Preface

This collection of papers reflects the diversity of concepts, methods, and case studies that address the challenge of *Managing for Healthy Ecosystems* as holistic environmental management in the context of health, integrity, and sustainability. *Ecosystem health* embodies the capacity of ecosystems to function without impairment, while *management* concerns the assessment of ecosystem conditions relative to social goals and adoption of interventions to achieve designated goals.

An international congress, Managing for Ecosystem Health, an activity of the International Society for Ecosystem Health, was hosted by the University of California, Davis, at Sacramento in August 1999. The congress was designed to cover most aspects of ecosystem management, hence the congress provided a solid framework for this book. The many contributors expressed widely diverging views as to the meanings and relevance of ecosystem health as a goal and practical guide to environmental management. The conventional means of dealing with problems in the environment by technological fixes, by relying solely on reductionist science, is directly confronted. What is sought is a balance between reductionist and holistic approaches to gain a clearer understanding of the complexity of the Earth's ecosystems and the interconnectivity between the condition of ecosystems and human activities and aspirations.

The contributions are grouped into three major parts. The first, Emerging Concepts, explores the diverse meanings of ecosystem health within ecological, socioeconomic, and human health perspectives, and the linkages to related concepts such as ecological integrity, sustainable development, and ecological footprints. In the second part, Issues and Methods, more than 60 chapters introduce methods for assessing and monitoring ecosystem health, including strategies for gaining political and stakeholder input and support for science-based ecosystem management. Both large- and small-scale ecosystem management schemes are evaluated. New representational and statistical approaches to compiling and summarizing complex data derived from the field and remote sensing are introduced and analyzed. The final part, Case Studies, reports experiences of interdisciplinary teams grappling with specific issues in a variety of aquatic and terrestrial ecosystems. Throughout these contributions, one underlying theme prevails: the necessity of forging interdisciplinary solutions, integrating across the natural, social, and health sciences, and of incorporating considerations of ethics, policy, and politics to put human ingenuity to the service of managing change in the world's ecosystems.

Over the past decade great attention has been paid to the fact that degradation of the Earth's ecosystems is curtailing ecosystem services and thus adversely impacting people by undermining the economy, social structures, and public health. Evidence for this abounds: loss of fisheries and forests; impacted local and regional economies; soil fertility harmed by salinity and other factors that adversely affect agricultural communities in developed and developing countries; loss of soil by wind and water erosion, threatening agriculture around the world; negative impacts of coastal pollution and eutrophication on marine and freshwater fisheries; mounting risks to public health; and many other direct and secondary effects of anthropogenic impacts on large- and small-scale ecosystems. It is encouraging that these issues have received wide recognition, and the goal of achieving healthy ecosystems has been articulated by many agencies and incorporated into the basic principles for achieving sustainable development. However, the challenge remains: how to manage for healthy ecosystems — that is, how to go beyond good intent and achieve results.

This book was not designed to be encyclopedic or a how-to manual; rather, it presents snapshots of the condition or health of our physical environment and how researchers and managers are approaching the need for systematic data and rational analysis for repairing damaged ecosystems. The reader will find numerous examples among the chapters in this book from which to draw future work. This snapshot of managing for healthy ecosystems is indeed an indication of the vigorous research and desire for mitigating the trends and directions of impaired environmental conditions throughout the globe. There is by no means consensus on the

most appropriate concepts and methods to achieve healthy ecosystems, but the growing body of knowledge relevant to managing for ecosystem health is embedded in a growing number of case studies that demonstrate applications to environmental management with holistic approaches crossing disciplinary boundaries.

The contributions in this volume form an important part of that ongoing inquiry. They will not, and should not, put closure to the issues of how to achieve ecosystem health; rather, they serve to broaden the discussion of useful approaches toward achieving this goal. At present, degradation of the Earth's ecosystems continues virtually unchecked due to human population growth, consumerism, and the dominance of economic growth-oriented policies over environmental concerns. Thus, it is timely to redouble efforts to devise more effective strategies for achieving ecological as well as socioeconomic sustainability. This volume points the way by providing holistic concepts, state-of-the-art methodologies, and leading examples of integrative science that recognize and more effectively tackle these real-world complexities that challenge our common future.

The basic structure of this book was planned by the program committee that designed the content of the international congress. An international steering committee provided topical ideas and assisted in identifying authors. Many of the program committee members served as associate editors to conduct peer review of the manuscripts within sections and provide interpretation of the chapters in overviews that precede each of the 23 sections. The editors are extremely grateful for these contributions to the quality of this book. We especially acknowledge Deborah Rogers, who so ably facilitated the program committee for more than a year of intense activity. Claudette Oriol and Nancy Barker provided excellent logistical support before, during, and after the congress. Angela Moskow coordinated fund raising, Susan Donohue edited the Web site, and Heather Todd coordinated poster presentations and abstracts. A book of abstracts was produced that can be viewed at <http://www.grcp.ucdavis.edu/publications/index.htm>.

The congress could not have been held, nor could this book have been produced, without financial and in-kind support from many organizations. These are acknowledged with great appreciation elsewhere in this volume. Jennifer Hounsel provided important linkage of the International Society for Ecosystem Health between the congress secretariat at the University of California Genetic Resources Conservation Program throughout the whole activity. The CALFED Bay-Delta Ecosystem Restoration Program provided financial support, allowing us to engage the following for detailed editing of all of the manuscripts: Marti Childs, Jeff March, Linda Sears, Eileen O'Farrell, Penny Walgenbach, Joyce Nettleton, Jill Nicholls, and Susan Schideler. Their expert editing skills helped to smooth out much of the diversity in presentations by the authors. We are pleased that CRC Press/Lewis Publishers had the courage to join in this large effort. CRC's David Packer and staff, especially Randi Gonzalez, Debbie Vescio, and Erika Dery, and Gail Renard and James Yanchak of the Production Department, have worked so diligently and efficiently to produce an excellent book. Among the book editors we must confess to unequal participation by Ardeshir Damania, who handled each of the manuscripts and correspondence with authors persistently and efficiently. Patrick McGuire at the Genetic Resources Conservation Program assembled the electronic version in preparation for publishing.

The Center for Ecological Health Research, largely supported by grants from the U.S. EPA and ably managed by Cheryl Smith, provided logistical and financial support to the Congress.

Table of Contents

Preface
International Congress on Ecosystem Health
List of Contributors

Part I

Emerging Concepts

Section I.1

Setting the Stage.....3

Chapter 1 Regaining Healthy Ecosystems: The Supreme Challenge of Our Age.....5
David J. Rapport

Chapter 2 The Politics of the Environment.....11
Ola Ullsten

Chapter 3 Environmental Health Research Challenges15
Kenneth Olden

Chapter 4 Toward Ecoresponsibility: The Need for New Education, New Technologies,
New Teams, and New Economics.....21
William S. Fyfe

Section I.2

Perspectives on Ecosystem Health.....27

Chapter 5 Overview: Perspectives on Ecosystem Health29
David J. Rapport

Chapter 6 The Ethics of Ecological Integrity and Ecosystem Health: The Interface.....31
Laura Westra

Chapter 7 Ecological Integrity and Material Growth: Irreconcilable Conflict?41
William E. Rees

Chapter 8 Population Health Issues in the Management of Air Quality.....55
Richard T. Burnett, Barry Jessiman, David Stieb, and Daniel Krewski

Chapter 9 Global Environmental Changes and Health: Approaches to Assessing Risks69
Anthony J. McMichael and R. Sari Kovats

Chapter 10 Climate Change and Health: New Research Challenges.....77
Jonathan A. Patz

Chapter 11	Use of Meteorological Data to Predict Mosquito-Borne Encephalitis Risk in California: Preliminary Observations in Kern County	87
	<i>William K. Reisen</i>	
Chapter 12	Preparing for the Quantum Leap to Sustainability: A Toolkit for Future-Friendly Cities.....	95
	<i>Mathis Wackernagel and Diana Deumling</i>	
Section I.3		
Building Policies and Linkages		105
Chapter 13	Overview: Building Policies and Linkages	107
	<i>Barry W. Wilson</i>	
Chapter 14	The CALFED Bay–Delta Ecosystem Restoration Program: Complexity and Compromise	109
	<i>Rick Soehren</i>	
Chapter 15	Understanding the Politics of Ecological Regulation: Appropriate Use of the Concept of Ecosystem Health.....	121
	<i>John Freemuth</i>	
Chapter 16	Attitudes and Their Influence on Nature Valuation and Management in Relation to Sustainable Development.....	127
	<i>Hans A.M. de Kruijf, Ekko C. van Ierland, C. Martijn van der Heide, and Jos N.M. Dekker</i>	
Chapter 17	Humane Values as a Basis for Ecosystem Health.....	145
	<i>John W. Grandy and Allen T. Rutberg</i>	
Chapter 18	The Role of the Water Education Foundation in Creating Factual Awareness and Facilitating Consensus in Western Water Issues	151
	<i>Rita Schmidt Sudman</i>	
Chapter 19	Addressing Threats to the Health of Coastal and Near-Coastal Ecosystems — The Gulf of Mexico	157
	<i>James D. Giattina</i>	
Section I.4		
Setting Goals and Objectives in Managing for Healthy Ecosystems		163
Chapter 20	Overview: Setting Goals and Objectives in Managing for Healthy Ecosystems	165
	<i>Robert T. Lackey</i>	

Chapter 21	Adaptive Restoration: A Strategic Approach for Integrating Research into Restoration Projects	167
	<i>Joy B. Zedler and John C. Callaway</i>	
Chapter 22	Appropriate Use of Ecosystem Health and Normative Science in Ecological Policy	175
	<i>Robert T. Lackey</i>	
Chapter 23	Ecosystem Health: A Flawed Basis for Federal Regulation and Land-Use Management	187
	<i>Allan K. Fitzsimmons</i>	
Chapter 24	Quality of Life, Recreation, and Natural Environments: Exploring the Connection	199
	<i>Alan Ewert</i>	
Chapter 25	Natural Capital Differentiation, Sustainability, and Regional Environmental Policy	207
	<i>Cecilia Collados</i>	
Section I.5		
Finding Indicators		229
Chapter 26	Overview: Can We Develop and Utilize Indicators of Ecological Integrity to Manage Ecosystems Successfully?.....	231
	<i>Gary N. Cherr</i>	
Chapter 27	A Conceptual Framework for Choosing Indicators of Ecological Integrity: Case Study of the San Francisco Bay–Delta–River System.....	235
	<i>Karen Levy, Terry F. Young, and Rodney M. Fujita</i>	
Chapter 28	Establishing Specifications for Ecological Indicators for the Prediction of Sustainability	247
	<i>Wayne G. Landis and John F. McLaughlin</i>	
Chapter 29	Measuring the Impact of Ecological Disintegrty on Human Health: A Role for Epidemiology	259
	<i>Colin L. Soskolne</i>	
Chapter 30	Development of a Terrestrial Index of Ecological Integrity (TIEI), a New Tool for Ecosystem Management.....	267
	<i>James K. Andreasen, Reed Noss, and Nicholas C. Slosser</i>	
Chapter 31	U.S. EPA Office of Research and Development Guidelines for Technical Evaluation of Ecological Indicators	277
	<i>William S. Fisher, Laura E. Jackson, and Janis C. Kurtz</i>	

Chapter 32	Toward a Forest Capital Index.....	285
	<i>Bruce A. Wilcox, K. Shawn Smallwood, and James R. Kahn</i>	
Section I.6		
Monitoring, Learning, and Adjusting.....		299
Chapter 33	Overview: Monitoring, Learning, and Adjusting	301
	<i>David Waltner-Toews</i>	
Chapter 34	Ecosystem Health and Economic Development: Rural Vision to Action.....	303
	<i>Jock R. Anderson</i>	
Chapter 35	Agricultural Biodiversity: A Key Element of Ecosystem Health and Sustainable Food Security	317
	<i>Lori Ann Thrupp</i>	
Chapter 36	Evolving Opportunities for Management of Agricultural Landscapes and Ecosystem Health: Sustainability by Opportunity	333
	<i>Julian Dumanski, Steen Joffe, E.R. Terry, and Christian Pieri</i>	
Chapter 37	The Ecological Footprint as Indicator for Sustainable Development — Results of an International Case Study	343
	<i>Detlef P. van Vuuren, E.M.W. Smeets, and Hans A.M. de Kruijf</i>	

Part II

Issues and Methods

Section II.1

Managing for Biodiversity		355
Chapter 38	Overview: Managing for Biodiversity	357
	<i>Jonna A.K. Mazet</i>	
Chapter 39	The Greater Addo National Park, South Africa: Biodiversity Conservation as the Basis for a Healthy Ecosystem and Human Development Opportunities.....	359
	<i>Graham I. H. Kerley, André F. Boshoff, and Michael H. Knight</i>	
Chapter 40	The Role of an Accidentally Introduced Fungus in Degrading the Health of the Stirling Range National Park Ecosystem in Southwestern Australia: Status and Prognosis	375
	<i>David Newsome</i>	
Chapter 41	Mangrove Conservation and Restoration for Enhanced Resilience.....	389
	<i>Nguyen Hoang Tri, Phan Nguyen Hong, W. Neil Adger, and P. Mick Kelly</i>	

Chapter 42	A Comparison of Landscape Change Detection Methods	403
	<i>Curtis M. Edmonds, Anne C. Neale, Daniel T. Heggen, James D. Wickham, and K. Bruce Jones</i>	
Chapter 43	Relationships among Environmental Stressors and Fish Community Composition and Health: Case Study of Chesapeake Bay	413
	<i>Susanna T.Y. Tong</i>	
Section II.2		
Assessing and Monitoring Biodiversity		429
Chapter 44	Overview: Assessing and Monitoring Biodiversity	431
	<i>Santiago Carrizosa</i>	
Chapter 45	Management and Conservation of Tropical Forests with Emphasis on Rare Tree Species in Brazil	435
	<i>Flávio Bertin Gandara and Paulo Y. Kageyama</i>	
Chapter 46	The Effects of Roads on Carnivores: A Case Study of Mountain Lions (<i>Puma concolor</i>) in California	441
	<i>Melissa M. Grigione and Mike B. Johnson</i>	
Chapter 47	A Rapid Method in Ecosystem Mapping and Monitoring as a Tool for Managing Costa Rican Ecosystem Health	449
	<i>Maarten Kappelle, Marco Castro, Heiner Acevedo, Pedro Cordero, Luis González, Edgar Méndez, and Huberth Monge</i>	
Chapter 48	Identification and Monitoring in the Context of the National Biodiversity Strategy in Uruguay	459
	<i>Victor Canton</i>	
Section II.3		
Climate Change and Ecosystem Health		463
Chapter 49	Overview: Climate Change and Ecosystem Health	465
	<i>Ruth A. Reck</i>	
Chapter 50	Climate Change, Birds, and Ecosystems — Why Should We Care?	471
	<i>Jeff Price</i>	
Chapter 51	A Checklist for Historical Studies of Species' Responses to Climate Change....	477
	<i>Raphael D. Sagarin</i>	
Chapter 52	Use of Long-Term Field Trial Datasets in Forestry to Model Ecosystem Responses to Environmental Change	487
	<i>Csaba Mátyás</i>	

Chapter 53	The Possible Impacts of Climate Change on Pacific Island State Ecosystems	495
	<i>William C.G. Burns</i>	
Chapter 54	Modeling Assessment of the Biological and Economic Impact of Increased UV Radiation on Loblolly Pine in the Middle Atlantic States.....	513
	<i>John J. Streicher and Keith Endres</i>	
Section II.4		
	Exotic Species: Eradication Revisited	529
Chapter 55	Overview: Exotic Species: Eradication Revisited.....	531
	<i>James R. Carey</i>	
Chapter 56	Eradication: Is It Ecologically, Financially, Environmentally, and Realistically Possible?.....	533
	<i>Judith H. Myers</i>	
Chapter 57	Why Not Eradication?	541
	<i>Daniel Simberloff</i>	
Chapter 58	Eradication of Introduced Marine Pests	549
	<i>Armand M. Kuris</i>	
Section II.5		
	Landscape Health Assessment	557
Chapter 59	Overview: Landscape Health Assessment.....	559
	<i>Ganapati P. Patil</i>	
Chapter 60	Multiscale Advanced Raster Map Analysis System for Measuring Ecosystem Health at Landscape Scale — A Novel Synergistic Consortium Initiative	567
	<i>Ganapati P. Patil, Robert P. Brooks, Wayne L. Myers, and Charles Taillie</i>	
Chapter 61	Application of Landscape Models to Alternative Futures Analyses	577
	<i>Anne C. Neale, K. Bruce Jones, Maliha S. Nash, Rick D. Van Remortel, James D. Wickham, Kurt H. Riitters, and Robert V. O'Neill</i>	
Chapter 62	Echelon Screening of Remotely Sensed Change Indicators	589
	<i>Wayne L. Myers and Francis R. Beck</i>	
Chapter 63	Grassland Bird Communities and Environmental Health: The Role of Landscape Features	595
	<i>Douglas H. Johnson, Sharon F. Browder, and Maiken Winter</i>	
Chapter 64	An Ecosystem Approach to Human Health	603
	<i>Lada V. Kochtcheeva and Ashbindu Singh</i>	

Chapter 65	Predictability of Bird Community-Based Ecological Integrity Using Landscape Measurements	617
	<i>Glen D. Johnson, Wayne L. Myers, Ganapati P. Patil, Timothy J. O'Connell, and Robert P. Brooks</i>	
Chapter 66	Landscape Biodiversity and Biological Health Risk Assessment: The Map of Italian Nature	639
	<i>Giovanni Zurlini, Orazio Rossi, and Vittorio Amadio</i>	
Chapter 67	Interior Columbia Basin Forests and Rangelands, 1930s to Present	661
	<i>Paul F. Hessburg, Bradley G. Smith, R. Brion Salter, Roger D. Ottmar, and Ernesto Alvarado</i>	
Section II.6		
	Communities, Politics, Culture, and Tradition	693
Chapter 68	Overview: Communities, Politics, Culture, and Tradition	695
	<i>Alexander H. Harcourt</i>	
Chapter 69	Gambling for Sustainability — Local Institutions for Pasture Management in Bhutan	697
	<i>Karma Ura</i>	
Chapter 70	Environmental and Socioeconomic Indicators of Great Lakes Basin Ecosystem Health	703
	<i>Paul Bertram, Harvey Shear, Nancy Stadler-Salt, and Paul Horvatin</i>	
Chapter 71	Control of Natural Resource Degradation to Restore Ecosystem Health and Help Secure Peace in the Middle East	721
	<i>Scott Christiansen</i>	
Chapter 72	Biological Conservation in Mexico: An Overview	731
	<i>Exequiel Ezcurra</i>	
Chapter 73	Environmental Impacts of Mobility and Urban Development: A Case Study of the Brussels-Capital Region	741
	<i>Paul Safonov, Vincent Favrel, and Walter Hecq</i>	
Chapter 74	Relating Indicators of Ecosystem Health and Ecological Integrity to Assess Risks to Sustainable Agriculture and Native Biota — A Case Study of Yolo County, California	757
	<i>Minghua Zhang, K. Shawn Smallwood, and Erin Anderson</i>	
Chapter 75	Nature Policy Assessments: Strategic Surveying and Assessing Progress across Policy Levels	769
	<i>H.J. Verkaar, Hans A.M. de Kruijf, G.W. Lammers, and Rudo Reiling</i>	

Chapter 76	Land-Use Change Due to Urbanization for the Middle Atlantic Integrated Assessment Region of the Eastern United States.....	777
	<i>Ronald W. Matheny and Keith Endres</i>	
Section II.7		
Agriculture and Human Health		787
Chapter 77	Overview: Agriculture and Human Health.....	789
	<i>Marc Schenker</i>	
Chapter 78	Effects of Agriculture on Ecosystem and Human Health	793
	<i>Paul D. Gunderson, Nancy B. Young, and Dean T. Stueland</i>	
Chapter 79	Infectious Disease Hazards to Agricultural Workers	799
	<i>Dean O. Cliver</i>	
Chapter 80	Size Distribution of PM ₁₀ Soil Dust Emissions from Harvesting Crops	801
	<i>Robert T. Matsumura, Lowell Ashbaugh, Teresa James, Omar Carvacho, and Robert Flocchini</i>	
Chapter 81	Evaluating Pesticide Effects on Ecosystems and Human Health: The Rotenone Application at Lake Davis	807
	<i>Marylou Verder-Carlos and Michael A. O'Malley</i>	
Section II.8		
Mining Impacts		815
Chapter 82	Overview: Mining Impacts	817
	<i>Jean Lebel</i>	
Chapter 83	The Ecosystem Approach to Human Health in the Context of Mining in the Developing World.....	819
	<i>Jean Lebel and Lisa Burley</i>	
Chapter 84	Issues of Scale in the Selection and Interpretation of Mineral Indicators.....	835
	<i>Deborah J. Shields and Slavko V. Šolar</i>	
Chapter 85	Conceptual Approaches to Health and Well-Being in Minerals Development: Illustrations with the Case of HIV/AIDS in Southern Africa	843
	<i>Camilla Maclean, Alyson Warhurst, and Philip Milner</i>	
Chapter 86	Mining and Indigenous Peoples: Contributions to an Intercultural and Ecosystem Understanding of Health and Well-Being	863
	<i>Cristina Echavarría Usher</i>	
Chapter 87	Integrating Human Health into an Ecosystem Approach to Mining	881
	<i>Donna Mergler</i>	

Chapter 88	A Conceptual Framework for the Development of Tools to Track Health and Well-Being in a Mining Region: Report from an Indian Study	891
	<i>Ligia Noronha</i>	
Chapter 89	Addressing Gaps in Ecosystem Health Assessment: The Case of Mineral Resources	905
	<i>Joy Jacqueline Pereira and Ibrahim Komoo</i>	
Section II.9		
	Forest Health Monitoring and Restoration	917
Chapter 90	Overview: Forest Health Monitoring and Restoration.....	919
	<i>Bruce A. Wilcox</i>	
Chapter 91	Resistance and Elasticity: A Conceptual Framework for Managing Secondary Forest Ecosystems in Switzerland.....	921
	<i>Peter Brang</i>	
Chapter 92	The Precautionary Principle and Ecosystem Health: A Case Study from the Jarrah Forest of Southwestern Australia.....	935
	<i>Michael C. Calver</i>	
Chapter 93	National Indicators of Forest Ecosystem Health: A Science Perspective on the Canadian Initiative.....	949
	<i>Harry Hirvonen</i>	
Chapter 94	Forest Health Monitoring in the U.S.: A West Coast Perspective.....	963
	<i>Sally Campbell, Barbara Conkling, John Coulston, Peter Neitlich, Iral Ragenovich, and William Smith</i>	
Section II.10		
	Agroecosystems.....	977
Chapter 95	Overview: Integrating Agricultural Production with Ecosystem Health	979
	<i>Terrell P. Salmon</i>	
Chapter 96	Fallow Land Patches and Ecosystem Health in California's Central Valley Agroecosystem	981
	<i>John D. Hopkins</i>	
Chapter 97	Reduced-Disturbance Agroecosystems in California.....	993
	<i>Jeff P. Mitchell, W. Thomas Lanini, Steve R. Temple, Peter N. Brostrom, E.V. Herrero, E.M. Miyao, Timothy S. Prather, and Kurt J. Hembree</i>	
Chapter 98	Ecologically Based Pest Management: A Key Pathway to Achieving Agroecosystem Health	999
	<i>Miguel A. Altieri and Clara Ines Nicholls</i>	

Chapter 99	Irrigation, Agricultural Drainage, and Nutrient Loading in the Upper Klamath Basin.....	1011
	<i>Stephen R. Kaffka, Ashk Dhawan, and Donald W. Kirby</i>	

Section II.11

Grazing Animals and Rangelands	1027
---	-------------

Chapter 100	Overview: Grazing Animals and Rangelands.....	1029
	<i>Albert C. Medvitz</i>	

Chapter 101	Changing Public Perceptions of the Ranch: A Preliminary Review of Ancient and Contemporary Claims and Processes.....	1031
	<i>Sally K. Fairfax</i>	

Chapter 102	A Rancher's Eye View of Grazing Native Grasslands in California	1037
	<i>Richard R. Hamilton</i>	

Chapter 103	California Grazing Lands: Science Policy and the Rancher.....	1041
	<i>Jack Hanson</i>	

Chapter 104	Reinventing the Range: To Graze or Not to Graze Is Not the Question.....	1047
	<i>Lynn Huntsinger</i>	

Chapter 105	California Grazing Lands: Wither They Go	1055
	<i>Albert G. Medvitz</i>	

Chapter 106	Protecting the Biodiversity of Grasslands Grazed by Livestock in California...	1065
	<i>Richard J. Reiner</i>	

Part III

Case Studies

Section III.1

The Colorado River Delta Ecosystem, U.S.–Mexico	1073
--	-------------

Chapter 107	Overview: The Colorado River Delta Ecosystem: Ecological Issues at the U.S.–Mexico Border	1075
	<i>Daniel W. Anderson</i>	

Chapter 108	Physical and Biological Linkages between the Upper and Lower Colorado Delta	1077
	<i>Saúl Alvarez-Borrego</i>	

Chapter 109	Migratory Bird Conservation and Ecological Health in the Colorado River Delta Region.....	1091
	<i>Daniel W. Anderson, Eduardo Palacios, Eric Mellink, and Carlos Valdés-Casillas</i>	

Chapter 110	Wildlife Disease in the Colorado Delta as an Indicator of Ecosystem Health...1111 <i>Tonie E. Rocke and Milton Friend</i>	
Chapter 111	Contaminants without Borders: A Regional Assessment of the Colorado River Delta Ecosystem.....1125 <i>Miguel A. Mora, Jaqueline García, Maria Carpio-Obeso, and Kirke A. King</i>	
Chapter 112	Conservation Value and Water Management Issues of the Wetland and Riparian Habitats in the Colorado River Delta in Mexico1135 <i>Michael Cohen, Edward P. Glenn, Jason Morrison, and Robert J. Glennon</i>	
Section III.2		
	Canadian Prairie Ecosystem1147	
Chapter 113	Overview: Sustainability of the Semiarid Prairie Ecosystem, Canadian Prairie Ecosystem Study (PECOS).....1149 <i>Darwin W. Anderson</i>	
Chapter 114	Historical Land Use and Ecosystem Health of the Canadian Semiarid Prairie Ecosystem1153 <i>Lisa L. Dale-Burnett and Darwin W. Anderson</i>	
Chapter 115	Health and Well-Being in a Changing Environment: Perceptions of a Rural Senior Saskatchewan Population1161 <i>Mary B. MacDonald and Gail Remus</i>	
Chapter 116	Prairie Ecosystem Study (PECOS): From Community to Chemical Elements, the Essential Role of Questionnaires1169 <i>Helen H. McDuffie, K.M. Semchuk, Margaret M. Crossley, A. Senthilselvan, Alan M. Rosenberg, Louise Hagel, Allan J. Cessna, D.G. Irvine, and D.L. Ledingham</i>	
Chapter 117	Ecosystem-Level Functional Changes in Breeding Bird Guilds in the Mixed Grassland since Agricultural Settlement1183 <i>Todd A. Radenbaugh</i>	
Chapter 118	Evaluating Agroecosystem Sustainability Using an Integrated Model1209 <i>Ken W. Belcher and M. Boehm</i>	
Chapter 119	Prediction of Soil Salinity Risk by Digital Terrain Modeling in the Canadian Prairies1227 <i>Igor V. Florinsky, Robert G. Eilers, and Glenn W. Lelyk</i>	
Section III.3		
	Aquatic Ecosystems: Lake Tahoe and Clear Lake, California1235	
Chapter 120	Overview: Aquatic Ecosystems: Lake Tahoe and Clear Lake, California.....1237 <i>Dennis E. Rolston</i>	

Chapter 121	Evaluating and Managing a Multiply Stressed Ecosystem at Clear Lake, California: A Holistic Ecosystem Approach.....	1239
	<i>Thomas H. Suchanek, P.J. Richerson, D.C. Nelson, C.A. Eagles-Smith, Daniel W. Anderson, Joseph J. Cech, Jr., R. Zierenberg, G. Schladow, J.F. Mount, S.C. McHatton, D.G. Slotton, L.B. Webber, Brian J. Swisher, A.L. Bern, and M. Sexton</i>	
Chapter 122	Trans-Gill and Dietary Uptake of Methyl Mercury by the Sacramento Blackfish, a Planktivorous Freshwater Fish.....	1273
	<i>Joseph J. Cech, Jr., Monica Heekyoung Choi, and Ann G. Houck</i>	
Chapter 123	An Integrated Watershed Approach to Studying Ecosystem Health at Lake Tahoe, CA–NV	1283
	<i>John E. Reuter, Thomas A. Cahill, Steven S. Cliff, Charles R. Goldman, Alan C. Heyvaert, Alan D. Jassby, Susan Lindstrom, and David M. Rizzo</i>	
Section III.4		
Aquatic Ecosystems: New York, Maryland, and Florida		1299
Chapter 124	Overview: Aquatic Ecosystems: New York, Maryland, and Florida	1301
	<i>Dennis E. Rolston</i>	
Chapter 125	A Tale of Two Models: IMPLAN and REMI on the Economics of Everglades Restoration	1303
	<i>Richard Weisskoff</i>	
Chapter 126	Analysis of Land Cover and Water Quality in the New York Catskill–Delaware Basins	1327
	<i>Megan H. Mehaffey, Timothy G. Wade, Mahila S. Nash, and Curtis M. Edmonds</i>	
Chapter 127	Using a Knowledge Base to Assess the Effects of Stream Stressors.....	1341
	<i>Lester Yuan</i>	
Section III.5		
The Langat Basin of Malaysia		1357
Chapter 128	Overview: The Langat Basin of Malaysia.....	1359
	<i>Nicholas W. Lerche</i>	
Chapter 129	Ecosystem Health in Malaysia: A Case Study of the Langat Basin.....	1361
	<i>M. Nordin, Joy Jacqueline Pereira, Ahmad Fariz Mohamed, Saiful Arif Abdullah, Ibrahim Komoo, Shahrudin Idrus, Pauzi Abdullah, Abdul Hadi Harman Shah, Abdullah Samat, Rospidah Ghazali, W. Mohd Muhiyuddin, and Muhammad Abu Yusuf</i>	

Chapter 130	Manufacturing Industries and Ecosystem Health: The Case of the Langat Basin	1371
	<i>Ahmad Fariz Mohamed and M. Nordin</i>	
Chapter 131	Diagnosing Ecosystem Health of the Langat Basin in the Context of Geohazards	1385
	<i>Ibrahim Komoo, Joy Jacqueline Pereira, and W. Mohd Muhiyuddin</i>	
Chapter 132	River Water Quality Assessment and Ecosystem Health: Langat River Basin, Selangor, Malaysia	1395
	<i>Muhammad Abu Yusuf, M. Nordin, and Pauzi Abdullah</i>	
Chapter 133	Forest Areas and Wildlife Diversity in the Langat Basin: Indicators for Assessing Langat Basin Ecosystem Health.....	1421
	<i>Saiful Arif Abdullah</i>	
Section III.6		
Pollution: MTBE		1431
Chapter 134	Overview: Environmental Impacts of a Motor Fuel Additive: Methyl Tertiary Butyl Ether (MTBE)	1433
	<i>Daniel P.Y. Chang</i>	
Chapter 135	MTBE in Groundwater of the U.S.: Occurrence, Potential Sources, and Long-Range Transport	1435
	<i>Michael J. Moran, John S. Zogorski, and Paul J. Squillace</i>	
Chapter 136	The European Perspective of MTBE as an Oxygenate in Fuels	1447
	<i>Eberhard Morgenroth and Erik Arvin</i>	
Chapter 137	Cost–Benefit Considerations for the Introduction of Gasoline Additives Such as MTBE	1459
	<i>Arturo A. Keller and Linda Fernandez</i>	
Index		1469

PART I

Emerging Concepts

SECTION I.1

Setting the Stage

Regaining Healthy Ecosystems: The Supreme Challenge of Our Age

David J. Rapport

RECOGNIZING THE CONCEPT

The first sign of progress toward any goal is recognition that the goal is worthy of the effort. A decade ago, applying the concept of health beyond the individual and population level was deemed foolhardy. Ecologists in particular were adamant that ecosystems were not organized as organisms. Thus the concept of health, which applied to individuals and, later, populations, was inappropriate for ecosystems. They were partly right; indeed, ecosystems are not organized in the same manner as organisms. Ecosystems are not superorganisms. Ecosystems do, however, have organization, structure, and function. They constitute another level above that of populations — but below that of landscapes and biomes — in the biological hierarchy from cells to the biosphere. Thus, ecologists were wrong to assume that, because ecosystems are not organized in the same manner as organisms, the concept of *health* had no application to this level.

Clearly the concept of health — which at root refers to the capacity of a system (whether biological, social, or mechanical) to perform normal functions — is not restricted to the hierarchical levels in which the particular systems operate. There are healthy and unhealthy cells, tissues, organs, organisms, populations, biotic communities, ecosystems, and landscapes. When it comes to the biosphere, that all-encompassing dimension of life, its state of health also depends on the degree to which its functions are unimpaired.

Today the notion of healthy ecosystems, if not yet mainstream, has more than a toehold in the public domain. Numerous programs within government agencies are targeting the health of ecosystems as a key priority. For example, in a national audit of Australia, ecosystem health is one of the focus areas. In the guidelines for a recently launched project of the National Round Table on the Environment and the Economy (Canada) on indicators of sustainability, ecosystem health indicators with respect to natural resource systems are specified in the design. Major projects in managing forests, estuaries, and lakes around the world now focus on the degree to which the essential functions of these ecosystems have become compromised and how they may be restored. And, while species at risk are still major drivers of public concern about the environment, that concern has widened to consider ecosystems at risk.

The goal of managing for healthy ecosystems recognizes explicitly the human component. No longer is it tenable to consider ecosystems isolated from humans. Of course it has been recognized for decades — even made explicit in the writings of Aldo Leopold in the 1940s — that human

activity has compromised ecosystem functions. However, the connections between humans and ecosystems go much deeper. True, humans have compromised ecosystem functions; but it is also true that ecosystem degradation has compromised humans physiologically, socially, economically, culturally, and psychologically.

How could it be otherwise? We are part of ecosystems and fully dependent on the functions of these systems for our very lives. We rely on the food, water, and shelter they provide, on their value for spiritual healing, and on the cultural aspects, particularly in those societies in which whole cultures co-evolved in intimate association with particular ecosystems. Destroy those ecosystems, and inevitably the cultures are destroyed as well.

Clarification of the concept and the role of culture in defining the meaning of healthy ecosystems are central to a number of the themes within this volume. It is particularly prominent in the section on Emerging Concepts (Part I). In a practical vein the CALFED Bay–Delta Program is building a broad consensus among the stakeholders as to what constitutes a healthy environment, bringing together landowners, farmers, natural resource managers, nongovernment organizations (NGOs), and others. At root the issues are political: what steps can be taken to rehabilitate the Bay Delta without undermining the economy or the social/cultural values of the area?

