and propyl gallate are commonly added to fish oils to prevent lipid oxidation. Other quality concerns with fish oils are the percentages of free fatty acids, moisture, and nitrogen. Free fatty acids are always present in fish oils, but high levels of them suggest that the oil has been subjected to abusive processing and has undergone the hydrolysis of triglycerides to free fatty acids. High levels of moisture and nitrogen suggest that the separation of the oil fraction from the stickwater fraction during manufacturing was not done properly, and so there was some carryover of water and water-soluble protein into the oil. For a more thorough discussion of fish oil quality and oxidation, see the separate entry in this volume.

Table 11. Specifications for Fish Oils Used in Aquatic Feeds[a]

Category	Recommended Value
Free fatty acids	<3%
Moisture	<1%
Nitrogen	<1%

FEED HANDLING AND STORAGE

TIMOTHY O'KEEFE
Aqua-Food Technologies, Inc.
Buhl, Idaho

OUTLINE

INTRODUCTION

Prepared feeds for fish and shrimp are perishable products. Depending on the type of feed, they are also more or less fragile. Feed processors attempt to formulate and manufacture aquaculture feeds to extend their shelf life and improve durability. However, the degree to which aquaculturists can reduce wasted feed and realize its full purchase value is ultimately dependent on how well the basic principles of feed storage and handling are understood and applied.

Little practical information has been published specifically on proper storage and handling of the most common types of feed currently used in aquaculture. Even though feed most often represents the greatest percentage of the total cost of producing aquatic species, and substantial amounts can potentially be wasted through spoilage and breakage, proper storage, and handling of dry, semimoist, and moist feeds are usually only addressed in the literature in a general sense. The specifics are left to assumption.

This article is intended to provide some detailed discussion, and information references where possible, on the most common causes of degradation and waste of aquaculture feed on the farm. It is impractical to address every conceivable storage and handling situation that may occur with each type of feed. However, the guidelines presented here, along with some practical recommendations, should help in those instances where judgments or compromises are required.

STORAGE

For reasons of cost and convenience, dry and semimoist diets are currently the most widely used feeds in aquaculture. The general rule for preservation of both types of feeds is to store them in a dry, well-ventilated area that affords some protection from rapid changes in temperature. Cooler temperatures are best, although actual ambient temperature is less important than minimizing extreme changes. Any storage facility should also provide adequate containment for control of pests.

Moist feeds, such as the Oregon Moist Pellet (OMP), require more demanding and costly storage conditions. With moisture levels averaging between 30 and 35%, these feeds must be received in freezer vans or containers and maintained in a frozen state until ready for use. The length of time they can be held in good condition is highly dependent on the storage temperature. The recommended temperature for maximum, long-term storage of OMP feed is $-18\,°C$ (1). Under practical conditions, however, temperatures below $-11\,°C$ are sufficient to hold OMP for up to 3 months (2).

No matter what type of feed is used, there is little or nothing that can be done to enhance its potential storage stability once it has been delivered to the farm. Much of what is subsequently done during storage, however, can substantially affect whether a feed can remain acceptable over the intended shelf life. A practical knowledge of some factors contributing to feed degradation and a little attention to maintaining proper storage conditions for dry, semimoist, and moist feeds can significantly minimize the loss of vitamin potency, mold growth, fat rancidity, and infestation by insects and rodents.

Vitamin Potency

The potency of most vitamins contained in formulated feeds declines during storage, because many of the organic compounds are highly reactive and unstable. Under certain conditions, they can be easily denatured by heat, oxygen, moisture, and even ultraviolet light (3). The rate of vitamin activity loss in a given feed formulation is dependent on the particular vitamin, its source, and the conditions under which feed is stored. The average storage stability values of different vitamins and vitamin sources in dry feeds are summarized in Table 1. These data can be used to estimate normal vitamin activity losses under proper storage conditions (4,5). Most manufacturers of aquaculture feeds recognize these potential losses. They attempt to fortify their diets with sufficient overages of each vitamin to provide the intended levels of activity within the declared product shelf life.

Typical changes in vitamin activity levels that occur in both dry and moist feeds have been studied during prolonged storage (2). Results showed that after three months, if stored under proper conditions, vitamin levels in well-formulated diets of both types of feeds could meet or exceed the National Research Council (NRC) recommendations for Pacific salmon. Further monitoring of vitamin activity losses in these feeds revealed that, after doubling the recommended storage time, only vitamin C activity declined below minimum acceptable levels.

It is important to recognize that even significant losses of vitamin activity during storage need not render feed unusable. Vitamin requirements are actually a function of feed consumption and desired biological response of the fish, rather than a specific concentration in the feed (6). As long as storage deterioration of feed is restricted to vitamin loss, meaning that there are no other quality problems such as molding or fat rancidity, feed stored over

Table 1. Average Vitamin Stability in Stored Feeds

Vitamin	Ingredient Source	Percentage of Vitamin Retention at Month:		
		1	3	6
A	Beadlet	83	69	43
D_3	Beadlet	88	78	55
E	Acetate	96	92	88
	Alcohol	59	20	0

a long period of time can still be put to beneficial use. Some appropriate applications of feed with low vitamin activity levels would be short-term feeding of harvest-size fish, or prolonged feeding of fish or shrimp raised under extensive culture conditions. Conversely, those feeds should not be used where increased vitamin activity is required to promote an adaptive response such as disease resistance, or to achieve maximum tissue storage as required in broodstock feed.

Mold Growth

All too often, feed stored in fish hatcheries and on farms is destroyed by common molds. The potential for this to occur is always present because of the fact that mold producing fungi and other microorganisms exist naturally throughout the environment. They are present in grains after harvest and in animal carcasses prior to rendering. Food processing operations involved in stabilizing feedstuffs and in manufacturing feeds typically use heat and dehydration steps, that are sufficiently destructive to eliminate the original contaminating microflora. However, some fungal spores can survive harsh processing conditions. Other airborne spores may also recontaminate the feed during handling and storage. All of these spores then remain dormant in and on the feed until conditions exist that are favorable for growth.

Contaminating fungi grow best when the moisture content of the feed is 14.5 to 20% and in equilibrium with a relative humidity of 70 to 90% (7). Most dry feeds are manufactured at considerably lower moisture levels, allowing a safety margin for variability among individual feed particles. The maximum recommended moisture content for extruded pet feeds is 12% (8). Most aquaculture feed manufacturers take this a step further,

keeping moisture levels at or below 10%. This is generally done because of the superior handling characteristics of low-moisture pellets in bulk bins, and the tendency for fish feeds to be stored over prolonged periods.

Special additives, which reduce water activity and inhibit germination of fungal spores within the feed, can be used to further diminish the possibility of mold growth. However, many of these additives are relatively expensive. Cost-effective application is mostly in specialty diets such as semimoist feeds that have moisture levels of 14 to 20%, but do not require storage conditions different from dry feed.

On a large production scale, there is no economical way of eliminating fungi spores in feed. The most effective mold-prevention strategy, therefore, is to maintain moisture levels in stored feed below requirements for fungal growth. To do this, it is obviously necessary to provide a dry area where feed can be protected from rain. Less obvious is the need to control moisture migration within the feed. Sufficient temperature differentials, even in feed with only 10% average moisture, can cause that moisture to concentrate at much higher levels in the cooler areas of a sack or bulk bin.

It is usually not practical to provide climate-controlled storage for large quantities of feed. However, every effort should be made to avoid conditions that allow extreme temperature changes to occur over a short period of time. In situations where bagged feed is stored outdoors under tarpaulins or bulk feed is held in dark-colored and poorly ventilated bins, moisture in the feed can volatilize during the heat of the day and condense near the top and surrounding container surfaces when the temperature rapidly decreases at nightfall. Similar moisture migration can even occur when bags of feed at ambient temperature

are stacked on or against cool concrete floors and walls. Once feed has been subjected to these kinds of storage conditions, it is only a matter of time before mold growth begins in localized areas of high moisture.

The first species of fungi to develop in feed is usually *Aspergillus glaucus*, which has a minimum environmental moisture requirement of only 14.5% (7). If identified at an early stage, feed containing trace amounts of pellets with this type of mold can usually be fed to fish with little risk of adverse consequence. With more time, however, the number of mold colonies multiply quickly, creating higher temperature and moisture conditions. As the environmental conditions within the feed undergo a succession of changes caused by the growth of these spoilage microorganisms, other species quickly emerge and proliferate.

At moisture levels near 18%, there is a possibility that molding feed will become infested with *Aspergillis flavis* (7). This is an especially dangerous species of mold because it is capable of producing aflatoxins. Rainbow trout are particularly sensitive to these carcinogenic metabolites (9,10). Consumption of only 0.5 mg of aflatoxin B_1 per kg of body weight causes mortality within 3 to 10 days. Feeding aflatoxin-contaminated feeds with as little as 0.1 to 0.5 ppb aflatoxin B_1 results in hepatomas after 4 to 6 months. Other aquatic species, such as coho salmon (9), catfish, (11) and shrimp (12–14), are believed to be more tolerant, though similarly affected.

The probability of aflatoxin production in complete feed is actually quite low. It is much more likely to occur in high-moisture crops such as peanuts, cottonseed, and corn. Studies have shown that the presence of other microorganisms in a complex substrate like fish feed tends to interfere with aflatoxin production (7). However, among these interfering microorganisms, there are also species of *Fusarium* and *Penicillium* fungi that can produce their own mycotoxins. For this reason, the practice of using feed that is obviously molded should be avoided.

Lipid Rancidity

Lipids used in aquaculture feeds are usually the type that contain significant levels of unsaturated fatty acids, which are required for good health and growth of most species of fish and shrimp. The high degree of unsaturation of these fatty acids causes them to be particularly prone to oxidative rancidity. Feed manufacturers attempt to prevent oxidation in lipid sources such as fish oil by stabilizing them with antioxidants. However, the commonly used antioxidants such as ethoxyquin, butylated hydroxyanasole, and butylated hydroxytoluene, are sacrificial in the way that they protect the oil. Once they are used up, free radicals that are already present in the oil begin to react with unsaturated fatty acid components and the process of oxidation begins.

It is often thought that freezing is the best method of long-term preservation. However, cold temperature in the range achievable with most freezers is not effective in reducing the rate of free radical formation or the resulting lipid oxidation. In actuality, the experience with low-moisture feeds has been that freezing accelerates lipid oxidation (15). It is believed that the reason for this is that only free water is frozen at ordinary freezer temperatures. This results in the concentration of metal salts and other pro-oxidants in an unfrozen phase, making interaction with lipids more probable. It is also thought that the further reduction of water activity caused by freezing dry feed allows oxygen to penetrate the pellets more freely.