In a more theoretical vein, the issues of ecosystem health, quality of life, and ecological integrity are the topics of Section I.4, Setting Goals and Objectives in Managing for Healthy Ecosystems. Questions arise as to the appropriate use of ecosystem health concepts in public policy, whether the use of the concept should be the basis for federal and land use management, and the degree to which the concept relates to sustainability.

DEVELOPING THE INDICATORS

Management requires information, and information requires both data and understanding. Recognition is increasing about the importance of maintaining ecosystem functions and the high costs to society if these are impaired or lost (in terms of human health vulnerabilities, access to safe food and water, and the ensuing risks of civil disobedience). This increased recognition has led to a growing concerted effort to report on the state of health of major ecosystems: forests, coastal marine systems, great lakes, prairies, etc. Such reporting requires a judicious choice of indicators (Rapport, 1992). Obviously, when major ecosystems such as the San Francisco Bay or Lake Tahoe have become radically transformed as a consequence of chronic cumulative stress from human activities, there will be inevitable changes in nearly all of their biophysical, socioeconomic, human health, and cultural dimensions. What are the most sensitive and meaningful parameters to measure as indicators of the entire process of transformation? To what degree can one validate the indicators as correlating with the larger system change? In other words, which are the most informative parameters to track? Which are the most reliable groups of indicators that provide an overview of changes in the state of the ecosystem over time? This is one of the major challenges within the ecological indicator field.

A framework for addressing this issue arises from the notion of an *ecosystem distress syndrome* (EDS) (Rapport et al., 1985). EDS comprises a group of signs commonly observed in ecosystems under stress, such as the loss of biodiversity, altered primary productivity, altered nutrient cycling, increased dominance of biotic communities by exotic (non-native) species, and the like. One of the common patterns in all of these changes is that the ecosystems under stress appear to have the characteristics of *retrogression* — that is, the appearance of a system moving to an earlier stage of succession. Under these conditions, terrestrial ecosystems lose accumulated nutrients (within the soils), while aquatic systems (lower in the landscape) tend to accumulate nutrients. In both cases, the biotic community tends to become dominated by a few opportunistic species and biodiversity within the ecosystem declines.

However, an important distinction separates a healthy ecosystem at an early stage of primary or secondary succession from an ecosystem that is in retrogression. In the healthy system, these early stages of colonization set the stage for later stages, characterized by increasing biocomplexity. In the unhealthy (stressed) system, retrogression is not often reversed without outside intervention (rehabilitation). Even with such interventions, success in restoring health is not a foregone conclusion (Rapport and Whitford, 1999).

Ecological (biophysical) signs of degrading ecosystems are now well documented in the literature (e.g., Hilden and Rapport, 1993; Vitousek et al., 1997). While a variety of specific mechanisms are involved in producing any one of the indicators (for example, many different ecological pathways may result in a decrease in nutrient availability to the biotic components of the ecosystem), the broad manifestations of ecosystem degradation are highly similar (Rapport and Whitford, 1999).

The question of indicators is, as one might expect, a central underlying theme in almost all of the chapters of this book, for obvious reasons: indicators are the basis for managing for ecosystem health or any other societal goal. Section I.5, Finding Indicators, includes indicators for forest ecosystem health, for the impact of ecological degradation on human health, for terrestrial and aquatic system function, and for ecological and economic sustainability.

The concrete application of indicators is the subject of Part II, Section II.1, in which environmental issues are the focus. These issues include biodiversity, climate change, and invasion of exotic species, among others. Each issue requires hard information upon which to make judgments, calling into play indicators of ecosystem health.

INTEGRATING THE DISCIPLINES

Ecosystem health is now emerging as a societal goal, and in this process it has become clear that the concept of healthy ecosystems extends well beyond the ecological domain. Ecosystem health assessments require an understanding of the social/cultural determinants of human health and of evolving systems of governance, ethics, and environmental management. Each of these dimensions has largely been a world unto itself. Integrative concepts, such as ecosystem health, however, force communication among the silos of disciplinary knowledge and the emergence of new, more effective transdisciplinary approaches to problems.

There are various possible levels of integration within a branch of science. For example, within ecology, integration among subdisciplines may bring together behavioral ecology with population ecology. Understanding changes in biological community structure may require integration across fields within a branch of science such as sociology, anthropology, and economics. Understanding the dynamics of human communities and the factors which interactively alter the health of ecosystems may call for integration of social, biological, and health sciences. There are even further possibilities in transcending disciplines, such as crossing the great divide between the arts and the sciences. Some fields are, by their nature, more naturally predisposed to integration than others. For example, medicine attempts to train physicians to integrate all the elements of medical education (a whole host of fields, e.g., immunology, physiology, anatomy, neurology) as well as ethics, and, to some extent, social factors.

Bringing these heretofore largely isolated silos into contact with one another is very much in evidence in the chapters that comprise this volume. For example, in the CALFED project to restore health to the San Francisco Bay, biotic communities, politics, culture, and tradition are viewed as interactive. In the case studies presented in Part III, particularly those on mining, forest health, and grazing animals/rangelands, long-overdue connections are being forged between the social sciences and natural sciences. People are not only part of (and not *apart from*) the ecosystem, but their views, values, and goals must also be central to any viable path for managing for ecosystem health.

MOVING THE CONCEPT TO PRACTICE

As amply illustrated within the present work, the notion of ecosystem health has now moved far beyond mere philosophical discussion. While still debated in terms of its fundamental meanings, it has entered the world of policy and practice (e.g., Lackey, 2001).

What is evident, even at this comparatively early stage, is that the link between healthy ecosystems and healthy people has begun to resonate within the body politic. As a consequence, ecosystem health is finding new academic homes within the health sciences and the associated professional schools, particularly human and veterinary medicine (e.g., Rapport et al., 2001) and public health (de Gruijl, 2000; Hales et al., 2000; Haines and Kammen, 2000).

One of the major factors providing the impetus to move ecosystem health into practice has been the support from the medical and public health fields. I have long puzzled over why ecosystem health found its initial acceptance within medicine and public health rather than within ecology. One reason, no doubt, is the fact that the terminology initially established for ecosystem health derived from medicine (Rapport et al., 1979; 1989). Description of ecosystem conditions in terms of health, pathology, and distress syndromes has a familiar ring to medical practitioners, but not to ecologists. Indeed, the notion that ecosystems have the property of *health* has been actively resisted by some ecologists. They contend that health implies value judgments (as to the desirable state of nature) and that, while this may be accepted with respect to individuals, it does not extend to higher levels of biological organization. If this argument were to be accepted, it would invalidate the entire field of public health and population medicine.

Perhaps the overriding reason why ecosystem health has more readily found acceptance in the health sciences than in ecology is that the health sciences are, by their nature, caring professions and mission oriented. Their mission of restoring function, alleviating suffering, etc. is not unlike the mission of ecosystem health — restoring functions to degraded landscapes and ecosystems. Thus, ecosystem health and medicine do have a similar orientation. Another connection between these fields is that interventions aimed at restoring ecosystem functions serve directly to enhance human health (e.g., by enhancing the availability of such basic amenities as water and food). Permanent solutions to certain public health problems may demand a different perspective. For instance, New York City recently suffered an increased risk to public health from declining water quality due to land use changes in the drainage system. The solution may be found not by technical interventions (i.e., by building a bigger and better sewage treatment plant), but rather by managing the Catskill watershed (that supplies New York City with its water) in a manner that restores health and the ecological services that healthy watersheds provide.

Since the Stockholm Conference on the Environment (1972) and the United Nations Conference on Environment and Development (Rio Declaration, 1992), it is also recognized that economic development (and more generally the health of economies) is also dependent on maintaining healthy ecosystems. The Rio Declaration on Environment and Development was explicit on this point and committed the parties to develop a new legal framework that integrates resource management, protection of the environment, and future economic growth (Cicin-Sain, 1993). This mandate calls for a comprehensive approach to human futures, integrating economic policies with full recognition of environmental constraints. Principle 7 of the Rio Declaration calls upon nation states, individually and collectively, to take responsibility to “conserve, protect and restore the health and integrity of the Earth’s ecosystems” (Rio Declaration, 1992). It is this declaration that has given rise to the so-called Agenda 21, the action plan to achieve the goals of the Rio Declaration. In effect, the action plan details through treaties and accords (such as the Kyoto Protocol) the means of achieving healthy ecosystems.

In Part III of this work, case studies illustrate how the concepts of ecosystem health are applied to practical efforts to restore function to some of the world’s most damaged environments. Five studies ranging from the Colorado River delta to the Canadian prairies to the Langat Basin of Malaysia all demonstrate the potential for improving the health of large-scale ecosystems by taking

a broad systems approach. These studies also suggest that times are changing, and that today one finds teams of applied ecologists that are adopting an ecosystem health perspective. An additional study also found in this section (on the impacts of a motor fuel additive on human health and the economics of the transport industry) further illustrates the potential applications of an ecosystem health perspective in action.

NEW GOALS FOR ENVIRONMENTAL MANAGEMENT

The history of environmental management dates to times of antiquity, when it was observed that humans impact their surroundings and that some practices are more deleterious than others. The earliest applications were undoubtedly in agriculture, where, particularly in dry or relatively infertile regions, managing the environment has long been practiced and continues to this day.

Over the past half century it has become apparent that many agricultural and industrial activities have cumulatively rendered ecosystems and landscapes less functional. These deleterious changes have often had dramatic and negative impacts on the human community through loss of income, medicinal plants, and culture, and increased threats or risks to human health. It has also become apparent that neighboring ecosystems, particularly aquatic systems, have become degraded as a consequence of certain management practices, such as agriculture and urbanization. As the interconnections of human activity, ecosystem dynamics, human health, international trade, and sustainable economic development have become better articulated, many new concerns are coming to light. Among these are the likely role of antibiotics (used as growth promoters in poultry, swine, and cattle production) in directly and indirectly increasing the prevalence of antibiotic resistance in certain human pathogens, especially those that invade the gut. Climate change increases human health vulnerabilities by spreading the range of vector-borne diseases as well as contributing to a greater frequency of extreme weather events.

These realities are encouraging a rapid evolution in the practice of environmental management, from protection of the environment from various sources of contamination — the focus being on clean air and clean water — to protection of the vitality, organization, and resilience of whole ecosystems, of which humans are an integral part. The new approach to environmental management goes well beyond crisis-driven management. No longer are single factors identified as the likely sole cause; rather, the search is for multiple stresses that singly and interactively degrade major ecosystems over time. Efforts at restoration are increasingly directed toward reestablishing critical ecosystem functions rather than one particular species.

Finally, monitoring for ecosystem health is far broader in scope than simply monitoring biophysical attributes. A watchful eye is also required to identify the socioeconomic, cultural, and human health manifestations of dysfunctional ecosystems (Maffi, 2001). Clearly the great challenge ahead in applying ecosystem health to environmental management is to make use of new methods that allow continuous monitoring (particularly from remote sensing) of biophysical conditions of large-scale ecosystems (Rapport et al., 1995) and to integrate these findings with socioeconomic, cultural, and human health trends. Further, if ecosystem health is to be maintained — and restored where it has been lost — what is needed above all else is the recognition that the politics of the environment inevitably must change. The current stance of *politics as usual* that applies to events that seem of no particular consequence must change to one of *politics of urgency* that applies to extreme threats to the future of humanity. While the insidious erosion of ecosystem health has none of the public appeal aroused by the September 11 crisis, it may well cost ultimately far more in lives. If ecosystem health is to be restored, it is time to back away from politics as usual and play hardball with the environment. Toward this end, the present volume provides abundant evidence not only that ecosystem health is a worthy goal for environmental management, but also that the concept finds ready application in solutions to real-world problems. In the past few years a multitude of new programs in ecosystem health (and ecosystem approaches to human health) have been

initiated in the U.S., Canada, Australia, South America, and elsewhere, both within academic institutions and within government programs. Increasingly, there is recognition that healthy ecosystems perform services upon which humans and other biota are dependent. Thus, actions that threaten ecosystem health and threaten the continued supply of ecosystem services are coming under more intense scrutiny. The public and decision makers are becoming aware that, unless the health of the world's ecosystems is restored and maintained, socioeconomic aspirations will become increasingly compromised.

The Politics of the Environment

Ola Ullsten

People are becoming more aware that we live in the transition from a world with an abundance of natural resources to one of severe limits. The world population is likely to increase with another 90 million per annum and will reach another doubling from today's 6 billion before it levels off. At the same time, access to water, soil, land, fishery, and forest resources is becoming increasingly scarce. Global warming adds to the problem. The space for expansion of the human enterprise is shrinking rapidly, and nothing seems to be stopping this trend. This is a somewhat dismal picture.

On the other hand, we can see ambitious efforts by governments in most countries introducing new legislation for environmental protection. In addition, numerous examples of successful projects of pollution control have given us cleaner air, lakes, and rivers, locally and regionally. A noticeably more proactive stand has been taken on environmental issues within the corporate world. Scientific achievements, emerging popular pro-environmental movements, and a subsequent growing awareness of the public are pushing government and businesses to do their part in protecting the environment.

How do we explain those two very contradictory pictures of the same piece of reality? Does it prove that current attempts to remedy what is wrong with our environment are meaningless? Is it meaningless to plant trees to combat deforestation; to establish protected areas of forest and marine reserves to preserve plant and animal species and to save wildlife; to treat industrial waste to protect groundwater; to prohibit the use of chemicals that are hazardous to the environment; to sort out garbage; and to ecolabel agricultural and manufactured products?

All these efforts are useful in themselves. Great value can be attained by having cleaner air and water. Earnings go down for businesses as a result of a more effective use of raw material, cleaner equipment, less waste, and less energy. However, ecology-minded businesses know they look good on the stock market and to their customers. Destroying forests and fisheries can hardly be justified from any point of view, especially if it happens voluntarily, and other options are available. All of these policies, when properly pursued, are as good for the local environment as they are for the economy of governments, businesses, or individuals.

The problem may be that they are only policies and nothing more. Actions may not reach beyond the improvement in the local environment and are limited to a handful of high-tech, high-income, and generally prosperous countries with a well-educated population. It is part of business as usual in the affluent societies, but with an ecolabel attached.

Technical solutions, upon which environmental policies are usually based, are necessary means for achieving tangible results in a process toward sustainable development. But sustainable development, solemnly embraced by political leaders worldwide, is meant as a new paradigm for

development with an important new message — the health of the ecosystems places restraints on human economic activities. The message asks for something more than technical solutions. It speaks about the need to review the conventional wisdom that relies on the opposite assumption — that the economy and what is technologically possible set the limits.

It could hardly have been expected that the politically bipartisan Brundtland Commission, in which this new eco/economic doctrine was framed, could have given it a clear political interpretation. It is even less likely that the Earth Summit in Rio in 1992 could have approved the doctrine and what it embodies in political terms. The summit, after all, was a highly politicized event representing all possible political persuasions and well-defined national interests.

Sustainable development is a deceptive term. It is logical and easy to accept by most people until they begin dismantling the parts on which it is built. Then it becomes clear how many challenges it offers in its implementation. We endorse sustainable development in principle, but we have only a blurred vision of what it implies in terms of practical politics. It is too politically costly, too challenging for the political cultures of the Northern Hemisphere, and it is beyond the reach of the Southern Hemisphere. The farsighted approach, which is the doctrine's strength, is difficult to fully embrace by people who are fighting day by day, and by whatever means, for their survival.

The term *sustainability* is intrinsically holistic and interdisciplinary, which requires a policy-making process that has proven to be difficult to implement by any national administration, in rich or poor countries, or by international organizations, regardless of the issue. It embodies an extreme degree of complexity, ethically and technically. It makes value judgments about equity, which is a matter at the core of controversy in all domestic politics and an issue that flares up north/south tension at all international gatherings. It is long-term in character, which is inconsistent with the timescale of both elected governments and profit-driven business activities, particularly in developing countries. It demands changes in the way people behave, the true meaning of which repels the conservative instinct that dominates all societies (Dowdeswell, L., personal communication).

Most new development doctrines have an initial phase of popularity that tends to hide the costs, politically and financially, for making them work. Sustainability is no exception. One popular line is that sustainability is a win-win strategy. Sustainable management of the world's renewable resources is a condition for human survival, so what is good for the environment is good for development. Businesses like it, because it sounds like a low-cost investment. Politicians like it because they never like asking the electorates for sacrifices. Nongovernment organization (NGO) activists like it because it makes an easier sell.

There is a catch, though. Sustainability is a doctrine of limits, while conventional politics is caught up in an always-more-never-enough syndrome. That culture will have to change. It is not to be taken for granted that the world's natural resources can sustain a continued growth of the world's population coupled with a constant increase of consumption in already affluent countries. It is indeed an illusion to think that such consumption is possible if we also want to be serious about alleviating poverty in developing countries and elsewhere.

Thus, environmental policies so far have become halfway measures. They are tolerated as long as they help maintain established economic wisdom, which still remains based on the assumption that societal goals are to be expressed in economic terms, and environmental concerns are secondary. Typically, if not explicitly expressed that way, new environmental demands are always viewed as expensive concessions to the environmentalists and as something that compromises the overriding and more important economic goals. It is basically a conservative approach.

As necessary as they are, technical solutions to environmental problems can never be fully effective globally unless they become part of structural reforms with implications for our economic and governmental systems. We will have to accept that today's pressures on all resources limit the choices in management of human affairs. The policy measures this requires should not be dictated by a fear that abiding by the laws of ecology typically hurts the economy, but rather by the greater risk that declining ecosystems eventually may undermine a nation's prosperity and threaten the stability of the biosphere.

Ample examples exist, historically and in the present, of countries and regions that suffer widespread social misery, political instability, and cultural impoverishment due to declining ecosystems. The signs are easily visible for anyone to read about or view firsthand. Historically, the fall of the Mycenaean state and, later the civilization in ancient Greece, paralleled the loss of forests and the impoverishment of the landscape. Today's Haiti, Somalia, Ethiopia, parts of Russia, and Afghanistan (to mention a few) show signs of dysfunctioning landscapes — barren lands that were once majestic forests; deserts of salt due to diversion of rivers; uncovered rock instead of fertile soil; dried-up lakes and rivers; groundwater too deep for poor people to access; shortage of fuel wood; and farming conditions in decline.

Declining ecosystems are also present in more prosperous countries. The difference so far is that they have financial and technical means by which to remedy the damage and make the negative consequences of the decline less visible. But this can come only at some cost. The North American Free Trade Agreement (NAFTA) study (January 2002) concluded that Canada, over a 5-year period, spent 1.9 billion Canadian dollars in unemployment programs due to excessive fishing. And the country is likely to spend another half billion dollars over the next 3 years. The same report also supports the view that something can be done about this, if the desire is strong enough, and that environmental conservation measures can have dual benefits. It was found that the implementation of the U.S. Clean Air Act over 20 years ago has cost the U.S. \$524 million but has saved the economy more than \$6 trillion.

In a discussion on how to build into the decision-making process the understanding that unhealthy ecosystems also destroy the economy and the well-being of people, focus must be placed on *the politics of the environment* and how leaders in politics and business, and their electorates and shareholders, perceive the task of restoring a declining environment. It is also a matter of how progress is defined and, not least, how we measure progress so that the relationship between economic achievements and ecological costs becomes clear. The NAFTA study mentioned above suggested that Mexico's average GNP between 1985 and 1992 would have to be reduced by as much as one fourth (from 2.2 to 1.3% annually) when the depletion of natural assets was taken into account.

A distinction can be made between *soft politics* with local reach, which is what we basically have today, vs. *hard politics*, yet to be practiced (MacNeil, J., personal communication). Although commendable, as such, what we have seen so far are reforms that have been politically cost-free — with no demands for changes in how we are used to doing things; no claims on changing of lifestyle — basically about actions for which politicians and business leaders easily received approval from voters and stock markets, and safely within the framework of established models for how to achieve economic growth.

Hard politics is likely to be less cozy. It would have to be about abolishing billions of dollars in subsidies that favor special interests and unsustainable practices. It will have to do with gradually moving away from levying taxes on labor to increasing taxes on, for example, energy. It involves ratifying (and implementing) treaties on greenhouse gas reductions even if a hint of inconvenience and a need for thorough adjustments of economic policies are involved. It is about reviewing trade policies, structural adjustments, and privatization by paying as much attention to ecological factors as to economical aspects. Hard politics will mean a change of focus from the treatment of symptoms to challenging the causes of environmental degradation. It implies admitting that solving the big environmental issues carries big political costs. And, again, that the health of ecosystems places restraints on human economic activities.

A need exists for a process of change that is based both on the seriousness of our situation and on a realistic assessment of a practical way of achieving results. One obvious but important observation is that people are not exploiting the world's natural capital beyond its regenerating capacity out of ill will. The declines occur as an unintended result of values, priorities, and behaviors that have become part of political cultures.

We depend on the social and economic circumstances that surround us. The landless shifting cultivators and their families in Brazil, or elsewhere in the tropics, live under extreme poverty. They have no choices other than to survive by clearing a piece of virgin forest on which to grow their

crops. Hundreds of thousands of landless farmers live in tropical countries, and the only farming practice available for them is to move on from one woodlot to another as the fertility of the cleared land runs out. So they account for a substantial part of deforestation in the tropical areas.

Governments can change this situation by providing the landless with other types of land, by changing tax and subsidy policies that encourage mining, logging, and other such activities in sensitive forest areas that open up roads so crucial for the encroachment of people into the forests. The reason governments do not act to change these situations, at least on any broad scale, is that it means challenging the status quo. Generally the entrenched interests that are promoting the status quo are far stronger than those of poor farmers and more convincing in the short term than the international communities' pleas for an improved global environment.

It is easy for pro-environmental movements, media, and individuals in the West to place blame on governments in third-world countries for not daring to show more courage in challenging those interests. And, no doubt, their people would benefit if governments would have the means and the will to do that.

The politics become more delicate and complicated when the same reasoning is applied to our own situation. The behavior of ordinary suburbanite families in a typical Western city also has implications for the health of ecosystems and the global environment. Not because they lack choices — they have lots of choices — but typically they choose to live as lavishly as they can and consume as much as their economic situation permits. There is nothing that forces them to do so, but there are lots of incentives created through political decisions or by prevailing economic systems to encourage them. In fact, governments tend to be rather worried if we do not spend enough because it hurts our economy. We all get worried when Christmas shopping is down or other planned spending feasts do not deliver as expected.

It is natural that people, given existing values and available choices, tend to do what is best for them in the time perspective they can foresee. As individuals, we have little chance of knowing what impact our choices may have on the global environment. It is the responsibility of governments to look after the public interest and to set the objectives for a country's environmental policies. Governments, nationally and through international agreements, have a duty to assess how to keep the landscape integral and functioning for humans and other species. The marketplace does not serve that function.

The search is on again for a new order in the world. We are confronted with a deepening of the conflict between growing ecological decline and challenges to established patterns of social behavior on the one hand, and economic expansion on the other. The free market models, the liberalization of trade, globalization, the role of technology, and the degree of virtue of economic growth are targets of considered analyses and populist protests.

We probably cannot do without either globalization or economic growth. So the discussion should be about what kind of globalization and what kind of growth we want to have — a globalization for all, or for the rich only? An economic growth with a social purpose and based on a sustainable use of natural resources, or one for the sake of growth itself? If economic growth is to be what it claims to be, it cannot be based on the use of resources of others or paid for by others (e.g., by future generations). If economic growth has its origin in an increase in efficiency and productivity, it can be sustained. As we know, the most important source of growth is innovations based on acquired new knowledge. Such new knowledge that the capacity of the renewable natural resources to sustain our economic activities sets the limits for growth. Today's economic strategies are based on the opposite order of things and will have to be changed.

Also consider this: a sixth of the world's population receives 78% of the world's income, while *three fifths* of the world's population living in 61 countries receive only 6% of the world's income. Still, equity, within and between generations, is a crucial element in the doctrine of sustainability.

Faced with a system that does not work, it is no surprise that people who care are looking for a system that works. They are eager to see the gaps filled between awareness of the problems and actions to solve them.

Environmental Health Research Challenges

Kenneth Olden

Over the past 50 years, we have dramatically reduced the human health threats posed by the environment. Environmental remediation and pollution reduction have been one of the nation's public health success stories. In fact, we have been so successful in improving the quality of our environment that there are those who argue that the environment no longer represents a serious threat to human health. They argue that the job is done, that the low-level exposures experienced by most Americans pose no significant health threat.

Well, we have cleaned up the “big dirties” of the 1950s and 1960s. Rivers are no longer catching on fire and burning for days. Stacks bellowing smoke have largely disappeared from our urban landscape. And the density of particulates and other pollutants in the air of most American cities has been greatly reduced. For most Americans, high-dose exposure is no longer a reality. Managing today's risks at low-dose exposures will require new science, new technologies, and new ways of conceptualizing and managing the risks. Managing today's risks will also require consideration of biological concepts that were not part of the environmental health science vernacular as recently as 10 years ago. Concepts such as susceptibility, environmental genomics, high-throughput screening, and transgenic technology were not among the priorities of the environmental health research enterprise.

Environmental health decisions of the future will require better information than now exists. The default assumptions and uncertainties used to assess risk at high-dose exposures are even more unreliable at low-dose exposures.

First, I want to make the point that human illnesses are caused by both genetic and environmental factors acting alone or in concert over the course of many years. In fact, we know of only a few diseases that are caused solely by genetic factors or solely by environmental factors. Most diseases are caused by gene–environment interactions. Therefore, to understand the etiology and prevent chronic illnesses, we are going to have to make the investment to understand both the genetic and environmental contributions to disease.

Behavior is also an important contributor to human illness, but behavior is either genetically predisposed or environmentally acquired. So it is captured in my earlier statement about genes and environment, as a function of age or stage of development, being the major determinants of health. However, children may be at increased risk to environmental exposures because of their behaviors in addition to their rapid growth and development. Seniors may have increased risk because of a compromised immune system and an accumulation of genetic lesions.

A quotation in *USA Today* by Judith Stern, Professor of Nutrition and Internal Medicine, University of California, Davis, captures the nature of the interaction between genes and the

environment: “Genetics loads the gun but environment pulls the trigger.” As you know, a loaded gun by itself causes no harm. It is only when the trigger is pulled that the potential for harm is released or initiated. Likewise, one can inherit a predisposition (a susceptibility) for a devastating disease (e.g., Alzheimer’s, Parkinson’s, cancer) yet never develop the disease unless exposed to the environmental trigger. A well-known example of this is asthma. People with asthma are not always in respiratory distress (although somewhat compromised with respect to respiratory capacity). It is only when they are exposed to certain environmental triggers (such as tobacco smoke, dust mites, cockroach allergens, acid aerosols, or ozone) that they experience their severe symptoms.

Let me take a moment to define the environment. The environment is the chemical, physical, and biological agents to which humans (as well as plants and other animal species) are exposed during the course of their lives at home or at work. The environment also includes diet, nutrition, behavior, lifestyle choices, and poverty. So the environment is more than synthetic chemicals and industrial by-products. In fact, the thousands of natural chemicals to which humans are exposed are often overlooked as possible causes of human illnesses. But there is no reason to conclude that natural products are harmless.

I am pleased to say that I expanded the definition of the environment to encompass all the factors I have just mentioned when I became director of the National Institute of Environmental Health Sciences (NIEHS) in 1991. Today, the institute supports research dealing with all aspects of the environment with an emphasis on prevention and public health.

Diseases once thought to be genetically determined by one or two genes are now proving to be more complex. For example, in early reports, the contribution of the breast cancer susceptibility gene (BRCA1) to early onset of premenopausal breast cancer was overestimated. When first isolated by Dr. Roger Weisman (scientist at NIEHS) and Dr. Mark Skolnick (University of Utah), it was estimated that 85% of women who inherited BRCA1 would have breast cancer and/or ovarian cancer. Now the estimate is that only about 50 to 60% of women who inherit BRCA1 will have breast cancer. It now appears that other genes (i.e., polygenic inheritance) and/or environmental agents play a role in the development of these diseases. There are numerous examples like this where the penetrance (i.e., the expression) of specific genes is much lower than originally thought. The fact is we now know what the causes are for most chronic diseases.

We know much more about curative treatment than we do about the initiation and progression of disease. As a nation, we are preoccupied with the development of treatment strategies or “magic bullets” to prevent death from end-stage disease, whereas our public health success stories over the past two centuries have been in the arena of prevention through public health measures. Yet we continue to emphasize treatment in our public health policies even though we have been unable to develop effective treatments or cures for the most devastating diseases such as Alzheimer’s, Parkinson’s, diabetes, and most cancers.

The good news about gene–environment interaction is that the environmental triggers can be manipulated. All the components discussed under the definition of the environment (chemical, physical, and biological agents, lifestyle choices, behavior, and poverty) can be controlled or manipulated. Even though one is genetically predisposed to develop a specific disease, one can prevent initiation and/or progression by manipulating the environmental triggers.

However, to realize the public health potential of environmental health research, several critical investments will be required. The necessity for better science is clear if the public is to have confidence in government decisions.

The first critical investment that we need to make is to develop new high-throughput technologies to assess environmental agents for carcinogenicity and toxicity. Estimates are that 70 to 75% of the high-volume, high-use chemicals in commercial use in the U.S. have not been assessed for human toxicity. While many of these (if not most) may not require testing since they are very similar to chemicals already tested, several do need more testing. In fact, we can never satisfy the testing requirements using current technologies. Without better test systems (ones that are faster

and cheaper), we will continue to operate in a state of “toxic ignorance.” By exploiting recent advances in human genetics and recombinant DNA technology, we can develop animal models and *in vitro* assay systems to identify carcinogens and toxicants in a matter of days or weeks rather than years. Two promising approaches involve manipulation of the expression of tumor suppressor or proto-oncogenes in animal models and development of cDNA microarray systems for measurement of gene expression.

The second crucial investment is to determine the genetic basis for the wide variation in susceptibility to environmental toxicants. It is well known that most smokers do not develop lung cancer and most women exposed *in utero* to diethylstilbestrol (DES) never develop cancer of the reproductive organs. A common question asked of physicians is, “Why me, Doc?” Well, genetically determined differences in susceptibility are at least in part responsible for individual or population differences in susceptibility.

With rapid advances in cloning and sequencing of the human genome, it is now possible to identify the genetic polymorphism responsible for differences in susceptibility. For example, by identifying genetic alterations that lead to functional changes in critical pathways involved in the metabolism of xenobiotics, one will have a better understanding of differences in susceptibility. The important point here is that the current use of the *one size fits all* approach in environmental health risk assessment is not consistent with our understanding of human biology and surely leaves some individuals or subpopulations unprotected from risk for diseases from environmental exposures.

Also, susceptibility is influenced by the timing (childhood vs. adulthood) of exposure, the gender and behavior of the individual, the nutritional state, and the socioeconomic status. For example, exposure during rapid or critical stages of development of the various organ systems is likely to be an important consideration in the development of disease. Critical stages include embryonic development, adolescence, puberty, and old age. At present, we have little information to guide decision making with respect to these issues because most toxicologic assessments have been done in adults, both animals and humans, under otherwise optimal conditions.

To investigate the genetic basis for differences in susceptibility or predisposition to disease, two related gene resequencing efforts were initiated at the National Institutes of Health (NIH). The first to be initiated is called the Environmental Genome Project, and the second is the Single Nucleotide Polymorphism Project. Both seek to identify genetic changes that increase risk for disease development. The results from these studies will have profound implications for the practice of medicine and environmental health risk assessment.

To address the concern about timing of exposure, we have initiated studies in which animals are exposed corresponding to the various stages of human development (e.g., *in utero*, infancy, adolescence). We have also developed eight Children’s Environmental Health and Disease Prevention Research Centers, in collaboration with the Environmental Protection Agency, to focus on basic research, prevention, and treatment of pediatric illnesses. Vice President Gore announced the creation of the Centers Program and recipients of the awards from the White House in August 1998.

The third crucial investment for the NIH is to understand the causes of health disparities in American society. It is well established that the poor and racial and ethnic minorities have higher morbidity and mortality from various diseases. Since members of these groups are more likely to live and work in the most hazardous environments, they experience higher levels of exposure to environmental stressors in terms of both frequency and magnitude. They are also less able to deal with these hazards because of limited knowledge and a higher level of disenfranchisement from the political process. Several important questions need to be answered. What are the causes of the observed disparities? Which of the causes require more research, and which can be addressed by application of current knowledge and technologies? Health disparity is a very complex issue with important social and economic implications. To address this issue we need a well-thought-out strategic plan.

I am very pleased to report that The Office of Minority Health of the Department of Health and Human Services (DHHS) has identified health disparities as a top priority.

Gender differences in response to environmental insults is another area requiring special attention. Because of the important role that hormones play in regulating homeostasis, gender-specific responses can be expected. For example, hundreds of synthetic and natural chemicals in the environment can modulate hormone responses. Of the so-called endocrine disruptors, those that mimic estrogen are the best studied. Environmental chemicals with estrogenic activity are putative risk factors for breast and ovarian cancers, uterine fibroids, various autoimmune diseases, and endometriosis. NIEHS has been very interested in research on the health effects of synthetic estrogen since the early 1970s. In fact, our current understanding of the carcinogenic and reproductive health effects of DES can be largely attributed to the body of research generated with NIEHS support over the past 30 years.

Researchers at the NIEHS and elsewhere are developing transgenic animal models containing the mutated human breast cancer genes (BRCA1 and BRCA2) for use in identifying environmental agents that interact with these genes to promote mammary cancers in rodents.

NIEHS scientists have also developed animal models that lack functional estrogen receptors. Since these receptor molecules are crucial for estrogen action, the so-called knockout animal models are useful in studying the mechanism of estrogen action. Also, we and others have now identified 39 to 40 chemicals in the environment that cause mammary tumors in mice. Chemicals that cause tumors in rodents (mice and rats) have the potential to cause cancer in humans.

Recently, NIEHS joined forces with Phyllis Greenberger and the Society for the Advancement of Women's Health Research (SAWHR) to focus attention on the possible adverse health effects of herbal medicines. The products are used regularly by millions of Americans (mostly women), yet most have not been evaluated for either efficacy or toxicity (safety). The SAWHR brought this issue to our attention. To date, we have co-sponsored (with the SAWHR, the NIH Office of Dietary Supplements, the HHS Office of Disease Prevention and Health Promotion, and the Food and Drug Administration Office of Special Nutrition) a very successful symposium to assess the research needs to ensure that herbal products are safe for human use. We plan to evaluate several of these products for safety over the next 5 years. Exposure assessment is another critical area of investigation. The truth is that we do not know what the American people are exposed to. Exposure is typically estimated using indirect surrogates, based on toxic release and production inventories. Exposure is highly variable for individuals and subpopulations.

Exposure is really a function of individual uptake, metabolism, excretion, and behavior. So the assumption that all individuals (men, women, and children) living in the same geographic area have similar exposures is seriously flawed. We need direct measures of exposure based on tissue analysis or deposition. NIEHS has supported an effort by the Centers for Disease Control and Prevention (CDC) to develop methodologies for direct assessment of human exposure to environmental estrogen-like chemicals.

Exposure to complex mixtures is another area of environmental health research in need of attention. Typically, toxicity and carcinogenicity are assessed in animal models (mice and rats) one chemical at a time. This contrasts with the real world, where we are exposed to multiple agents (chemical, physical, and biological) at any given time in the form of mixtures. Current assumptions are that components of mixtures behave in an additive fashion (i.e., one plus one equals two). However, we are aware of situations in which components of mixtures behave synergistically (i.e., one plus one equals some number significantly higher than two). For example, carcinogens in cigarette smoke interact synergistically with radon to produce lung cancer, and aflatoxin B1 interacts synergistically with the hepatitis B virus to produce liver cancer. I believe that we now have the capacity to develop the technology (e.g., cDNA microarray gene expression systems) to assess the toxicity of mixtures.

Another critical area of investigation is understanding the mechanism by which environmental insults initiate or promote disease development. It is not sufficient to know that chemical A causes

cancer; it would be very useful to know *how* chemical A causes cancer in order to develop preventive, diagnostic, and treatment strategies. Also, knowledge of mechanisms is very important in assessing risk to humans based on experimental data generated in animal models. If disease initiation and progression due to a given chemical exposure occur by pathways common to both humans and rodents, then that chemical can be reasonably anticipated to be a human carcinogen based on data from animal studies.

The final critical investment of research that I want to discuss here is population-based studies. Most of the large cohort studies undertaken to identify disease risk factors were not designed to elucidate the role of most environmental agents in the etiology of disease. Nevertheless, epidemiology has been an important tool in identifying environmental causes of diseases. However, most of these studies were conducted using defined populations exposed accidentally or occupationally to high doses of the specific chemicals. To identify environmental risk factors at low-dose chronic exposures will require specially designed epidemiologic studies using large populations.

Toward Ecoresponsibility: The Need for New Education, New Technologies, New Teams, and New Economics

William S. Fyfe

INTRODUCTION

We have lived through the two giant centuries of science. Just imagine a world without the dynamo (Faraday, 1821), a world without antibiotics (Fleming, penicillin, 1928), or even a world without jet engines and atomic bombs. In a Royal Society of London publication, *Population: The Complex Reality* (1994), the past president of the Royal Society, Sir Michael Atiyah, wrote, “Most of the problems we face are ultimately consequences of the progress of science, so we must acknowledge a collective responsibility. Fortunately, science opens up possibilities of alleviating our problems, and we must see that these are pursued.” In the same volume, Sir Crispin Tickell, former British ambassador to the UN, wrote, “It would be nice to think that the solutions to some of our present problems could be drawn from past experience, but in this case the past is a poor guide to the future ... our current situation is unique.”

Yes, we are living in a new world with a new demography. Imagine the year 2050, when Europe and North America will make up only about 10% of the global population. And the present state of the global society is not sustainable. According to the *Manchester Guardian Weekly*, November 2, 1998, in its article “The Politics of Hunger,” in 1960 the richest 20% of world population made 30 times more than the poorest 20%; but by 1995, that ratio had changed to 82 times. They stated that 3 billion people live on less than \$2 per day, and at least 2 billion suffer from lack of food. Renner (1999) wrote a report on world conflict pointing out that, in the period 1900 to 1995, 110 million people had been killed. If we cannot accept such realities, admit to our failures, is there hope for a positive, sustainable future for all people who live on our planet?

In Canada (Mungall and McLaren, 1995), a group of us wrote a book for schools on the state of the planet. In this I used a quotation from Aldous Huxley (*Managing the Double Crisis*, 1948):

Industrialism is the systematic exploitation of wasting assets. In all too many cases, the thing we call progress is merely an acceleration in the rate of that exploitation. Such prosperity as we have known up to the present is the consequence of rapidly spending the planet’s irreplaceable capital. Sooner or later mankind will be forced by the pressure of circumstances to take concerted action

against its own destructive and suicidal tendencies. The longer such action is postponed, the worse it will be for all concerned. ... Overpopulation and erosion constitute a Martian invasion of the planet. ... Treat Nature aggressively, with greed and violence and incomprehension: wounded Nature will turn and destroy you. ... if presumptuously imagining that we can "conquer" Nature, we continue to live on our planet like a swarm of destructive parasites — we condemn ourselves and our children to misery and deepening squalor and the despair that finds expression in the frenzies of collective violence.

OUR POWER OF OBSERVATION

Considering Huxley's words, there is no longer any excuse today for incomprehension. Modern science has provided our incredible powers of observation. We can watch galaxies, planets, atoms, and molecules, and, today, the details of biosystems at the micro level. And we can watch the actions of humans in every part of the globe. We can see the changes in the chemistry of our atmosphere caused by our technologies. We can watch global soil erosion, deforestation. We can watch water pollution and its dramatic influences on human health as recently reported by Pimentel et al. (1999). The fact is that if our future population of about 10 billion continues to behave like my generation, we will destroy the life support systems for most humans and a host of our biological friends. Our systems of the past century have failed.

NEEDED NEW LIFE-SUPPORT TECHNOLOGIES

The quality of life for billions of people today is related to a number of major components. We all need clean air to breathe; and in many of the growing urban regions of the world, breathing has become a major cause of death (*Ecosystem Health*, 1998). Air in Tehran, Iran, contains 209 micrograms of SO₂ per cubic meter; Rio de Janeiro's air contains 129. (*The Economist Pocket World in Figures*, 1999). For example, the World Resources Institute, (1998) predicted that SO₂ emissions in Asia will rise to 110 million tons by 2020. Bright (1999) reports that in parts of the Smoky Mountains in the Appalachians, the dew can be at pH 2.1.

The quality of our nutrition depends on soil quality, water quality, climate, diversity of foods, and our transport systems (which allow Canadians to eat fresh fruit from Argentina and Chile all winter). But in almost all nations, soil quality and quantity are deteriorating due to catastrophic erosion (Fyfe, 1989). In work we started in Portugal (Fonesca et al., 1998) we showed that often the best soil components collect in hydroelectric reservoirs and other dam systems. And on a recent visit to the Yangtze region, China, I was amazed by recent soil erosion. Around the world, the need for irrigation increases. Few rivers today flow freely to the oceans. More and more groundwater is used for agriculture. In parts of India the water table is dropping 1 to 3 meters per year. If water does not flow off the continents, eventually the result is salinization of soils, a disaster on 15% of irrigated land.

The world climate is changing, and rainfall distribution is changing. As recently reported by the U.K. Department of the Environment (Fisk, 1997), it is predicted that the tropical forest may be transformed into desert in major regions of northern Brazil and the eastern Amazon basin, and it is happening now.

When I was a baby in the 1920s, who used bottled water? Water pollution is now a major cause of disease in the world (Pimentel et al., 1999). They estimated that 90% of all infectious diseases in developing nations are related to water quality. In many nations — Bangladesh is a prime example — arsenic in water is causing vast problems. We are working on this problem, and there are simple techniques to remove arsenic. But where do you put the filtered waste materials?

WASTES

One of the greatest problems today and in the future is that of managing our waste products. According to *The Economist* data of 1999, solid, hazardous waste generation has reached 2731 kg per capita in Belgium and 1059 kg in the U.S., the world leaders. In careful nations like Germany, the number is 82 kg. With industrial wastes and municipal wastes, the U.S. leads the world. I was recently in Hamburg, Germany, and met with city engineers. Hamburg no longer needs landfills. There is a rule: if waste cannot be reused or recycled, then the parent product cannot be used.

Two extreme cases of hazardous waste today involve combustion gases and nuclear wastes. These wastes perfectly illustrate international problems, the need for international systems and controls, and new ethics.

With regard to combustion gases (carbon dioxide, acid rain, nitrogen oxides, etc.), a key question is whether they can be disposed of underground. We have been studying disposal in rocks like the basalts of Hawaii; Parana; Brazil; and Deccan, India. These rocks, with help from microorganisms, can remove them (Fyfe, 1996). It is interesting to note that the Department of Energy (DOE) has recently announced programs in this area. I have found great interest in India and China, which will use coal for decades to come. If all the world produced CO₂ like North America, the planet would not be a greenhouse; it would be Venus.

Nuclear waste is another perfect example of the need for international responsibility. Given that such wastes are dangerous for a million years, who will live where in those future times? The great issue is the location of the best place on our planet where we can guarantee isolation from the biosphere (Fyfe, 1999).

NEEDED NEW TECHNOLOGIES, NEW SYSTEMS, NEW ECONOMICS

As Sir Michael Atiyah of the Royal Society of London wrote, we can solve many of the urgent problems. We must change our energy systems (Fyfe, 1998). With the sun and the deep warm Earth, we have an almost infinite source of clean energy. Slowly, the world is turning to solar (Brown et al., 1999). Many of the poorest nations are rich in potential solar energy. The production of solar, photovoltaic devices is rising. I was interested to read that in the U.K., large turbines using ocean currents may soon produce 19% of the energy and at reasonable cost. In my home country, New Zealand, over 30% of the electrical energy is generated by geothermal systems using the regions of active volcanism. I have seen an experiment in which a small town in Sweden is heated from drill holes using the normal geothermal gradient of about 30°C/km depth.

Recent work in many nations, Japan leading, has shown that when sunlight shines on the surface of certain materials, such as copper oxide (Cu₂O) with a film of water, the water is dissociated into 2H₂ + O₂, almost the perfect transport fuel (*Chem. Eng. News*, 1998). By using such fuels and electric motors, we can clean our cities.

When one examines these types of problems, it is obvious that solutions can be found by forming teams, integrating the work of experts from a range of disciplines. For example, to produce clean, sustainable solar energy, we need experts in climate and solar radiation, surface physics, and chemistry and engineering. To develop geothermal energy, we need experts from rock mechanics, geophysics, deep-water hydrology, geochemistry, and engineering. New Zealand developed such teams long ago and led the world in such developments.

But to accelerate the desperate, urgent need for the use of such systems, we must involve those from local government particularly from economics. What is the cost of polluted urban air, polluted water, or soil erosion on decade time scales? Recently the *Worldwatch Journal* (1999) had some spectacular, alarming reviews on such topics (Bright, 1999). The costs of environmental deterioration are becoming vast. I was recently at a meeting in Lebanon with earth scientists from more than 20 Arab nations. I met with many students from the region. They are angry. In many of these

nations one of their few ultimate resources, fossil fuels, are being wasted by advanced nations. When we plan, how often do our leaders think of the next generations? Here I again quote Sir Crispin Tickell (1993):

I was recently asked if I was an optimist or a pessimist. The best answer was given by someone else. He said that he had optimism of the intellect but pessimism of the will. In short we have most of the means for coping with the problems we face, but are distinctly short on our readiness to use them. It is never easy to bring the long term into the short term. Our leaders, whether in politics or business, rarely have a time horizon of more than five years.

We need new systems, new teams, new economics; and as *Worldwatch* wrote (Brown et al., 1999), “We need a new moral compass to guide us into the twenty-first century — a compass grounded in the principles of meeting human needs sustainably.”

EDUCATION THE KEY

When one examines the state of nations, the state of their environment, and their respect for ecology biodiversity, it is clear that the quality of education is the most fundamental factor. If one examines data on literacy (World Resources Institute, 1996) the message is clear. In most of Europe, literacy for both males and females is nearly 99%. But when we examine data from many of the poor nations, the situation is a disaster (e.g., female literacy in Ethiopia is 21%; in Niger it is 5%; and in India it is 34%). One of the most striking developments in recent times, the social acceptance of limits, is shown by trends in fertility. The World Resources Institute (1998) reports that fertility (the number of children per family) is 7.1 in Niger; 7.0 in Ethiopia; 3.1 in India; 1.2 in Italy; 1.5 in Japan; and 1.8 in China. It is clear that the state of nations is related to female literacy.

It is essential that those with expertise devote more effort to world problems. At the present time I am involved in problems such as water purification, combustion gas disposal, nuclear waste disposal, and soil remediation. But recently, while trying to find financial support, a reviewer of a project wrote that this was not at the cutting edge of science! I often observe that many of my academic colleagues devote their lives to finishing their Ph.D.s. During many of our university programs, the students are rarely exposed to the great world problems. Yes, we must have experts, but experts who can communicate with other experts and society.

If we are to have a positive 21st century, one priority must be to universally educate the populations of the world in literature, math, and the sciences. Those of us in the rich nations must help those less fortunate. It is interesting to examine the nations who give foreign aid generously. The largest donors as a percentage of gross domestic product (GDP) are Denmark (1), Norway (2), and Sweden (3), with the U.S. ranking 23. Denmark gives 1.04% of GDP; in contrast, the U.S. donates only 0.12%.

If our planet is to be a beautiful place by the year 2100, we must increase our foreign aid; and priority number one must be universal education, training teachers, building schools, and providing infrastructure.

Are we *Homo sapiens*, or did Linnaeus (Carl von Linné of Sweden) make a mistake? Are we *Homo horribilis*? As the great French philosopher Montaigne said in 1580, the most universal quality is diversity, and diversity is security! And as Ayres (1999) recently asked, “Why can we not learn from history?”

SECTION 1.2

Perspectives on Ecosystem Health

Overview: Perspectives on Ecosystem Health

David J. Rapport

Ecosystem health is about a lot of things. It is about the state of a community of organisms (including humans as part of that community) that interact with their environment, sometimes in ways that compromise ecological functions, and in the process compromise the health of the entire ecosystem and its components. It is about questions of the relationship between the health of ecosystems and their integrity, i.e., how far they may diverge from a pristine state. It is also about human health — a topic that is receiving increased attention as issues of climate change, ozone depletion, food safety, exotic pathogens, and drinking water come to the fore. And at root it is about sustainability — that is, about the conditions necessary to sustain the functions of the ecosystem, the human community, and the other species that are totally dependent on those functions. The trend continues for more of the world's population to be concentrated in urban areas (more than half the world's population now lives in urban ecosystems, and in developed countries the percentage is substantially higher). Therefore, it is about the health of those systems and their interrelations with other ecosystems (forests, lakes, rivers, grasslands, etc.). Section I.2 provides a kaleidoscope of many of the philosophical, ethical, and practical issues that are part and parcel of the ecosystem health perspective. The chapter by Laura Westra examines the conceptual, historical, ethical, and philosophical dimensions of ecosystem health. Her chapter provides guidance in making a useful distinction between ecological integrity, which is oriented toward the preservation of unfettered nature, and ecosystem health, which is oriented toward preserving the functions of ecosystems, even though the system may be considerably altered as a result of human domination. The ethics of integrity (and ecosystem health) can be boiled down to this: if integrity (or, one might argue, ecosystem health) is basic for life, then the duty “to respect/protect life must come before all other obligations we might have, as no other *good* and no other *right* may be present, if life is absent.” Westra's chapter goes on to explore the implications of this ethic, as well as to explore the relative strengths and the interface of ecosystem integrity and health. Both ecological integrity and ecosystem health are gaining in popularity as policy goals for environmental management.

The chapter by William Rees argues that ecosystem integrity and health require movement toward a steady state economy, and that neither goal is likely to be achieved with a conventional economic growth scenario. The reasoning is simple and convincing. Human-dominated ecosystems are sapping the materials and energies (both finite, even allowing for ever-increasing technological efficiencies) needed to sustain life systems. Rees emphasizes that the real issue is not an environmental crisis, as many would have us believe, thereby externalizing the problem, as if it were something outside of our control that has run amok. Rather, the crisis is a human ecology issue, whereby the pressures that humans have brought to bear on ecological systems have become so

great as to place these systems in critical condition. Reviewing the fundamentals of human ecology, and drawing upon principles of nonequilibrium thermodynamics and the evidence that human pressures have coincided in many areas of the world with massive prehistoric extinctions, the conclusion seems clear: unless we rein in the size of our ecological footprint — particularly in the developed countries — we will continue to extinguish not only species but whole ecosystems and, finally, the very foundations of our life support.

The next four chapters focus on some specific consequences of degrading environments, namely, the threat posed to human health. This topic is given much attention as the range of threats to human health from the loss of ecosystem health becomes more apparent. Burnett et al. address one of the long-suspected problem areas: the impact of air pollution on human health. They conclude that, although there are many confounding factors, the overall consistency of epidemiological data suggests strongly that premature mortality, cardiorespiratory hospitalization, and emergency department visits for respiratory diseases, asthma attacks, etc., are correlated with air pollution. Placing these findings within a cost–benefit analysis, it appears that billions of health care dollars (and much human misery) would be spared if more stringent air quality standards were adopted.

McMichael and Kovats shift the focus from the local to the regional and global changes that endanger human health. Climate change (climate warming), stratospheric ozone depletion, and invasive species are separately and interactively exacerbating existing threats to human health and giving rise to new ones. While mathematical model-driven estimates of likely impacts from global change have wide ranges owing to underlying uncertainties, it seems clear enough that the impacts of degrading environments on human health are significant. For example, one scenario-based model of the impact of stratospheric ozone destruction indicates that European and North American populations will experience significant increases in skin cancer — on the order of 5 to 10% in excess of present rates by the middle decades of this century. Among the many kinds of ecological disruptions that threaten human health are invasions of exotic species that provide habitat for human pathogens. The introduction of the water hyacinth to East Africa's Lake Victoria from Brazil, for example, has provided fertile breeding grounds for the water snail that transmits schistosomiasis as well as for bacteria causing diarrheal diseases.

Jonathan Patz looks at quantitative methods that might be used to assess public health implications of global climate change. He focuses on six specific threats: (1) mortality related to heat waves in the U.S.; (2) hantavirus, which is transmitted by human contact with rodents and can be fatal; (3) malaria, which is on the rise owing to habitat disturbances that create more breeding grounds for the mosquito vector; (4) dengue fever (another vector-borne disease, also involving mosquitoes); (5) water-borne cryptosporidiosis; and (6) cholera. Patz examines how ecological and climatic factors might be related to specific human health risks. His work provides quantitative evidence that the loss of ecosystem health is associated with increased risks to human health.

William Reisen's chapter focuses more specifically on the potential of correlating meteorological variables to encephalitis risk in California. Both western equine encephalomyelitis and St. Louis encephalitis are public health concerns in the area. They are thus the motivation for mosquito abatement actions. Reisen explores the complexities of the transmission cycles of the pathogens (in this case the viruses that live in their mosquito hosts) and explores how changes in temperature alter both mosquito abundance and the virus transmission rates. Some meteorological variables (snow pack and river runoff) were correlated with mosquito abundance during the following season, while others (winter rainfall) were not. This is illustrative of the potential for *data mining* — associating meteorological variables with ecological change and ultimate consequences for human health.

Mathis Wackernagel returns to the “big picture,” examining the demands of people for the limited energy and material resources of the planet. He focuses on cities, and describes the toolkit that Redefining Progress is developing for assisting cities and towns to achieve a better balance between material and energy consumption and the capacity of ecosystems to supply these requirements on a sustained basis. His focus is on assessing current progress toward sustainability and on developing activities that maintain community interest in building a sustainable future.

The Ethics of Ecological Integrity and Ecosystem Health: The Interface

Laura Westra

INTRODUCTION TO INTEGRITY

Despite the bad press that generally followed the most recent occurrence of El Niño on November 1, 1997, the Italian News Channel (RAI) and the *U.S. Sunday Report* showed a marvel engendered by El Niño: the flowering of the Chilean desert. It is important to note this example, because it shows clearly why the insistence on largely unmanipulated (if not intact, pristine, or virgin) systems is so vital to the understanding of integrity and to life on Earth. A seemingly barren desert area in Chile, without a discernible complement of species in recent times, changed dramatically after El Niño. Because the latent biological processes specific to deserts were present there, the unusual rains brought by El Niño produced a wonderland of flowers and grasses, with all the accompanying complementary species of insects, such as bees, ants, butterflies, and an abundance of other species.

This burst of life occurred because anthropogenic stress was largely absent from the history of the desert; that is, that landscape was not subjected to the chemical technological stress that prevails in exploited ecosystems around the world. In essence the desert retained its capacity because its vital state had not been reduced by human disturbance. The main point of this example is to emphasize the difference between a landscape that has been heavily utilized and one that has been left — at least for the most part — in its natural condition, following its own evolutionary trajectory. At one end of the spectrum, the remote desert area retained most of its capacities for development; largely untouched, the desert flowered. At the other end, the petroleum-laced fields where Royal Dutch/Shell Oil carries on its ecologically destructive enterprise in Ogoniland, Nigeria, will not burst into flower under any circumstances. Note that we, the general public, did not know the immense potential for diverse life that was present in that “barren” desert in Chile (although desert ecologists may be familiar with such phenomena). But its integrity guaranteed that — under changed conditions — one of its possible developmental evolutionary trajectories might come to be.

The generic concept of integrity connotes a valuable whole, “the state of being whole, entire, or undiminished,” or “a sound, unimpaired, or perfect condition” (*Random House Dictionary of the English Language*, 1967). We begin with the recognition that integrity, in common usage, is an umbrella concept that encompasses a variety of other concepts (Westra, 1994). The example of the blooming desert illustrates a number of the themes associated with ecological integrity.

1. The example is drawn from *wild nature*, i.e., nature that is relatively unimpacted by human presence or activities. Although the concept of integrity may be applied in other contexts, wild nature provides the paradigmatic examples for our reflection and research. Because of the extent of human exploitation of the planet, such examples are most often found in those places that, until recently, have been least hospitable to dense human occupancy and industrial development: deserts, the high arctic, high-altitude mountain ranges, the deep ocean, and the less accessible reaches of forest and jungle. Wild nature is also found in locations whose capacity to evoke human admiration won their protection in natural parks.
2. The rapid bloom of desert organisms illustrates in a dramatic fashion some of the *autopoietic (self-creative) capacities* of life to organize, regenerate, reproduce, sustain, adapt, develop, and evolve.
3. These self-creative capacities of life are *dynamically temporal*. The present display of living forms and processes in the desert gains significance through its past and its future.
 - a. Conjoined with its past, the Chilean desert is a part of *nature's legacy*, the product of natural history. Because of the relative absence of anthropogenic impacts, the desert biota is the creature largely of “evolutionary and biogeographical processes at that place” (Angermeier and Karr, 1994). It thus illustrates what nature is and does in the absence of the human design and impacts that dominate the built, modified, and impacted environments in which we live most of our lives.
 - b. The events of their past and present demonstrate the capacity of desert life forms to maintain their functions, to respond to changing conditions, and to evolve. If those capacities are not destroyed, we may anticipate their evolving *future realizations*. Indeed, continued evolution provides evidence that these adaptive capacities have not been destroyed.
4. Desert conditions, relieved by rains at rare intervals, are themselves the products of larger regional and global weather patterns. Indeed, both the biological and geoclimatic processes that led to the blooming desert play themselves out on a stage with much larger *spatial scope* (Westra et al., 2000).
5. Note finally that ecological integrity is *valuable* and *valued*. In the case of the Chilean desert, the dramatic transformation of “barren” desert into a vital and diverse biotic community provoked wonder and appreciation. Other ecological communities, such as reefs and rain forests, display their prolific lives in a more continuous, less seasonal or episodic fashion. More generally, the kinds of processes at work in these instances gave rise to the totality of life on Earth, including ourselves, and together maintain the conditions for the continuation of life as we know it. Thus, natural ecosystems are valuable to and in themselves for their continuing support of life on Earth, for their aesthetic features, and for the goods and services they provide to humankind. Ecological integrity is thus essential to the maintenance of ecological sustainability as a foundation for a sustainable society. For these reasons, a growing body of policy and law mandates the protection and restoration of ecological integrity (Pimentel et al., 2000).

THE GLOBAL INTEGRITY PROJECT AND THE ETHICS OF INTEGRITY

This project was initiated in 1992, when I first sought funds to investigate the meaning of the expressions *ecosystem integrity* or *ecological integrity* that appeared in regulations, laws, and mission statements, not only in Canada and the U.S. but all over the world (Westra, 1994). The concept of integrity had been introduced in 1972 in the U.S. Clean Water Act, and its use multiplied and accelerated in the years after that. The Great Lakes Water Quality agreement (1978, ratified 1988) is a clear example of its use.

The purpose of the agreement is to restore and maintain the chemical, physical, and biological integrity of the waters of the Great Lakes Basin Ecosystem, where the latter is defined as: “the interacting components of air, land, water and living organisms, including humans within the drainage basin of the St. Lawrence River” (Westra, 1994).

In most documents that refer to integrity, only the vaguest definition of the concept is available; and most of the time no attempt is made to clarify it. This is surprising, to say the least, in regard to a concept that is intended to represent the goal of legislation. For this reason, my first effort was to secure funding to examine the concept of integrity from many points of view and from the perspective of several disciplines. The funding we received was used to conduct workshops on

business, business ethics, agriculture, fisheries, and other enterprises. The questions were, in each case, how do we understand ecosystem integrity and how do we define it?

Following a series of meetings, a team comprised of two complex-systems theorists and ecologists, James Kay and Robert Ulanowicz; an ecologist, Henry Regier; and a physicist and ecologist, Don de Angelis; and I drafted a definition after careful discussion of each word and concept (Westra, 1994). This definition was later shown to conservation biologist Reed Noss and to ecologist and biologist James Karr, both of whom were largely in agreement with most of the language of the definition.

I believed then, as I do now, that if integrity is so vitally important, so fundamental to life on Earth as we jointly believed it to be, then morality must also acknowledge its centrality, and so should public policy. The *Principle of Integrity* (PI) recognized this centrality and proposed an obligation for morality as such, not simply an “environmental ethic.”

The reasoning employed is simple: If integrity is basic for life, then our duty to respect and protect life must come *before* all other obligations we might have, as no other *good* and no other *right* may be present if life is absent. In *Perspectives on Ecological Integrity* (Westra, 1995) scientists and philosophers argued about the meaning of integrity from various points of view. In the PI, I set out what seemed to follow from the recognition of the centrality of integrity, and considered the role other *basic* fundamental goods such as *justice* or *happiness* played in providing a starting point and central consideration for moral theories.

If we trace briefly the history of ethics in recent times, say from the 18th to the 20th century, we note that some of the major figures we study today (Bentham, Mill, Kant, and — more recently — Rawls), all depend on at least *one* factual or natural characteristic of human beings and, from that starting point, move to construct the moral principles for which they argue. *Pace* Hume, unless human (and many non-human animals) were capable of feeling pain and pleasure, (a fact), Bentham’s “ought” would have no basis. A similar case can be made for the work of John Stuart Mill and again for Immanuel Kant, whose categorical imperatives prescribe universalized and reversible respect for the dignity of autonomous humans. Dignity and autonomy are grounded in the presence of rationality and the capacity to exercise free will, and both abilities are unique to humankind, according to Kant. Finally, Rawls’ principles, required to establish fairness and justice in society, are also based on discourse among rational contractors. The capacity to enter into this discourse also requires rationality, a human factual characteristic (Figure 6.1).

All these approaches then depend and are based on a *single* factual characteristic, whose presence is acknowledged and taken as a given, rather than argued for. But when we come to the work of Aldo Leopold, we discover that his main maxim, “a thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise” (Leopold, 1949) appeals to a whole as the object of moral action, rather than to a single component of that whole, or even less to a single characteristic of any individual.

One might argue that something underlying Leopold’s position is unique and general enough to guarantee the value of individuals and processes as well as the value of the whole: there is the biotic connectedness Leopold emphasizes — that is, the presence of life. I have argued from this point of view because I believe that the reconnection between anthropocentrism and nonanthropocentrism is possible only at the most basic level, based on the value of life, intrinsic as it is to individuals, aggregates, and wholes — although the latter encompass abiotic components as well (see Figure 6.1).

With the arrival of Aldo Leopold on the scene of ethics and public policy, we have a new approach that is not flawed, as some would argue, by its reliance on the *naturalistic fallacy*. We have instead a radically new approach — one that is based on a wider actual reality and one that recognizes the primacy of natural wholes, in line with the new science of ecology. In addition, the insights of conservation biology, complex systems theory, and even environmental epidemiology are compatible with Leopold’s principle, as they indicate clearly that both moral theory and public policy must be integrative rather than reductionist; holistic, rather than individualistic or aggregative; and, most of all, fundamentally nonanthropocentric, as they must recognize the value of *all* life, human and nonhuman.

Table 6.1 Moral Theories, Principles, and Natural Characteristics

Philosopher	Principle	Factual/Natural Characteristic
Jeremy Bentham (1748–1832) Basis of principle: The promotion of pleasure	Principle of Utility An action conforms to the utility principle (or promotes the interests of the individual) when it tends to add to the sum total of his pleasures, or ... to diminish the sum total of his pains	Capacity for pleasure/pain in sentient creatures (includes human and nonhuman animals; individualistic)
John Stuart Mill (1806–1873) Basis of principle: The greatest happiness overall	Greatest Happiness Principle Actions are right in proportion as they tend to promote the greatest good for the greatest number	Human capacity for pleasure/pain (anthropocentric individualistic)
Immanuel Kant (1724–1804) Basis of principle: The dignity of human reason and free will	The Categorical Imperative (two formulations) 1. Always act so that you may also will your maxim (for action) to become a universal law 2. Always act so as to treat humanity in your person or that of another, as an end in itself, never merely as means	Human reason and free will (anthropocentric individualistic)
John Rawls Basis of principle: Justice as equality/fairness contractarianism	Original Position: Two Principles of Justice 1. The first principle of justice requires an equal distribution (since it is not reasonable for anyone to expect more than an equal share of social goods) 2. Inequalities are permissible when they maximize or at least contribute to the long-term expectations of the least fortunate group in society	Rational contractors' dialogue (anthropocentric)
Aldo Leopold (1887–1947) Basis of principle: Interdependence of all nature	The Land Ethic A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community; it is wrong when it tends otherwise	Interconnectedness of all life <ul style="list-style-type: none"> • holistic • integrative • non-anthropocentric

Based on this point of view, the ethics of integrity proposes a first *principle of integrity* and a series of eight second-order principles (SOPs) intended to clarify, apply, and implement the PI (Westra, 1994; 1998). These principles do not simply employ a deductive argument starting from *what is* to prescribe *what ought to be*. The principles acknowledge that, as *ought* indeed implies *can*, moral prescriptions must incorporate the actual conditions and circumstances that render both first-order principles and second-order, derived prescriptions consonant with reality.

For instance, on utilitarian grounds we might say that because human beings can and do feel pain, it is morally wrong to cause them pain-producing harms. We should add yet another specific natural fact or law — that is, the law of gravity, as applied to dropping heavy objects from above on innocent citizens. We can therefore conclude that because of *two* actual facts (one, the capacity of humans to feel pain; two, the law of gravity as it applies to heavy objects and their earthbound trajectories), it is morally wrong to drop bricks from my window on those who might pass below because it would harm them.

The addition of a holistic perspective to this procedure ensures the inclusion of all life, sentient or not (as the latter also participates in providing natural services in support of all life; see Figure 6.1), as an object of our concern to avoid inflicting harm.

In addition, this approach does justice to the mutualism and the interdependencies present in all nature as facts and laws that will inform our decisions about what kind of interference with

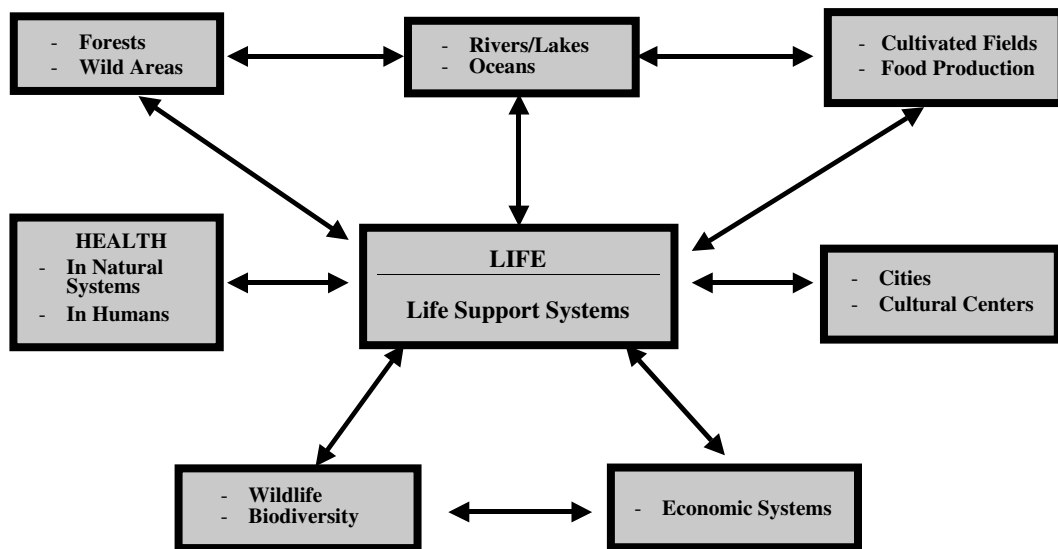

Figure 6.1 Mutual and reciprocal impacts for an integrated ethic (symbolizing the work of the Global Integrity Project, 1996–1999).

natural systems would or would not inflict a harm (such as diminished integrity) upon the wholes under consideration.

In this way, the discourse and the argument are radically different as they necessarily include an ongoing dialogue with scientists, who can research and update the true meaning of *harm* as well as that of *interference*.

Public policy then should not depend on bureaucrats or politicians, let alone the interests and biases of transnational corporations. A dialogue between ethicists and scientists, as envisioned by both postnormal science (Funtowicz and Ravetz, 1995) and by the Precautionary Principle (Brown, 1995) will be required to characterize the true impact of our interference, hence to suggest the limits required for all our activities. Such a dialogue will best help us to understand and explain what constitutes a *harm* and to whom or to what these harms will apply. These procedures will ensure that the principles used will be radically integrative and holistic. As a consequence, the role of the moral philosopher will also be radically altered, as her contribution must also be integrated within scientific discourse in a way that will enrich both science and morality (see Table 6.1).

In fact, there have always been two parallel paths originating from the same starting point in the Global Integrity Project: one tracked the *ethics* of integrity, the other the *science* of integrity. The main point is that the latter is basic to the formulation of the former. This is because, through integrity as a factual condition, we recognize the need for a holistic, integrated approach that the ethics of integrity support a moral stance *quite different* from that of other traditional moral theories (see Table 6.2). With such a radical departure from traditional approaches, the principle I provided was also viewed as giving little or no guidance for specific cases and situations, without fitting into any other established approach.