What all of this means is that there is very little that can be done on the farm to improve lipid stability in stored feed. Rotating the feed inventory as quickly as possible is the only effective strategy to avoid having feed go rancid before it is used. This can usually be accomplished easily with feeds that are fed in high volume. However, inventories of starter feeds, crumbles, and broodstock pellets are usually more difficult to manage. Animals that eat these feeds are also most likely to be at a point in their life stage where they are extremely vulnerable to the negative effects caused by consuming rancid lipids.

Pest Infestation

The presence of insects and rodents in feed storage areas can often be an overlooked but serious problem in aquaculture. These pests not only consume feed, but also cause additional and sometimes greater feed losses through packaging damage and the creation of environmental storage conditions that promote mold growth. They also have the potential to serve as vectors for transmission of disease to humans.

Insects. Insect infestation can be a very serious problem in feeds stored over a prolonged period of time. Jokes about how insects "just add a little protein to the feed" tend to divert attention from the magnitude of feed loss that they can cause. An actively reproducing population of insects can quickly consume significant amounts of food and deteriorate the physical quality of the remaining feed (16). Internal infesting species such as grain weevils and warehouse beetles can bore through feed sacks, providing a port of entry for other insects. If present in sufficient numbers in bulk feed, they also have the potential to create localized heating, moisture migration, and molding. External infesting species, however, are more frequently the cause of problems in complete feeds. These include Indian meal moths and flour beetles, which prefer to obtain nourishment from processed grain products, along with carpet beetles that feed on meat meal, feather meal, and other ingredients of animal origin.

Most of these insects thrive on food containing 12 to 14% moisture. They are capable of completely developing from an egg to a reproductively active adult within 30 days when temperatures are between 20 and 30 °C. At 16 °C, most of these species cease to lay eggs. They usually become dormant at about 4.5 °C. Under optimal environmental conditions, propagation of tremendous numbers of insects can occur in a very short period of time because of their short maturation time and relatively high fecundity.

With the knowledge and ability to recognize conditions that promote insect infestation and rapid population growth, it is easy to see that effective control requires a sustained and concerted effort with several prevention and housekeeping tasks. Rapid inventory rotation is perhaps

the most important control process. However, regular inspection of feed and early detection of bugs, along with good sanitation in storage areas, are proactive practices that can greatly reduce the incidence of feed contamination with bugs. As a final resort, insecticides can be used to eliminate a persistent infestation.

In the United States, all chemicals used as insecticides must be registered for this purpose and be properly labeled according to Environmental Protection Agency (EPA) regulations. Fumigants such as hydrogen phosphide (phosphine gas), methyl bromide, and chlorpyrifos-methyl require application by individuals that are certified by controlling state agencies. These insecticides are highly effective and leave no residue in the feed. However, the vapors are very toxic. Fumigant insecticides should always be used with extreme caution and only according to the manufacturer's recommendations for treatment of feed.

Rodents. Populations of rats and mice that become established in storage areas obviously consume some amount of feed. However, the losses they cause through packaging damage and the resultant feed spillage, exposure to insects, and molding conditions are probably far greater. They also pose a substantial health hazard to workers handling the feed.

As with insect pests, several methods of control must be employed in a concerted manner to be effective. The basis for a rodent control program should always be good housekeeping, both inside the warehouse as well as around the exterior perimeter. Combining this with maintenance of physical barriers that limit entry and an aggressive trapping effort will noticeably minimize feed loses caused by rodents.

Use of poisons should only be considered as a last resort to control rodent populations in feed storage areas. Baits containing strychnine or other acute rodenticides, in close proximity to stored feed, impose an increased risk of feed contamination and dangerous contact with humans or pets. These same risks exist with the use of anticoagulant rodenticides, such as warfarin, even though they are much less dangerous.

HANDLING

Movement of feed on the farm can only be considered as a necessary evil. Some amount of feed or nutrient loss occurs each time it is handled in the processes of receiving, storing, and feeding. These chronic losses are usually small, but they accumulate over time. A good general control strategy is to identify the causes of greatest loss, and make any practical modifications necessary to handle feed as gently and as little as possible. More specifically, there are distinct differences between the physical and nutritional characteristics of moist and semimoist feeds and those of dry feeds. These different characteristics impose some handling requirements that are unique to each type of feed.

Moist and Semimoist Feeds

Moist feeds such as OMP probably present the greatest number of handling challenges. They are reasonably durable and shelf stable at temperatures below 0 °C. When thawed, however, their soft texture and highly perishable nature cause a number of handling problems. Relatively small compression forces cause moist feeds to clump and compact. Pellets are easily broken or smashed by conventional feed-handling equipment. Perhaps more importantly, the high-moisture content of the feed promotes vitamin activity loss and growth of bacterial contaminants. When combined with warm temperatures, this process of nutrient loss and food spoilage becomes greatly accelerated.

Good feed-handling procedures for moist feeds therefore include some means of keeping it frozen until the last few minutes before feeding. At many farms and hatcheries, feed for each pond is weighed into individual containers on the day before it is required and then kept in a freezer until feeding begins on the next day. The amount of time between removal from the freezer and feeding is kept to a minimum. To accommodate multiple feedings per day, containers holding each daily ration of feed are either returned to the freezer after every feeding or equipped with insulation to maintain feed in a frozen state. A further requirement to limit growth of contaminating bacteria and mold is the routine and thorough cleaning of these containers and other handling equipment used to distribute the feed.

Over the past several years, use of moist feed has been steadily declining in favor of feed products that are not as perishable and much easier to handle. Semimoist diets have subsequently attained widespread application where soft textured feed particles are required. The very low water activity in these feeds provides much better nutrient stability at ambient temperatures. However, clumping and compacting of pellets is still a problem because of their soft texture. These problems can be minimized by using low-profile containers, which help avoid having feed pile up and being compressed by its own weight. Movement and dispersion of feed can also be done by gentle means such as belt conveyors or vibratory feeders that allow feed to move freely without damage.

Dry Feeds

Both pelleted and extruded dry feeds have excellent handling characteristics compared to any other type of feed. Unlike moist feeds, handling procedures on the farm have no effect on nutrient quality of dry feeds. Pellet durability of both types of dry feed is also usually quite good, although variability in the consistency of feed ingredients may cause some batches of feed to be softer and more fragile. In addition to these attributes, the cylindrical or spherical particle shapes allow dry feed to flow easily from trucks, bins, and feeders.

The physical characteristics of dry feeds are so well suited to the handling and distribution requirements of aquaculture that inherent limitations are often challenged. It is easy to overlook the fact that even the most durable crumbles and pellets can break down into dust and fines when subjected to sufficient amounts of compression and abrasion. In handling any feed in bag or bulk form, it is important to give ample consideration to moving the feed as little as possible and as gently as possible.

With bagged feed, the challenge is to reduce the amount of particle size attrition that occurs when pellets or crumbles are forced to rub against each other. Use of forklifts and pallets, or hand trucks and minipallets, allow bags to be handled in multiple units. This minimizes the amount of feed movement within each bag and reduces the creation of dust and fines. When it is necessary to handle single bags, the process should be done as gently as possible. Obviously, rough treatment such as throwing or walking on sacks of feed should be avoided.

Pellet-against-pellet abrasion in bulk feed is more difficult to control. The very nature of this method of storing and handling feed requires that pellets flow from the delivery vehicle to a bin, and from the bin throughout the farm. It also necessitates the use of conveying equipment. These mechanical devices are often the source of, or solution to, most problems with excessive levels of dust and fines in bulk feed.

Among the types of conventionally used feed conveying equipment, bucket elevators, belt conveyors, and drag conveyors are the least destructive (17). These work well because they control movement of feed against feed and minimize the potential of shearing or pinching pellets in conveying mechanisms. Pneumatic, oscillating, and vibratory conveyors cause only slightly more abrasion. However, they almost eliminate losses from pellet breakage when properly maintained and operated.

The most potentially destructive conveyance mechanism for feed is the auger. Tube-type screw conveyors, as well as flexible augers, are widely used in feed-handling systems on farms because of their low cost and simplicity of operation. Their most frequent use is in unloading bulk bins. In this application, the equipment design is usually more appropriate for handling mash feeds or whole grain, where the auger turns at a high rate of speed and has an inclined discharge. Most are also "choke loaded," meaning that the feed completely covers the inlet to the conveyor, causing compression and breakage as pellets enter the tube. While proper equipment design can minimize many of these problems, the added expense usually ends up favoring the selection of conveyors that are more appropriate for use with feed.

SUMMARY

Aquaculture feeds, like most food products, have a finite shelf life and special handling requirements. In order to realize the full economic and nutritional value of these feeds, it is necessary to store and handle them properly. Deterioration of feed quality during storage can be minimized by frequent rotation of the inventory, and a concerted effort to maintain good housekeeping and environmental conditions that discourage mold growth and insect and rodent infestation. Proper handling techniques can also reduce nutrient loss and pellet breakage just prior to feeding.

The importance of careful attention to the specific requirements for proper storage and handling of aquaculture feeds cannot be overstated. At most farms that raise fish or shrimp, feed cost is the largest single expense item. Therefore, even a small reduction in wasted feed can significantly affect production cost and directly impact bottom-line profitability.

OUTLINE

INTRODUCTION

Supplying complete nutrition in a formulated feed for fish is more of a challenge than doing so for terrestrial species. A major component of this challenge is obvious. Feed for aquatic animals is exposed to water before it is eaten, often for long periods of time. This can result in loss of water-soluble nutrients due to leaching, and breakdown of the feed pellets, which degrades water quality. This is a greater problem for larval fish, crustaceans, and slow-feeding species like sturgeon than for species like trout, which consume feed rapidly. Another factor that makes aquatic feed manufacturing a challenge is the necessity of processing fish feeds in some fashion. For many terrestrial species (e.g., poultry and cattle), ingredients can be just mixed together and fed without any further processing. Feeds for fish must always be processed into pellets, flakes, or some other particle.

The aquaculture feed industry uses several feed-processing technologies. Each processing method imparts different characteristics to the feed (e.g., floating, sinking, high nutrient stability, or high palatability). Various fish-rearing situations often require unique feed particle characteristics. No single feed-processing method can produce the best feed for all situations. The effect of the processing method on the physical characteristics of fish feed must be understood to develop an effective fish-rearing program.