Following on the path of the *PI*, I saw the necessity to provide second-order principles to render the *PI* operational. Even for that endeavor I still needed interaction and dialogue with other disciplines so that the SOPs would reflect the joint conclusions of our research. This goal was eventually met as I wrote *Living in Integrity* (1998), a work for which I relied on the critique and advice of the collaborators and the co-investigators in the new grant (1996–1999). I proposed eight SOPs that seemed to capture best the meaning of living out the principle of integrity and its rather sketchy categorical mandates.

Table 6.3 Integration and Synthesis in Ethics: the Ethics of Integrity.

Philosopher	Principle of Integrity (PI)	Factual/Natural Characteristics
Laura Westra (living)	The first moral principle is that nothing can be moral that is in conflict with the physical realities of our existence or cannot be seen to fit within the natural laws of our environment in order to support the primacy of integrity	Interconnectedness of all life; holistic, integrative nonanthropocentric
Basis of principle: Primacy of life and life-support systems		
Scientific collaborators:	Second-order principles (SOPs) (to render <i>PI</i> operational)	
J. Karr	1) In order to protect and defend ecological integrity, we must start by designing policies that embrace complexity	
R. Noss	2) Accepting the paradigm change of postnormal science for public policy	
O. Loucks	3) Human activities ought to be limited by the requirements of the Precautionary Principle	
D. Pimentel	4) We must accept an <i>ecological worldview</i> and thus reject our present <i>expansionist worldview</i> and reduce our <i>ecological footprint</i>	
R. Goodland	5) We must reject the pressures of <i>technological maximality</i> and reduce many of our wasteful human rights	
W. Rees	6) It is necessary for humanity to learn to live as in a buffer; zoning will impose limits on both the <i>quality</i> and the <i>quantity</i> of our activities	
C. Soskolne	7) We must respect micro-integrity (for single organisms)	
J. Kay	8) We need to accept both <i>risk thesis</i> and <i>potency thesis</i>	
R. Ulanowicz		
1996–1999 The Global Ecological Integrity Project (two recommendations)		
No. 9 Reduce consumption in northwest affluent countries at least by 50%		
No. 10 Practice contextual vegetarianism and always attempt to eat lower on the food chain		

Beyond the efforts to find appropriate prescriptions for an ethic derived from integrity, the primary strand of our investigation is and has been the transdisciplinary research that leads to an understanding of the actual conditions that define a landscape with integrity. This understanding informs all efforts to defend it as an ultimate value in morality and in public policy.

INTEGRITY AND HEALTH: THE INTERFACE

The focus of this publication is on ecosystem health, so it is important to show why concern for ecosystem integrity and for ecosystem health are different but compatible. In fact, they represent two aspects of the same concern. The difference between the two concepts is an important one. The simplest way to distinguish one from the other is to start by saying that ecological integrity includes health (Westra, 1994), but ecosystem health as such does not include integrity. The starting section of this chapter makes clear that biological integrity is intended to refer to the areas that are largely unmanipulated and that are “the product of bioevolutionary processes” (Karr, 1995; 1996). But a healthy ecosystem is, almost by definition, one that *functions* and *produces* well in response to various human needs and wants — that is, one that is used or manipulated in a nondestructive appropriate way. This is the reason integrity is absolutely necessary, even if our main focus might be an interest in ecosystem health. In Costanza et al. (1992), B. Haskell says:

Since fast-changing human cultures are embedded in large-scale, slow changing ecological systems, we must develop policies that allow human cultures to thrive *without changing the life-support, functions, diversity and complexity of ecological systems*.

The authors do not seem to appreciate the inherent conflict between “human thriving,” at least as it is understood in the modern technologically advanced countries in the northwest, and the possibility of maintaining “without change the life-support functions, diversity and complexity of ecological systems.” Any natural system that has been substantially altered by human beings has correspondingly lost its ability to provide life support, and this occurs in proportion to the severity of the disruption and modifications that have happened over time. Nor is it sufficient to regulate

for ecosystem health, as it does not exclude human use and presence. Unless use and presence are understood in terms a hunter-gatherer society or a native tribe might accept, these are incompatible with the *full* presence of life support, as can be provided by a system that is largely unmanipulated and intentionally left wild.

Some argue that if we have the concept and the goal of ecosystem health, integrity is unnecessary. After all, there are no “untouched” places left on Earth, so why — so the argument goes — should we insist on integrity rather than health as an environmental goal? This argument, like the one in the paragraph cited, is incorrect. It is disingenuous to expect the same services from a cultivated field or a suburban park that one can expect from an old-growth forest. Of course, human beings need various natural products to survive. But if they assume the freedom to co-opt the whole Earth for their purpose, they will eliminate the most important elements needed for their survival, as Costanza et al. indicate, when they speak of the conditions for life support.

Some percentage of wild (if not pristine) nature *must* be preserved, if the goal advocated by Costanza et al. (1992) is to be achieved. Once again, it is not possible to utilize and manage all corners of the Earth and expect — at the same time — that it will provide the services that only the wild can offer. Whether the idea offends modern sensibilities, we do not *belong* anywhere we choose on Earth; because we, unlike nonhuman animals, are not prepared to enter nature as we are, without all the technological aids we take for granted, from computers to chemical toilets, from all-terrain vehicles to televisions. Given this inescapable aspect of modernity, it is absurd to say that we are “animals like other animals” and that the disruptions we cause can be compared to those caused by other animals, beavers, ants, or wolves.

If we were prepared to live in nature like those other animals, fostering the limited, localized disruptions, maybe even extinctions, that animal activities and predations produce, then that line of argument might be valid. As it is, and because we are not, for the most part, prepared to live an existence that might bring us close to the land and its rhythm, the argument that we still are just natural animals, one among many, will not stand. We need only to consider that even nonhuman animals, if they have been technologically altered, wreak havoc in their (formerly) natural habitats. Consider, for instance, farmed salmon when it escapes into wild ecosystems and, in general, the effect of all “alien” plants and creatures in ecosystems (Westra, 1998).

In essence, if we admit the necessity for life support systems, then we need wild areas in some proportions to provide sufficiently for those functions (Noss and Cooperrider, 1994). In addition, it is also true that we must support ecosystem health for all areas we need to utilize. But both our life and health, and that of areas intended for careful human use, *also* require some percentage of wildness and wild areas to ensure continued support.

Thus the main message I want to convey is that there is no conflict between the concern for biological integrity and the concern for human and ecosystem health, as the former supports the latter and the two remain complementary. Because of the way we understand ecosystem health, another difference arises: integrity is a basic value from both an anthropocentric and a nonanthropocentric perspective. Health remains an anthropocentric concept when applied to ecosystems. For integrity, the main point is that “nature’s services” provide life support for all biota, within and without the confines of the wild areas, with minimal human impacts, where integrity can be recognized. All that live within those areas need both components and processes for their optimum flourishing as they have evolved naturally in that landscape.

Hence, from a moral point of view, the primacy of integrity mirrors the primacy of nonanthropocentrism. That is, by emphasizing the intrinsic value of all natural things, individuals, aggregates, wholes, and processes, it establishes a clear starting point for moral considerability. Why the necessary connection between integrity and natural services? Common sense indicates that parking lots, city centers, and skyscrapers do not provide the natural services on which we all depend; in contrast, an old-growth forest does a lot better in that regard, although the precise point where natural services are sufficiently provided (or totally lost) is not obvious. Both need to be identified

through scientific research and placed somewhere along the continuum from “nothing” to (almost) “everything” that is required for the presence of integrity and the life support upon which it is based.

In addition, in order to understand better the connection between integrity and ecological health, we need to understand that human and nonhuman health, in general, are best protected by the presence of areas of integrity, in some proportions and percentage (somewhere around 30% of the whole Earth), on both land and water (Noss and Cooperrider, 1994; Lubchenco, 1999; Pauly, 2000). But humans, like most other animals, also need to disrupt natural evolutionary development to some extent. When we use earth or sea, whether we extract resources or modify and cultivate, we need to be aware of the necessity to maintain health (hence sustainability) in the areas we modify and to ensure that our interventions do not cause stress to the components or the processes of those other areas, the “core” or “wild” areas of integrity, that we do not use.

During the period from 1992 to 1999, the Global Ecological Integrity Project established a transdisciplinary dialogue among various experts that led to a number of discoveries for each one of us. One of the most important discoveries for me was the extent to which even set-aside protected forests had suffered from the impact of modern human civilization as it proliferated just outside their borders. Orié Loucks’ research showed unequivocally a 50% loss of biomass (worms) in the “protected” forests he studied in Ohio (Loucks, 2000).

This discovery emphasizes the main point I have been making: a *healthy* functioning forest is good and necessary, as are sustainable fields, sustainable fisheries, and sustainable plantations of all kinds. However, all of these are not *sufficient*, because unless humankind manages and restrains its activities outside wild protected areas, hence ensuring that enough fully protected areas exist to provide the life support we all need, their sustainability and that of all life is — at best — temporary. Their functions (like ours) need to be supported by areas of integrity, smaller than healthy areas used for human purposes, but stronger in themselves as more “complete,” as they approximate as closely as possible the products of natural bioevolution.

Therefore, areas of integrity are fundamental for health and sustainability for all biota but are also required to support a moderate and respectable amount of human industrial enterprise. Neither economy nor trade can subsist without sustainable practices and a healthy natural base, protected by human restraints about the activities they practice and the areas they occupy. The ethics of integrity recommend that humans should live “as in a buffer” in order to ensure that areas of integrity retain the full range of their capabilities, as appropriate to their geographical location. Hence, health and integrity are essentially two aspects of the same sustainable whole.

Those who imagine a conflict between ecosystem health and ecosystem integrity as a goal of protection and regulation are simply mistaken. Those who perceive a conflict between the respect for integrity and that for human health are equally fundamentally in error. The World Health Discussion Document (Soskolne and Bertollini, 1999) makes this fact abundantly clear. The workshop’s executive summary says:

Humans, like other forms of life on Earth, are dependent upon the capability both of local ecosystems and of the global ecosphere for maintaining health. However, in relatively recent times, humans, particularly in industrialized countries, have developed an erroneous perception of being separate from nature’s processes.

That is why we believe that the emphasis on “ecosystem health,” as the focus of sustainability for our human projects and enterprises, must be balanced by the focus on ecological integrity and, with it, on the sustainability of all life, not only our own. Adopting integrity as the main focus is also best for human health, despite the nonanthropocentric thrust of this approach. The WHO Discussion Document says:

The Workshop assessed that current world-wide patterns of over-consumption, population growth, and the inappropriate uses of technology, are unsustainable. Assessment methods included the eco-

logical footprints of nations, the Index of Biological Integrity, the Measure of Mean Functional Integrity and the World Wide Fund for Nature (WWF) analyses. The use of each of these indices reveals that environmental degradation has the potential for severe negative human health impact. Infrastructure is needed to establish and maintain data that are adequate for improved scientific assessments of resource depletion and health risks (Soskolne and Bertollini, 1999).

Paradoxically, then, adopting a nonanthropocentric holistic perspective based on Leopold's first normative concern, the promotion of integrity, is more conducive to the protection of human life and health than any other perspective one might adopt. In addition, even ecosystem health is protected if the ethics of integrity are implemented. A perspective based on respect for life embraces both humans and nonhumans, individuals, wholes, processes, and natural functions. Although no one — to my knowledge — has proposed an ethic of ecosystem health, that approach might ultimately be self-defeating. Because it would highlight only anthropocentric values, it would fail in its support of the very value it intended to protect. The ethics of integrity, with its wider reach, can extend protection and support to all life, including all the components that are vitally necessary for it.

Ecological Integrity and Material Growth: Irreconcilable Conflict?*

William E. Rees

INTRODUCTION AND ANALYTIC FRAMEWORK

Many ecologists, other scientists, and ordinary citizens who simply love nature see the loss of biodiversity and the threat to ecosystems integrity as one of the most pressing problems confronting humankind. Maintaining ecosystems structure and function has become part of even the mainstream sustainable development agenda. For example, the Brundtland (United Nations) World Commission on Environment and Development, the commission that popularized the concept of *sustainable development*, argued that we could protect the environment by using more benign technologies, even as we strive for a five- to tenfold expansion of industrial activity by 2040 (WCED, 1987).

This is a tall order. I argue below that there is an unavoidable conflict between such growth-oriented economic development and maintaining ecological integrity. This conflict is rooted in the very nature of human beings as a highly successful species but one whose activities are now constrained by planetary limits governed ultimately by the second law of thermodynamics.

The problem goes beyond concern for the natural world — some analyses suggest there is virtually no possibility for an industrial society of 6 to 10 billion people using prevailing or anticipated technologies to live sustainably on Earth. Greenhouse gas accumulation, climate change, ozone depletion, fisheries collapse, land degradation, falling water tables, deforestation, toxic contamination, endocrine (hormone) mimicry, accelerating species loss — these and related trends, both local and global, are indicators that the scale of the human enterprise already exceeds the long-term carrying capacity of the ecosphere.

Despite increasing scientific awareness of biophysical limits, human pressure on the planet is relentlessly increasing. Global population reached 6 billion in July, 1999, and was growing by 80 million per year. By the end of the decade it had almost doubled twice in the 20th century. All these people, rich and poor alike, have rising material expectations sustained by an economic system that assumes the latter are insatiable.

Unfortunately, society seems paralyzed by conflicting perceptions of the so-called environmental crisis. The majority, including mainstream policy makers, most economists and techno-optimists,

* Parts of this chapter are revised from Rees, W.E., Patch disturbance, eco-footprints, and biological integrity: revisiting the limits to growth, in Pimentel, D., Westra, L., and Noss, R.F., Eds., *Ecological Integrity: Integrating Environment, Conservation and Health*, Island Press, Washington, D.C., 2000, pp. 139–156. An extended earlier version appears in Nemetz, P., Ed., *Bringing Business on Board*, JBA Press, Vancouver, B.C., 2002. It is reprinted here with permission.

and many humanists, remain dedicated to growth and consumer ideals. They see freer markets and a new efficiency revolution as the only politically feasible solution to both global ecological decline (wealth can allegedly purchase a “cleaner” environment) and to the social problems caused by persistent poverty and growing material inequity.

On the other hand, a growing minority, mainly ecocentric and community-oriented groups and individuals, see the growth ethic and consumerism themselves as the issues. They emphasize that excess production and consumption are the *causes* of resource depletion (including biodiversity loss) and pollution. Moreover, at least in high-income countries, there may be few compensating benefits. The evidence suggests that beyond a certain income level there is actually an *inverse* relationship between income growth and perceived well-being (Lane, 2000). Further growth may therefore be unnecessary for either ecohealth or social sustainability — the solutions lie more in changing consumer behavior to ease pressures on ecosystems, and in policies to ensure more equitable distribution of the world’s present economic output. (Certainly growth-through-globalization is not effective in reducing inequity. In 1970 the richest 10% of the world’s citizens earned 19 times as much as the poorest 10%. By 1997, the ratio had increased to 27:1. At that time, the wealthiest 1% of the world’s people commanded the same income as the poorest 57% (income ratios reflect purchasing power parity; data from UNDP, 2001).

Environmentalism Is *Not* Human Ecology

Whatever the proposed solutions, almost everyone in the mainstream shares the perception that this is an *environmental crisis* rather than a *human ecological crisis*. The distinction is not a trivial one. The former term literally externalizes the problem, effectively blaming it on an environment gone wrong or on defective resource systems that need to be managed more effectively. This perception reduces the destruction of the ecosphere to mere mechanics, a problem readily amenable to the “technical quick fix” approach favored by industrial society. By contrast, seeing the crisis as a human ecological problem places blame squarely where it belongs — on the nature and behavior of people themselves. It also suggests that it is human wants that must be better controlled. This is probably the least comfortable policy domain for the denizens of modern consumer societies to contemplate.

In this chapter, I start from the premise that the current dilemma is at least partly rooted in this perceptual or psychological tension. The Cartesian dualism that underpins Western techno-scientific culture has created a psychological barrier between humans and the rest of nature that keeps us from truly knowing ourselves. Indeed, it is a deep irony of the human-induced environmental crisis that people have a dimly ill-developed understanding of themselves as ecological beings.

My overall purpose, therefore, is to reinterpret the environmental crisis as a problem of gross *ecological dysfunction* stemming, ironically, from humanity’s unquestionable evolutionary success. This requires acceptance of two material facts that are virtually ignored in conventional analysis. First, the human ecological niche is now so extensive that *Homo sapiens* has become a significant participant in most of the world’s major ecosystems. Second, human economic activity (like the economic activity of any other species) requires continuous, irreversible energy and material transformations that are ultimately subject to constraints imposed by the second law of thermodynamics (Georgescu-Roegen, 1971; Daly, 1991a,b; Rees, 1999). In this light, we can see that material economic activity is really human ecology and that the economy itself is an inextricably integrated, completely contained, and wholly dependent growing subsystem of a nongrowing ecosphere (Daly, 1992; Rees, 1995).

As noted, this perspective contrasts sharply with the dominant worldview. The latter assumes that the human enterprise is now more or less independent of nature so that the “environment” no longer constrains the economy. It is this ecologically empty vision that drives the prevailing global development paradigm and has created the sustainability conundrum.

FUNDAMENTALS OF HUMAN ECOLOGY

Far-from-Equilibrium Thermodynamics

The second law of thermodynamics is fundamental to all processes involving energy and material transformations. Since ecosystem analysis often begins with energy and material relationships, understanding the second law is essential to understanding both the structure of whole ecosystems and the functional *niches* of individual species, including humans.

In its simplest form, the second law states that any isolated system* will tend toward equilibrium; alternately, the entropy of any isolated system always increases. This means that available energy spontaneously dissipates, concentrations disperse, and gradients disappear. An isolated system thus becomes increasingly unstructured in an inexorable slide toward thermodynamic equilibrium. This is a state of maximum entropy in which “nothing happens or can happen” (Ayres, 1994).

Early formulations of the second law referred strictly to simple isolated systems close to equilibrium. We now recognize, however, that *all* systems, whether isolated or not, near equilibrium or not, are subject to the same forces of entropic decay. Thus *any* differentiated far-from-equilibrium system has a natural tendency to erode and crumble.

But not all such systems unravel as expected. Indeed, for much of this century, people believed that living entities were exempt from the second law since they obviously do not spontaneously run down (they do not “tend toward equilibrium”). On the contrary, biological systems from individual fetuses to the entire ecosphere seem to gain in mass and organizational complexity over extended periods of time — they actually *increase* their distances from equilibrium. It seems that for describing nature, “distance from equilibrium becomes an essential parameter ... much like temperature [is] in equilibrium thermodynamics” (Prigogine, 1997).

This seemingly paradoxical behavior can be reconciled with the second law in light of the hierarchical organization and relationships of thermodynamic systems in nature (Kay, 1991). Bio-physical systems exist in loose, nested, and overlapping hierarchies, each component system being contained by the next level up and itself comprising a chain of linked subsystems at lower levels.**

Living systems are thus able to import available energy and material (essergy) from their host environments and use it to maintain their internal integrity and to grow. The second law also dictates that such self-producing systems export or dissipate the resultant waste (entropy) back into their hosts. In short, modern formulations of the second law posit that all highly ordered systems develop and grow (increase their internal order) “at the expense of increasing disorder at higher levels in the systems hierarchy” (Schneider and Kay, 1994). Living systems maintain their distance from equilibrium by “feeding” on their hosts. Because such systems continuously degrade and dissipate available energy and matter, they are called *dissipative structures*.

Self-Production by the Ecosphere...

The highest order dissipative structure on Earth is the ecosphere itself. The ecosphere comprises all the biomes and individual ecosystems on the planet, and all of these subsystems develop and maintain themselves in a far-from-equilibrium steady state by dissipating light from the sun (the next level up in the systems hierarchy). In effect, the ecosphere feeds on the sun. (The existence of a gradient of exogenous energy is a prerequisite for life.)

In nature, green plants are the factories. Through photosynthesis, plants use solar energy and the simplest of low-grade inorganic chemicals (mainly water, carbon dioxide, and a few mineral nutrients) to assemble the high-grade fats, carbohydrates, proteins, and nucleic acids upon which

* An isolated system can exchange neither energy nor matter with its environment.

** For example, consider the following nested hierarchy of biological organization (from high to low): ecosystem, population, individual, organ-system, organ, tissue, cell, cellular micro-organelles. Kay et al. (1999) define such complex hierarchic structures as “self-organizing holarchic open (SOHO) systems.”

most other life forms and the overall functioning of the ecosphere depend. Because they are essentially self-feeding and use only dispersed (high-entropy) substances for their growth and maintenance, green plants are called primary *producers*.

By contrast, all animals, bacteria, and fungi are primary, secondary, or tertiary *consumers* whose growth and development is achieved through the assimilation and dissipation of organic energy and matter originally assembled by plants. Although dependent on plants, consumer organisms are also essential to the continuing functioning of the ecosystem. Consumers degrade the complex energy-rich chemicals produced by plants, dissipating the energy and releasing simple organic and inorganic chemicals back into their host ecosystems for reuse by the producer plants. (Nature invented material recycling.)

... and Consumption by the Economy

Where do humans and their economies fit in? Both economists and ecologists would agree that human beings are consumer organisms. In fact, in today's increasingly market-based society, people are as likely to be called consumers as they are citizens, even when the context is a noneconomic one.

Ecologists would actually refer to humans as *macro*-consumers. In general, macro-consumers are large organisms, mainly animals, that consume (i.e., dissipate) either green plants or other animals to grow, develop, and satisfy their own basic metabolic needs. Humans are particularly catholic and adaptive consumers — we have wide-ranging omnivorous tastes; and if we cannot consume something directly (such as grass), we domesticate an animal that will and then eat the animal. “Indeed, if one feature sets humans apart from other animals, it is the breadth of the ecological niche we presently occupy” (Flannery, 1994). This, combined with learning and cumulative technology, makes us particularly formidable competitors in the global ecological arena.

Economists and ecologists also both see humans as producers. However, there is a fundamental difference between production by green plants and production by the economy. As noted, green plants are *primary* producers that assimilate simple dispersed materials and sunlight (a relatively low-grade form of energy) to produce the most complex and energy-rich molecules known to science. By contrast, human beings are strictly *secondary* producers. The production and maintenance of our bodies, and all the products of human factories, require enormous inputs of high-grade energy and concentrated material resources from the rest of the ecosphere. That is, all production by the human enterprise, from the increase in population to the accumulation of manufactured capital, requires the consumption and dissipation of a much larger quantity of available energy and material *first produced by nature*.

This relationship implies, on theoretical grounds alone, that the continuous growth of the economy will ultimately generate an ecological crisis. Both the economy and the ecosphere are self-organizing, far-from-equilibrium dissipative structures; but as previously noted, the former is an embedded dependent subsystem of the latter. In structural terms, therefore, the expanding human enterprise is potentially parasitic, positioned to consume the ecosphere from within (Rees, 1999).

HOMO SAPIENS: THE ARCHETYPAL PATCH-DISTURBANCE SPECIES

The consequences of this relationship have been felt at every stage of human evolution. The mere existence of people, even pre-industrial hunter-gatherers, in a given habitat invariably results in significant changes in ecosystem structure and function. This is the inevitable consequence of two simple (but generally unacknowledged) facts of human biology: first, humans are large animals with correspondingly large individual energy and material requirements; and second, we are social beings who universally live in extended groups. The invasion of any previously stable ecosystem by people therefore necessarily produces changes in established energy and material pathways. There will be a

reallocation of resources among species in the system to the benefit of some and the detriment of others. To this extent at least, humans invariably perturb the systems of which they are a part.

These facts, together with food productivity data for typical terrestrial ecosystems, are enough to suggest the following hypothesis: *in most of the potential habitats on Earth, groups of human hunter-gatherers will sooner or later overwhelm local ecosystems and be forced to ramble farther afield in search of sustenance.* The productivity of most unaltered ecosystems is inadequate to support more than a handful of people for very long in the immediate vicinity of a temporary camp. In pre-agricultural times, when a group of human foragers had hunted out and picked over a given area, they were forced to move on. This enabled the abandoned site to recover, perhaps to be revisited in a few years or decades. Thus, by moving among favored habitat sites, exploiting one, allowing others to rebound, early humans could exist in an overall dynamic equilibrium with the ecosystems that sustained them, albeit across their total home ranges. Hunting-gathering and closely related swidden (slash-and-burn) agriculture, with their long fallow periods after episodes of intensive use, may well be the most nearly sustainable lifestyles ever adopted by humans (Kleinman et al., 1995, 1996).

Such quasi-steady-state systems, established after long periods of human habitation, would, of course, be quite different from the ecosystems that would exist in the same regions in the absence of people. Perhaps the most dramatic evidence of this is the major ecosystem alterations that occur when humans first invade and settle a new habitat or land mass. Some of these changes are permanent. The recent paleoecological, anthropological, and archaeological literature tells a convincing story of the extinctions of large mammals and birds that accompanied first contact and settlement of their habitats by human beings (Ponting, 1991; Diamond, 1992; Flannery, 1994; Pimm et al., 1995; Tuxill, 1998). “For every area of the world that paleontologists have studied and that humans first reached within the last fifty thousand years, human arrival approximately coincided with massive prehistoric extinctions” (Diamond, 1992).

The species so extirpated include not only those upon which humans preyed, but also various other predators to whom humans proved to be competitively superior (Table 7.1). The resultant changes to ecosystem structure were considerable. In North America, South America, and Australia, about 72, 80, and 86%, respectively, of large mammal genera became extinct after human arrival (Diamond, 1992). Pimm et al. (1995) estimate “that with only Stone Age technology, the Polynesians exterminated >2000 bird species, some ~15 percent of the world total.”

Table 7.1 Example of Areas Where Significant Extinction Is Thought to Have Accompanied Human Occupation

Geographic Area	Species Extinguished by Humans (in last 50,000 years)
Africa	Giant buffalo, giant hartebeest, giant horse
Australia	Diprotodonts (marsupial equivalent of cows, and rhinos), giant wombat, giant kangaroo
Crete and Cyprus	Pygmy hippos and giant tortoises, dwarf elephants and deer
Europe	European rhino, cave-bear, long-tusked elephant, hippopotamus, Irish elk, woolly mammoth and woolly rhino
Hawaii	Flightless geese and ibises; 50 species of small birds
Henderson Island	Three large pigeons, one small pigeon, three seabirds
Madagascar	Half-dozen species of giant flightless “elephant” birds, two giant land tortoises, a dozen species of large lemurs, pigmy hippo, large mongoose-like carnivore
New Zealand	Moas; giant duck, goose, coot, raven, and eagle; pelican; swan; numerous small songbirds and mammals; frogs; snails, and giant insects
North and South America, Australia	Numerous large mammals
West Indies	Several monkeys; ground sloths, bear-sized rodent; several owls — normal, colossal, and titanic

Data from Diamond (1992, 1998), Flannery (1994), Ponting (1994).

As noted, prehistoric humans eventually came to live in a more or less stable dynamic equilibrium (or steady state) within their altered ecosystems, perhaps for thousands of years. However, with improvements in tools and weapons such as the shift from stone to metal, these long-term stable relationships ultimately broke down. Human hunter-gatherers seem to have been instrumental in the eventual extinction of various large animals with which they had long coexisted in many parts of the world. These species include everything from giant deer and mammoths in Eurasia, through giant buffalo, antelopes, and horses in Africa, to bears, wolves, and beavers in Britain (Diamond, 1992). All in all, the slow spread of pre-agricultural humanity over the Earth, accelerated by the diffusion of more advanced hunting technologies and the inexorable expansion of human numbers, seems, invariably, to have been accompanied by significant, permanent changes in the structure and function of ecosystems at all spatial scales.

Upping the Impact Ante

The already significant impact of humans on ecosystems escalated dramatically with the shift away from the hunter-gatherer lifestyle. With the dawn of agriculture 10,000 years ago and the much larger populations it could support, people acquired the capacity permanently to alter entire landscapes. For the first time, we were not merely consuming other species; humans were now appropriating entire ecosystems and diverting much of the photosynthetic energy flow to their own use.

Increased food production enabled the establishment of permanent settlements, the division of labor, the evolution of class structure, the development of government including bureaucracies and armies, and other manifestations of civilization. Indeed, as Diamond has eloquently argued, “the adoption of food production exemplifies what is termed an autocatalytic process — one that catalyzes itself in a positive feedback cycle, going faster and faster once it has started” (Diamond, 1998). More food calories made higher population densities possible, enabled large permanent settlements with the specialized skills and inventiveness this implies, and shortened the time spacing between children. This, in turn, enabled the higher populations to produce still more people, which increased both the demand for food and the technical and organizational capacity to produce it. Pressure on the land and ecosystems increased accordingly and, in the process, ended even the possibility of returning to hunting-gathering for the majority of people. The ancient trend has accelerated throughout the scientific-industrial era: for example, 11% of the 4400 mammal species extant today are endangered or critically endangered, and 25% of all mammal species are on a path of decline which, if not halted, is likely to end in extinction (Tuxill, 1998).

All this is to emphasize that humans are, *by nature*, a typical patch-disturbance species, a distinction we share with other large mammals ranging from beavers to elephants (*BioScience*, 1988).*

In simple terms, “large animals, due to their size, longevity, and food and habitat requirements tend to have a substantial impact on ecosystems” (Naiman, 1988). Thus, a patch-disturbance species may be defined as *any organism which, usually by central place foraging, degrades a small “central place” greatly and disturbs a much larger area away from the central core to a lesser extent* (definition revised from Logan, 1996).

Patch Disturbance and Ecological Integrity

The fact that humans are natural patch disturbers is problematic when it comes to understanding the relationships among humankind, biodiversity, and ecological integrity. As noted, there can be little question that the species composition and developmental trajectory of an ecosystem inhabited by even pre-agricultural humans would be different from the trajectory it would follow without them. However, the same statement could be made about many other ecosystems with reference to their respective keystone species. For example, the extirpation of large predators (jaguars,

* Predictably, with the exception of a passing reference to modern humans as “primary agents of environmental change,” people are not included in this special issue on “How Animals Shape Their Ecosystems.”

cougars, and harpy eagles) on Barro Colorado Island in Panama was followed by a ripple effect that saw major increases in the relative abundance of smaller predators and medium-sized seed-eaters which, in turn, led to the local extinction of small antbirds and several similar species, as well as to a large-scale shift in forest tree composition (Diamond, 1992). It seems that the presence of large predators significantly affects the structure of the entire ecosystem, a fact that may not be fully appreciated until their *removal* appears to disrupt the established order of things.

Now, biological integrity is sometimes seen as a property of near-pristine ecosystems, i.e., ecosystems not significantly modified by human intervention. But this begs the question of why ecosystem modification by humans should be treated differently from that induced by other species like jaguars and cougars. After all, the presence of these large cats results in a different climax system from that which develops in their absence; yet few would argue that Central American forests naturally populated by jaguars and cougars lack ecological integrity because of the unseen structural effects of their presence.

In fact, I would argue that there *is* a major difference, that the quality of human predation and patch disturbance should be distinguished from those of other species. Other large mammals may significantly affect the structure of their ecosystems, but the resultant relationship is relatively stable over the very long term. By contrast, *H. sapiens* has unique qualities that continuously increase the pressure on ecosystems and whose cumulative impacts now affect the entire ecosphere.

First, *H. sapiens* displays a uniquely broad and ever-widening food niche that extends from nearly pure carnivory to obligate herbivory and thus affects a wide range of plant and animal species. Second, humans are uniquely adaptive, which enables the species to exploit virtually all the ecosystems and habitats on Earth. Finally, and most important, because of the evolution of language and culture, human knowledge and technology are cumulative. As a result, human patch disturbance has tended over the millennia to intensify both gradually and in irregular spurts and now threatens to diverge permanently from equilibrium with supporting ecosystems. Humanity's drift from long-term steady state with nature has been accelerating since the Neolithic era. It received a major boost with agriculture, and really broke free with the use of fossil fuels* and the industrial revolution.

In summary then, I am arguing that the makings of the ecological crisis are genetically programmed into the ecology and sociobiology of our species. We are naturally a highly successful patch-disturbance species whose capacity to disrupt the ecosphere has been greatly augmented by behavioral plasticity and cumulative learning. Because of our extraordinary energy and material demands, and the “nesting” of the economy within the ecosphere, the growth of human numbers and cultural artifacts (manufactured capital assets) inevitably occurs at the expense of other organisms. (A form of competitive exclusion is operating here — what we get, other species do not.) The loss of ecosystems integrity or health associated with human beings is thus measured by persistent trends, accelerating biodiversity loss, and increasing systems variability.

OUR ECOLOGICAL FOOTPRINT: QUANTIFYING THE MODERN HUMAN “PATCH”

Despite — or because of — the marvels of modern technology, the industrial era has brought little change to the nature of human–ecosystems interaction except to increase the scale of the “patches” we disturb, the intensity of the disturbance, and the risk to our own survival. This can be shown using ecological footprint analysis, a method I have pioneered with my graduate students. In effect, eco-footprinting estimates the area of the modern human patch (Rees, 1992, 1996, 2000; Rees and Wackernagel, 1994; Wackernagel et al., 1999).

Ecological footprint analysis is an adaptation of trophic analysis, applied to humans and extended to include both our biological and industrial metabolisms (Ayres and Simonis, 1994). It

* Cheap, plentiful fossil fuels have enabled humans to accelerate the exploitation of everything else.

recognizes that all our toys and tools, factories and infrastructure are “the exosomatic equivalent of organs” (Sterrer, 1993) and, like bodily organs, require continuous flows of energy and material from and to the ecosphere for their production, maintenance, and operation.

We start by constructing what is, in effect, an elaborate food web for a specified human population, showing its material connections to the rest of the ecosphere. This step quantifies the material and energy flows (resources) required to support that population and identifies significant sources and sinks for its wastes.

Eco-footprinting is further based on the fact that many material and energy flows can be converted into land- and water-area equivalents. These are the ecosystem areas effectively appropriated for human use to produce food, fiber, and minerals, and to assimilate selected categories of waste.* Thus, the theoretical ecological footprint of a specified population is *the area of productive land and water ecosystems required on a continuous basis to produce the resources that the population consumes, and to assimilate the wastes that the population generates, wherever on Earth the relevant land/water may be located* (Rees, 2001). It therefore includes both the area appropriated through commodity trade and the area needed for the referent population’s share of certain ecosystems-based services of nature (e.g., waste assimilation and nutrient recycling).**

How Big Is Our Ecological Footprint?

Since the beginning of the industrial revolution, the economy has been largely propelled by the constantly expanding use of extrasomatic (outside the body) energy supplies, particularly fossil fuels. By the early 1990s, extrasomatic energy consumption totaled about 407.5×10^{15} Btu annually by a population of about 5.5 billion people. “It is as if every [person] in the world had fifty slaves. In a technological society like the United States, every person has more than 200 such ‘ghost slaves’ ” (at an assumed working level of consumption of 4000 Btu person⁻¹ day⁻¹) (Price, 1995).***

As might be expected, much of this energy subsidy has been used to increase humanity’s harvest of biomass (photosynthetic energy) and, indeed, of all other resources from groundwater to mineral ores. As a result, humans have become the dominant consumer organism in virtually all the major ecosystems types on Earth. For example, we are certainly the most ecologically significant marine mammal. Fossil energy and modern technology enable the global fishing fleet to appropriate seafood for humans that represents 25 to 35% of net marine primary productivity from shallow coastal shelves and estuaries. This 10% of the world’s oceans produces 96% of the catchable fish (Pauly and Christensen, 1995). Similarly, humans are the principal consumer in most of the world’s significant terrestrial habitats, diverting from grasslands and forests at least 40% of the products of photosynthesis for direct and indirect human use (Vitousek et al., 1986; Haberl, 1997).

It should therefore be no surprise that the residents of wealthy developed countries now have per-capita ecological footprints of 5 to 10 hectares (Wackernagel et al., 1999; WWF, 2000). This means that the ecosystem area required to support a typical high-income city is two to three orders of magnitude larger than the geographic area it physically occupies. For example, assuming Vancouverites are typical Canadians with an ecological footprint of about 7.7 hectares per capita, the 472,000 residents of Vancouver proper require an area of 3,634,400 ha, or 319 times the political area of their city (11,400 ha) to support their consumer lifestyles. In a particularly comprehensive analysis, Folke et al. (1997) estimate that the 29 largest cities of the Baltic basin in Northern Europe appropriate for their resource consumption and waste assimilation an area of forest, agricultural, marine, and wetland ecosystems 565 to 1130 times larger than the area of the cities themselves.

* To facilitate simple international comparisons, we generally use world average land productivities in eco-footprint estimates.

** In practice, only a limited number of wastes (e.g., carbon dioxide and plant nutrients such as nitrates and phosphates) can readily be converted to land-area equivalents with present knowledge. Some contaminants such as ozone-depleting chemicals or endocrine mimics cannot be included at all in eco-footprint analyses.

*** So dependent is industrial society on fossil energy that some authors predict the decline and collapse of civilization as supplies run out in the next few decades (e.g., Price, 1995; Duncan, 1993).

We usually think of cities as the productive engines of national economic growth. However, the strictly biophysical perspective of ecological footprint analysis adds another layer of complexity. Cities and urbanized regions are also intensive nodes of *consumption* whose economic and social activities are sustained almost entirely by bio-production and life-support processes occurring in a vastly larger area outside their political and geographic boundaries (Rees and Wackernagel, 1996; Rees, 1997).

Ecological Disparity and the Fair Earth-Share

Ecological footprinting reveals another insight relevant to future human development and conservation efforts. As noted, the citizens of high-income countries typically have eco-footprints of 5 to 12 hectares. This compares to a hectare or less per capita for most developing countries, such as India and Bangladesh, and a world average eco-footprint of 2.8 hectares (Figure 7.1, 1996 data from WWF, 2000). Because of their large per-capita footprints and high population densities, many first-world countries have an aggregate ecological footprint several times the size of their domestic territories. They are living on trade and imposing heavily on the global commons — i.e., by importing ecosystems goods and services (carrying capacity) from elsewhere. This poses a problem for prevailing international development strategies. Such strategies assume that we can relieve chronic poverty through sheer economic growth, thus avoiding political pressure for income redistribution. Indeed, the Brundtland Commission believed we could bring 8 to 10 billion people up to 1980s Western European material standards by the middle of the 21st century (albeit using more ecologically benign technologies [WCED, 1987]). Regrettably, on a finite planet, not all countries can be net importers of carrying capacity.

This reality begs the following question: What would be the global ecological footprint if the entire world attained a typical late-1990s Western European lifestyle using prevailing fossil fuel-based technologies? At about 6 hectares per capita, the present world population of over 6 billion people would need approximately 36 billion hectares to supply its resources and assimilate its wastes. If the human family grows by an additional 3 billion by, say 2050, the human eco-footprint could reach 54 billion hectares. The problem is that there are only about 12 billion hectares of adequately productive land and water on Earth. If the world’s ecologically productive space were evenly divided among the present human population, we would get only about 1.5 ha of terrestrial

Figure 7.1 Ecological footprints of selected countries.

and 0.5 ha of aquatic ecosystem for a total of 2 hectares per capita.* In other words, the citizens of wealthy countries already inadvertently appropriate three to six times their “fair Earthshare” (Rees, 1996). (Note that these data take no account of the needs of other species.) Since we are unlikely to acquire three or four additional Earth-like planets over the next half century, it seems that the world will have to deal with socioeconomic and ecological inequity by means other than economic growth if it is serious about achieving sustainability.

DISCUSSION AND CONCLUSION

Many technological optimists believe that industrial “man” is no longer bound by ecological constraints. As the late famed growth advocate, Julian Simon, recently wrote: “We have in our hands now ... the technology to feed, clothe, and supply energy to an ever-growing population for the next seven billion years ...” (Simon, 1995). By contrast, this chapter shows that humankind is as dependent on nature as ever. Rather than substitute for nature, the principal ecological effect of technological advance has been to extend the scope and intensity of human exploitation of supporting ecosystems beyond sustainable limits. Humanity’s ecological footprint is steadily expanding.

Because it remains a dependent subsystem of the ecosphere, the continuous growth of the human economy inevitably reduces the diversity, biomass, and resilience of exploited ecosystems. Energy and material flows appropriated from the ecosphere for humans are irreversibly unavailable for use by other species or to help maintain life-support functions. Indeed, since the Paleolithic era, humans have invariably expanded their presence on Earth by:

1. Depleting both self-producing and nonrenewable “natural capital” stocks (e.g., other species populations such as flightless birds, large slow mammals, fish; whole ecosystems such as forests; groundwater; soils; and petroleum and other hydrocarbons).
2. Displacing other species from their niches and appropriating their habitats (e.g., various ungulates in Africa, bison in North America, and thousands of species from tropical forests).
3. Eliminating competition for “our” food (e.g., seals in the case of fisheries; wolves in the case of ungulates, wild and domestic; and insects in the case of crops).

Production agriculture has been particularly damaging in its gross simplification of ecosystems to channel the product of photosynthesis to humans through a relatively few crop species. The spread of energy-intensive technologies, and most recently, globalization, has intensified all these processes.

Because of the expanding human ecological footprint, the Earth is now experiencing the greatest extinction episode since the natural catastrophes at the end of the Paleozoic and Mesozoic eras (Wilson, 1988; Pimm et al., 1995). Overharvesting, pollution, and particularly habitat destruction are producing what some analysts are calling the *sixth extinction*. The current extirpation rate is 100 to 1000 times prehuman levels inferred from the fossil and paleontological record (Pimm et al., 1995).

Ominously, evidence is gathering that humans themselves will increasingly bear the consequences of ecological degradation. In 1998, a record number of natural disasters caused massive property damage and drove more people from the land and their homes than war and civil conflict combined. According to the International Red Cross 1999 *World Disasters Report*, singular events such as Hurricane Mitch and the El Niño weather phenomenon, plus declining soil fertility and deforestation, drove a record 25 million people from the countryside into crowded underserved shantytowns around the developing world’s fast-growing cities. This is 58% of the world’s total refugees. The *World Disasters Report* predicts that developing countries in particular will continue to be hit by super-disasters driven by human-induced atmospheric and climatic change, ecological degradation, and rising population pressures.

* Recall that the world average eco-footprint is already 2.8 ha per capita (Figure 7.1). This discrepancy shows that even at current average levels of consumption, the population of *H. sapiens* already exceeds the long-term carrying capacity of the Earth. We are living, in part, by depleting *our* natural capital by consuming the ecosphere from within (Rees, 1999).

Where does all this leave prospects for maintaining ecosystem health? It seems clear at this stage in global development that there is an irreconcilable conflict between further expansion of the human enterprise and contemporary conservation efforts. Nevertheless, *and this is critical*, the majority of humankind is understandably not satisfied with its present material lot and is determined to improve it. In these circumstances, conservation initiatives based on large set-asides of relatively undisturbed habitat may be absolutely necessary but by no means constitute a sufficient strategy for biodiversity preservation or the maintenance of ecosystems health. Population pressures, ecological collapse elsewhere, economic desperation, and hunger will eventually drive millions of impoverished people to seize ecological reserves, wilderness areas, national parks, and related conservation areas to satisfy their own needs. This is already happening in some developing countries. The illegal landings of unregistered ships overloaded with desperate Asian would-be immigrants on the Pacific Coast of Canada and the U.S. and in Australia in recent years is a striking reminder of the same general problem.

This chapter started from the premise that the “environmental crisis” is really a problem of human evolutionary success. Our competitive superiority has led to widespread human ecological dysfunction as the growing human enterprise breaches the biophysical limits of a finite planet. Those who would work to maintain biodiversity and ecosystem health must first confront this reality. Humanity has outgrown the Earth: we cannot for long safely consume more than nature produces and produce more wastes than nature can assimilate. To ensure local ecosystems health and the long-term integrity of the ecosphere, humanity’s efforts must be directed toward the most effective means of reaching a stable steady state in our material relationship with nature.

Achieving a steady state will be no mean task in a world addicted to growth and material consumption — it requires nothing less than an absolute reduction in the total dissipative load imposed on ecosystems by people. The main items on the agenda include (1) lowering human populations everywhere; (2) reducing material consumption in the high-income countries (both through more efficient technologies and by adopting simpler, less materially intensive lifestyles); and (3) improving living conditions for the chronically impoverished. Unfortunately, in the prevailing geopolitical and economic climate, discussion of the first objective is suppressed (one is likely to be labeled racist); most politicians, particularly in North America, dismiss the second objective as too politically volatile (moreover, the available evidence suggests that efficiency gains in market economies result in increased per-capita and gross consumption [WRI, 2000.]); and policies to achieve the third objective through sheer economic growth are failing. Chronic poverty prevails in much of the south, and the absolute income gap between high-income OECD countries and developing countries is still increasing. Even the relative income gap is growing except in the case of East Asia (UNDP, 2001).

This state of affairs makes clear that despite the rise in political rhetoric, the goal of an ecologically sustainable, socially equitable, and economically viable global village is eluding us. Society has misunderstood the problem, our solutions have deepened the crisis, and we remain in deep denial of the evidence that the present approach to sustainability is failing on its own terms. In this light, the greatest contribution to ecospheric health and sustainability will come, not from better resource management and nature conservation per se, but rather from a direct focus on prevailing cultural beliefs and values and on fundamental human behaviors. Shifting policy attention from proximate symptoms to deeper causes provides the greatest leverage in moving humanity toward a collective steady state with nature.

It also presents a daunting challenge because it requires a confrontation between human nature and present reality. *Homo sapiens* will become truly human — i.e., different from other species’ populations that exceed their carrying capacity and crash — only if we succeed in culturally overriding the same hard-wired behavioral tendencies that have led to our evolutionary success. This will require a reasoned collective international response to the evidence that these tendencies are now maladaptive, that they have taken us too far. It is therefore unfortunate that for the past quarter century global culture has emphasized individual self-interest, sanctified greed, and downplayed the role of governments, all at the expense of community and a sense of shared commitment to the common good.

Population Health Issues in the Management of Air Quality*

Richard T. Burnett, Barry Jessiman, David Stieb, and Daniel Krewski

INTRODUCTION

Historical extreme air pollution events, such as those experienced in London in the 1950s and 1960s, clearly demonstrated the potential of ambient air pollution to exacerbate cardiorespiratory disease, as reflected in premature mortality and admission to the hospital. In the intervening years, considerable effort has been made to reduce pollution from the combustion of fossil fuels. Several countries, including Canada and the U.S., have established new stringent guidelines and standards for air pollutants such as sulfur dioxide, nitrogen dioxide, carbon monoxide, ozone, and particulate matter. At present, Canadian National Ambient Air Quality Objectives for these pollutants are rarely violated.

In 1983, David Bates and Ron Sizto published their analyses of the association between the daily variations in ambient summertime ozone concentrations in southwestern Ontario and daily fluctuations in the number of admissions to the hospital for respiratory diseases in 79 acute care hospitals (Bates and Sizto, 1983). The existence of a positive association between ozone and respiratory conditions was somewhat unpredicted in that, although southwestern Ontario experiences the highest levels of ozone in Canada, these concentrations are considered low to moderate for many locations in the U.S. and Europe. In subsequent analyses, Bates and Sizto (1987) suggested that this association could be explained by daily variations in ambient particulate sulfate levels.

The most striking aspect of their work was that ambient air pollutants were apparently related to adverse health effects in the Canadian population at concentrations much lower than previously thought possible. The adequacy of the National Air Quality Objectives in protecting human health was thus brought into question. As summarized below, this pioneering work by Bates and his colleagues spawned an extensive series of epidemiological investigations on the effects of ambient air pollution on population health in Canada. These studies have been of value not only in assessing population health risks within a Canadian context but also in contributing to a growing international literature on the adverse health effects of ambient air pollution.

* This chapter has been published in *Ecosystem Health*, 6:67–78. It is reprinted here with permission of Blackwell Science, Inc.

SUMMARY OF CANADIAN STUDIES

Over the last decade, a series of studies has been published linking daily variations in either deaths or admissions to the hospital for cardiorespiratory diseases and daily fluctuations in a number of ambient air pollutants (Lipfert and Wyzga, 1995). Although the majority of studies have focused on U.S. and European locations with much higher air pollution levels than normally experienced in Canada, some of the most convincing evidence linking air pollution to health has been obtained from data collected in Canada.

Burnett (1990) demonstrated a positive association between decrements in lung function of both asthmatic and nonasthmatic children at a summer camp in central Ontario and the ambient air pollution mix including particulate matter. Similar associations were observed in another summer camp study on the north shore of Lake Erie (Raizenne et al., 1989). Residing in communities experiencing elevated concentrations of sulfates and acid aerosols was associated with declines in the lung function of primary school children in Canada (Stern et al., 1989, 1994) and North America (Raizenne et al., 1996).

Following Bates and Sitzo's previous work, summertime concentrations of both ozone and particulate matter have been linked to respiratory hospitalizations in southern Ontario (Burnett et al., 1994), Toronto, Ontario (Thurston et al., 1994; Burnett et al., 1997) and for 16 of Canada's largest cities (Burnett et al., 1997a). Summertime ozone levels have also been associated with visits to the emergency department in the Saint John Regional Hospital for patients presenting with asthma (Stieb et al., 1996) and to emergency department visits for respiratory diseases in Montreal (Delfino et al., 1996). Elevated ambient levels of carbon monoxide have been linked to hospitalizations for respiratory (Burnett et al., 1997a) and cardiac diseases (Burnett et al., 1997b) in several Canadian cities. Particulate sulfates were related to respiratory hospitalizations in southern Ontario (Burnett et al., 1994, 1995) and the coefficient of haze was linked to increases in respiratory hospitalizations in 16 cities spanning the breadth of the country (Burnett et al., 1997a). Particulate matter and carbon monoxide were also associated with daily mortality in Toronto over the 15-year period from 1980 to 1994 (Burnett et al., 1998).

AMBIENT AIR POLLUTION POLICY INITIATIVES

Based on the epidemiological evidence collected from Canadian studies and investigations demonstrating similar associations between ambient air pollution and adverse health effects worldwide, the Canadian government has embarked on several new initiatives, including redefinition of the National Ambient Air Quality Objectives (NAAQOs) for established criteria pollutants, establishing new PM₁₀ and PM_{2.5} air quality objectives, and assessing the public health benefits of reducing the sulfur content in gasoline.

National Ambient Air Quality Objectives (NAAQOs) and Canada-Wide Standards

Until 1998, air quality risk management initiatives were predicated largely on the development of NAAQOs for specific pollutants. The criteria for their development and use must be based on scientifically defensible evidence while incorporating a margin of protection that reflects three factors: variability in the levels of exposure and their associated effects, uncertainty in the degree of both health and environmental risk, and the values of Canadian society.

The legal basis for NAAQOs is the Canadian Environmental Protection Act (CEPA) (Armstrong and Newhook, 1992), originally passed into law in 1988 (a new version came into effect in 1999), which established a comprehensive legal framework to manage toxic substances in Canada. It addresses pollution problems on land, in water, and through all layers of the atmosphere. NAAQOs are developed by the Working Group on Air Quality Objectives and Guidelines (WGAQOG), which reports to the Federal/Provincial Advisory Committee (F/PAC) under CEPA. The Working Group includes representatives of federal, provincial, and territorial departments of environment and health.

In January 1998, an agreement between federal and provincial environment ministers led to the development of a Harmonization Accord on joint actions to address environmental issues of pressing concern. A major subagreement, the Canada Wide Standards (CWS), established a framework for the development of national standards for the highest priority pollutants. This subagreement laid out a process for selecting national targets with associated compliance dates and management plans. At the time the CWS process was agreed upon, NAAQOs for particulate matter (PM_{2.5} and PM₁₀) were in preparation. These proposed NAAQOs for PM were withdrawn and replaced by CWSs in 1999. The framework for the development and implementation of NAAQOs and CWSs is described in Figure 8.1.

The ambient air quality objectives are designed within a two-tier framework, in which the first tier identifies the scientific reference level, defined as “a level above which there are demonstrated adverse effects on human health and/or the environment (Working Group on Air Quality Objectives and Guidelines, 1996). The second tier, called the Air Quality Objective, is a subjective interpretation of the scientific information designed to provide protection to the general population and environment. The formal definition of the objective is: “the air quality management goal for the protection of the general public and the environment in Canada. It is a level selected based upon the consideration of scientific, social, economic and technical factors” (Working Group on Air Quality Objectives and Guidelines, 1996).

The principles by which objectives are developed are embodied in a formal protocol (Working Group on Air Quality Objectives and Guidelines, 1996) that provides a framework for evaluating the scientific basis for ambient air quality objectives. This protocol is designed to ensure consistency in the evaluation approach and the degree of protection and to provide guidelines for the scientific evaluation that can be systematically reviewed with respect to completeness, rationale, and degree of protection.

For the CWSs, the basis for action is developed elsewhere; initiation of the process generally means governments have accepted the need to take some action. The purpose of the CWS process is to set achievable targets based on technological and economic considerations while providing some measure of population health or environmental protection.

For both NAAQOs and CWSs, federal and provincial governments have specific and sometimes overlapping responsibilities. Federal responsibilities rest largely in the international arena (such as the Canada–U.S. Air Quality Agreement) or on national standards for specific issues (such as the sulfur content of gasoline). Provincial responsibility rests largely, but not exclusively, with pollution sources and related processes that are local or regional in nature. Whereas CWSs have considerable government support in advance of their formal deployment, NAAQOs remain recommendations until such time as they are incorporated in legislation or other formal controls.

Canada-Wide Standards for PM₁₀ and PM_{2.5}

The first application of the CWS process in Canada involved particulate matter and ozone. Previously, the only air quality objective in Canada for particles was the set of Total Suspended Particulate (TSP) guidelines (a desirable concentration of 0 to 60 µg/m³; acceptable annual and 24-hour average concentrations of 60 to 70 µg/m³ and 0 to 120 µg/m³ respectively; and a 24-hour average tolerable level of 120 to 400 µg/m³). Ozone has an existing NAAQO of 80 ppb (1-hour average).

The major impetus for a regulatory review of particulate matter in Canada came from the appearance of a large number of well-conducted epidemiological studies linking ambient particulate matter levels with adverse health outcomes over the last several years. These included both short-term (time-series) and long-term (cohort) studies demonstrating associations between particulate matter and a spectrum of adverse cardiorespiratory outcomes, including mortality and hospitalization, increased illness, reduced activity days, and decreased lung function.

It has been noted that there are several important confounders that need to be considered in the interpretation of the above studies. Most studies have used techniques that reduce the effect of these confounders and covarying pollutants, though it is not possible to eliminate this concern completely. Nonetheless, given the wide variety of locales, pollutant mixtures, and exposure levels

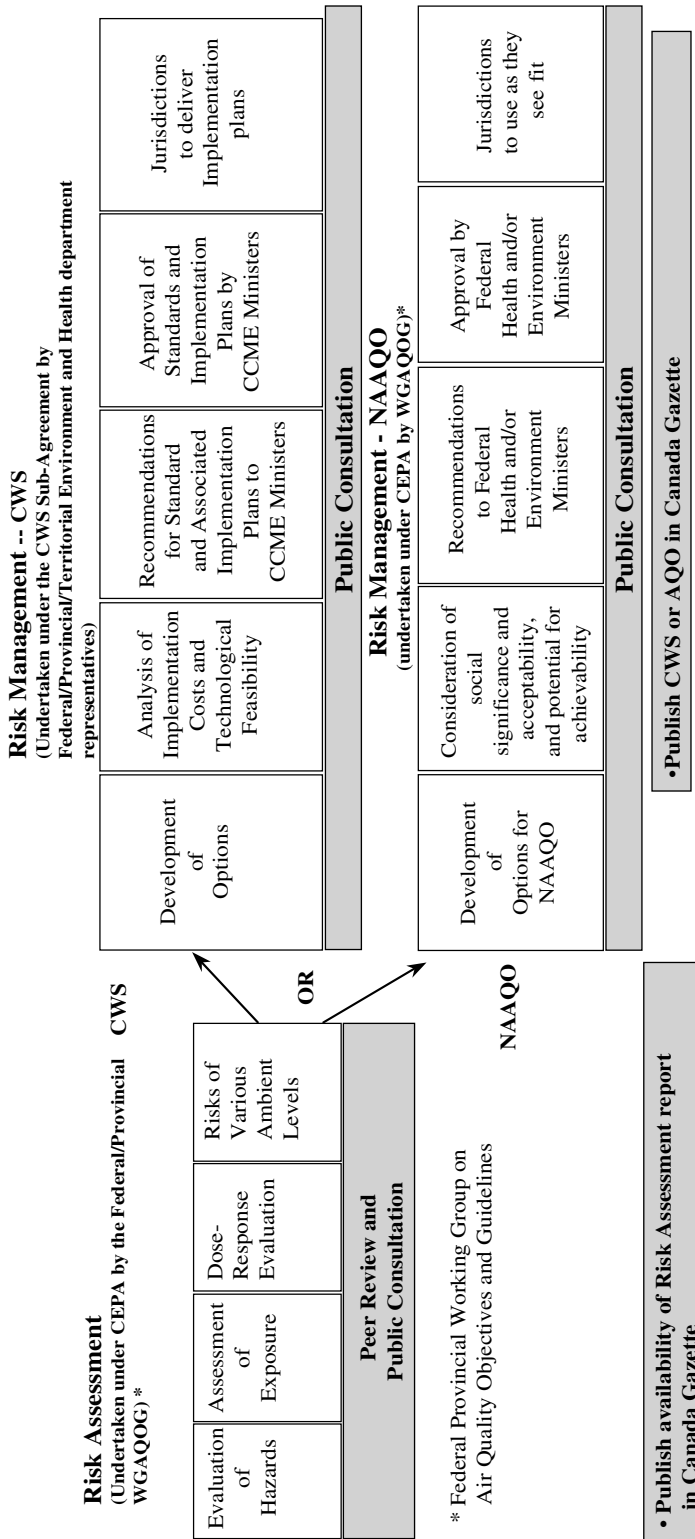

Figure 8.1 Developing and implementing NAAQOs and CWSS.

assessed in these studies and the consistently strong evidence of association, confounding cannot explain all the observed impacts.

Though the mode of action is not clear, and potential causal mechanisms are only now being elucidated, the coherence and consistency of the body of evidence cannot be dismissed. It was judged by several government bodies that it would be prudent to act on the assumption that the association between particulate matter and cardiorespiratory disease is causal.

At this time, the available evidence provides little indication of a threshold, with mortality and morbidity increasing with ambient particle concentrations. While there remains uncertainty as to the most biologically relevant index of particulate matter, there is sufficient evidence to warrant targeting of the fine fraction ($<2.5 \mu\text{m}$ in aerodynamic diameter) along with gaseous co-pollutants in any contemplated control measures. This perspective acknowledges both the covarying nature of the pollutant mix and the precursor nature of many of these gaseous pollutants with respect to fine particulate matter. While control measures should emphasize the importance of the fine fraction, there remains sufficient concern with the coarse fraction of PM_{10} to warrant the development of standards for both PM_{10} and $\text{PM}_{2.5}$.

The federal–provincial Working Group (WG) has developed a science assessment document (Working Group on Air Quality Objectives and Guidelines, 1999) that details the scientific basis for conclusions on the health effects of PM. This WG has also developed reference levels for both PM_{10} and $\text{PM}_{2.5}$. Options for CWSs for both PM_{10} and $\text{PM}_{2.5}$ as well as ground-level ozone have been developed and presented to a multi-stakeholder forum.

Economic Evaluation

Methods for assessing the value for money obtained from alternative public policies or programs can essentially be divided into cost-effectiveness analysis (CEA) and cost–benefit analysis (CBA). CEA compares the cost of introducing a program with its incremental effects, measured in natural units (such as the cost per life saved or quality-adjusted life years — QALYs — gained). CBA, on the other hand, expresses all effects of the program in dollar terms and determines net benefits by subtracting costs (the dollar value of negative effects) from benefits (the dollar value of positive effects). Although CEA avoids measurement issues associated with “monetization” or “valuation,” it does not provide guidance whether the positive effects justify the costs (Gold et al., 1996; Drummond et al., 1987). Also, it must be borne in mind that any decision about whether to implement a program to improve health or environmental quality implicitly involves valuation. CBA makes the valuation process systematic and explicit (Mooney, 1986).

Although measures such as avoided health care costs and avoided lost wages as a proxy for increased productivity (essentially the costs of illness) can be used to represent the value of avoided adverse health effects, these are likely to result in underestimates of value because they exclude the value of avoided out-of-pocket expenses to individuals as well as the value of improved quality of life and increased longevity. The basic approach to determine more comprehensively the value of a *good* in a manner consistent with fundamental welfare economics axioms is to determine individuals’ willingness to pay (WTP) to obtain the good, or willingness to accept compensation (WTA) to give it up (Gafni, 1991).

There are a variety of empirical methods for measuring WTP or WTA that fall into essentially two categories — those which rely on observed market behavior (*revealed preference methods*) and those which do not (*stated preference methods*) (Gafni, 1991). Some aspects of the value of health and environmental quality can be assessed using market data; examples include analysis of wages in relation to occupational risks to determine the value of avoided mortality (WTA), or of costs of travel or use permits for recreational sites to determine the value of wilderness areas (WTP). In other cases, market data are not available and surveys are used to directly measure people’s preferences for various goods in the context of a hypothetical market.

Contingent valuation (CV) studies have in particular been the subject of considerable discussion. The basic concern about CV or stated preference studies in general is whether investigators have the technical skills to measure values using CV surveys and whether survey respondents have the cognitive capabilities to express accurately their own preferences for nonmarket goods.

A number of attempts have been made to synthesize the evidence on the reliability and validity of CV studies (Portney, 1994; Hanemann, 1994; Diamond and Hausman, 1994; Mitchell and Carson, 1989; Cummings et al., 1986; National Oceanic and Atmospheric Administration, 1994). Although some authors have highlighted perceived shortcomings of CV, the prevailing view appears to be that, when carried out meticulously and in the appropriate context, CV or stated preference methods can generate valid and reliable valuations.

A number of activities have been undertaken involving the application of economic evaluation techniques in assessing the health effects of air pollution. In addition, methodological advances have led to the development of a framework for the application of economic evaluation principles devised for health care settings to environmental health risk management programs (Krewski et al., 1989; Torrance and Krewski, 1986; Letourneau et al., 1992). The essence of this framework is the damage function approach. *Damages* refer to negative impacts on human health or the environment. The converse of damages is *benefits*, which refers to the reduction in damages as a consequence of a given policy or program (Freeman, 1993; Freeman et al., 1994).

In the context of air pollution control programs, this approach involves four principal steps: (1) estimating the impact of the proposed policy on emissions of air pollutants; (2) modeling the impact of emission changes on ambient air quality; (3) applying dose–response relationships to predicted changes in air quality, thus estimating the number of avoided health and environmental impacts; and (4) applying monetary values to the avoided impacts (Freeman, 1993; Freeman et al., 1994). Values are then aggregated across the range of impacts; uncertainty analysis is carried out to determine a range of possible results given observed uncertainty in the various steps described above; and, finally, sensitivity analysis is conducted in order to test the sensitivity of results to alternative assumptions at various stages of the assessment. This approach is consistent with the economic theory of environmental impact valuation and is generally preferred to alternative approaches (Freeman, 1993).

This approach, or components of it, has been applied in a number of studies of the benefits and costs of air pollution control programs (Cannon, 1985; 1990). A study by Hall (1989) in the South Coast Air Basin in California estimated that the annual benefits of meeting the federal ozone and PM₁₀ standards (120 ppb and 150 µg/m³, respectively) ranged from \$4.8 to 20.4 billion, with a central estimate of \$9.4 billion. The annual benefits of meeting the more stringent California standards (90 ppb and 50 µg/m³, respectively) ranged from \$7.4 to 31.1 billion, with a central estimate of \$14.3 billion (all estimates in 1988 \$U.S.).

When this approach was applied to the Lower Fraser Valley in British Columbia, it was determined that the annual economic value (1990 \$Canadian) of health impacts due to mobile source particulates was approximately \$600 to 700 million, depending on assumptions about background particulate concentrations (SENES Consultants Limited, 1994). An additional study in this region determined that the Air Quality Management Plan for the Greater Vancouver Regional District (GVRD) generated \$5.4 billion in benefits in the GVRD at a cost of \$3.8 billion (1993 \$Canadian) over the years 1985 to 2020 (ARA Consulting Group Inc. and Bovar-Concord Environmental, 1994). A study by Oxman and Julian (1993) found that the benefits of eliminating exceedances of Canada's national ambient air quality objective for ozone (80 ppb) amounted to \$40 million per year (1990 \$Canadian); however, this study examined only reductions in the occurrence of symptoms for which dose–response functions were available from randomized–controlled trials, ignoring more severe effects of air pollution for which evidence is derived from nonexperimental studies.

A recent study for the U.S. Environmental Protection Agency estimated that by 2010, U.S. Clean Air Act amendments to reduce SO₂ emissions by 40% from 1980 levels will result in annual

health benefits in the eastern U.S. and Canada of \$12 to 80 billion, with a central estimate of \$40 billion (1994 \$U.S.) (Chestnut, 1995).

The study on Environmental and Health Benefits of Cleaner Vehicles and Fuels (Lang et al., 1995) was commissioned by the Canadian Council of Ministers of the Environment (CCME), Task Force on Cleaner Vehicles and Fuels. It was one of a series of studies commissioned by the CCME to provide information to policy makers on economic aspects of proposed policies on vehicle emission standards and the reformulation of transportation fuels. This study utilized the damage function approach to assess the health and environmental benefits of two vehicle emission and fuel reformulation scenarios. Innovative aspects of this study included assessment of the impact of age on the value of avoiding death (this was seen as an important consideration, given that air pollution-associated death is suspected of disproportionately affecting elderly individuals with host conditions favoring susceptibility to the adverse effects of ambient air pollution); and adjusting cost of illness-based valuations upward, based on the ratio between willingness to pay and cost of illness valuation estimates (Rowe and Chestnut, 1986).

This study estimated that 100% use of low-sulfur diesel by 1997, Canada-wide use of gasoline containing reduced levels of sulfur (200 ppm) and benzene (1% by volume) by 1998, and introduction of alternative low-emission vehicles into Canada's fleet in 2001 would result in a wide spectrum of avoided health effects that would translate into \$11 to 29 billion in cumulative health benefits (central estimate of \$23 billion) between 1997 and 2020 (1994 \$Canadian). An accelerated program including a phased approach for implementing various classes of low-emitting vehicles, a minimum requirement for zero-emission vehicles, introduction of lower-sulfur-content gasoline (40 ppm), and the same target for low-sulfur diesel as the previous scenario, would result in \$14 to 38 billion in cumulative health benefits (central estimate of \$30 billion) between 1997 and 2020. (Benefits estimates exclude British Columbia, which was the subject of a separate study, as well as the Yukon Territory and Northwest Territories, for which vehicle fleet data were not available.)

The approach utilized in the Cleaner Vehicles and Fuels study was subsequently generalized to a spreadsheet model, the Air Quality Valuation Model (AQVM), applicable to a wide variety of air pollution control programs that result in improvements in ambient air quality (Lang et al., 1996). This model includes baseline air quality and population data; dose-response relationships for health and ecological impacts; economic value measures for these impacts; and Monte Carlo simulations for the purpose of uncertainty analysis. It requires as inputs absolute or percent changes in ambient air quality specified at the national, provincial, or census division level and predicts the annual number and value of avoided health and environmental impacts. Although the AQVM is based largely on the approach used in the Cleaner Vehicles and Fuels study, it quantifies the value of environmental as well as health impacts, including material damages and soiling, visibility, recreational fishing, agricultural crops, and climate change. This model ensures consistency in approaches to benefit assessment, while allowing for flexibility to change key parameters (e.g., dose-response functions or valuations) as new epidemiological and economic data become available. The AQVM was utilized to expand on the work carried out in the Cleaner Vehicles and Fuels study, more specifically to examine the benefits of reduced levels of sulfur in gasoline, as described in the next section.

Several new primary valuation studies have also been undertaken. The basis for the Saint John Emergency Department study is an examination of the relationship between daily levels of air pollution and the daily frequency of cardiorespiratory emergency department visits (Stieb et al., 1995). This study expands on the limited amount of data normally available from administrative databases by collecting enhanced data, both at the time of the emergency department visit and in follow-up 2 weeks later. In addition to attempting to answer specific epidemiological questions related to the role of air pollution relative to other triggers in precipitating disease episodes, this study is also attempting to measure the broad quality of life and economic impacts of the health effects of air pollution. Analyses to date confirm that outcomes such as reduced activity days, bed days, additional medication use, lost time from work and school, physician office visits, and hospital

admissions commonly accompany emergency department visits and that health care costs associated with these episodes are significant (Stieb et al., 2000; Anis et al., 2000).

To complement these data on the costs of air pollution-related illness, a survey has been developed to measure the value to Canadians (willingness to pay) of improved health and increased longevity in relation to cleaner air (Johnson et al., 1999). This survey uses *conjoint analysis* methodology to measure trade-offs between costs and health status, thus determining willingness-to-pay values. The cardiorespiratory health conditions that form the basis of the trade-off questions in this survey were specifically selected because they have been linked with air pollution in various studies. Each health condition is described in terms of several attributes including symptoms, number of episodes per year, effects on daily activities such as work, physical activity, social activities, and costs. While this is a primary valuation study, the systematic classification of health conditions into a set of several attributes facilitates benefit transfer to a variety of conditions and policy contexts.

The cost of illness and WTP-based results of these new valuation studies will be integrated to reflect a comprehensive societal value for Canada of avoiding air pollution-associated morbidity and incorporated directly into the AQVM for subsequent benefits assessments.