TYPES OF FEED

Aquaculture feeds can be categorized in many ways, but the most common categorization is based upon the life-history stage of the fish for which the feed is designed. In this manner, feeds are designated as larval, starter, grower, and broodstock feeds. Feeds for those life-history stages differ in particle size and in formulation (choice of ingredients and the percentage in the feed mixture). For example, larval feeds are usually less than 500 μm in size and are manufactured with specialized processing equipment. The processing methods used to produce starter feeds are not as exacting as those used for larval

feeds, and the feeds are correspondingly less expensive. Trout, salmon, catfish, and tilapia fry are all species that thrive when given starter feeds. Species that produce very small larvae (e.g., striped bass and walleye) do not flourish on starter feeds and require the more expensive larval feeds.

Grower feeds are fed after fish have passed the juvenile stage. Grower feeds constitute the largest proportion of feed used during a production cycle, over 90% in some species. Since feed costs account for a large portion of production costs and grower feeds represent the major portion of feeds used in a production cycle, the cost of grower feeds greatly affects the overall cost of producing fish. However, feed cost should be compared on the basis of unit (kg, lb) of product produced per unit feed rather than just on the unit cost of feed. Broodstock feeds are formulated to support high levels of egg production. Fecundity and gamete viability are more important considerations with these feeds than weight gain of the brood fish.

There are other types of special-application diets that are generally grouped into the category of specialty diets. These include transition feeds and low-pollution (i.e., environmentally friendly) feeds. Transition feeds were developed to ease the transition of young fish being switched from live feeds to formulated (artificial) feeds. Low-pollution feeds are designed to decrease the level of nutrients, leaving a hatchery in the effluent water. Even though the overall nutrient contribution of hatcheries and fish farms is relatively low, they are a point source of nutrients and subject to increasing regulation by state and federal authorities.

Some overlap exists in the processing technology used to produce the different types of feed. The methods that are appropriate for producing one type of feed may not be right for another type of feed. For example, a common processing method for grower diets (cooking extrusion) increases carbohydrate availability to fish. This method is not desirable for larval fish that have a limited capacity to utilize carbohydrates. The additional expense and effort of processing the feed to increase carbohydrate digestibility may not be justified for larval feed production.

MANUFACTURING METHODS

Manufacturing methods are categorized based on the equipment used to produce the feed particle or pellet, but in all feed manufacturing processes, ingredients are ground and mixed before particle formation or pelleting takes place (1). Complete mixing of the ingredients is crucial for the production of a homogeneous product, and both the design and operation of the mixer are critical (2). After mixing, the feed blend is conditioned by adding steam and then is pelleted and cooled, or dried, depending on the pelleting method. Also, it is often top-dressed with additional oil. Next, pellets are placed into bags, stacked on pallets, stored, and eventually shipped to the fish farm. Some feeds, such as those for catfish, are delivered in bulk without being bagged. This simplifies handling large quantities of feed.

Particle-Size Reduction (Grinding)

Most feed ingredients arrive at feed mills as coarse particles. Ingredients are commonly ground before mixing. This step of feed preparation is time-consuming and expensive (3). Some feed ingredients are difficult to grind alone and must be combined with other ingredients. Thus, in some feed mills, particle-size reduction is performed on feed mixtures rather than on single ingredients. Many types of equipment are used to reduce particle size by impact, crushing, and cutting. Feed ingredients and mixtures used in aquaculture feeds are most commonly ground using impact mills, also known as hammer mills. Hammer mills operate by impacting the feed mixture until it shatters into particles small enough to pass through a screen. The screen size determines the degree of particle-size reduction. Hammer mills are effective and efficient grinders, unless the ingredients contain high levels of oil (fat), as do some types of fish meal. The heat generated by grinding can separate residual fish oil in fish meal, thereby clogging the screens. High-oil feed ingredients must be mixed with other low-oil ingredients, to allow grinding to proceed efficiently without clogging, or ground using a pulverizer. Pulverizers can be identified by the lack of retaining screens and a very large volume of air passing through the mill (2). The high volume of air passing through the pulverizer keeps ingredient temperatures low and thus inhibits separation of residual oil in fish meals.

The degree of grinding or particle-size reduction depends on the type of pelleting or particle formation that will be produced. For example, larval feeds require very fine particles while grower feeds do not need to be ground as finely. Grinding requires energy and generates heat, which can damage some nutrients. Therefore, feed ingredients are ground to pass through the largest screen opening allowance for the feed being produced. A common rule of thumb is to reduce the ingredient particle size to 20% of the diameter of the holes in pelleting dies. This degree of grinding is sufficient to prevent holes from becoming plugged during pelleting. Ingredient grinding also facilitates the production of more durable and water-stable pellets (4). Another benefit of grinding is that it allows the feed ingredients to be mixed into a homogeneous mixture. This presumably results in nutrients being evenly distributed within feed pellets or particles.

After the feed ingredients are ground, they are mixed together in proportions dictated by the feed formulation. Mixing is carefully timed to ensure even particle distribution and to avoid overmixing, whereby ingredients can become separated based upon particle density. Oils are generally not added to feed mixtures, at least when the mixtures contain more than 4 to 5% residual oil. Rather, oil is added after pelleting. Too much oil in feed mixtures reduces compression during pelleting, resulting in soft, breakable pellets.

Feed mixtures are then subject to conditioning, pelleting, drying, and, often, top-dressing (adding fish or plant oils to cooled pellets). Conditioning involves the addition of moisture, generally in the form of steam. The amount of moisture and degree of heat added varies with the pelleting method. The purpose of conditioning is to add sufficient moisture to enable the feed mixture to pellet and stick together, and to gelatinize (cook) a portion of the starch in the feed mixture, both to facilitate pellet binding and to increase the digestibility of starch. Common pelleting methods used to produce fish feeds include cold extrusion, steam pelleting, and cooking extrusion.

Cold Extrusion

Pelleting is accomplished by forcing the feed mixture through a plate or die containing holes. Cold extrusion, a process that does not use steam, but simply adds water or water-containing ingredients, is accomplished by forcing the mixture through a plate with holes in it, similar to the production of pasta. The feed mixture must contain at least 25% moisture for this process to work properly. The feed mixture is carried down a barrel by a rotating auger, and as the feed squeezes out of the holes in the die, it is cut by a rotating knife into the desired pellet length, which is usually similar to the diameter of the pellets. After the pellets are cut, they are quickly frozen or dried. Cold extrusion is used to make the semipurified feeds used in research studies, larval feeds, and semimoist feeds, such as the Oregon moist pellet or its derivatives.

Several designs of cold extruders are available, differing in configuration to allow for the production of very small particles. The most common design is the front-discharge extruder, also called an axial-discharge extruder, which can produce pellets as small as 1.5 mm diameter. With this design, the pellets exit the machine at the end of the extruder barrel through a flat plate. Radial-discharge and twin-dome extruders can produce pellets down to 0.5 and 0.3 mm diameter, respectively. (See the entry "Microbound feeds.") Even though these extruders have fixed-screw configurations, they are usually equipped with a variable-speed drive on the main screw which enhances the versatility of the machine.

Because of the range of characteristics of products that can be produced using cold extrusion, it is difficult to define the particle characteristics for all cold extruded products. In general, however, these feeds have a soft texture, are highly palatable, and have not been exposed to heat. The low-temperature processing reduces or eliminates destruction of heat-labile nutrients. High palatability and soft texture are particularly advantageous for larval and starter feeds, and are also beneficial in starter, grower, and broodstock feeds for undomesticated strains or species of fish.

Pellet binders used in cold extrusion include both nutritive and nonnutritive materials. Nutritive binders include cooked oats, wheat gluten, pregelatinized starches, and gelatin. Nonnutritive binders include tapioca, carboxymethlycellulose, alginates, agar, and various gums (5).

Compression Pelleting

Compression pelleting, also known as steam pelleting, is the most common type of feed pelleting used to produce animal and fish feeds. In this process, the feed mixture is conditioned by steam to achieve a moisture content of 16−18% and a temperature of 65−80 °C (6). Conditioning partially cooks or gelatinizes starch and activates binders, such as lignin sulfonate, a wood product. Conditioning is a

continuous process that takes approximately 30 seconds, after which the feed mixture is conveyed into the middle of a rotating die, similar in shape to a doughnut. On the inside of the die is a stationary, rotating roller, which forces the feed mixture into holes that radiate from the inside of the rotating die to the outside. The feed mixture emerges from the outside edge of the rotating die and is cut off by a stationary knife. The length of the holes in the die dictate the amount of compression and frictional heat to which the feed mixture is exposed, and thus, the density and hardness of the resulting pellets. As pellets emerge from the die, they typically have a glazed, smooth surface. This is the result of gelatinization of starch on the pellet surface caused by frictional heat, generated as the mixture goes through the die. The pellets are hot when they emerge from the die, typically about 90 °C. They are conveyed to a cooler, where the moisture level is reduced to less than 12% by the residual heat of the pellets in combination with flowing air. After cooling, the pellets can be top-dressed to a maximum of 18% total fat. The upper limit of oil addition by top-dressing is a consequence of pellet density and the glazing that occurs on the outside of the pellets. Compressed pellets are hard, but they are subject to fracture, thus making conveying, bagging, and subsequent handling procedures important to avoid excessive pellet disintegration into dust, also known as fines.

Expanders

Expansion is a feed mixture conditioning step that occurs after mixing, but before compression pelleting. The process involves steam injection and mixing in a preconditioning chamber, followed by applying pressure (shear) along a barrel. The mixture is then forced through a narrow gap, created by the presence of a cone in a tapered outlet of a chamber. Heat from steam, pressure (shear), and frictional energy, generated as the feed mixture squeezes through the gap, causes starch gelatinization. As the pressure is lost when the mixture exits the gap, moisture is lost. The mixture is then conveyed through a normal compression pelleting system. The resulting pellets are identical to steam pellets, except for the degree of gelatinization, which also affects pellet density and the amount of oil that can be top-dressed. Pellets made by this process can be top-dressed to achieve up to 22% total fat.

Cooking Extrusion

This conditioning and pelleting process is more sophisticated, versatile, and more expensive than compression pelleting. Cooking extrusion technology is used to produce puffed breakfast cereals, snack foods, and dog foods. Feed or foods are actually cooked using this method and the starch in the mix is gelatinized, binding the pellet together. No extra binders are added to fish feeds made using cooking extrusion pelleting. Gelatinized starch is sufficient.