A survey instrument for eliciting information on valuation of mortality risk reductions has also been developed (Krupnick et al., 1999). This instrument will provide alternative valuation estimates to those based on wage premiums in relation to occupational mortality risks. Like the morbidity valuation survey described above, the mortality risk valuation survey is computer administered and makes extensive use of interactive graphics and voice-overs to communicate risk information. After pilot tests in Japan and the U.S., the survey was taken into the field in Canada in the summer of 1999. This instrument will probably also be used in a number of countries around the world, facilitating internal comparisons on the valuation of mortality risk reductions.

Reduced Sulfur in Gasoline: A Case Study in Air Quality Management

Based on concerns over the contribution of vehicles to poor air quality, the Canadian government, in conjunction with the petroleum industry, undertook a detailed analysis of the impact of sulfur levels in gasoline on air quality, resultant health impacts, and the implications for the fuel industry in Canada. This process was a multi-stakeholder one with the direct participation of government, petroleum and motor vehicle manufacturers, and public interest groups. Additionally, a component of the process allowed for the participation of any interested party in the fact-finding portion of the analysis (Figure 8.2).

This process was designed in three stages: process setup, fact-finding, and options and recommendations. The first stage involved government and industry determining the structure of the effort and led to stage two, wherein three expert panels were established to deal with atmospheric modeling (Report of the Atmospheric Science Expert Panel on the Sulphur Content of Gasoline, 1997), health and environmental impact (Report of the Health and Environmental Impact Assessment Expert Panel on the Sulphur Content in Gasoline, 1997), and industry cost and competitiveness issues (Report of the Cost and Competitive Expert Panel on the Sulphur Content of Gasoline, 1997). The third stage took the results of the fact-finding stage and, in an intergovernmental forum, developed regulations for sulfur levels in gasoline for Canada. Sulfur levels in gasoline had not yet been regulated and varied widely across the country according to feedstock quality and refinery capability.

The fact-finding stage focused on a number of scenarios, including six potential regulated levels of sulfur in gasoline ranging from 30 to 350 ppm. The atmospheric modeling panel used these scenarios to project tailpipe emissions changes and resultant effects on air quality. The health and environment panel used these projected changes to estimate impacts on human and environmental health. The most significant changes in air quality were for SO₂ and SO₄. The human health benefits resulting from these changes focused on sulfate and were quantified using the available epidemiological health effects literature. This literature contained sufficient material to estimate benefits

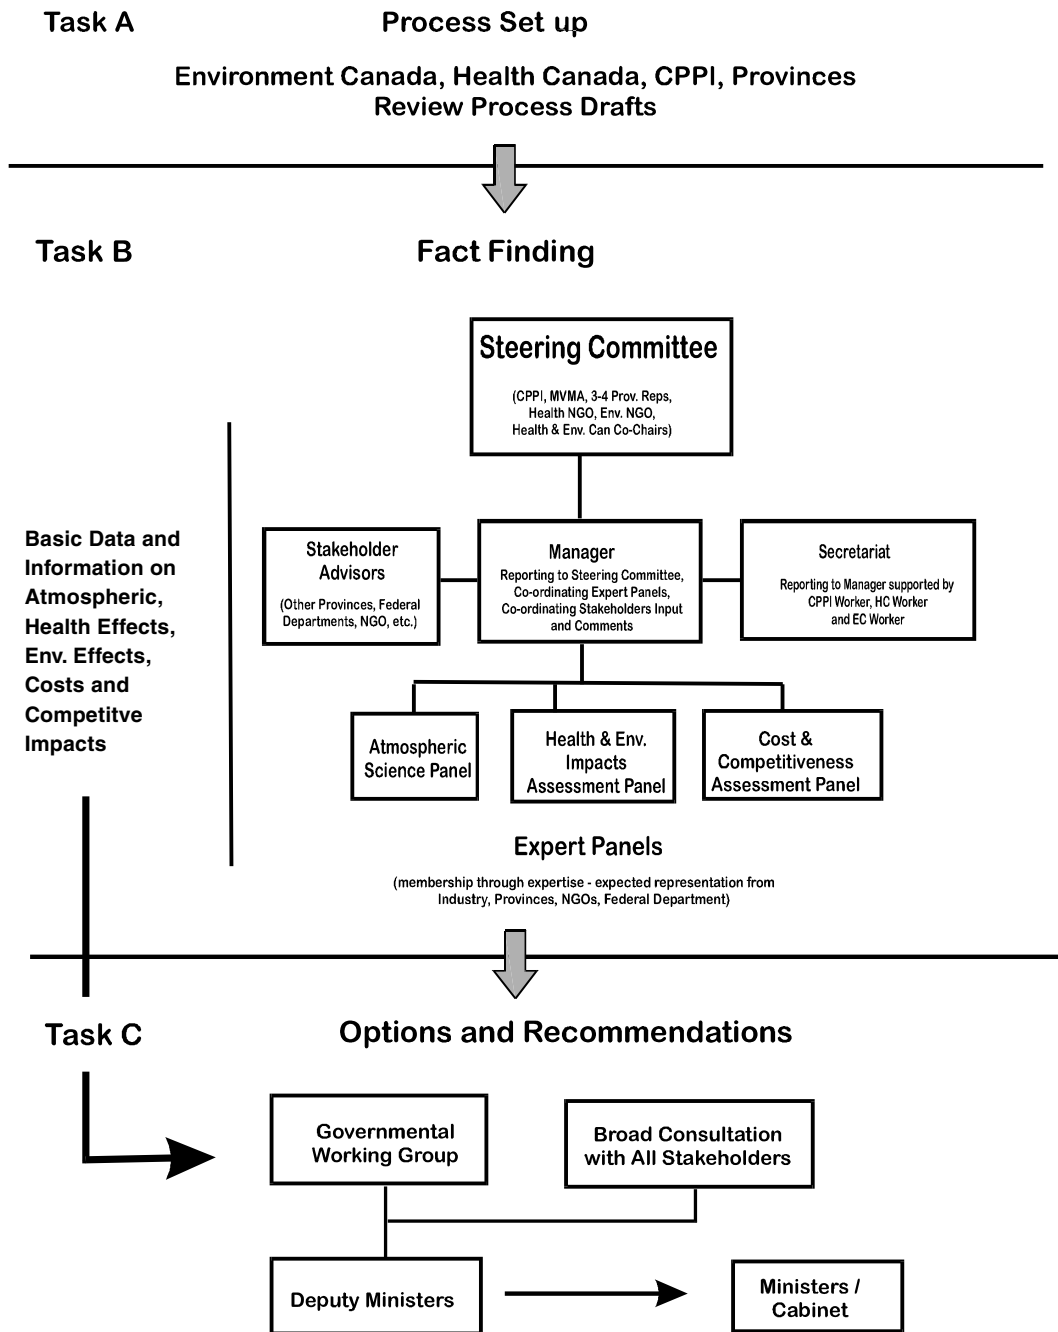

Figure 8.2 Studying air quality management.

of avoided premature mortality, chronic respiratory disease, cardiac and respiratory hospitalization, emergency room visits, asthma symptoms, restricted activity, acute respiratory symptoms, and lower respiratory illness in children. The health panel also performed a monetary valuation of the avoided effects based on the health economics literature. The cost and competitiveness panel examined the actual costs to retrofit refineries to meet the various proposed sulfur standards, and the impact on the competitiveness of the industry, both within Canada and in the international setting.

After considering the findings of the panel process and the recommendations of the intergovernmental working group, the Government of Canada decided on the most stringent option examined, 30 ppm. Key factors were the effects on catalytic converters, direct health benefits, and reasonable costs. A modifying factor in the details of the regulation (a 3-year transition period) was designed to allow independent gasoline marketers to maintain access to supply. The regulation as embodied under CEPA requires a 150 ppm (average) standard to be met starting in July 2002, with the 30 ppm provision following in January 2005. This regulation will bring Canadian sulfur levels into line with current Japanese and California standards, as well as with proposed U.S. and European standards.

FUTURE DIRECTIONS

It has now become apparent that more people visit emergency departments, are admitted to the hospital, and die on days of elevated air pollution compared to those days during which ambient air pollution concentrations are relatively low. There is limited evidence from clinical and toxicological studies to support a causal link with such adverse health effects at the relatively low ambient concentrations observed in these studies. We hypothesized that air pollution may be disrupting homeostasis through a variety of potential mechanisms (Burnett et al., 1995; 1998) in those people already severely compromised with preexisting disease. These mechanisms may include effects on macrophage function leading to increased bacterial infectivity, regulation of metabolic activities in the lung endothelium, and effects on coronary circulation and vasculature.

Three epidemiological studies were conducted to examine this hypothesis. In the first, patients visiting the emergency department for cardiorespiratory diseases of the Saint John, New Brunswick Regional Hospital were interviewed between April 1994 and March 1996 (Stieb et al., 1995). Saint John experiences the highest concentrations of acid aerosols in Canada and has the highest acid-to-particle mass ratio ever recorded anywhere. Use of medication, time activity patterns in the 2 weeks prior to the visit, date of onset of signs or symptoms, smoking habits, and disease history were obtained. The purpose of the study was to examine the influence of these factors on the air pollution–visit association. In the second study, death certificates were linked to physician billing, hospital use, and drug prescription records in Montreal. Death prediction indices were developed based on this co-morbid information to test the hypothesis that those people who were severely ill were at the greatest risk of death from air pollution exposures.

In the final study, the daily number of nonaccidental deaths in metropolitan Toronto over the 15-year period from 1980 to 1994 was related to ambient air pollution measures. A clear positive association was detected (Burnett et al., 1998). It is not clear, however, what percentage of these deaths were due to *mortality displacement*, a process in which air pollution plays a role in setting the specific date of death but accelerates the death process by only a few days. Under this scenario, those people would have likely died shortly after their actual date of death in the absence of exposure to ambient air pollution.

CONCLUSION

Concentrations of ambient air pollution currently experienced by Canadians have been clearly linked to adverse health events in the population, increasing the numbers of daily visits to emergency departments, hospital admissions, and even deaths. This information has been used to assess the impact of air pollution on public health. Further research is being conducted to examine the role that severity of preexisting disease plays in the association between ambient air pollution and health in Canada. Estimating the independent adverse health effects of each pollutant that comprises the atmospheric mix has proven to be a challenge (Moolgavkar and Luebeck, 1996) due to the high collinearity between ambient air pollutants and the varying degree of exposure error. Studies have

been undertaken to examine the health effects of ambient air pollutants at selected locations in Canada with diverse populations, climates, and pollution mixes. Further work has focused on determining the relation between concentrations measured at fixed outdoor monitoring sites and personal exposure levels, using time activity patterns and spatial modeling techniques.

Weighing the costs and benefits of public programs is a central feature of Canada's regulatory policy, as administered by the Treasury Board (Treasury Board Secretariat, 1995) and of similar policies in the U.S. (Arrow et al., 1996). It has been suggested that, although cost-benefit analysis should be viewed as neither necessary nor sufficient for making good public policy, it represents a useful analytical tool. At a minimum, it provides a systematic framework for organizing and synthesizing a wide variety of information that is salient to a given policy question (Arrow et al., 1996). In terms of impact, a recent assessment of regulations introduced by the U.S. government revealed that departments (notably the Department of Transportation) that consistently applied cost-benefit analyses had a record of regulations that more effectively maximized benefits and minimized costs (Viscusi, 1996). Agencies such as Health Canada, with a mandate to manage environmental health risks, can play a similar role by ensuring that programs to improve environmental quality represent the best possible investment in population health.

Global Environmental Changes and Health: Approaches to Assessing Risks

Anthony J. McMichael and R. Sari Kovats

INTRODUCTION

In the 18th century, Europe's main continuing environmental health hazard — as in many preceding centuries — was malnutrition and famine. After the 1740s this ancient health hazard began to recede in Europe as the modern agricultural revolution began. The extreme urban crowding and working-class poverty due to early industrialization in the 19th century resulted in infectious diseases becoming the dominant environmental health hazard. With the rise of modern large-scale industry and of synthetic organic chemistry in the 20th century, pollution of local environments — air, water, soil, and food — became the major focus of environmental health concern in developed countries.

Thus, for the past two centuries, our environmental health concerns have typically focused on toxicological or microbiological risks to health from factors within the local environment. However, as we enter the 21st century, the scale of environmental health hazards is increasing. As the scale of human impact on the environment has begun to alter global biophysical systems (such as the climate system), a range of larger-scale environmental hazards to human health has emerged. This includes the health risks posed by climate change, stratospheric ozone depletion, loss of biodiversity and its effects on ecological systems, stresses on terrestrial and ocean food-producing systems, changes in hydrological systems and the supplies of fresh water, and the global dissemination of persistent organic pollutants (McMichael, 1999; Watson et al., 1998). We are learning, today, to understand better the determinants of human health at the population level and within a predominantly ecological framework.

This *ecological* perspective recognizes that the foundations of long-term good health in populations reside in the continued stability and functioning of the biosphere's ecological and physical systems — often referred to as *life-support systems*. The deliberate modification of these natural systems by human societies throughout history has conferred many social, economic, and public health benefits. However, disturbance of these systems has also often caused new risks to health. A major subtext to the development of agriculture, beginning ten millennia ago, has been the acquisition and mobilization of infectious agents, the depletion of fresh water, and the emergence of various nutritional deficiencies (McNeill, 1976).

In this chapter we first say a few things about the long human prehistory and history that has brought us to the major environmental crossroads at which we now stand. Then we examine

these contemporary global environmental changes in a little more detail. Finally, we consider how to develop appropriate research methods, both for empirical study and for scenario-based health risk assessment.

HUMAN BIOLOGICAL AND CULTURAL EVOLUTION: DEMOGRAPHIC, ENVIRONMENTAL, AND DISEASE TRANSITIONS

The story of the modern human species *Homo sapiens* spans several hundred thousand years. The highlights are these:

- Continuing biological and cultural adaptation, including the refinement of toolmaking, in Africa — our place of origin
- Dispersal of hunter–gatherer humans out of Africa from around 100,000 years ago
- Adaptation and survival, in diverse environments, during the last long glaciation from around 80,000 years ago to 15,000 years ago
- Onset of agriculture and village life, in favored centers, from around 10,000 years ago — and acquisition of many new infectious diseases from domesticated animals
- The rise of city-states, trade, and warfare
- During the past 3000 years, increasing transcontinental and, later, intercontinental exchange of local germs
- Since 1500, the rise of Europe, favored by climate, soils, coastline, and the robust legacy of Middle East farming and animal husbandry
- Onset of industrialization and urban consumerism — and their associated diseases

During the 19th century, the wealth of imperial Europe increased and industrialization spread. Living conditions in urban–industrial environments were predominantly crowded, squalid, and disease-ridden. From around midcentury, conditions became better with improvements in sanitation, food supplies, literacy, and domestic hygiene. Death rates from infectious diseases declined, especially in infancy and childhood. Meanwhile, a new set of diseases of later adulthood emerged. These diseases, characteristic of the *epidemiological transition* and reflecting a radical shift in human ecology, include chronic bowel disorders, heart disease, stroke, diabetes, various cancers, chronic respiratory disorders, arthritis, and dementia. With improved material living conditions, the decline in infectious diseases, and modern medical science to keep us alive longer, life expectancy has continued to edge up.

Meanwhile, the disease profile of low-income countries has also been changing. Rapidly developing countries, especially those of East and Southeast Asia, are acquiring “Western” disease profiles (Shetty and McPherson, 1997). Recently, however, a long shadow has been cast over life expectancy projections in many poorer countries by the spread of HIV/AIDS, along with the resurgence of tuberculosis and the widespread increases in malaria. Average life expectancy in several sub-Saharan African countries has dropped by 10 to 15 years over the past decade (WHO, 1999).

GLOBAL ENVIRONMENTAL CHANGE: A LENGTHENING SHADOW OVER HEALTH?

Another long shadow is now appearing over human population health — a shadow that extends well into the future. It is the consequence of humankind’s capacity to deplete and damage the Earth on such a scale that Earth’s basic life-supporting processes are being weakened (Daily, 1997; McMichael, 1993). This great aggregate impact of humankind is a function of our increasing numbers, our levels of consumption of energy and materials, and our massive waste generation.

Like other large terrestrial mammal species, we are *patch disturbers*: we reduce the biodiversity and the integrity of ecosystems in our immediate living environment, and we then move on and

disturb a nearby patch (Rees, 1999). Unfortunately, modern, energy-intensive, consumer urban society no longer sees the evidence of its patch disturbance. Urban populations require much larger areas of Earth's surface to supply materials and to absorb waste. London, which occupies 160,000 hectares of space, depends on a surface area of 20 million hectares to supply and absorb — i.e., a ratio of 125. This ratio is a measure of our *ecological footprint* (Rees, 1992). There is simply not enough of planet Earth for all of next century's cities to have urban footprints with even half that ratio.

Increasingly, our patch disturbance is regional and global in scale, hence, the recent advent of *global environmental changes* — including stratospheric ozone depletion, climate change, the accelerating loss of biodiversity, the spread of invasive species, the degradation of food-producing ecosystems on land and at sea, and the global dissemination of persistent, biologically active, organic chemical pollutants.

IDENTIFYING AND ESTIMATING RISKS TO HEALTH

These global environmental changes have substantial implications for the future of human population health. These changes therefore present a great and somewhat unfamiliar challenge to epidemiologists and other public health scientists. Let us explore this, first, in relation to global climate change.

Greenhouse Gas Accumulation and Global Climate Change

Global climate change will occur — indeed, it is apparently already occurring (IPCC, 2001) — because of the human augmentation of greenhouse gases in the lower atmosphere. Average world temperatures have been increasing for over two decades. Other changes in physical and biological systems — glaciers, plant migration, animal behaviors, insect distributions — corroborate this apparent change in world climate (Epstein et al., 1998). Questions about the future health consequences of climate change are therefore now firmly on our environmental health agenda (McMichael et al., 1996; McMichael and Haines, 1997).

Epidemiologists face a major challenge in estimating future health impacts. This requires working from projected scenarios of future environmental conditions — e.g., a possible world climate, as modeled by climatologists for the 2020s or the 2050s. To these scenarios we apply our existing knowledge of how gradients in climatic conditions affect some particular health outcome. For example, if we know how death rates in certain cities are affected by heat waves in today's world (e.g., Rooney et al., 1998), then we can estimate how those urban populations would respond to a summer season in a future warmer world in which the frequency of heat waves is, say, tripled.

A more complicated task is to estimate how climatic changes would affect the potential geographic range of transmission of mosquito-borne infectious diseases such as malaria and dengue fever. Considerable effort has recently gone into developing mathematical models for making such projections (Martens, 1998; Patz et al., 1998). The models in current use have well-recognized limitations — but they have provided an important start. For example, the latest malaria models estimate (1) the future geographical distribution of changes in the seasonal transmission of malaria, based on the climate model-generated scenarios; (2) the potential geographical limits to malaria transmission; and (3) changes in future populations at risk of malaria (Martens et al., 1999).

Other modeling studies have estimated the impacts of climate change upon regional and global cereal grain yields (which account for two thirds of world food energy). Integrated assessment is now often used to link models together. For example, the crop yield models are first used to simulate the effects of climate change (with a global climate model scenario) and increased CO₂ (which has a fertilization effect) on the yield of the major cereal crops. An established world food trade model is then used to simulate the economic consequences of yield changes to determine future populations at risk of hunger (Parry et al., 1999).

Stratospheric Ozone Depletion

Meanwhile, higher in the atmosphere, depletion of stratospheric ozone by human-made gases such as chlorofluorocarbons (CFCs) is already occurring. As a result, ambient ground-level levels of ultraviolet irradiation (UVR) are estimated to have increased by up to 10% at middle to high latitudes over the past two decades. Via the Montreal Protocol of 1987, we have managed to curtail the release of many of these gases; but a problem remains with black-market sales and with the rapid increase in production of halons by China and other low-income countries temporarily exempted from the production ban.

Scenario-based modeling, integrating across four submodels (gaseous emissions, stratospheric ozone destruction, UVR flux at Earth's surface, and cancer induction) indicates that European and U.S. populations will experience a 5–10% excess in skin cancer incidence during the middle decades of the coming century (Slaper et al., 1996). With a better information base in future, similar modeling could be carried out for UVR impacts on the human eye (e.g., cataract formation) and immune system activity.

Other Global Environmental Changes and Health

As the human demand for space, materials, and food increases, so populations and species of plants and animals are being extinguished — apparently faster than the great natural extinctions that have occurred in eons past. This has been referred to as the *Sixth Great Extinction* (Leakey and Lewin, 1996). The most important consequence for humans is the weakening and disruption of ecosystems such that *natural goods and services* decline (Daily, 1997; Griffo, 1997). The loss of biodiversity also means that we are losing, prior to their discovery, many of the chemicals and genes available from nature of the kind that have already conferred enormous medical and health improvement benefits upon us. Myers has calculated that the usual hit rate in the bioprospecting of tropical plant extracts for new medicinal drugs is of the order of one in half a million (Myers, 1997). Therefore, as an indicative estimate, he points out that the as-yet-unprospected extracts should yield at least 375 new drugs, compared with the 48 in current use (including curare, quinine, codeine, and the life-saving cancer treatment drugs vincristine and vinblastine).

Meanwhile, invasive species are spreading into new non-natural environments as a result of intensified methods of human food production and long-distance commerce and mobility (McMichael and Bouma, 2000). As with species loss, these changes in the composition of the living world have myriad consequences for human health. Just one example: the choking spread of water hyacinth in eastern Africa's Lake Victoria, introduced from Brazil as a decorative plant, is now a fertile breeding ground for the water snail that transmits the infectious disease schistosomiasis and for bacteria causing diarrheal diseases (Epstein, 1998).

The ever-increasing pressures of agricultural and livestock production are stressing the world's arable lands and pastures. We enter the 21st century with an estimated one-third of the world's previously productive land seriously damaged by erosion, compaction, salinization, waterlogging, and chemicalization that destroys organic content (WRI, 1998). Similar pressures on the world's ocean fisheries have left a majority of them severely depleted or seriously stressed. All these changes to the integrity of soils and waterways and to the productivity of fisheries are compromising the capacity of the world to continue to provide, sustainably, sufficient food to nourish humankind. Unless we find environmentally and socially acceptable applications of genetic engineering to increase food yields, we will face a struggle over the coming decades.

There are three other great worldwide environmental changes that portend risks to future human population health. First, freshwater aquifers in all continents are being depleted of their ancient "fossil water" supplies. Agricultural and industrial demands, amplified by population growth, often greatly exceed the rate of natural recharge. Water-related political and public health crises loom in some regions within decades (Gleick, 2001).

Second, various semivolatile organic chemicals (such as PCBs) are now known to be disseminated worldwide via a sequential “distillation” process in the cells of the lower atmosphere, thereby transferring chemicals from their usual origins in low to middle latitudes to high — indeed, polar — latitudes (Watson et al., 1998). Consequently, there is growing evidence of maximal levels occurring in polar mammals and fish and in traditional human groups that depend on those food sources. Chemical pollutants are no longer just an issue of local toxicity.

Third, we have greatly altered the biogeochemical circulation of sulfur and nitrogen (Watson et al., 1998). Since the 1940s there has been a marked upturn in the human “fixation” of nitrogen, converted from the inert form to biologically active nitrate and ammonium ions. Most of the sixfold increase in humankind’s contribution has been due to the use of nitrogenous fertilizers. Likewise, we have changed the cycling of sulfur. By affecting the acidity and nutrient balances of the world’s soils and waterways, these two chemical changes are already affecting various ecosystems (including the enhancement of algal blooms) and are likely to impair the capacity of food-producing systems.

HEALTH IMPACT ASSESSMENT: METHODOLOGICAL STRATEGIES AND DIFFICULTIES

Scientist and policy maker must both now contend with assessing the health impacts — and the avoidance strategies and costs — of these global environmental changes. The three main challenges for scientists are (1) operating within an enlarged spatial and temporal frame, (2) dealing with complex, dynamic, nonequilibrium natural systems, and (3) handling the irreducible uncertainties inherent in such scenario-based modeling. For policy makers the challenges are (1) understanding these complex environmental processes, (2) taking a long-term, precautionary, and perhaps electorally unrewarding view, and (3) achieving cooperation and equity with other constituencies with whom the future is to be shared.

Most of the anticipated health effects of global environmental change have yet to occur — that is, they will occur in response to future configurations of environmental change. Meanwhile, some other health effects may now be occurring, but we are not yet able to discern them.

There are three different logical strategies for assessing the health impacts of global environmental change:

- By direct inference from existing (past or present) analogue situations that are believed to approximate aspects of future environmental change. The analogue situations, which arise from (apparently) naturally occurring situations, may entail either temporal or geographic variation in environmental conditions.
- By seeking evidence, in response to observed anthropogenic environmental change, of changes in indicators of health risk or health status that are especially climate sensitive. (While related to the preceding item, this study strategem depends on the existence of identifiable global environmental change or its local manifestation. Further, one must rely on the assessment of the climatologists that the environmental change is anthropogenic and not a manifestation of natural variability.)
- By using existing knowledge and theory to conduct mathematical modeling (or other types of formalized assessment) of likely future health outcomes (McMichael, 1997). The three main types of models are (1) empirical statistical models (based on statistical equations derived from directly relevant sets of observations), (2) process-based models (in which key processes are represented by theoretically formulated relationships, widely accepted in the literature), and (3) integrated assessment modeling (which extends the other two approaches by the inclusion of a much fuller range of interacting and modulating influences, including social, economic, behavioral, and technical influences).

The fact that there is as yet little evidence of changes in population health attributable to the incipient change in global environmental conditions poses a problem for scientists, policy makers,

and the public. Science classically operates empirically — via observation, interpretation, replication, prediction, and, as necessary, modification of hypotheses. However, having unintentionally initiated a one-off global experiment, we cannot sensibly plan to wait decades for the accrual of sufficient empirical evidence of health consequences. That would be too great a gamble with an uncertain future. We must therefore conduct risk assessment in relation to future environmental scenarios — i.e., scenario-based health risk assessment. Further, the inherent complexity and dynamic properties of the world’s biophysical systems means that we should expect interactions, feedbacks, threshold phenomena, and surprises (Levins, 1995).

The research task of assessing the actual and potential health impacts of climate change has several distinctive characteristics and poses four major challenges to scientists:

1. The anticipated anthropogenic climate change will be a gradual and long-term process. This projected change in mean climatic conditions is likely to be accompanied by regional changes — mostly increases — in the frequency of extreme weather events. Changes in particular health outcomes may already be occurring, or may soon begin to occur, in response to the recent and ongoing change in world climate (whatever the cause of that change). The identification of such health effects will require carefully planned epidemiological studies and the implementation of appropriate monitoring activities (Haines and McMichael, 1997). Meanwhile, much research effort in the near future is likely to continue to go either into studies of the *acute* health impacts of natural climate variability (e.g., El Niño events) or into the scenario-based forecasting of health outcomes as projected by simple extrapolation, mathematical modeling, or expert judgment. There will also probably be increased research into intervention strategies (adaptations) to reduce the health impacts of climate change.
2. In empirical epidemiological studies, there are nearly always difficulties in estimating the role of climate per se as a cause of change in health status. Most diseases have multiple contributory causes. Often, two or more of the established causal factors are present, which makes it difficult to apportion causation between or among them. In other situations pertaining to health outcomes for which the causal factors have been less well established, it is difficult to know which factors have truly influenced the disease occurrence and which are merely “guilty by association.” For example, in a particular locale the clearing of forest to plant crops and the extension of the irrigation system may coincide with a rise in regional temperature. Since all three factors could affect mosquito abundance, it is difficult to apportion between them the causation of any change in malaria incidence. This category of the problem is well recognized by epidemiologists as the *confounding* of effects.
3. It is equally important to distinguish coexistent *confounding* factors that can independently influence health outcomes from factors that modify the vulnerability of a particular population to climate stress. The latter factors comprise either endogenous characteristics of the population (such as nutritional or immune status in relation to infectious disease) or contextual circumstances that influence the sensitivity of the population’s response to the climate change (such as access to air conditioning during heat waves). This modification of the effect of one factor by the action of another is commonly called *interaction*.
4. The assessment of scenario-based health risks with mathematical models entails three key challenges relating to validity, uncertainty, and contextual realism:
 - The adequate and valid representation of the central set of environmental and biological relationships, and of the interacting ecological and social processes that influence the impact of those upon health, is difficult. A balance must be attained between complexity and simplicity (transparency).
 - The complex configuration of causal and modifying factors results in substantial uncertainties in the model’s output projections. In the first instance, there is the uncertainty attached to the input scenarios of climate change (and of associated social, demographic, and economic trends). Subsequently, there are three main types of uncertainties in the modeling process: (1) *normal* statistical variation (reflecting the stochastic processes of the real world); (2) uncertainty about the correct or appropriate values of key parameters in the model; and (3) incomplete knowledge about the structural relationships represented in the model.

- None of the global environmental changes impinges in isolation upon human health. As processes, these changes frequently modify one another, and they can impinge on human population health simultaneously and often interactively (Watson et al., 1998). An obvious example is in relation to agricultural crop yields, where climatic conditions, ultraviolet radiation levels (reflecting stratospheric ozone depletion), soil fertility, freshwater availability, and the ecological balance between pests and their predators all affect yields. Similar configurations of environmental stresses influence patterns of vector-borne infectious diseases.

Human populations, as with individuals, vary in their vulnerability — or susceptibility — to the impact of environmental exposures upon their health status. The vulnerability of a population depends on factors such as population density, level of economic development, food availability, local environmental characteristics, pre-existing health status, and the quality and availability of public health care. In the specific context of climate change, a population's vulnerability has been described as a function of the extent to which a health outcome is sensitive to climate change and of the capacity of the population to adapt to new climate conditions (Parry and Carter, 1998).

CONCLUSION

It is becoming increasingly clear that global environmental changes will have a range of impacts — some of them beneficial, most of them adverse — upon human health. While some of these health impacts would result from direct changes in the physical conditions of living, many of the impacts would result from more complex changes in the biophysical and ecological systems that are the preconditions for good, sustained population health. Epidemiologists and other public health scientists must therefore think about environmental health problems not only within the framework of environment-as-hazard but also within the framework of environment-as-habitat (McMichael, 1999).

There are great and interesting challenges to researchers: in the imaginative use of historical and spatial analogues to enhance understanding and foresight; in the development of mathematical modeling techniques; and in the handling of unusual configurations of uncertainties. Koopman, recognizing this general contemporary challenge, states that “epidemiology is in transition from a science that identifies risk factors for disease to one that analyzes the systems that generate patterns of disease” (Koopman, 1996). We should not, of course, replace the former with the latter — but, substantively and soon, we must *supplement* the former with the latter.

Climate Change and Health: New Research Challenges*

Jonathan A. Patz

According to the United Nations Intergovernmental Panel on Climate Change (IPCC), anthropogenic greenhouse gas emissions are significantly accelerating current global surface warming trends and are inconsistent with natural climate variation (Houghton et al., 1996). This century the Earth has warmed by about 0.6°C, and the midrange estimates of future temperature change and sea level rise are 2.8°C and 40 cm by the year 2100, respectively. If such changes occur, diseases that are influenced by weather factors could be expected to respond to an altered climate regime.

The commonly used term *global warming* is inadequate to describe the range of climate effects of greenhouse gas accumulation. In addition to concerns about temperature and sea level rise, climatologists, ecologists, and health and other scientists are concerned that accelerated evaporation will drive a more extreme hydrological cycle, producing more frequent or severe floods and droughts. The regional impacts of these climate changes will vary widely depending on existing population vulnerability.

Extreme weather variability associated with climate change may add an important new stress to developing nations that are already vulnerable as a result of environmental degradation, resource depletion, overpopulation, or location (e.g., low-lying coastal deltas). Persistent poverty, accompanied by inadequate sanitation and public health infrastructure, will also limit many populations' capacities to adapt to this newly recognized environmental risk factor.

The broad spectrum of multisectorial impacts posed by climate change illustrates the need for truly multidisciplinary research and integrated assessments that address the range of regional climate and health effects. This chapter reviews major climate-sensitive health outcomes, many of which are currently being studied by our program and collaborating institutions.

OVERVIEW OF HEALTH IMPACTS OF CLIMATE CHANGE

There are three well-recognized physical consequences of climate change: (1) temperature rise, (2) sea level rise, and (3) extremes in the hydrologic cycle. A recent paper in the journal *Nature* (Shindell et al., 1998) presented a fourth complication, accelerated ozone depletion, which results from the trapping of heat in the troposphere, thereby cooling the stratosphere. These four physical attributes of climate change are expected to increase the frequency of heat waves and potentially air pollution episodes; increase the number of extreme weather events; cause coastal flooding and

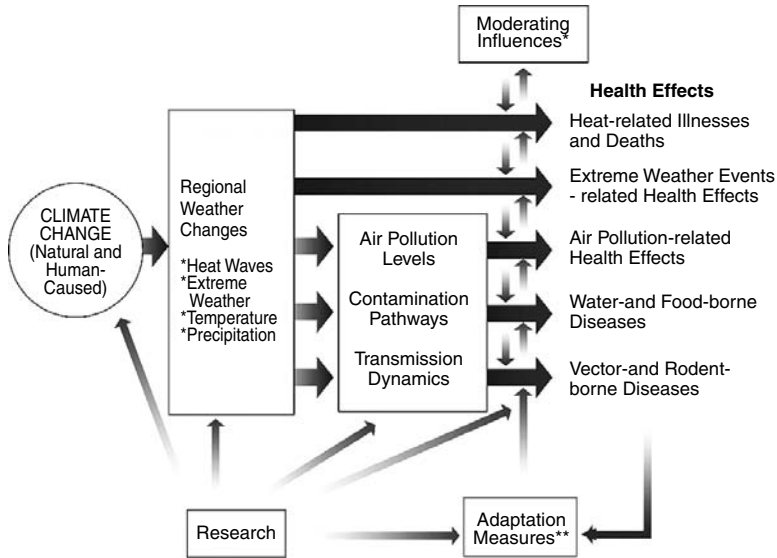

Figure 10.1 Schematic of potential health effects (and moderating factors) of climate variability and change. (From Patz, J.A. et al., *Environ. Health Perspect.*, 108:367–376, 2000.)

salination of freshwater aquifers; and (if ozone depletion is exacerbated) increase ultraviolet radiation exposure. Potential health effects from these consequences are illustrated in Figure 10.1.

Seasonality in disease incidence can often infer an association with weather factors. In sub-Saharan Africa, epidemics of meningococcal meningitis consistently erupt during the hot dry season and subside soon after the onset of the rainy season (Moore, 1992). In the southwestern U.S., rodent-borne hantavirus has been linked to El Niño-driven flooding, leading to an upsurge in mouse populations (Glass et al., 2000). In Peru, prevalence of the diarrheal disease cyclospora peaks in summer and wanes during cooler winter months (Madico et al., 1997). The current extent of our understanding of climate/disease relationships varies considerably, as discussed in more depth for other examples below.