Cooking extruders are effective at heating and thus, cooking the feed. Heat is applied to the ingredients in three main ways. First, steam is added to the feed mixture in a condition chamber prior to entering the extruder. Preconditioning the mix is an important to insure starch

gelatization in any processing method (4). After being vigorously mixed for several minutes, the feed mixture enters the extruder barrel, usually consisting of sections which can be heated or cooled. If additional heat is required, steam is injected into barrel sections, or, less commonly, the feed mixture is heated with electric barrel heaters. The third and greatest burst of energy is through shear, and the frictional energy contributed by the screw in the extruder barrel.

Extruders are available both in single- and twin-screw configurations. With both types of extruders, the screw consists of multiple segments that can be assembled in different ways to add more or less energy to the product. The screw segments are available in different lengths, pitch, and design (7). The single-screw configuration is less expensive and capable of producing a high-quality product. The twin-screw design is more expensive, but is capable of adding more energy to the feed mix with shear produced by self-wiping screws.

The mixture moves down the barrel, transported by the screw, which compresses the mixture as it gets close to the die. This pressure can be sufficient to change the steam in the feed into a liquid state. The mixture then exits the barrel through a die that shapes and further compresses the mixture, forming a noodle that is cut into pellets upon emerging from the die. The sudden release of pressure as the feed exits the die causes the feed mixture to expand as super-heated water turns suddenly to steam. This, in turn, creates small air pockets within the pellet, mainly associated with gelatinized starch, which then bind the mixture into a water-stable, hard pellet. The moist pellets are then conveyed to a hot-air dryer to lower the moisture level to less than 10%. After drying and cooling, pellets are top-dressed to achieve high fat levels. Extruded pellets can absorb high quantities of fish or plant oils due to the relatively low density associated with their tiny air pockets.

The density of the pellets can be controlled by adjusting the formulation and the amount of moisture added during conditioning. The feed can be cooked, but also can be made to sink by reducing the pressure and/or the temperature of the feed mix before it leaves the extruder (7). Many times a neutrally buoyant feed is desired for particular feeding situations. This is very difficult to produce consistently due to the many variables that are difficult to control. The variables include atmospheric conditions, ingredient composition and characteristics (which vary from batch to batch of the same ingredient from the same source), and the addition of oil, which affects buoyancy. It is easier to produce either floating or slowly sinking pellets with cooking extrusion. Extruded pellets can be very hard and resist fracture or compression during conveying, bagging, and shipping to fish farms. Because of these qualities [e.g., high fat content, floating or slowly sinking, water stability, and a low percentage of fines (pellet hardness) (7)], extruded pellets are increasingly being used in aquaculture. The disadvantage of extruded pelleting is that it increases the cost of feed when compared to steam pelleting, due to lower throughput per horsepower of energy expended per unit feed produced. Extruded pellets contain more moisture than compressed pellets,

increasing the cost of drying compared to compressed pellets. As previously mentioned, the cost of feed is less important to fish farmers than the feed cost per unit of product grown and sold.

Universal Pellet Cooker

Recently, a new system of feed pelleting was introduced which combines some aspects of compressed pelleting and cooking extrusion. This system is known as the universal pellet cooker, or UPC, and the pelleting equipment resembles cooking-extrusion equipment. Basically, the UPC process involves enhanced preconditioning for 2–3 minutes, during which the addition of steam results in 40–50% starch gelatinization. Less steam and water is added during preconditioning than in cooking extrusion, resulting in a feed mixture with 16–18% moisture. The other major difference in the UPC system is the modified action in the barrel of the pelleter, where the auger or rotor turns 2–3 times faster than a conventional cooking extruder. This increases production levels to 18–20 Mt/hr, nearly the same as steam pelleting. The fast-turning rotor adds much more energy to the feed mixture, and the frictional energy associated with the faster-turning rotor and lower moisture in the feed mixture further gelatinizes the starch, to 60–80%. In addition, the combination of frictional energy and steam pasteurizes the feed mixture, unlike compressed pelleting, even when expansion is used. Because the moisture content of the feed mixture is lower than in cooking extrusion, there is less water entrapped in the feed mixture and thus, less expansion when pellets exit the die. This results in a higher bulk density for UPC pellets than for cooking extrusion pellets, but the UPC system can produce pellets from 400 g/L to 600 g/L,

depending on how it is operated (Table 1). Pellets can be dried in a cooler rather than in a dryer. This reduces the amount of equipment and lowers the cost of production. The UPC produces higher-density pellets than cooking extrusion, but without the glazed surface associated with compressed pelleting. By top-dressing, up to 30% higher levels fat can be added to the dried pellets. An additional benefit of the UPC pelleting system is that the dense particles for starter feeds can be produced by turning the external knife faster. This eliminates conventional crumbling by rollers and the inevitable production of fines. As is the case with cooking extrusion, gelatinized starch acts as a pellet binder.

Comparing the Types of Pellets

The main issues important to fish farmers concerning feed pellet type are starch digestibility (determined by the degree of gelatinization), pellet density (buoyancy), water stability, durability, nutrient destruction during pelleting, and cost. How the types of pelleting processes affect these issues is summarized in Tables 1 and 2. Each pelleting process has advantages and disadvantages, but for each major species of farmed fish, there is generally a clear advantage of one type of pelleting process (Table 3). The UPC process is not likely to replace either compressed pelleting or cooking extrusion, but for some sectors of aquaculture, it may produce a product that fills a niche between compressed and extruded pellets.

Crumbles (Starter Feeds)

Steam pelleting is used mostly to produce grower feeds, but starter feeds have also been produced for many years using the same method. Since the minimum size of a

Table 1. Typical Physical Qualities of Various Types of Fish–Feed Pellets

Physical Quality	Compressed	Annular Gap	Extruded	UPC
Density (g/L)[a]	590	680	400–550	400–600
Maximum temperature (C)	95	135	150	150
Time exposed to steam	<1 min	<1 min	2–5 min	2–3 min
Starch gelatinization (%)	<40	65–70	>80	60–80
Maximum fines (%)	2–3	<1	<1	<1
Maximum fat level (%)	18	25	38	30

[a]480 g/L is the breakpoint for pellets to float; higher-density pellets sink, lower-density pellets float in freshwater.

Table 2. Attributes of Pellet Types Important to Fish Farmers

Attribute	Compressed	Annular Gap	Extruded	UPC
Starch digestibility[a]	Low	High	High	Medium to high
Pellet buoyancy	Sinking	Sinking	Floating/sinking	Floating/sinking
Water stability	Low	Low	High	High
Durability	Low	Medium	High	High
Nutrient destruction[b]	Low	Low	Medium	Medium/low
Cost of pelleting	Lowest	Low	Highest	Medium

[a]Starch digestibility is a function of the degree of gelatinization.
[b]Nutrient destruction during pelleting is caused by high temperature, high pressure, length of time that feed mixture is exposed to high temperature, and most greatly affects certain vitamins and the carotenoid pigment, astaxanthin.

Table 3. Current Applications of Various Pellets for Selected Types of Aquaculture[a]

Aquaculture Sector	Pellet Type	Important Qualities
Catfish, pond culture	Cooker extruded	Starch, floating
Salmon, marine net-pen culture level	Cooker extruded	Slowly sinking, high fat
Rainbow trout, raceway culture durability, medium fat	Compressed, extruded	Cost, density, level
Shrimp, semiintensive pond culture	Compressed, extruded	Water stability, cost
Sea bass, sea bream	Cooker extruded	Slowly sinking, starch

[a]UPC pelleting has just been introduced and is not yet widely used.

steam pellet is usually limited to 3 mm, crumbling is necessary to produce smaller feeds. Crumbles are made by crushing steam pellets between rollers moving at different speeds, and the resulting pellet fragments are screened to produce several size ranges of particles (4). Crumbling creates particles that have jagged irregular shapes, with a high surface area-to-volume ratio. These feeds disintegrate in water relatively quickly and thus care must be taken to avoid water-quality deterioration when crumbles are being fed to fry.

LARVAL FEEDS

Many technologies have been used and are being developed for the production of aquatic larval feeds. The technology for larval feed production (8–10) is necessarily different from that used for the production of starter feeds (1) due to the extremely small size of larval feeds (less than 400 μm), and thus the high surface area-to-volume ratio of such small particles. Leaching of water-soluble nutrients is a major problem in larval feeds (11). These feeds also need to be highly palatable, and the nutrients must be digestible to larvae that may not have a completely functional digestive system at first feeding. Some methods of larval-feed binding lower nutrient availability and palatability of the feed.

The methods for producing larval feeds can be classified into three major categories. These are microbound, microencapsulated, and complex particles. The first two feed types are differentiated by the type of binding that holds the particles together. Microbound particles are held together from the inside of the particle by a variety of different binders (12,13). Microbound feeds can be produced in the appropriate particle size with some processing methods, or a cake or flake is formed and then crumbled to the appropriate size. Ornamental fish feeds have been traditionally produced using flaking technology, a microbound processing method.

Microencapsulated feeds are surrounded by a layer of material, a capsule that retains the feed-ingredient mixture inside the particle (11,14). These particles can be designed to have a slow release of the material inside the capsule, or to totally prevent leaching of the water-soluble nutrients. Complex particles consist of embedded and carrier particles. A smaller embedded particle is placed inside a larger carrier particle. The embedded particle can be produced using the same manufacturing method that is used to produced the carrier particle, or by a different method.

Combining particle types takes advantage of the benefits from different processing methods and hopefully, eliminates some of the disadvantages of each. For a detailed discussion of the production of microbound and microencapsulated feeds and complex particles, please refer to the articles on microbound feeds, microparticulate feeds and complex particles, and microencapsulated feeds.

OUTLINE

Before Fertilizing
Types of Fertilizer
Applying Fertilizer
Troubleshooting
Bibliography

Fish farmers and recreational farm pond owners fertilize ponds to increase fish production and to prevent rooted aquatic weeds from becoming established. Aquaculture ponds are fertilized to increase the available natural food organisms (phytoplankton and zooplankton) for fry or larval fish, or for use by species that are efficient filter feeders. Recreational ponds are also fertilized to increase the available natural food organisms. A well-managed fertilized recreational pond can produce 227 to 455 kg of fish/ha (200 to 400 lb/acre) annually (1,2). This is three to four times the fish production that can be obtained without fertilization. Fertilizer nutrients stimulate the growth of microscopic plants (phytoplankton) in the water. Phytoplankton, in turn, serve as the plant food base for other organisms (zooplankton and larger animals) that are then consumed by fish. Abundant growth of phytoplankton gives water a greenish color called a "bloom" that can prevent light from reaching the pond bottom and thereby reduce the potential for growth of rooted aquatic weeds.

Not every pond should be fertilized. In many cases, increased production of fish is not desirable. If a pond's primary purpose is for watering cattle or wildlife habitat, fertilization is unnecessary (3). Similarly, pond owners desiring clear water should not fertilize. In clear water, however, rooted aquatic vegetation is more likely to become abundant than in waters where transparency is reduced either by plankton blooms or clay turbidity. Fertilization of recreational ponds to increase fish production is of little value if the angling pressure is not high enough to utilize the increased fish biomass.

Fertilization is a common practice to increase yields of bass and sunfish from ponds. An overcrowded sunfish population or a pond that is otherwise out of balance in terms of the relative proportions of bass and sunfish should be corrected before initiating a fertilization program. Also, ponds dominated by undesirable fish species should not be fertilized until the contaminating fish are eradicated. It is usually not necessary to fertilize catfish ponds in which the fish are fed regularly, since the provided feed represents a supplemental nutrient source, especially from uneaten or wasted feed. Raising catfish with feed is an excellent choice for producing fish in ponds that have low alkalinity water and where liming is not an option.

BEFORE FERTILIZING

Before beginning a fertilization program, test the alkalinity, total hardness, and calcium hardness of the pond water. Waters that are low in alkalinity or total hardness (below 20 ppm) will need liming for fertilizers to be effective (4,5). Most ponds that receive runoff from watersheds with acid soils will have low-alkalinity and/or low-hardness water. Typical application rates for agricultural or dolomitic limestone are 1 to 3 tons/acre (6). The recommended liming rate is based on the lime requirement of the pond bottom soils, as determined by soil testing. Ponds should not be fertilized at the same time that lime is applied, since the calcium in lime will remove phosphorus from the water.

Ponds that are muddy, infested with weeds, or subject to excessive water flow should not be fertilized until the problem is corrected. Mud prevents light from entering the water, thereby inhibiting phytoplankton growth. Weedy ponds should never be fertilized, as the nutrients will simply stimulate the growth of more weeds, rather than phytoplankton. Excessive water flow (where the pond water volume is exchanged in less than two weeks) dilutes the fertilizer nutrients to the point where they are ineffective. In addition, nutrients flushed from the pond can pollute downstream waters.

Although the plankton blooms that result from fertilization can be highly desirable, excessive fertilization can cause problems. Dense plankton blooms [Secchi disk visibility <30 cm (12 in.)] can lead to plankton die-offs (and, in turn, dissolved oxygen depletions), critically lower dissolved oxygen readings in the morning, and elevated afternoon pH levels, which increase the concentration of un-ionized (toxic) ammonia in the water and can stress fish. In some cases, dense algae blooms result in direct production of toxins in the water. These factors should be considered when weighing the benefits of implementing a fertilization program for a pond.

TYPES OF FERTILIZER

The formulation of a fertilizer, or grade, indicates the percentage by weight of nitrogen (N), phosphorus (as P_2O_5), and potassium (as K_2O). For example, an 11-37-0 fertilizer contains 11% nitrogen, 37% phosphorus (as P_2O_5), and 0% potassium (as K_2O). Phosphorus is the most important nutrient in pond fertilization (4,7,8), but occasionally nitrogen or potassium may limit plankton production (9,10). In new ponds, some nitrogen may be beneficial, while potassium is rarely, if ever, needed. In selecting a fertilizer, choose a formulation that is high in phosphorus.

Inorganic fertilizer comes in liquid, powdered, or granular forms. Liquid fertilizer dissolves the most readily (11), followed by powdered, and then granular forms. Powders are generally more expensive than liquid or granular forms, but are relatively easy to apply.

Although more expensive than other fertilizer forms, controlled-release fertilizer is now available for pond owners (12). The resin-coated granules slowly release nutrients into the pond water, with the rate of release corresponding to water temperature and water movement. Ideally, one application of controlled-release fertilizer in the spring will be sufficient for the entire growing season. However, this is subject to other environmental factors that may result in reduced blooms or bloom die-offs, and supplementation with a more readily available source of nutrients may be necessary following these events.

Organic fertilizers, such as cottonseed meal, are used in combination with inorganic fertilizers for preparing larval fish ponds (13,14). Organic materials are generally not recommended as recreational farm pond fertilizers, since excessive amounts of organic fertilizer may result in critically low dissolved oxygen levels, possibly killing fish. In addition, they can promote the growth of undesirable filamentous algae (commonly known as pond moss or pond scum).

All of these pond fertilizers should be readily available through any farm supply dealer. Numerous name brands exist, and some are formulated specifically for pond fertilization. However, any fertilizer formulation providing the appropriate nutrient levels can be used, unless the product contains other ingredients that may be harmful to fish or other aquatic organisms. For example, some fertilizer products marketed primarily to homeowners and intended for lawn or turf application may contain either herbicides or insecticides. Although the nutrients supplied may be suitable for pond applications, these should be avoided.

APPLYING FERTILIZER

Table 1 gives suggested fertilization rates for ponds based on water calcium hardness and type of fertilizer (7,15). Provided that the alkalinity of the water exceeds 20 ppm, the rates listed in the table are based upon calcium hardness, since some phosphorus applied in the fertilizers can be removed by calcium before it is taken up by plankton. This becomes a greater problem as hardness increases. Rates should be adjusted based on the response of each individual pond. For example, ponds that receive runoff from active pastures are likely to require less fertilizer, due to nutrient influx from the surrounding watershed.

The risk of low dissolved oxygen conditions in a pond is increased somewhat with the application of fertilizer, although the benefits likely outweigh the added risks. Even unfertilized ponds will experience turnovers or bloom die-offs that can lead to low dissolved oxygen (16). Excessive fertilization should be avoided as it can produce such a dense bloom that the risk of oxygen depletion increases greatly. Allow at least one week, preferably two, between fertilizer applications to evaluate the result of each application. As pond water becomes warmer, the response to a fertilizer application will be stronger and more rapid.

Begin fertilizing in the spring when the water temperature stabilizes above 15 °C (60 °F). Make three applications of fertilizer two weeks apart, then make additional applications whenever water transparency exceeds 45 cm (18 in.). A Secchi disk can provide a consistent means of evaluating the density of the pond bloom. Recreational ponds will require additional applications of fertilizer at intervals during the summer months and into the fall. In some cases, depending upon the weather and rainfall amounts, as well as water hardness, up to 10 to 12 applications are required (15). Aquaculture ponds, especially if fish are fed a commercial ration, will not require many applications. In ponds where fish are fed, a few fertilizer applications in the spring may be all that is needed to get a bloom established.

If the decision is made to fertilize a pond, it is important to follow a fertilization schedule and to continue to monitor the pond and add fertilizer as needed. Especially in recreational ponds, the increased weight of fish produced as a result of the initial fertilizer applications cannot be sustained without maintaining a good bloom. Fish will

Table 1. Suggested Fertilization Rates (per application)[a]

| Fertilizer | | Water Calcium Hardness[b] | | |
Type	Grade	Low Hardness	Moderate Hardness	High Hardness
Liquid:	11-37-0	0.5−1 gal/ac	1−2 gal/ac	2−4 gal/ac
	13-37-0			
	10-34-0			
Powder:	12-52-4	4−8 lb/ac	8−16 lb/ac	16−32 lb/ac
	12-49-6			
	10-52-0			
Granular:	0-46-0	4−8 lb/ac	8−16 lb/ac	16−32 lb/ac
	0-20-0	8−16 lb/ac	16−32 lb/ac	32−64 lb/ac
Time release:	10-52-0	25 lb/ac	30−40 lb/ac	50 lb/ac
	14-14-14	75 lb/ac	100−125 lb/ac	150 lb/ac

[a]Use this table as a starting point and modify for pond conditions by adding more or less fertilizer per application.
[b]For pond waters with calcium hardness below 50 mg/L, use the low rates. For water with calcium hardness between 50 and 100 mg/L, use the moderate rates. For waters with calcium hardness above 100 mg/L, use the high rates. Most recreational farm ponds will be low in hardness. After the initial application, apply one-half of the recommended application rate. It is likely that high hardness waters will require more frequent fertilizer applications to maintain pond blooms.

lose weight and be in poor condition if the bloom is not maintained. Discontinue fertilization for the year when the water temperature drops below 15 °F (60 °F) in the fall. Fertilization of ponds during the winter is ineffective (17) and can lead to excessive growth of undesirable filamentous algae the following spring.

Fertilizers are generally caustic materials. In applying fertilizer, take precautions to avoid unnecessary exposure to the fertilizer and clean the equipment thoroughly after each application. Always read and follow label directions for the product that you are applying. Wearing protective eyewear and clothing is advisable when handling any fertilizer formulation.

Methods for applying fertilizers vary with the form of the product. Mix one part liquid fertilizer with 5 to 10 parts water and splash or spray over as much of the pond surface as is practical. This dilution is essential, since liquid formulations are more dense than water and will sink to the bottom and become lost in the soils if not prediluted. For ease of application in larger ponds, diluted fertilizer can be poured into the prop wash of a boat as it is driven around the pond. Broadcast powdered fertilizers over as much of the pond surface as is practical. Powders are highly water soluble and most of the fertilizer will dissolve before reaching the pond bottom.

Granular fertilizers, such as triple superphosphate (0-46-0), are the least desirable choice for pond fertilization when a rapid bloom response is needed because they dissolve relatively slowly and will sink rapidly to the pond bottom if they are broadcast (18). However, triple superphosphate is also one of the least expensive pond fertilizers, and can be used with great success in recreational fish ponds. If a granular fertilizer is used, it must be applied in a manner that avoids soil contact. Granular fertilizers should not be broadcast onto a pond. Granules can be poured onto an adjustable platform that can be maintained at a depth of 4−12 in. below the water surface. One properly placed platform will serve for a pond up to 2.0 to 2.4 ha (5 to 6 ac) (19). Although the design of a platform is not critical, and many shapes and configurations can be utilized, platform construction and placement can be difficult in existing ponds. Alternatively, fertilizer bags may be slit on the larger, flat side in an "x" fashion, corner to corner, so that one side of the bag can be removed. The bags can be slit prior to being placed in the water, or they can be placed in shallow water and then slit to reduce spillage of granules. Controlled release granules must also be kept from contact with the mud and should be applied in the same manner as other granular fertilizers.