Heat-Related Illness

While the relationship between ambient temperatures and seasonal variability in mortality rates has been extensively studied, this expected direct health consequence of climate change is far from resolved. Cardiovascular mortality in elderly people comprises the largest number of heat-related fatalities; however, physiological responses to both extreme heat and cold are not straightforward. For example, blood viscosity and cholesterol have been found to increase with high temperatures (Keating et al., 1986), whereas blood pressure and fibrinogen levels increase during winter (although outdoor temperature does not seem to determine the seasonal variation of fibrinogen) (van der Bom et al., 1997). In some cases, rainfall and snowfall have been found to influence winter mortality more than temperature, further complicating the health assessment of future winters that may be warmer but wetter.

Mortality curves assume a classic J- or V-shape, with highest mortality occurring at both temperature extremes. Generally, populations in warmer regions tend to be most vulnerable to cold (Eurowinter Group, 1997), and those residing in cold climates are most sensitive to heat. In temperate regions, mortality rates are highest during the winter.

The Chicago heat wave of July 1995 led to over 700 excess deaths in the metropolitan area. Climatologists project a doubling in the frequency of heat waves associated with a rise of 2 to 3°C in average summer temperature. A study of 44 U.S. cities found that, after adjusting for some expected acclimatization, heat-related mortality could increase by 70 to 150% (Kalkstein and Greene, 1997). A meta-analysis of 20 international cities, however, found a reduction in mortality

due to less deaths during winter (Martens, 1998). In short, there is a need for more extensive net annual mortality estimates stratified by season, cause of death, and other main confounders.

Air Pollution

Increased ambient temperature and altered wind and air mass patterns can affect atmospheric chemistry and, thereby, air pollution. For example, there is a nonlinear relationship between temperature and the formation of ground-level ozone (photochemical urban smog): above 90°F there is a strong positive relationship with temperature. The relatively high ozone levels in the U.S. during 1988 and 1995 were likely due in part to the hot, dry, stagnant conditions.

With increasing demand for automobiles, ozone is a growing problem in the developing world and continues to be the most pervasive air pollution problem in the U.S., with an estimated 71 million people living in counties that exceeded the National Ambient Air Quality Standards (NAAQS) in 1995 (U.S. EPA, 1996). Ozone is a potent lung irritant and can heighten the sensitivity of asthmatics to allergens. An increased frequency of heat waves could be expected to worsen ozone problems in urban areas. One study that held emissions and other weather factors constant showed that a 4°C warming could (1) increase maximum ozone concentration by about 20% and double the area out of compliance with the ozone NAAQS in the San Francisco Bay area; and (2) nearly triple the areas exceeding national standards in the U.S. Midwest and Southeast (U.S. EPA, 1989).

Malaria and Other Vector-Borne Diseases

Malaria is believed to be the most climate-sensitive vector-borne disease and thus most sensitive to climate change (Figure 10.2) (WHO, 1996). There are 300 to 500 million new cases of malaria

Figure 10.2 Temperature-relative risk functions for 11 U.S. cities, 1973 to 1994. (From Curriero, F.C. et al., *Am. J., Epidemiol.*, 155: 80–87, 2002. With permission.)

annually, with an estimated 2 million annual malaria fatalities, the majority young children. Infectious disease agents that must cycle through cold-blooded insect vectors to complete their development are quite sensitive to subtle climate variations (Patz et al., 1996).

The minimum temperature for parasite development of *Plasmodium falciparum* and *P. vivax* approximates 18 and 15°C, respectively. In the typically nonendemic highlands of Kenya (Garnham, 1948), Rwanda (Loevinsohn, 1994), and Zimbabwe (Freeman and Bradley, 1996), increases in ambient temperature have been linked to malaria epidemics. Also, the incidence and prevalence of malaria is closely associated with altitude (Taylor and Mutambu, 1986), a good proxy for temperature. One scenario-based climate change/malaria modeling study concludes that the global population living within a potential malaria transmission zone could increase from 45% to 60% by the year 2100 (Martens et al., 1995).

While malaria tends to be seasonal, there is substantial interannual heterogeneity of malaria incidence around the globe (Fontenille et al., 1997). Extremes of rainfall (both drought and floods) associated with El Niño events have been linked to variability in malaria incidence in some regions (Bouma et al., 1994, 1997). But the link between El Niño frequency and future climate change is still uncertain.

Other climate-sensitive diseases include mosquito-borne arboviruses, such as encephalitis, dengue fever, and Ross River virus. Field and lab studies on St. Louis encephalitis (Reeves et al., 1994), as well as lab studies on dengue virus, indicate that higher temperatures hasten viral development (or extrinsic incubation period, EIP) inside the mosquito (Watts et al., 1987). Human outbreaks of St. Louis encephalitis are highly correlated with several-day periods when the temperature exceeds 29°C (Monath and Tsai, 1987). Ross River virus, causing epidemic polyarthritis in Australia, shows a positive association with increases in minimum temperatures and rainfall (Tong et al., 1998).

Disease dynamics and insect ecology are complex. For example, higher temperatures also reduce adult mosquito survival. However, since minimum temperatures are expected to rise disproportionately compared to maximum temperatures, pathogen EIP may rise faster than adult survival declines. Climate change modeling studies of dengue fever using a vectorial capacity model (which combines variables including mosquito survival, EIP, biting rates, and others) have found increases in the potential transmission of dengue due to climate change (Jetten and Focks, 1997; Patz et al., 1998). Yet actual risk, as opposed to potential global or regional risk, will depend on site-specific factors; fully parameterized climate-driven models have successfully predicted dengue risk as validated against historical data in some locations (Focks et al., 1995).

Water-Borne Diseases

In 1995, 3.1 million people died from diarrheal diseases, 80% of them children (WHO, 1996). Extremes of the hydrologic cycle could worsen the problem since both water shortages and flooding are associated with diarrheal diseases. In developing countries, water shortages cause disease through poor hygiene. On the other extreme, flooding can contaminate drinking water from watershed runoff or sewage overflow. Since 1900, many regions of the U.S. have experienced an increased intensity of precipitation, e.g., more frequent heavy downpours, and the trend is expected to strengthen due to climate change (Karl et al., 1995).

Cryptosporidiosis, a zoonotic disease associated with domestic livestock, may be affected by altered weather patterns. Floods, storms, heavy rainfall, and snow melt wash material of fecal origin into surface drinking water sources, and the oocyst is resistant to chlorine treatment. The Milwaukee outbreak in 1993, which resulted in 403,000 reported cases, coincided with unusually heavy spring rains and runoff from melting snow. Preliminary research results from our program show that the majority of historical water-borne outbreaks in the U.S. (involving multiple agents) are preceded by heavy rainfall events.

In the marine environment, warm water and nitrogen favor blooms of dinoflagellates that cause red tides, which can cause paralytic shellfish poisoning, diarrhetic shellfish poisoning, and amnesiac shellfish poisoning. During the 1987 El Niño, a red tide of *Gymnodinium breve*, previously confined to the Gulf of Mexico, extended northward after warm Gulf Stream water extended far up the East coast, resulting in human neurological shellfish poisonings and substantial fish kills (Tester, 1991).

Similarly, that year an outbreak of amnesiac shellfish poisoning occurred on Prince Edward Island when warm eddies of the Gulf Stream neared the shore and heavy rains increased nutrient-rich runoff.

Copepods (or zooplankton), which feed on algae, can serve as reservoirs for *Vibrio cholerae* and other enteric pathogens. In Bangladesh, cholera follows seasonal warming of sea surface temperature that can enhance plankton blooms (Colwell, 1996). The Peruvian outbreak in 1991 coincided with an El Niño event, and satellite images of sea surface temperature confirm a close temporal relationship between the arrival of warmer waters along the Peruvian coast with the epidemic starting soon afterward. Simultaneous initial coastal outbreaks that occurred hundreds of kilometers apart imply a marine environmental reservoir (likely zooplankton), and this hypothesis is under epidemiologic investigation.

Water Resources and Agriculture

Several factors come into play when predicting the impact of climate change on crop and livestock production. First are the direct effects of temperature, precipitation, CO₂ levels (e.g., the CO₂ fertilization effect), and extreme climate variability and sea level rise (McCarthy et al., 1996). Next are the indirect effects of climate-induced changes in soil quality, incidence of plant diseases, weed and insect populations, and enhanced food spoilage from heat and humidity. Finally, the extent to which adaptive responses are available to farmers must be considered.

Developing countries already struggle with large and growing populations and malnutrition and would be particularly vulnerable to changes in food production. A recent analysis indicates that an additional 40 million to 300 million people (relative to a projected baseline of 640 million people by year 2060) could be at risk from malnutrition due to climate change (Rosenzweig and Parry, 1994).

Extreme Weather Events

Tropical cyclones represent the most destructive form of recurring natural disaster. Historical analysis shows that hurricanes only form in regions where sea surface temperatures are above 26°C (Gray, 1979). A recent modeling study of the western Pacific concluded that a sea surface warming of just over 2°C would intensify hurricane wind speed by 3 to 7 meters per second (or 5 to 12%) (Knudson et al., 1998). Yet hurricane frequency has not increased in the last 50 years, and current climate models lack the spatial resolution to predict a change in cyclone formation.

While hurricane predictions are still elusive, heavy rainfall events are anticipated with climate change. In the U.S., flash floods are currently the leading cause of weather-related mortality (Noji, 1997). In addition to immediate drowning deaths, floodwaters can cause the release of dangerous chemicals from storage and waste disposal sites and precipitate outbreaks of vector- and waterborne diseases. For example, extreme flooding and hurricanes have been responsible for outbreaks of the spirochetal zoonosis leptospirosis in Nicaragua and Barbados (Centers for Disease Control and Prevention, 1995). Mosquito-borne Rift Valley fever occurs in association with El Niño-driven flooding in east Africa (Nicholls, 1993), as demonstrated by the serious outbreak in Kenya during this year's strong El Niño.

Environmental Refugees

Sea level rise, in combination with extremes of the hydrologic cycle, could pose serious repercussions for coastal communities and cause large population displacement. Of the world's 20 current megacities, 13 are at sea level. A 1-meter sea level rise would inundate low-lying areas affecting 18.6, 13.0, 3.5, and 3.3 million people in China, Bangladesh, Egypt, and Indonesia, respectively (Strzepek and Smith, 1995).

Rising seas result in salination of coastal freshwater aquifers and threaten drinking water resources and coastal farmland. Far larger numbers than those threatened by frank inundation may be indirectly impacted in this way. For example, a 1-meter sea level rise could affect 60%

of the population of Bangladesh and 100% of many island nations (Strzepek and Smith, 1995). In places such as Alexandria, Egypt, agricultural depletion of groundwater and reduced siltation from upstream dams and levees are already causing land subsidence, thus decreasing the threshold for impact. Lagos, Nigeria, acquires 60% of its water from a shallow aquifer that is merely 1 meter above current sea level. Finally, sea level rise could disrupt stormwater drainage and sewage disposal, compromising sanitation.

The multisectoral impacts of sea level rise, combined with more severe drought and floods in varying regions, may displace substantial numbers of persons (Myers and Kent, 1995). Environmental refugees could potentially present the most serious health consequences of climate change, considering the associated risks that stem from overcrowding, virtually absent sanitation, scarcity of shelter and natural resources, and heightened tensions leading potentially to war. Environmentally forced population migration may unfold to be the largest challenge beneath the “tip of the iceberg” of climate change health impacts.

Ozone Depletion and Ultraviolet Radiation

By trapping heat at the Earth’s surface, greenhouse gases cool the stratosphere, which enhances chlorofluorocarbon (CFC) destruction of the ozone layer (UNEP, 1991). The direct health impacts from increases in UV-B include (1) skin cancer, (2) cataract and other ocular diseases, and (3) immunosuppression. Indirect effects to health may occur primarily through UV-mediated crop damage and by photochemical formation of tropospheric ozone (Figures 10.3 and 10.4).

Figure 10.3 Ozone and temperature relationship.

Figure 10.4 Daily time series between January 1, 1993, and November 15, 1998, for admissions for diarrhea, mean ambient temperature, and relative humidity in Lima, Peru. Note that winter temperatures during the 1997–1998 El Niño were approximately 5°C above normal, and admissions for childhood diarrhea doubled during that winter period. (From Checkley, W., et al., *Lancet*, 355: 442–450, 2000. With permission.)

It is estimated that for a sustained 10% decline in the stratospheric ozone layer, non-melanoma skin cancer cases could rise by 26%, or 300,000 globally per year; melanoma could increase by 20%, or 4500 more cases annually (UNEP, 1991). Cataracts account for half of all blindness in the world. A 10% sustained loss of stratospheric ozone would result in nearly 1.75 million extra cataracts annually (UNEP, 1991).

RESEARCH TOOLS AND STRATEGIES

The following research methods are among those required to address this cross-cutting, ecologically complex, and long-term public health challenge:

1. Time-series and regression analysis of historical data, including analogue situations of extreme climate variability (e.g., El Niño)
2. Geographic analysis of disease incidence based on weather and land use/land cover variables (taking advantage of geographic information systems, or GIS, and satellite remote sensing)
3. Scenario-based mathematical and predictive modeling with uncertainty analysis
4. Generalized integrated assessments that include demographic, social, and economic disruptions

For any of these analytical methods, human health data are the most unreliable due to reporting bias and variability in detection methods. There is a critical need for *capacity building* to improve

surveillance and monitoring to detect changes that may be a result of global climate and ecological change. Yet surveillance alone is not sufficient to prevent illness, and continued efforts to develop predictive models should be a priority.

Comment on Modeling: Predictive models are essential to improving proactive preventive health measures. Even though no model can completely simulate real life, models are useful in conceptualizing dynamic processes and their outcomes. Although empirical studies have limits, they are the foundation upon which modeling parameters are determined. While not necessarily more accurate, mathematical models can achieve a better conceptual representation of interrelated systems. Multiple iterations of well-conceptualized models that help identify key knowledge gaps, thus obtaining a “correct” model projection, might not uniformly be the most valuable outcome for scientists.

CONCLUSION

New understanding of linkages between public health and global life-support systems is emerging in the literature (McMichael, 1993). The long-term and complex problems posed by climate change may not be readily discernible over short time spans and therefore demand an expanded effort in scenario-based risk assessment in parallel with historical validation.

The results of the studies reviewed in this article must be viewed in the context of many other environmental and behavioral determinants. Future studies must consider, along with climatological factors, key variables such as poverty, sanitation, land use changes, and public health surveillance and mitigation programs. Studies of potential risk at the level of global climate models, while instructive, can only translate directly into actual risk or vulnerability when these local factors are included in assessments.

Analyzing the role of climate in determining human health outcomes will require interdisciplinary cooperation among health scientists, climatologists, biologists, ecologists, and social scientists. Increased disease surveillance, integrated modeling, and use of geographically based data systems will afford more anticipatory measures by the medical community. Understanding the linkages between climatological and ecological change as determinants of disease will ultimately help in constructing predictive models to guide proactive prevention.

Use of Meteorological Data to Predict Mosquito-Borne Encephalitis Risk in California: Preliminary Observations in Kern County

William K. Reisen

INTRODUCTION

In 1952 above-normal snowpack in the Sierra Nevada, a cool, wet spring, and a strong earthquake centered in the Tehachapi Mountains combined to produce conditions that led to the largest epidemic of mosquito-borne encephalitis in California history (Reeves and Hammon, 1962). The elevated snowpack and wet spring led to flooding along the Kern River and the emergence of a large mosquito population — while the earthquake destroyed most of the city of Bakersfield, forcing the population into temporary shelters and thereby increasing human contact with mosquitoes. Morbidity rates for western equine encephalomyelitis virus (WEE) were as high as 100 per 100,000 population in infants (<1 year age group), and many of these patients experienced serious neurological sequelae requiring institutional care (Finley et al., 1955; Longshore et al., 1956). Additional clinical cases were diagnosed with a second virus, St. Louis encephalitis virus (SLE). This epidemic occurred when the size of the human population residing in the southern San Joaquin Valley was relatively small and residents in rural high-risk communities had acquired immunity rates >75% (Reeves and Hammon, 1962). Clearly, an epidemic of this magnitude under current conditions would be devastating and overwhelm the health care system, because population size has increased dramatically and the current population is essentially nonimmune (Reeves and Milby, 1989), with seroprevalence rates <1% (Reisen and Chiles, 1997).

Both arboviruses remain of public health importance in California today. WEE, an alphavirus, is amplified during spring and summer in a primary cycle involving wild birds (mostly house sparrows and house finches) and the mosquito, *Culex tarsalis* (Reisen and Monath, 1989). As summer progresses, *Cx. tarsalis* expands its blood meal host selection pattern to include other birds such as doves, chickens, and blackbirds as well as rabbits. Rabbits develop a viremia (virus concentration in the peripheral bloodstream) of sufficient titer to infect susceptible *Aedes* mosquitoes, and a secondary rabbit-*Aedes* cycle may become established by mid to late summer (Hardy, 1987). Humans and equines (horses, mules, donkeys) become infected tangentially to these primary or secondary cycles, but fail to develop sufficient viremias to infect mosquitoes and therefore are dead-end hosts for the virus. SLE, a flavivirus, is amplified during spring and summer in a parallel primary cycle involving the same avian hosts and *Cx. tarsalis* (Tsai and Mitchell, 1989). In urban/

suburban environments, a secondary cycle involving other *Culex* mosquitoes may become established during summer. Human involvement again is tangential to these cycles.

Concepts germane to both cycles have emerged. First, despite over 50 years of investigation, the mechanisms responsible for virus persistence between seasons remains unknown (Reeves, 1990). This precludes focusing surveillance on meteorological or other factors responsible for the initiation of transmission. Second, most of the virus life history is spent in the mosquito host. Birds produce a high-titered viremia of short duration (2 to 3 days), whereas mosquitoes become infected for life. Transmission requires that the mosquito host acquire virus infection during one blood meal, amplify and disseminate the infection to its salivary glands, and then transmit to a susceptible host during a subsequent blood meal. Because mosquito body temperature approximates environmental temperature, virus transmission rates are related to ambient temperature (Reisen et al., 1993). Third, WEE and SLE are zoonoses. Therefore, human cases provide a poor indication of virus activity, and extensive avian epizootics may occur without detectable human infection (Reisen et al., 1995). Investigations of the impact of meteorological factors on virus transmission dynamics therefore must focus on components of the primary enzootic cycle.

The threat of a widespread epidemic in California has led to the development of a statewide Encephalitis Virus Surveillance (EVS) program under the direction of the California Department of Health Services to forecast the risk of human infection (Longshore, 1960) and to the establishment of an extensive assemblage of special tax-funded districts to provide intervention through mosquito control. The surveillance program currently monitors information on (1) funding for mosquito and encephalitis virus surveillance and control, (2) weather, (3) mosquito abundance, (4) enzootic virus activity, and (5) human and equine cases. The Center for Vector-borne Disease Research, in collaboration with the California Department of Health Services and the Mosquito and Vector Control Association of California and its corporate members, is conducting research to modernize this system (Eldridge et al., 1999). Developing quantitative forecasting relationships among climate variability, mosquito abundance, and encephalitis risk is one of five objectives of this program and the goal of the preliminary research described in the current chapter.

DATA SOURCES

Weather data are measured by California Irrigation Management Information System and National Oceanographic and Atmospheric Administration stations throughout California, and data are available from their Web site (<http://www.dla.water.ca.gov/cgi-bin/cimis/cimis/hq/main.pl>). Precipitation, river runoff, and snow water content data are available from the California Department of Water Resources Web page (<http://cdec.water.ca.gov>). Information on sea surface temperatures and the El Niño–Southern Oscillation (ENSO) anomaly was obtained from the National Oceanographic and Atmospheric Administration (<http://www.cpc.ncep.noaa.gov/data/indices/>).

Mosquito abundance data were obtained from the Kern and Coachella Valley Mosquito and Vector Control Districts and were collected by two types of traps:

1. New Jersey light traps (Mulhern, 1942) were operated for 2 to 5 consecutive nights per week at 9 to 15 permanent locations from April through October each year. Data from these traps are available for >30 years, but recent information is confounded by increased human populations and associated competing illumination in the form of street and security lighting (Milby and Reeves, 1989).
2. CDC-style traps (Sudia and Chamberlain, 1962) were baited with dry ice and operated without lights on alternate weeks at 25 to 28 permanent locations on the floor of the Coachella and San Joaquin Valleys from April through October each year since 1990. CDC traps collect more mosquitoes per night and therefore are more sensitive to low population abundance levels, rely on a CO₂ chemotaxis as the primary attractant, and are less affected by background illumination (Reisen et al., 1999a).

Enzootic virus activity is monitored by testing pools of ≤ 50 *Cx. tarsalis* for virus infection and by sequentially bleeding sentinel chickens in 9 to 10 flocks to detect seroconversions (Reisen, 1995a). Chicken sera were submitted for testing to the California Department of Health Services or the University of California at Davis.

ANALYSIS

Temperature and precipitation affect host populations and therefore encephalitis virus transmission in different ways. Temperature alters the rates of biological functions and has been shown to be an important factor in mosquito population modeling attempts (Eisenberg et al., 1995). Warming temperature increases the rate of mosquito immature development, decreases population generation time, and therefore increases the rate of population growth (Reisen, 1995b). In contrast, adult survivorship decreases by about 1% per day for every 1°C increase in temperature (Reeves et al., 1994). The duration of the extrinsic incubation period (time between virus acquisition and transmission) in the mosquito vector decreases as a function of increasing temperature that exceeds the minimal developmental temperature threshold for virus replication, thereby increasing the transmission rate (Reisen et al., 1993). The impact of these temperature effects can be observed in nature by comparing the dynamics of virus transmission between the relatively warm Coachella Valley and cool San Joaquin Valley. The Coachella Valley averages approximately 3 to 5°C warmer than the San Joaquin Valley each month of the year (Reisen et al., 1993). *Culex tarsalis* abundance (measured by number of females collected per CDC trap per night) increases more rapidly during spring in the Coachella Valley, but then declines in midsummer when mean daily temperatures exceed 30°C, producing in a bimodal pattern (Figure 11.1A). In contrast, abundance in the southern San Joaquin Valley (Kern County) increases later in the spring and most typically exhibits a unimodal pattern with a peak during late summer (Figure 11.1A). WEE activity as indicated by seroconversions of sentinel chickens similarly peaks earlier in the summer in Coachella than Kern as shown in Figure 11.1B.

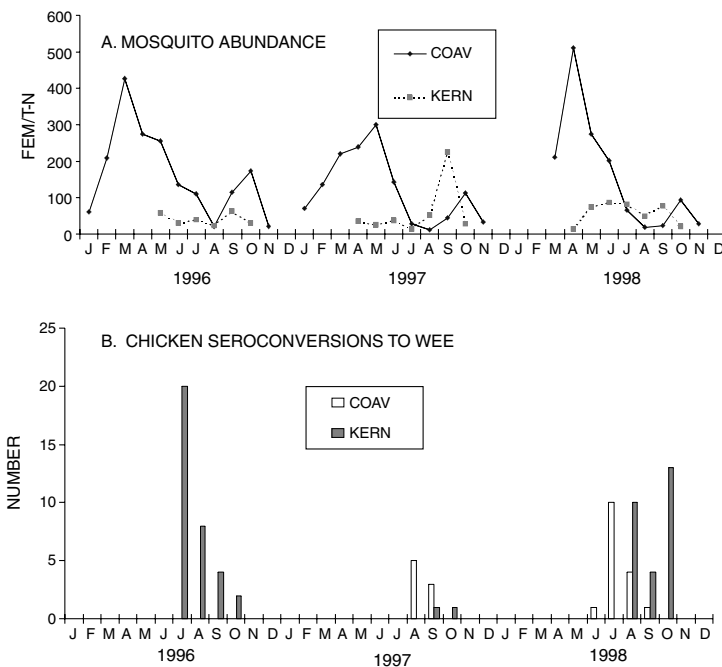

Figure 11.1 A, Mosquito abundance in females per CDC trap-night. B, The number of sentinel chicken seroconversions to WEE in Coachella Valley (COAV) and the southern San Joaquin Valley (KERN) per month, 1996 to 1998.

The effects of water on mosquito abundance were investigated using data from Kern County, because 10 years of CDC trap data were available in electronic format (Wegbreit and Reisen, 1999). Rainfall in California falls primarily during the winter months, whereas mosquitoes are most abundant during summer. Consequently, there was no simple positive correlation between the quantity of winter rain on the valley floor and mosquito abundance the following summer ($R^2 = 0.13$), even when lags of 1 to 4 months were included (Wegbreit and Reisen, 1999). *Culex tarsalis* terminates reproductive diapause by January, immediately blood-feed, and then shortly thereafter must locate a suitable site for oviposition (Bellamy and Reeves, 1963). Therefore, the quantity of winter rain would seem critical in providing surface water habitats for oviposition prior to the initiation of agricultural irrigation or snowmelt. Abundance was well correlated with the impaired runoff of the Kern River, lagged 1 month ($R^2 = 0.67$) (Wegbreit and Reisen, 1999). Impaired runoff was measured at Bakersfield after irrigation water was removed and therefore reflected discharge onto the San Joaquin Valley floor. Presumably, these data also were indicative of the general magnitude of vernal runoff from other smaller drainage systems that frequently inundate considerable areas of the west valley. As expected, vernal runoff was well correlated ($R^2 = 0.88$) with the water content of accumulated snowpack during the previous winter and, therefore, the annual mean abundance of *Cx. tarsalis* during the following summer ($R^2 = 0.70$) (Wegbreit and Reisen, 1999).

Models for long-term weather forecasting based on Pacific Ocean sea surface temperature anomalies recently have been developed, and studies have related these phenomena to climatic variation and the occurrence of mosquito-borne arboviruses outbreaks (Linthicum et al., 1999). Having developed firm associations among winter snowpack, vernal river runoff, and mosquito abundance over a 10-year period, it seemed useful to examine long-term relationships among sea temperature, snowpack, and WEE activity. WEE was extremely active in Kern County during the strong ENSO event of 1982–83 (Reisen, 1984) but then disappeared until 1996–98 (Reisen et al., 1999b), a period also dominated by a strong ENSO event. To examine this relationship further, surface sea temperature anomaly and snowpack in the southern Sierra Nevada were plotted for the past 30 years and years when WEE was detected in the southern San Joaquin Valley indicated (Figure 11.2). No relationship was readily apparent. A simple deviation analysis (Figure 11.3) indicated that changes in sea temperature did not appear to be related directly to snowpack ($R^2 = 0.07$) (Wegbreit and Reisen, 1999).

The long-term prediction of climate variation and its impact on mosquito abundance and encephalitis risk could be of considerable value in planning intervention strategies. However, establishing quantitative relationships among meteorological events, mosquito abundance, enzootic virus activity levels, and the risk of human infection will require additional detailed retrospective analyses of existing weather and surveillance data, a topic we plan to address in future research.

ACKNOWLEDGMENTS

We especially thank the Kern MVCD (Robert Quiring, manager; Richard Takahashi, entomologist) for providing mosquito abundance data. The Kern MVCD surveillance system was established by Dr. R.P. Meyer, the data collected each summer by Boyd R. Hill, and the database maintained by Sherry Sharp. Data from Coachella Valley was collected by Hugh Lothrop, University of California, Davis. This research was funded, in part, by a subcontract of a grant from the Human Health Initiative, NASA, to Jonathan Day, University of Florida. The following MVCDs provided partial financial support: Butte, Coachella Valley, Contra Costa, Greater L.A., Marin–Sonoma, Northwest, Orange, Sacramento–Yolo, San Joaquin, and Sutter–Yuba. The Viral and Rickettsial Disease Laboratory, California Department of Health Services (DHS) and the Arbovirus Research Laboratory of the University of California at Berkeley and now at Davis tested mosquito pools and sentinel chicken specimens. Selected surveillance data summaries were provided by Lucia Hui and Stan Husted of the Vector Control Section, DHS. Bruce Eldridge, University of California, Davis, provided office space, logistical support, and helpful assistance during the protocol and manuscript preparation phases of this project.

Preparing for the Quantum Leap to Sustainability: A Toolkit for Future-Friendly Cities

Mathis Wackernagel and Diana Deumling

WHY A MUNICIPAL TOOLKIT FOR PLANNING A SUSTAINABLE FUTURE?

Why Municipal?

Although the challenge of sustainability has implications from the global to the individual level (WCED, 1987), it is the local level, where all its components visibly interact, that offers a key leverage point for confronting the challenge. Towns and cities that set a sustainability agenda are the pioneers of the sustainable future. We call such communities future-friendly, and they hold the potential to find ways out of the sustainability dilemma.

But local stakeholders have a more powerful motivation than the distant prospect of solving the long-term problems of humanity. More important from their point of view is the fact that future-friendly places also reap many immediate benefits. Because they are ahead of the game, future-friendly communities are more competitive, more livable, and more secure. They are more competitive because they can use resources more efficiently and run lower ecological deficits (Sturm et al., 1999; von Weizsäcker et al., 1997; Hawken et al. 1999). They are more livable, because sustainable communities offer more attractive features (Fodor, 1999; Engwicht, 1993; Roseland, 1998) and they are more secure because they are economically prepared for a more resource-scarce world and tend to build stronger social communities.

Why Indicators?

Without proper feedback, no organism, whether a bacteria, an organization, or a society, can secure its health and vitality. Sensors tell the organism where danger looms and rewards wait. If these sensors do not operate adequately, the organism can get hurt because it does not find out in time that it needs to react. Therefore, health depends on a system of well-functioning sensors that respond quickly and that measure all signals relevant to the organism.

Indicators are society's sensors (Tyler Norris Associates et al., 1997). When they work properly, they furnish us with a feedback system. Once people get appropriate feedback they become well equipped to deal with complex challenges (Hanhart, 1989). Appropriate feedback tells them (1) what they are doing *now*, (2) what they *should do*, and (3) how they can improve the results. These are the conditions for self-improvement and learning; they also lie at the root of the quality control

principles widely accepted in Japanese industry (Juran, 1974). Therefore, the first step toward sustainability is building better sensors and feedback systems for society. With a more accurate picture of reality, people can more meaningfully perceive the costs and stresses of unsustainable living and act accordingly. Such sensors are most effective if they are tied to immediate concerns of decision makers in government, business, and households. The idea of the toolkit for future-friendly cities and regions is to develop sensors that link concerns to action.

Why Is the Toolkit the Best Next Step?

A first generation of initiatives on community indicators has focused on building such feedback systems and rapidly spread throughout the country. It has been able to mobilize many communities and get people actively involved in thinking about what matters to them.

What we have learned, however, is that the conventional indicator approach taken by these initiatives has not been sufficiently effective in moving beyond gathering information. Too much emphasis has been placed on the details of finding indicators for every single issue facing the community. Consequently, many participants get overwhelmed with the long list and the process gets bogged down. Common sense erodes, the thrust weakens, and the purpose becomes diffuse. Participants get disenchanted because the effort results in little action (Cobb and Rixford, 1998).

Building on these experiences, we plan to move to the next generation of sustainability indicators. Here, we propose to develop and test an indicators toolkit for future-friendly cities that should be more effective in generating adequate action because it:

- Is based on a clear purpose (here the purpose is building sustainability)
- Uses a simple yet comprehensive framework explaining the challenge and trade-offs (the framework is avoiding the dominant conflict of securing quality of life vs. maintaining the Earth's biocapacity)
- Is imaginative and realistic about possible intervention points (the focus is on generating the will rather than "planning ways")
- Envisions next steps beyond the project before starting it (the project is seen as a stage for a more informed and focused sustainability discussion that will be able to attract meaningful sustainability projects at the local level)

Because it is based on two simple measures, the municipal toolkit approach is simpler, more conceptual, and more engaging than conventional indicators initiatives. It provides tools and processes ideas designed to allow communities to measure how sustainable they are and how fast they are moving toward their goals. Indicators work most effectively when they are as clear and simple as a red traffic light and as tangibly linked with life concerns.

PROJECT APPROACH

We build our project on a simple and straightforward definition of the sustainability dilemma: *Everyone needs to be able to secure a satisfying life, within the means of nature.* Obviously, this shorthand refers to a much fuller agenda: healthy communities, equity (intragenerational, intergenerational, and interspecies), social cohesion, economic vitality, long-term competitiveness, and ecological integrity, to name a few larger items. Although this formulation is short and snappy, it synthesizes the essence of the sustainability agenda and makes "sustainability" accessible.

After all, the competition between these two goals — staying within the capacity of our ultimate means (natural capital) and reaching our ultimate ends (satisfying lives for everybody) — is the core of humanity's current self-destructive path. It is this conflict that becomes the

BOX 12.1**SUSTAINABILITY: LIVING WELL WITHIN THE MEANS OF NATURE**

Sustainability requires promoting everyone's quality of life within the means of nature. Living beyond our ecological means will lead to the destruction of humanity's only home. Having insufficient natural resources and living in unsatisfactory and inequitable ways will cause conflict and degrade our social fabric.

Sustainability means settling the conflict between two competing goals: the sustenance of human life and the integrity of nature. Indeed, this is the conflict between ultimate ends (a good life for everybody) and ultimate means (the capacity of the biosphere) we need to resolve.

We need to know how much quality we are getting — or losing — in our communities. We need to know the degree to which life quality can be nonmaterial and thus less resource-intensive, and whose quality of life is already eroding due to degradation of natural and social systems. We will explore this question by asking people how satisfied they are with their lives and their communities.

At the same time, we need to start monitoring whether we are living within our ecological means or at what rate humanity is depleting the biosphere. We must ask: "How much nature does humanity, our country, or our household use to sustain itself?" After all, people are part of nature and depend on its steady supply of the basic requirements for life: energy for heat and mobility, wood for housing, furniture, and paper products, fibers for clothes, quality food and water for healthy living, ecological sinks for waste absorption, and many life-support services for maintaining good living conditions on our planet. This use of nature is measured by the ecological footprint and compared to the biocapacity that exists on this planet.

hurdle to sustainability. Also, didactically, it is useful to capture sustainability in this format: two conflicting poles make it easy to understand and watch the development. It is like a soccer game. Two teams struggling for the ball is a simple and clear process to follow. However, once three, four, or even more teams play against each other simultaneously, the game becomes unintelligible and confusing. Not only will people lose interest, but they will be confused about how to intervene.

To frame this dilemma and to explain how it becomes the driving force behind today's self-destructive behavior, the toolkit will have two direct outcome measures capturing the ultimate means and the ultimate ends: (1) a *satisfaction barometer* that documents people's levels of satisfaction with their society, community, neighborhood, and personal life, as well as their attitude toward sustainability measures that helps identify what kind of sustainability initiatives people feel most excited about; and (2) the *ecological footprint* that compares people's consumption with the local and global ecological capacity. Each of these measures can then be fleshed out and enriched by subsidiary projects and applications that focus on more specific aspects of or interesting applications for future-friendly town and cities.