TROUBLESHOOTING

Every pond is different and will respond differently to an identical fertilizer application schedule. The recommendations given in Table 1 are suggested rates only. The number and frequency of fertilizer applications necessary to obtain a satisfactory bloom will vary from pond to pond. Fertilization to stimulate the development of an algae bloom in ponds will not be effective in many situations, and corrective action will be required. Table 2

Table 2. Trouble-Shooting Common Problems

Situation	Corrective Action
Water flow to pond is such that water is exchanged in less than two weeks.	Divert runoff or stream around pond.
Pond is excessively muddy (turbid).	Treat the pond with alum or gypsum (20−22).
Pond is heavily infested with aquatic weeds.	Control weeds through mechanical, biological, or chemical means. (23,24)
Alkalinity of the water is low (<20 ppm as $CaCO_3$).	Lime the pond. Contact your county extension office for assistance.
Water temperature is <15 °C (<60 °F.)	Delay applying fertilizer until the water warms.
Pond is heavily shaded by surrounding trees.	Clear overhanging vegetation from the shoreline.

lists many of the common problematic situations and corrective actions.

Particulate matter removal is a major design consideration and management task for intensive aquaculture systems. Externally, particulates discharged from an aquaculture system can cause environmental pollution due to the organic nature and nutrient content of the material. Internally, accumulation of suspended particles in a recirculating system can cause fish gill damage (1), mechanical clogging of biofilters, additional ammonia production due to mineralization, and increased oxygen demand as the particles decay. Consequently, particulate matter has to be removed from intensive aquaculture systems such as raceways and water recirculating systems.

The removal of suspended particles from an aquaculture system is typically accomplished in a filtration process, where the particles are mechanically separated from the liquid stream, and removed later. The term "mechanical filtration," as used in this entry, is broadly defined as a physical process that separates solid particles from the culture water by gravity or physical restrictions. Thus, the filtration processes discussed here include mechanical filtration and sedimentation. This entry discusses the characteristics of particles that are related to filtration,

filtration mechanisms, typical filtration processes, and process selection.

PARTICLE SOURCES AND CHARACTERISTICS

The amount of particulate matter in an aquaculture system is typically represented by the total suspended solids (TSS) concentration, which is defined as the mass of particles [in mg/L (ppm)] that are larger than $2 \, \mu m$ in diameter (2) contained in a known volume of water [1 L (0.26 gal)]. Virtually all the wastes generated in an intensive aquaculture system originate from feed. Of the different forms of fish excretory products, TSS primarily in the form of feces, is a major component. The mass production rate of feces is determined by the feeding rate. Quantitative investigations on several finfish species indicate that an estimation of feces production ranging from 20 to 30% of the feed consumed is well accepted. Other components of suspended solids in an aquaculture system include uneaten food and bacteria biomass.

The two most important physical characteristics of suspended solids, with regard to filtration, are particle density and size distribution. Density can be represented by specific gravity, which is the ratio of the density of a wet particle to that of water (2). The specific gravity is determined by the source of the particles, and depends largely on the characteristics of the feed and the feces. Size distribution is determined by the source of particles, the fish size, the temperature, and the turbulence in the system. Reported specific gravities of the particulate matter in aquaculture systems ranged from 1.004 to 1.19 (3,4).

Information on size distribution of fish feces is difficult to obtain because size distribution may vary according to certain conditions. When fecal material is first excreted from the fish, the particle size of the material is relatively large. The large particles may soon break down into smaller ones depending on the turbulent conditions and the stability of the fecal particles. Table 1 shows the particle size distribution of fecal particles 24 hours after being excreted from catfish fed with four types of feeds using different binders. Other reports on particle size distribution indicate that large particles (>30 microns) were dominant in fish feed, and fine particles (<30 microns) dominated the culture water of recirculating systems (5).

FILTRATION MECHANISMS

Suspended solids removal by filtration is a solid/liquid separation process, which is accomplished when the

Table 1. Particle Size Distribution (%) of Fish Excretion in Response to Different Feed Binders

Particle Size (μm)	Feed 1	Feed 2	Feed 3	Feed 4
1–30	18.8	18.5	18.6	18.3
30–105	76.3	77.8	76.5	76.5
105–1000	4.8	3.7	5.0	5.2

particles attach to an interface that provides a stronger attractive force to the particles than water. The dominant mechanisms in filtration processes include sedimentation, straining, interception, and diffusion.

Sedimentation

In the sedimentation process, solid particles are separated from water as a result of the density difference between the particles and water. For the typical TSS concentration range in an intensive aquaculture system, sedimentation is typically discrete. Each particle has a constant settling velocity that is independent of the settling velocities of other particles. Thus, the sedimentation efficiency depends on settling velocity. For the majority of the particles in aquaculture systems, the theoretical settling velocity, V_s (m/s), can be calculated using the equation

$$V_s = \frac{g(\rho_p - \rho)D_p^2}{18\mu} \tag{1}$$

where

g = gravitational acceleration (m/s^2),
ρ_p = density of particles (kg/m^3),
ρ = density of water (kg/m^3),
D_p = diameter of particles (m), and (3 ft),
μ = dynamic viscosity (Pa sec).

Equation (1) shows a direct relation between acceleration, particle density and particle size and the velocity with which the particles will settle out of water.

When sedimentation occurs in filtration processes that use granular material as a filter medium, the particles tend to deviate from the flow streamline due to the density difference. A particle's deviation from the streamline results in contact between the solid particle and the filtration medium. The efficiency of transport of the particles due to sedimentation in a granular filtration process can be calculated according to the equation (6)

$$\eta_s = \frac{(\rho - \rho)gD_p^2}{18\mu \cdot V_{sp}} \tag{2}$$

where

η_s = transport efficiency by sedimentation and
V_{sp} = superficial velocity (m/s).

Straining

Straining occurs when particles larger than the pore size of the filter medium (or opening of the screen) are strained out mechanically as the water passes through. In some cases, smaller particles can also be separated from the flow when several particles bridge together to form a cluster that is larger than the pore size.

Interception

If a particle has no significant settling velocity, it will follow the streamline of the flow while the liquid passes by an interface (e.g., a filter medium surface). When the distance between the streamline and the surface is less than the radius of the particle, the particle will collide with the surface, and the collision may result in subsequent attachment. The particle is then said to be intercepted by the interface. The efficiency of interception can be estimated by (7)

$$\eta_I = \frac{3}{2}\left(\frac{D_p}{D_s}\right)^2 \tag{3}$$

where

η_I = interception efficiency,
D_p = diameter of the particle (m),
D_s = diameter of the media or the interface (m).

Equation (3) indicates that the bigger the particle and the smaller the size of the interface, the higher the efficiency due to interception.

Diffusion

Diffusion due to Brownian motion is another important transport mechanism in filtration. This transport mechanism is most significant, for particles less than several microns. The efficiency of particle transport onto an individual interface can be estimated by the equation (6)

$$\eta_d = 0.9\left(\frac{kT}{\mu D_p D_s V_{sp}}\right) \tag{4}$$

where

η_d = diffusion efficiency,
k = the Boltzmann constant (1.38×10^{-23} J $^\circ$K), and
T = absolute temperature, $^\circ$K.

Equation (4) shows that at a given temperature, the efficiency of transport due to diffusion is inversely related to both particle and interface sizes.

In a granular filtration or floatation process, the ultimate separation efficiency also depends on the attachment efficiency after the solid particles have been transferred onto the interfaces (or the media). The attachment process is complicated since it is affected by many factors, including particle size and density, Reynolds number, and particle surface properties. Because the transport of a particle onto an interface is the first step in separation, Equations 1–4 should provide insight for evaluating the effectiveness of different processes for solids separation.

PROCESS DESCRIPTION

A variety of filtration unit processes have been applied to aquacultural operations. These processes, based on the filtration mechanisms, can be divided into the following main categories: gravity separation (clarifiers, tube settlers, and hydrocyclones), granular filtration [granular media (GM) filters, porous media (PM) filters],

screening (rotating drum filters, triangular filters), and floatation units (foam fractionation).

Settling Basins

Sedimentation is among the simplest of technologies available to separate solid particles in wastewater treatment. A sedimentation process is usually accomplished in a settling basin or tank (also called a clarifier). The key design parameter for settling basins is the overflow rate (V_o), which is defined as the volumetric flow rate per unit surface area of the basin. The overflow rate can be directly related to the settling velocity of the particles to determine if a particle will settle out. Any particle with a settling velocity (V_s) greater than the overflow rate (V_o) will settle out of the suspension. Finer particles, for which $V_s < V_o$, will be removed in the ratio V_s/V_o, depending upon their vertical position at the inlet of the tank.

Field investigations revealed that an appropriate overflow rate (V_o) for the design of settling basins in intensive salmonid aquaculture systems typically ranges between 40–80 $m^3/m^2/d$ (982–1964 gpd/ft^2). These overflow rates translate to particle settling rates (V_s) of 0.046–0.092 cm/s. At these settling rates, approximately 65 to 85% of the total suspended solids will be removed in the settling basin. A number of factors, such as turbulance, scour and short-circuiting, lower the performance of settling basins.

The main advantages of sedimentation processes include minimal energy input, low installation and maintenance costs, and low operational skills requirement. The main disadvantages are low hydraulic loading rate and poor removal efficiency of small particles (<100 μm). Settling basins (or tanks) have been widely used in effluent treatment for flow-through aquaculture systems. For recirculating systems, however, sedimentation alone may not be sufficient for solid removal as fine solids tend to accumulate.

The performance of settling tanks can be improved by installing tube settlers consisting of inclined tubes or plates (8). In a tube settler, sedimentation is enhanced in three ways: the multiple tubes stacked above one another provide a large effective settling area; the small hydraulic radius of the tubes maintains laminar flow and promotes uniform flow distribution; and the movement of particles against the direction of flow favors particle contact in steeply inclined tubes.

Hydrocyclones and swirl separators are another type of gravitational solids separator. The hydrocyclone is a cone-shaped structure. Water is introduced tangentially toward the top of the unit. The tangential flow causes a swirling motion within the unit. At sufficient velocities 15.2–18.3 m/s (50–60 ft/s) a vortex forms within the center of the hydrocyclone. Hydrocyclones employ the principle of centrifugal sedimentation whereby the weight difference between the particles and water is amplified, thus, enhancing the gravity separation by increasing the value of the acceleration. The density difference between the solids and water is the main factor determining the separation efficiency (9). The fact that solid particles found in aquaculture systems have low densities detracts from the benefits of the centrifugal separation approach.

Although the continuous operation of the hydrocyclone is advantageous, drawbacks to this system include poor removal of fine particles (<35 μm) and the need for large pumps to maintain flows with high head loss.

A swirl separator is a version of the hydrocyclone in which flow is introduced in a much slower velocity, and a vortex does not develop in the center. Water flows out of the unit by means of a cylindrical weir. A swirl separator can best be described as an accelerated settling basin. The swirl separator augments the natural gravitational force through utilizing the centrifugal force generated by the gentle swirling within the unit. As with the hydrocylclone, specific gravity becomes the limiting factor in a swirl separator.

Microscreen Filters

Screen filters are widely-used filtration devices that operate by straining particles from the water. There are two types of screens, stationary and rotary, which are used according to the mode of operation. Stationary screen filters are usually placed perpendicular to the direction of the flow. As water flows across the screen, the particles suspended in the water are strained onto the screen surface and become separated from the water. Stationary screens are one of the simplest filtration methods. When the screens become clogged, however manual backwashing is usually needed, thus the operation is intermittent. Triangle filters address this problem by passing the influent down an inclined screen surface. The water flows through the screen, while the particulates resting on the screen surface are pushed by the influent and by high-pressure cleaning water to the end of screen. In a triangle filter, the backwashing is automatic, and the process is continuous.

Rotary microscreen filters are designed to mitigate the clogging potential. A typical configuration of a rotary microscreen filter consists of a motor-driven rotating drum mounted horizontally in a rectangular chamber. A fine-screen medium covers the periphery of the drum. Influent water enters the drum at one end and passes radially through the screen with the accompanying deposition of suspended solids on the inner surface of the screen. When the pressure drop across the screen reaches a given level, pressure jets of clean (or effluent) water, at the top of the drum, are directed onto the screen to remove the mat of deposited solids. The dislodged solids, together with that portion of the backwash stream penetrating the screen, are captured in a waste hopper that discharges to a settling basin.

The design of a microscreen filter includes the selection of screen opening size, hydraulic loading rate, drum rotating speed, and backwash pressure. The desired screen opening size is determined by the specified operation. Typically, screen opening sizes of greater than 60 μm are used for aquaculture applications. Although smaller pore sizes increase suspended particulate removal, the associated increase in backwash frequency and high pressure requirements partially offset the benefits. Hydraulic loading rate to a microscreen filter is very sensitive to screen pore size and solids concentration in

the influent. The finer the opening size and the higher the solids concentration, the lower the hydraulic loading.

Screen filters have been used in aquaculture systems for both effluent polishing and solids removal in recirculating systems. Additionally, screening can be especially useful as a pretreatment before sand filters (or other biological filters) in recirculating systems. Compared to other solids removal processes, microscreen filters are more suitable for effluent polishing because they can handle large hydraulic loading, and the effluent quality can be controlled to meet specific requirements by selecting the right screen size.

Granular Media Filters

A granular (GM) media filter typically consists of a cylindrical vessel that contains a solid granular medium such as sand or plastic beads. A screen capable of retaining the medium, while still allowing water to pass, is placed at the effluent side of the medium. When water flows through the bed of the granular material, suspended particles deposit onto the medium surface through either sedimentation, straining, interception, or diffusion. The filters are operated in the filtration mode until the hydraulic conductivity of the bed drops due to solid accumulations. The filter is then bypassed, and the bed is washed (or backwashed) by increasing or reversing the flow through the bed until the bed expands and fluidizes, releasing the captured solids.

Three types of granular filters are commonly used in aquaculture applications: downflow pressurized sand filter, upflow sand filter, and floating plastic beads filters. The main advantage of upflow sand filters over downflow filters is that the upflow sand filters can avoid caking problems that plague traditionally designed downflow filters. The main advantage of bead filters is their ability to reduce water losses associated with backwashing the filter bed.

Solid removal efficiency of a GM filter depends mainly upon the size of the particles, the size of the filter medium, and the flow rate. For particle sizes above approximately 40 μm, straining is the controlling removal mechanism. For particles smaller than 1 μm, diffusion will control particle transport. Between the two limits, interception and gravity sedimentation dominate particle capture.

A major advantage to using granular filters in fish culture systems is that such filters can also be used for biofiltration as the medium provides surface areas for bacteria to grow on. It combines the two processes into one unit. The main disadvantage of using granular filters for solid removal is the high energy consumption. Granular media filters require between 3.3–10 m (10–30 ft) of head pressure to operate. Another disadvantage of some granular filters is the water loss during backwashing processes.

Porous Media Filters

Porous media (PM) filters usually have thicker media than screen filters and finer pore sizes than granular filters. Porous media filters are similar to screen filters since straining is the main mechanism for solid removal.

Porous filters usually have lower hydraulic loading rates and higher head losses than screen filters. Two examples of porous filters are diatomaceous earth filters (DE) and cartridge filters. A DE filter consists of a vessel in which a septum is supported. Deposited on the septum are thin layers of a filter aid known as a precoat, which is the effective filtering medium. Cartridge filters use disposable cartridges of different sizes. Due to their fine pore size, both DE and cartridge filters can remove very small solid particles (<1 μm). Consequently, they are very susceptible to clogging even at low influent TSS concentrations, and they experience high head losses. Recharging or replacement demands effectively prohibit the use of porous filters as the principal solid capture device in intensive production systems.

Foam Fractionation

A common name for suspended solids removal using dispersed air bubbles is foam floatation or, in a broader sense, bubble separation. A typical foam fractionation unit is a bubble column where bubbles generated at the bottom rise through a liquid in which solids are suspended. Solid particles attach to the bubble surface with the help of surfactants (e.g., a protein) in the water, forming foam that is removed at the top of the column. Like granular filtration, solid mass transfer from the liquid to the bubble surface is mainly through diffusion, interception, and sedimentation (10). Although foam fractionation is primarily designed for dissolved, surface active organics removal, it can also remove fine suspended solids with diameters smaller than 30 μm. Foam fractionation can be a continuous operation with no backwashing necessary. However, since foam fractionation is affected by the uncontrollable chemical properties of the water and the solids in a system, solids removal may be erratic.

PROCESS SELECTION

Understanding filtration processes is critical to the development of an integrated treatment scheme for either effluent polishing or wastewater treatment. One of the major differences among the processes is fine solids removal capability. Figure 1 illustrates particle size ranges over which each process is effective. The major goal in selecting a process for TSS control is to achieve the required water quality while minimizing capital and operating costs. The main factors to keep in mind are
Figure 1. Suitable particle size range for different filtration processes.

the objective of the filtration process, the integration with other system components and the simplicity of operation. Main criteria for evaluation of a TSS control process used in recirculating systems should include the following: (*1*) hydraulic loading rate, (*2*) fine solids removal capability, (*3*) head loss, (*4*) water loss during filter backwash, and (*5*) resistance to clogging.

Clearly, one filtration process may be more appropriate than others for a given application. Adequate consideration of alternatives, including an evaluation of the capabilities and limitations of each process, will assure a successful application. Additional information can be obtained in other literature (11,12).

FINANCING

DANNY KLINEFELTER
Texas A&M University
College Station, Texas

OUTLINE

As in any developing industry, financing for the aquaculture industry has been limited by the lack of experience of both lenders and producers, as well as by the rate at which the aquaculture industry infrastructure has developed. Despite the obstacles that still must be overcome, the prospects for aquaculture financing are brighter today than ever before.

This entry addresses the following topics: (*1*) current changes occurring in financing requirements, (*2*) financing issues specific to aquaculture, (*3*) sources of financing, and (*4*) recommendations for enhancing the availability of financing.

THE CHANGING FINANCING ENVIRONMENT

Although there are many specific concerns related to the availability of financing for aquaculture, the most significant changes in lending practices and policies are not unique to aquaculture financing and are applicable to all agricultural borrowers. The changes are primarily due to significant loan losses, the number of financial institution failures, and tighter regulatory requirements, all of which resulted from the financial experiences of the 1980s.

Most of the changes borrowers are experiencing fall into the following five categories:

1. Lender's more rigorous requirements for additional and accurate information.

2. More thorough analysis and verification of the information provided.

3. Greater emphasis on both repayment ability and risk management.

4. Increased requirements for monitoring business performance after loans are made.

5. Stricter adherence to the lending institution's policy guidelines, i.e., fewer exceptions to the rules.

Agricultural producers, including aquaculture producers, are beginning to be treated like any other commercial borrowers. They will be required to develop detailed business plans that rely on trends and past performance

and incorporate general economic and specific enterprise outlook analysis. Borrowing will become increasingly complex whenever operations are vertically integrated or involve multiple ownership. In cases where ownership interests involve a variety of businesses, loan analysis also will require more thorough evaluation of contractual arrangements between entities and financial statement consolidations.

Many borrowers tend to view much of the information lenders request as just more red tape but the marketing, production, and financial information a lender needs are important to the borrower if he is going to successfully manage his business.

When preparing a loan request and a business plan, prospective borrowers need to recognize and address the following questions:

1. How much is to be borrowed over the planning period?

    The loan request should not be an initial figure, but should account for the entire period, and the final purpose of, the loan request. Lenders don't want to loan the full amount they feel comfortable extending and then find they need to lend significantly more in order to see the situation to completion. Borrowers' estimates of repayment ability need to be realistic and conservative, and cost estimates need to address typical contingencies.

2. What is the loan going to be used for?

    Borrowers must be specific. It's not enough to say "operating expenses." In the past, too many operating loans have been used to subsidize lifestyles, refinance carryover debt, and finance capital purchases. Plans need to be supported not just by budgets, but by historical documentation showing that they represent past experience. Many projections appear to be based on realistic estimates, but further investigation often reveals that estimates represent performance levels out of line with what the business has actually been able to achieve in the past.

3. How will the loan affect the borrower's financial position?

    Borrowers should know their net worth, financial structure, historical cash flows, profitability, and risk exposure at the time of the loan request, and estimate what things will look like after the loan is made.

4. How will the loan be secured?

    Borrowers need to recognize the fact that collateral is adequate only if, under the worst conditions, enough collateral could be collected to generate sufficient cash to repay the loan and cover all the costs involved. Except for control purposes, collateral's primary purpose is to provide insurance in the event of default. Therefore, the important lending consideration is not the collateral's worth at the time of the loan request, but the expected value at the due date of the note or at the date of the next scheduled payment. The lender needs to account for the period of time involved, potential changes in collateral value and condition, legal and selling costs, and the fact that a distress sale will bring less than an arm's length transaction under normal market conditions. The changing nature of security has been one of the most significant factors affecting agricultural lending. More loans are now based on soft, rather than hard assets, i.e., contracts and leases versus land and chattel. There are also more joint ownership arrangements and market risks related to specific attribute raw materials than to straight commodities. All of these factors make it more difficult for the lender to assess a net realizable value.

5. How will the loan be repaid?

    Borrowers must decide if repayment will come from operating profits, from nonfarm income, from the sale of the asset being financed, from refinancing, or from the liquidation of other assets.

6. When will the money be needed and when will it be repaid?

    This two-part question should be answered by the projected cash-flow budget. Answering the question establishes that both the borrower and the lender know how the business operates. Almost as many credit problems have resulted from a lack of understanding and communication as from unrealistic expectations. Marketing plans and trigger points, contract terms and conditions, and various pooling arrangements are often not adequately communicated or documented.

7. Are projections reasonable and supported by documented historical information?

    Too many producers still do not have the production, marketing, and financial records necessary to demonstrate their financial track record and support their numbers. Many loans have not been made that probably could have been repaid, simply because of a borrower's inability or unwillingness to provide the lender with complete and well documented historical information on his or her financial position and performance.

8. How will alternative possible outcomes, in terms of both prices and quantities, affect repayment ability?

    Because cash-flow projections are based on expected values, the actual outcome is frequently very uncertain. Even under marketing and production contracts with established price bases, quality discounts, and premiums can still result in a great deal of uncertainty. However, the most common error occurs when borrowers and lenders actually believe they are addressing the issue and evaluate the impact of standard scenarios such as a 10 or 25 percent decrease in revenues. For some businesses this practice overstates the risk involved, while for others it may seriously understate the potential risks. Alternatives considered

should reflect the business's actual historical performance variability as well a the range of current forecasts.

9. How will the loan be repaid if the first repayment plan fails?

No commercial lender wants to enter into a situation in which foreclosure is the only alternative if things do not go as planned. Contingency planning is critical. Every plan should have a backup plan, and every entry strategy should have an exit strategy. This latter point is particularly true where niche markets are involved.

10. How much can the borrower afford to lose and still maintain a viable business?

The borrower must recognize that a viable net worth is not any amount above zero. Most commercial lenders require a minimum equity position, e.g., 30 percent, below which they will not continue financing without an external guarantee. With this in mind, the answer to the preceding question must be based on the effect of various combinations of both potential operating losses and declines in asset values. Then, both the borrower and the lender need to determine how likely it is that such a situation will occur.

11. What risk management measures have been, or are to be, implemented?

Risk management measures can cover anything from formal risk management tools to management strategies. The most important issue is that both the borrower and the lender understand how these measures work. It is also critical that the lender is supportive and committed. For example, incorrect use of commodity futures and options can increase, rather than reduce, risk. A lender's unwillingness to finance margin calls can also destroy a successful hedge.

12. What have been the trends in the business's key financial position and performance indicators? If these trends are adverse, what are the specific plans for turning things around?

Timely action and the ability to manage problems are hard to measure, but as risk increases, they become critical in the credit decision process.

In addition to the changes discussed previously, a more subtle but significant shift in lending practices is occurring in response to legislation. This shift provides for additional borrowers' rights, more liberalized bankruptcy laws, and the threat of lender liability lawsuits. Lenders are becoming more selective in terms of whom they finance. Litigation usually arises from situations where the borrower is in financial trouble, therefore, it will become increasingly difficult for marginal and higher risk borrowers to qualify for credit. Just as malpractice lawsuits have changed the practice of medicine, the fear of legal action has changed the lending environment and caused lenders to be more cautious and conservative.

ISSUES IN FINANCING AQUACULTURE

The following are some of the broader issues specific to financing aquaculture.

Lack of Aquacultural Experience

Because risk is a function of uncertainty, the less a lender understands about a business or an industry, the greater is the risk he perceives. This risk is compounded if both the lender and the management of the aquacultural operation lack prior experience. While part of the problem is perceptual, the risk of something going wrong is actually greater, until an adequate amount of experience is gained, because mistakes are naturally made during the learning process.

Early Stage of Development

The rate of development of the industry infrastructure and the size of the market create a second problem in aquaculture financing. This problem manifests itself in the collateral value of the specialized equipment and improvements required for aquacultural production. If a market is expanding or is well established, specialized items tend to have a more ready market. However, the current situation in aquaculture often requires a large discount from the construction or purchase price in order to protect the lender from a limited or illiquid market.

The marketability of an aquacultural operation can be judged roughly by the number of processors or marketing channels bidding for the farm's product. If there is only one processor or marketing channel, there is less competition and a lower assurance of a continuing market. Therefore, in a market in which there is only one processor of the farm's production, improvements may be valued at as little as 10 to 20 percent of cost or book value, while the existence of three or more processors may increase this value to 40 to 60 percent. Obviously, these valuation factors are also influenced by the size, financial strength, and reputation of the processors involved. The same factors affect the collateral value of contractual arrangements between producers and processors.

Inventory Questions

A third problem that affects the availability of financing for aquaculture is the difficulty in establishing a value for growing products. Despite many jokes about lenders using glass-bottom boats and scuba gear, there are significant limitations on inventorying the growing products, both in terms of quantity and quality.

These problems differ significantly with the species produced. There are both new and established aquacultural products. For example, channel catfish *Ictalurus punctatus*, have been produced successfully on a large commercial scale for year, and the market is well established. While individual lenders or producers may lack experience with catfish, there is at least information and experience available. This experience can be accessed through the study of published materials, the employment of consultants, and the hiring of experienced management or loan

officers. The same situation does not exist, however, for many aquacultural enterprises.

Factors Outside the Business

The importance of a well-developed business plan in obtaining credit has already been mentioned. However, many of the plans developed by aquacultural producers have focused almost entirely on the internal or technical aspects of the business. The concern of many lenders is that the greatest risks may be related to factors outside the business. Thus, prospective borrowers have to address these outside factors in their plans.

Two particular areas outside the aquacultural firm that need to be considered are the general environment and the specific industry. The general environment needs to be evaluated in terms of social, cultural, economic, government/legal, technological, and international issues. The specific industry needs to be evaluated in terms of market forces represented by potential new entrants, supplier market power, buyer market power, substitute products, and the existing degree of competition.

Social and cultural issues include general attitudes toward the health and safety of farm-raised aquacultural products, consumers' religious beliefs, consumers' education, etc. Economic issues are based upon the end-users' ability to purchase the product. Disposable income, leisure time, spending priorities, changes in interest rates, inflation rate, and unemployment rate are some specific economic considerations. Government/legal issues can play a major role in an aquacultural project and should be examined carefully. Rights to water, exotic species permits, environmental regulations, and taxing authorities all need to be addressed in the planning process.

Competition

The competitive forces in the industry also require close examination. The ease with which new competitors can enter the industry should be considered. How rapidly will new entrants come, or existing capacity expand, in response to favorable prices levels? How much will prices fall if production increases significantly? While price response is difficult to estimate, producers should at least conduct a breakeven analysis to determine how far prices could fall and still allow the project to be viable. If the aquaculture project relies on outside sources for inputs such as feed, seed stock, etc., particular attention needs to be given to the potential market power of those suppliers. The same issues arise relative to the market power of buyers or processors. How able and how likely are suppliers or buyers to squeeze margins if they have or obtain significant market power because of either their size or limited numbers? Competitive advantage is also a function of the number of available substitute products. How sensitive is the market to price differences between competitive products?

Market Contracts

In addition to the factors listed in the previous section and the biological risks involved in production, one of the factors that most affects a lender's willingness to finance an aquaculture project is the ability of the borrower to obtain market contracts for his or her production. Contracts will be examined in terms of their length, pricing terms, and quantity and quality restrictions, as well as the reputation and financial strength of the contracting firm. Currently, only limited contracting opportunities exist for aquacultural producers. However, processing capacity is increasing, and many of the new aquaculturists are interested in contracting.

SOURCES OF FINANCING

The third area to be addressed relates to sources of financing. Unlike the other areas addressed here, sources of financing tend to be specific to each country. In the developing countries of the world, development banks, the World Bank, and government lenders are often involved in financing aquaculture projects. In the developed countries, however, most of the financing comes from private investors and commercial lenders. This section focuses on describing how in the United States different types of institutions and different types of programs are used to provide financial support to aquaculturists.

Aquaculturists with established operations or sufficient financial strength are usually able to qualify for credit from the various types of commercial lending institutions, such as commercial banks, agricultural credit associations, production credit associations, federal land bank associations, and life insurance companies. Others, however, wishing to enter aquacultural ventures involving products that have a successful track record, e.g., catfish, may be unable to secure loans from such sources because the borrower lacks management experience or financial strength or because the lenders are unwilling to lend because the borrowers have no previous experience. Hence, these producers may be able to obtain assistance through the Small Business Administration (SBA) or the Farm Service Agency (FSA, formerly FmHA). There are also programs in several states that can provide limited assistance.

A third group of aquaculturists are those interested in high-risk, but potentially high-profit, operations such as shrimp fanning. It is possible to obtain support for such ventures from SBA or FSA, but many of these operations will be forced to seek venture capital or obtain outside guarantors to provide additional financial strength. Finally, there are aquaculturists who are interested in obtaining funding for the development of commercial operations based on technology that has not been demonstrated outside of the research laboratory. Projects of this nature include artificial upwelling and closed culture of various species. There is little or no credit available for these types of ventures. Funding must be obtained almost entirely through venture capital or by placing the developer's own equity capital at risk.

Nongovernment Funding Sources

Commercial Banks. Commercial banks lend for operating expenses, capital improvements, and real estate purchases. To receive such financing, a loan guarantee is sometimes required, depending upon the financial

strength and previous experience of the borrower and the riskiness of the project as perceived by the bank. Guarantees, which may be personal or through a state or federal program, assure repayment of a certain percentage of the loan. FSA and SBA, for example, can guarantee loans for up to 90 percent of their value for qualified borrowers.

There are two factors will make commercial banks more interested in diversifying their loan portfolios, but at the same time may make them more reluctant to take risk: the reform of the federal deposit insurance system designed to vary FDIC premium rates according to perceived risks and the raising of capital requirements for "higher risk" banks. These changes will encourage greater reliance on loan guarantees and reinforce the need for more education and a better understanding of aquaculture by both lenders and regulators (bank examiners).