BACKGROUND FOR THE SATISFACTION BAROMETER**Why Satisfaction?**

A sustainable society cannot be built on martyrdom and suffering. People want fulfilling lives. To make sustainability come true, we must find ways by which people can thrive in all senses, without senselessly overtaxing the ecosystems that support us. In other words, everybody should be able to realize a satisfying life in a way that limits humanity's ecological impact on the regenerative capacity of the biosphere.

BOX 12.2

SUMMARY OF THE ACCOUNTING TOOLS THAT REPRESENT THE TWO RIVALING POLES OF SUSTAINABILITY

“Does Everybody Secure A Satisfying Life

... Within the Means of Nature?”

The Satisfaction Barometer

The barometer is a psychological (or subjective) measure. It assesses people’s satisfaction with their society, community, and personal lives. In contrast, physical (or objective) measures of well-being oppose sustainability as it is by definition impossible to improve the material situation of a growing population without also increasing the resource throughput of society. Also, psychological outcomes are more meaningful to people. For example, subjective feelings such as depression, love, fear, hope, or loneliness more fundamentally determine people’s satisfaction with life than the number of television sets in their homes or even the number of doctors in their municipality.

Selling benefits, not features. A sustainable society cannot be built on martyrdom and suffering. People want fulfilling lives. To make sustainability come true, we must find ways that people can thrive in all senses without senselessly overtaxing the ecosystems that support us. In other words, everybody should be able to realize a satisfying life, and do that within the regenerative capacity of the biosphere.

The dimensions of satisfaction. We believe that nurture, pleasure, empowerment, acceptance, “flow,” control, excitement, and the sense of belonging and contributing are drivers of people’s satisfaction with life. It is control over one’s time and relationships rather than financial wealth that become critical. In fact, satisfaction may not be tied as closely to resource consumption as we seem to believe. Therefore, the barometer will ask such questions as: Do you have time to focus on what is important to you? Do you live in a community that you love and that loves you? Do you feel you can make a contribution to the world? Are you in control of your life, or is your life controlling you? How many times a week do you have to get up using an alarm clock? How important are these issues to you?

The Ecological Footprint

The footprint measures human impact on nature. In order to live, people consume what nature offers. Every one of us has an impact on our planet. This is not bad as long as we don’t take more from the Earth than it has to offer. But are we taking more than we should? The ecological footprint measures what we consume from nature. It shows how much productive land and water we occupy to produce all the resources we consume and to absorb our waste.

How big is your footprint? The average American uses 24 acres to support his or her current lifestyle. This corresponds to the size of 24 football fields put together. In comparison, the average Canadian lives on a third of that footprint, and the average Italian on half.

How much can nature provide? Nature provides an average of about 5 acres of bioproductive space for every person in the world. With a global population of 9 billion in the year 2050, the available space will be reduced to over 3 acres, and that is without setting aside area for the millions of other species. Our research shows that humanity’s footprint is over one quarter larger than what the planet can regenerate.

What can we do? We can become part of the sustainability movement and make it possible that everyone secure a satisfying life within the means of nature. We can better use resources, for example, by using energy-efficient lamps or by composting. We can consume less by having a smaller population and decreasing our consumption. Buying fewer cars and other disposable products will save us money and grief and give us more spare time.

Are People Satisfied with Their Lives? Measures of Well-Being

To get there, we need measurement tools that can assess whether society is moving in the desired direction of preserving both quality of life and the natural system that sustains it. While the ecological footprint tells us about the natural side of the equation, we need a complementary indicator to tell us about the side that addresses the quality of life, especially one that can identify where needs are.

Various measures have been developed to allow comparisons among the situations of people and societies. Although Gross Domestic Product (GDP), the most widespread and influential economic indicator, has been abandoned as an indicator for human welfare, new ones have emerged, including the Index of Sustainable Economic Welfare, developed by Clifford Cobb, John Cobb and Herman Daly and now further developed by Redefining Progress (RP) as the “Genuine Progress Indicator” (Daly and Cobb, 1989). As these modified national account approaches still focus primarily on economic performance rather than on a wider set of parameters determining social well-being, other measures have been developed, such as the Human Development Index, which is compiled annually by the United Nations Development Program (UNDP).

Subjective Satisfaction Measures

But these material or *objective* measures of well-being undermine the goal of sustainability, since by definition it is impossible to improve the material situation of a growing population without also increasing the resource throughput of society. Therefore, a more constructive way to address this dilemma is to emphasize the *subjective* side of well-being. Subjective well-being is as real as objective well-being, although its manifestation is more complex and, therefore, not directly measurable. In the end, however, it is more meaningful to people. For example, subjective feelings such as depression, love, fear, hope, or loneliness more fundamentally determine people’s satisfaction with life than the number of television sets in their homes or even number of doctors in their municipality. Focusing on subjective well-being does not deny the material dimension of human life. Obviously, subjective well-being depends on some material inputs. The point, however, is that material throughput does not determine people’s satisfaction with their lives.

The RP Satisfaction Barometer

The RP satisfaction barometer is a survey tool based on existing measures of well-being. It is designed to assess people’s satisfaction with their society, their community, and their personal lives in a subjective (nonmaterial-based) measure, doing so eventually at various scales. At the same time, the measure invites people to think about the bountiful possibilities of improving quality of life and to seek ways to develop more fulfilling lives while actually reducing their footprint. It focuses on issues that are central to fulfilled lives, flourishing communities, and a healthy biosphere. In this way it can address the need for positive and engaging outlets for people’s creativity, warm and gratifying relationships, and opportunities to connect with the natural world that supports our lives.

Do you have time to focus on what is important to you? Do you live in a community that you love and that loves you? Do you feel you can make a contribution to the world? Are you in control of your life or is your life controlling you? How many times a week do you have to get up using an alarm clock? How important are these issues to you? These are among the driving questions behind our search for exploring people’s satisfaction with life.

Apart from analyzing people’s satisfaction, we also need to find out what kind of sustainability initiatives people feel most excited about. Without understanding people’s attitudes and resistance toward sustainability, and without a clear idea of their perceptions of limitations and possibilities, the concept of sustainability remains abstract. Worse, the emergence of possibly synergistic and

widely supported sustainability strategies remains unlikely. To prepare the ground for such strategies, the satisfaction barometer will be refined through discussions with community leaders, extensive focus groups, surveys, and other complementary tools for identifying the sustainability strategies most likely to succeed.

BACKGROUND FOR THE ECOLOGICAL FOOTPRINT

The Ecological Context

Humanity has become the dominant species on the planet — the largest resource consumer and waste producer. Human activities have grown to such an extent that they have begun to exceed the global carrying capacity, resulting in a loss of ecological productivity. In other words, humanity has come to a point where further expansion impoverishes it. What is called *development* has more often become a liquidation of assets, mainly natural capital.

To be sustainable, humanity must not diminish nature's capacity to generate and regenerate its functions and services. Ecological economists call this *maintaining natural capital*. This capital is humanity's ultimate source of wealth without which human life and activities become impossible. Planning for sustainability, therefore, depends on measuring this ecological bottom-line condition. People need to know how much of nature a given population uses compared to how much there is. If a population exceeds ecological limits, it needs to be able to monitor whether it is reducing this deficit. If it cannot gauge this, it will continue to grope unproductively in the dark.

What an Ecological Footprint Analysis Offers

Ecological footprints are accounting tools for natural capital.* Such tools can help people assess their ecological impact and compare this impact to nature's capacity to regenerate. In other words, footprints contrast people's impact with nature's carrying capacity. Such analyses provide a benchmark for present ecological performance compared with potential available natural capital; identify challenges for lightening an economy's ecological load, and document gains as a country, region, or city moves toward sustainability.

Footprint-based assessments of regions start with an inventory of the ecologically productive spaces within that area. Most of these land-use data already exist and, in the case of more precise analyses, can be complemented by local surveys and remote-sensing data from satellites. Such an inventory would provide an estimate of the local ecological capacity — the supply side.

The demand side — that is, the footprint of the local population — can be documented with various degrees of precision. Given an estimated per capita demand for ecosystem services and the productivity of the ecologically productive space categories in a region, an estimate of the human carrying capacity deficit (or remainder) of the region can be obtained.

Applying the Footprint Measure at the Municipal Level

Applying the footprint measure at the municipal level expands the approach described for Santiago de Chile, completed for the International Council on Local Environmental Initiatives (ICLEI) (Wackernagel, 1998). Our ecological footprint analyses of nations and regions are continually improving and becoming more sophisticated (WWF et al., 2002; Wackernagel et al., 1999a,b,c.; van Vuuren et al., 1999). National footprints serve as reference data sets for assessing

* In the early 1990s, William Rees and Mathis Wackernagel developed the original Ecological Footprint concept. Their book *Our Ecological Footprint: Reducing Human Impact on the Earth* was published in 1996 by New Society Publishers. Ecological Footprint studies have become popular on all continents. Updates and links to footprint initiatives can be found at <http://www.redefiningprogress.org>.

subnational footprints. The footprint of a region is extracted from the national footprint by comparing the extent to which consumption patterns in the region differ from the national average and adjusting the national footprint accordingly. This approach to calculating local footprints generates results that are directly comparable to national and global averages. For instance, municipal footprints can be compared to global and national footprint and biocapacity averages as well as to local biocapacity. The latter can be assessed using maps or GIS data and local yield figures. RP has conducted local ecological footprint assessments for Duluth, MN; Marin County, CA; Ojai Valley, CA; Sonoma County, CA; Paris, France.

JOINING THE TOOLS TO BUILD THE TOOL BOX

We have not yet tested this package approach of joining an accounting tool for the ultimate means (natural capital) with one for the ultimate ends (quality of life) in a real community situation. We are discussing the package with potential partners who may join us in testing this concept.

We hope this approach could kick-start the next generation of sustainability indicators. Significant benefits could result from joining the satisfaction measure to the ecological footprint. A well-designed scale of social and individual satisfaction, combined with an effective tool for quantifying (and communicating) human impact, will allow people to document sustainability constraints and current conflicts between social and ecological sustainability imperatives; it will also help us discover ways to resolve these conflicts. Further, this approach will help advance the scientific understanding of the relation between ecological impacts and human well-being. It will identify opportunities for improving people's quality of life on lower ecological footprints, thus providing a tangible and useful base to further the public debate on sustainability and encouraging appropriate action.

This approach moves away from first focusing on indicators without having a framework to embed them. Past approaches have led to much discussion on a few details while obscuring the overarching questions. We hope that by putting the framework first and keeping the focus on the current contradiction between expanding human demands and limited ecological capacity, we will be effective in encouraging more systemic approaches at the community level. After all, sustainability is about reconciling difficult trade-offs.

This does not mean that traditional indicators are not useful. The question is more when and how to use them. The satisfaction barometer and the ecological footprint are not advocated to be the only indicators. We view them as an accounting framework. They summarize the points of tension. Indeed, the many indicators that are used at the community level are the elements that make up these two measures representing the poles of the sustainability tension.

NEXT STEPS FOR THE PROJECT

The first phase of the project began with outreach to communities and planners interested in measuring where they are in terms of sustainability and finding out what they can do about it. With their help, we propose to pilot the toolkit in municipal applications.

After testing and evaluating the indicators, we will develop the final toolkit, a handbook that should enable others to assess a U.S. municipality's present footprint and quality of life and generate scenarios for future paths of development. The simply written and well-illustrated handbook will include:

- Background on the ecological footprint and satisfaction barometer
- Instructions for calculating and interpreting the ecological footprint and for giving and interpreting satisfaction surveys
- Diskettes with calculation forms and reference data to help people perform their own community calculations

- Suggestions and practical strategies for engaging a community in a constructive debate on quality of life
- Suggestions and practical strategies for moving from framing issues to developing action and maintaining commitment to the sustainability agenda

To make the manual user-friendly, we will strongly emphasize evaluation and testing of the material. Therefore, the research will involve not only hands-on workshops with nongovernmental organizations (NGOs) and local government officials but also paid outside evaluation by experienced individuals in academia and the community.

EXPECTED RESULTS OF THE PROJECT

The municipal toolkit is intended to help communities frame sustainability in a more constructive way. It would provide local governments and NGOs with a standard for the tangible realization of their sustainability goals. It could become a platform for municipal planning of housing, energy infrastructure, transportation, education, etc.

The goal is to help communities build consensus for focusing on sustainability and to provide a meaningful context for decision making. More specifically, this kit should enable communities to:

- Define their sustainability goals in more specific and measurable terms
- Assess their ecological impact and compare it to nature's capacity to regenerate
- Evaluate the community's quality of life and identify its weak spots
- Identify areas for reducing an economy's ecological load while improving its performance in providing quality of life
- Assess current progress toward realizing goals
- Engage in constructive debate
- Create strategies for implementing goals
- Develop activities that maintain the community's interest in building a sustainable future
- Motivate policies and changes (such as local incentive programs) in the municipality that bias private and public decision making toward sustainable choices
- Communicate best practices to other communities, once the handbook has been developed in test communities

The concept we offer is new. The handful of communities that have explored parts of it or similar models worldwide show promising results. The Green Smiles Project in Holland is one example of an initiative inspired by ecological footprint work (Redczus, 1999). The Global Living Project in Canada invited researchers in a 6-week program to reduce their footprints while maintaining a high quality of life. For 2 years in a row, they achieved a footprint as low as 0.9 hectares per person, less than 1/10 of the average U.S. footprint (Merkel, 1999). Many local Agenda 21 initiatives have used the ecological footprint as a starting metaphor.

In the short term, we may have to judge the project's success with circumstantial evidence. Increasing demand for the handbook would be a good sign. A better sign would be community groups using the kit as a platform for developing more creative proposals for moving toward sustainability.

Over time, the toolkit for future-friendly cities and regions will have the benefit of being replicated easily in many places and helping to build the local stages for developing sustainability. We will know we are succeeding when a growing network of communities is fruitfully applying the toolkit to increase residents' satisfaction while decreasing footprints. Along the way, we hope that it can help current indicator initiatives to become more effective and inspire a new generation of local policies whose goals are reducing footprints while improving the quality of life of all their residents.

SECTION I.3

Building Policies and Linkages

Overview: Building Policies and Linkages

Barry W. Wilson

The cliché “all politics are local” expresses a general characteristic of human decision making, and the generalization “all ecosystems are local” defines a natural property of living communities, from molecules to ecosystems, from mountains to seas. The onrush of industrialization, the plundering of nonrenewable resources, and the pressure of increasing human population have set the stage for negative changes in species survival and the integrity of the soil. Such rapid changes have not occurred perhaps since the Permian era. In the past, shifts in the planet’s population were due to natural forces. In contrast, those facing us today are likely due to our own activities. Recognition of the problem is the first step in finding a solution. “We have met the enemy,” said comic strip character Pogo, “and he is us!” However, this is not enough. Avoiding disastrous global warming, stopping habitat destruction and overfishing, ending smog and acid rain, and correcting all the insults to which the environment is heir sometimes appear beyond our abilities. To whom shall we turn? Big Business? Big Government? Big Green?

There are no widely accepted rules regarding the formulation and application of environmental conservation and remedial programs. Some public policies are based on tradition, e.g., “We always plow this way,” and are unlikely to change. Change does occur as a result of a dedicated few who make heroic efforts. Some of these dedicated people influence policy makers directly, while others appeal to the masses by pointing out what we are losing. “Where have all the birds gone,” said Olga Owens Huckins to Rachel Carson (1962), “Spring is without bird song and I cannot bear it.” “Stick with it! And stick it to them!” is a motto of environmental groups that have taken a leaf from the stylebook of activist community efforts exemplified by Saul Alinsky’s Chicago projects in the 1940s and 1950s (Alinsky, 1946). Many despair that even these extreme actions will not make a dent in the planet’s wide destruction and pollution. But others, in spite of the many voices that preach environmental disaster, cling to the notion that there has been, and will continue to be, progress in reversing the destructive trends. Over the centuries, step by step, we learn about the web of life, its controls and limits, and what to do about it. But the level of inertia is high. Once, discussing the impact of humans on wildlife (Wilson, 1980), I said: “The issues lie between the living, the dead and the unborn. Each generation feels the Earth is theirs; each knows that they are the most modern, progressive and important of people. They see themselves as heirs to the ages, entitled to the riches of the Earth. Then they die, passing what is left to their children. The ethic of conservation is one of common sense; it says we are caretakers, holding the land in trust for future generations.” To hold the land as sacred requires a change not only of the mind but of the heart.

Words come easy, actions hard. As long as people look upon land as real estate and coastal waters and river dams as the makings of waterfront property, they are not apt to change their minds or the

habits of centuries. There is still much to learn about the determinants of the web and the tapestry of life and how to protect it. We seem to commit the same mistakes over and over again. Ecosystem truisms such as “everything must go someplace” and “everything is connected to everything else” (Wilson, 1998) too often take second place to the “law of unintended consequences.” When it comes to ecosystems, it is often not the future, but past mistakes that lie before us. Decision makers in the public and private sectors too often accept the most expedient or profitable process, tout convenient but unconfirmed research findings, or substitute benchmark data for hard-won field studies and modeling for reality. It may take more than facts to convince scientists and permit the lay public to understand the reality. In addition to an appreciation of the processes that underlie life on Earth, we need to understand the processes by which human beings decide what to do about themselves and their environment. The former is the province of ecological science, the latter the realm of politics and social psychology. There is a complex interplay between individual desires and government programs, a complex dance between the wishes of the individual and society.

Three chapters in this section touch upon several issues inherent in understanding the origins of environmental policies. Chapter 16, *Attitudes and Their Influence on Nature Valuation and Management in Relation to Sustainable Development*, by Hans A.M. de Kruijf et al., discusses some of the factors that determine the way people view policy making and management of nature. Chapter 17, *Humane Values as a Basis for Ecosystem Health*, by John Grandy and Allen Rutberg, focuses on one attitude, concern for the welfare of animals, and its increasingly important role in environmental decision making. Chapter 18, *The Role of the Water Education Foundation in Creating Factual Awareness and Facilitating Consensus in Western Water Issues*, by Rita Schmidt Sudman, is an example of the growth and impact of one foundation dedicated to water issues. Its mission is based on the insight that the apportioning of water more than the mining of gold is a determining factor in the history of the West.

Have we already turned an important corner? Only time will tell. Speaking at a ceremony dedicating a monument to the last passenger pigeon, ecologist, wildlife manager, poet, and prophet Aldo Leopold (1949) said that for one species to mourn the extinction of another is “a new thing under the sun.” Leopold’s formulation of a “Land Ethic” highlights the feelings of many of us: “When we see land as a community to which we belong, we may begin to use it with love and respect. That land is a community is the basic concept of ecology, but that land is to be loved and respected is an extension of ethics.” Looking back at the previous century, we see that more people are concerned about and learning about ecosystems and the health of the planet than ever before. Each in their own way, elected representatives work from the top down, forming government agencies like the Environmental Protection Agency (EPA) and writing the Endangered Species Act; individuals work from the bottom up, forming political lobbies like Friends of the Earth and the Sierra Club. These lobbyists work to change attitudes, bringing about a metamorphosis where a swamp is not only a piece of real estate but also a magical home for many creatures. Is time on our side? “Had we but world enough, and time” mourned Elizabethan poet Andrew Marvell (Marvell, 1997) as he tried to convince a coy lady to surrender. What persuasions will we use to convince the contemporary lumberman to put down his axe and the developer his steam shovel? Our failures litter the centuries; let us hope that our successes will provide a better world for our children.

The CALFED Bay–Delta Ecosystem Restoration Program: Complexity and Compromise*

Rick Soehren

GEOGRAPHY, HYDROLOGY, AND HISTORY

The great Central Valley of California, ringed by mountains, has only one outlet: the San Francisco Bay/Sacramento–San Joaquin Delta estuary (Bay–Delta). The two largest rivers flowing to the Bay–Delta are the Sacramento and the San Joaquin. Smaller streams include the Mokelumne and Cosumnes Rivers. Together these rivers and smaller tributaries in the system drain an area of 158,000 km². Runoff is highly variable and ranges from less than 10 km³ to over 60 km³ annually, and has averaged 29.6 km³ per year (Monroe and Kelly, 1992). The estuary itself is a maze of braided channels, sloughs, and diked islands covering just less than 300,000 ha in five California counties (California Department of Water Resources, 1993). It is the largest estuary on the west coast of North America.

The Bay–Delta is the hub of California’s two largest water distribution systems, the Central Valley Project (CVP), operated by the U.S. Bureau of Reclamation, and the State of California’s State Water Project (SWP). In addition, at least 7000 other water diverters, large and small, take water from the watershed feeding the estuary. Together, these water developments divert 20 to 70% of the natural flow in the system depending on the amount of runoff available in a given year. Water diverted from the system is used to irrigate about 2.8 million ha of highly productive farmland and provides a source of drinking water for two thirds of California’s growing population (CALFED Bay–Delta Program, 2000).

The estuary has a long history of disturbance. During California’s gold rush, a technique of hydraulic mining was used to wash away entire hillsides to extract the gold within. Between 1853 and 1884, when the practice was outlawed by federal injunction, silt streamed from the Sierra foothills. This silt raised the bed level of rivers and channels in the system and covered the floor of San Francisco Bay. Mercury was used in the gold extraction process, and much of it escaped with the silt, producing a toxic legacy that remains today.

Starting about 1869, settlers began to dike and drain the land of the estuary. Levees were built to protect parcels of land from surrounding channels, and these parcels came to be called *islands*. Fertile peat soils and an abundant water supply made the region attractive to farmers, and the lands of the estuary continue to be significant contributors to California’s agricultural economy. Within

* Opinions expressed are those of the author and do not necessarily represent positions of the CALFED Bay–Delta Program or the California Department of Water Resources.

about a generation, the estuary was converted from a sea of tules ringed by riparian forest to one of the garden baskets of California.

Peat soils are fertile but fragile. Once drained, the high proportion of organic matter in the soil is subject to oxidation, wind erosion, and even fire. The soil has been mined in this way for over a century. Today, some islands in the Bay-Delta are more than 5.5 m below sea level, ringed by channels that carry flood flows during most winters (California Department of Water Resources, 1993). Levee maintenance and repair has become a significant expense for those who depend on the integrity of Bay-Delta channels.

This highly disturbed system has become a haven for introduced species, including both intentional and accidental introductions. Nearly every new species survey turns up new organisms in the Bay-Delta, so an accurate count is impossible. A recent thorough review of exotics in the system (Cohen and Carlton, 1995) put the tally at 212 species. The diversity of introduced species is astonishing, and their effects on native biota are likely significant. An early and intentional introduction was the striped bass, *Morone saxatilis*. About 135 juvenile fish from the Navesink River in New Jersey were brought west by rail and planted in the Carquinez Strait at Martinez circa July 1879. Within 10 years there was a thriving commercial fishery. By the 1970s the bass population had begun to decline, and artificial propagation was used to bolster the population. In 1992 this stocking of hatchery fish was temporarily halted because of possible predation by stripers on native fishes (Dill and Cordone, 1997). Several of these native fish species are listed by state and federal governments as endangered, threatened, or species of special concern.

Invertebrate introductions are usually less visible to the lay public, but their roles in altering the food web of the Bay-Delta is at least as significant. The Asian clam; *Potamocorbula amurensis*, apparently introduced about 1986, has been recorded at densities of 48,000 individuals per m² of substrate in Suisun Marsh, a large wetland area in the estuary (Peterson, 1996). This filter feeder has reduced food availability for larval fish and increased the clarity of Bay-Delta waters.

Against this backdrop of disturbance, the CVP and SWP began diversions from the Bay-Delta in 1940 and 1967, respectively. Each project has its own massive pumping plant adjacent to channels at the southern edge of the estuary, far enough upstream so that the intrusion of saltwater from San Francisco Bay is usually moderated sufficiently by outflow from the rivers that feed the system. Aqueducts the size of rivers carry water south to local and regional water agencies that have contracted with the CVP or SWP for their water supplies. Water deliveries to farms in the San Joaquin Valley and urban areas of Southern California have allowed these areas to grow and prosper, contributing significantly to California's powerful economy. These water diversions have increased over time to satisfy growth, reaching some of their highest levels in the 1980s or 1990s before conflicts over endangered species protection began to force curtailment of water exports from the system.

The pumping plants of the CVP and SWP exert considerable influence on the hydrodynamics of the Bay-Delta when the pumps are in operation. At times, certain channels in the Bay-Delta reverse flow due to the influence of the pumps, flowing upstream toward the pumps rather than downstream toward the ocean. Throughout the estuary, there is an effect on natural flows as water is drawn from the largest tributary at the north edge of the Bay-Delta to the pumping plants in the south, rather than the generally east-west flows that predominate when the pumps are not in operation.

In addition to the effect of altered hydrodynamics on aquatic species, there is direct mortality of fish and eggs resulting from entrainment in the water diverted from the system. Despite ambitious efforts to screen fish at the pumps and return them to channels of the Bay-Delta, the water projects represent a major stressor on estuarine species. These effects on the biota of the system have placed water operations at odds with endangered species protection. By 1993, two fish species had been listed under the federal Endangered Species Act (ESA), petitions to list other fish had been filed, and the listings had resulted in restrictions on the operations of the projects. There was a significant effect on the amount of water the projects could deliver, jeopardizing the economic well-being of much of the state.

THE CALFED BAY-DELTA PROGRAM

In 1994, the confrontational demeanor that had been the hallmark of California water history yielded to an era of cooperation and compromise. In June 1994, state and federal agencies — those responsible for water deliveries as well as those responsible for environmental protection — signed the Framework Agreement, pledging cooperation and “development of a long-term solution to fish and wildlife, water supply reliability, flood control, and water quality problems in the Bay-Delta Estuary.” In December 1994, these agencies, together with representatives of water users and environmental organizations, penned an agreement that extended the level of compromise. These Principles for Agreement, often referred to as the Bay-Delta Accord, called for increased freshwater flows through the Bay-Delta to protect water quality and native fish. To provide greater certainty for water users, the agreement stipulated that any additional environmental water needs due to any new listings under ESA would be met by water purchases financed by the federal government and undertaken on a willing-seller basis, not through regulatory reallocation of water. These principles were intended to be in force for 3 years, reinforcing the need for state and federal agencies to develop a long-term solution (Rieke, 1995).

The resulting collaborative effort between California and the federal government has come to be called the CALFED Bay-Delta Program, or simply CALFED. The CALFED letterhead is a veritable *who’s who* of the government players in water and resource management. Current CALFED agencies are listed in Table 14.1.

The collaboration has not always come easily, and the process has been marked by occasional internal conflict because each agency maintains its separate responsibilities and authorities. Still, agencies that had sometimes seen themselves as adversaries are now working together. Staffers are forging personal working relationships that are making it easier to compromise and appreciate alternative positions on issues.

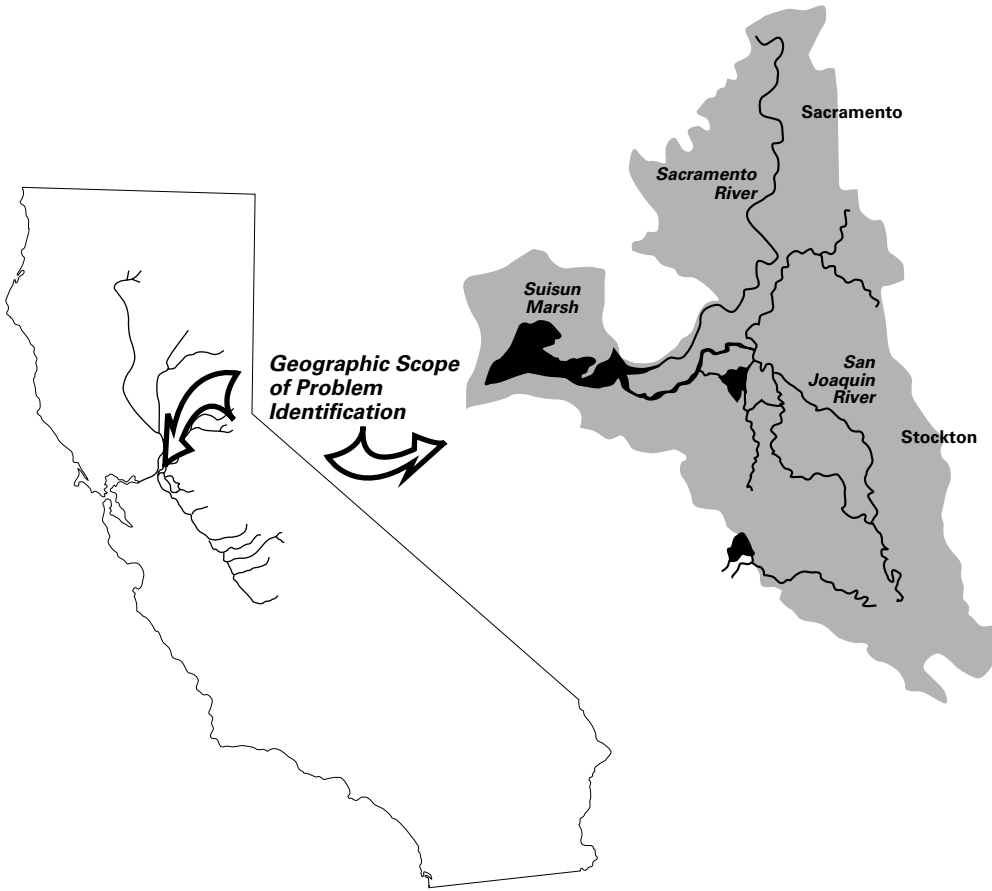

Figure 14.1 CALFED problem area geographic scope.

Initial CALFED planning began in 1995 and envisioned a three-phase program. In Phase I, completed in August 1996, CALFED identified the problems confronting the Bay–Delta, developed a mission statement and guiding principles, and devised three preliminary categories of solutions, or program alternatives. Figure 14.1 shows the geographic scope of the CALFED problem area. Solutions to problems in the Bay–Delta were sought throughout the watershed as well as in areas of Southern California that receive water exported from the system. The CALFED charge was to address four interrelated problem areas: water quality, water supply reliability, levee system integrity, and ecosystem restoration. Rather than solving problems in one of these areas at the expense of another, the goal was to develop a comprehensive solution that offered benefits for all interests.

Following scoping, public comment, and agency review, CALFED concluded that all three of the program alternatives could share many types of proposed actions. These types of proposed actions became central parts of the CALFED program and were called *program elements*. The program elements addressed ecosystem restoration, water use efficiency, levee system integrity, and water quality. Two additional elements (water transfers and watershed management) were added to each alternative because of their value in helping the program meet its multiple objectives. These six program elements have generally been referred to as the *common programs*. The three preliminary alternatives CALFED identified for further analysis in Phase II represented three differing approaches to conveying water through the delta, the uppermost freshwater end of the estuary. The first conveyance configuration relied primarily on existing channels with some minor changes near the project pumping plants at the southern edge of the delta. The second configuration relied on

enlarging channels within the delta. The third configuration included in-delta channel modifications and a new constructed conveyance channel that would move some water around the delta. This configuration was a variation on a project rejected by California voters in 1982, which had been known as the peripheral canal due to its intended transport of water in a constructed channel around the periphery of the delta. Each of the three alternatives also included consideration of new groundwater and surface water storage options.

The level of detail of planning was intended to be programmatic. That is, CALFED recognized that it would eventually specify hundreds of actions that together would constitute the CALFED solution. The intent was to outline these actions, refine them, and add more specifics later as the actions were being implemented. Accordingly, the environmental impact statement prepared during Phase II to comply with the National Environmental Policy Act (NEPA) was also programmatic in nature and is intended to be followed by site-specific or project-specific environmental documents. (The same programmatic document also served as the environmental impact report required under the California Environmental Quality Act, CEQA.)

During Phase II, CALFED developed a Preferred Program Alternative, conducted comprehensive programmatic environmental review, and developed an implementation plan focusing on the first 7 years of the anticipated 30 years needed to carry out the entire program. One of three delta conveyance alternatives — construction of a new conveyance channel that would move some water around the delta — was attractive to the CALFED planners for several reasons. It could be screened to protect fish more effectively than existing project pumping plants, it avoided effects on delta hydrodynamics such as reverse flows, and it protected export water quality from agricultural runoff and natural organic carbon in delta channels. But it also would make a huge change in the physical system, and the consequences of such a change would be impossible to predict in the complex and dynamic Bay–Delta environment. This alternative also suffered from the specter of a similar idea that the voters had rejected 18 years earlier. Ultimately, the compromise solution included in the Preferred Program Alternative was to continue the use of existing channels for water transport across the delta, with some modifications to channels and pumping plants.

The CALFED Ecosystem Restoration Program

The plan that CALFED released in July 2000 is one of the most comprehensive and ambitious resource management plans ever issued by government agencies in the U.S. It describes thousands of actions to be implemented during Phase III of the program, an implementation period of more than 30 years. During just the first stage of implementation, a period of 7 years, the estimated cost would be \$8.4 billion (CALFED Bay–Delta Program, 2000). The CALFED Bay–Delta Program’s Ecosystem Restoration Program Plan (ERPP) is the most detailed program element plan among those that CALFED published. It fills four volumes: Volume I describes ecological attributes of the San Francisco Bay–Delta watershed, and Volume II describes ecological management zone visions. In addition, there is a volume of maps and a strategic plan for ecosystem restoration volume.

Volume I, *Ecological Attributes of the San Francisco Bay–Delta Watershed*, presents the visions for ecological processes and functions, fish and wildlife habitats, species, and stressors that impair the health of the processes, habitats, and species. The visions presented in this volume are the foundation of the ERP and display how the many ecosystem elements relate to one another and establish a basis for actions, which are presented in Volume II, *Ecological Management Zone Visions*.

Ecological Management Zone Visions presents the visions for the 14 ecological management zones identified by CALFED and subdivisions of these zones called ecological management units. Each individual ecological management zone vision contains a brief description of the management zone and units, important ecological functions associated with the zone, important habitats, species that use the habitats, and stressors that impair the functioning or use of the processes and habitats. Volume II also contains strategic objectives, targets, programmatic actions, and conservation mea-

Table 14.2 CALFED Bay–Delta Ecosystem Restoration Program Goals

-
1. Achieve recovery of at-risk native species dependent on the delta and Suisun Bay as the first step toward establishing large, self-sustaining populations of these species; support similar recovery of at-risk native species in the Bay–Delta estuary and the watershed above the estuary; and minimize the need for future endangered species listings by reversing downward population trends of native species that are not listed.
 2. Rehabilitate natural processes in the Bay–Delta estuary and its watershed to fully support, with minimal ongoing human intervention, natural aquatic and associated terrestrial biotic communities and habitats in ways that favor native members of those communities.
 3. Maintain and/or enhance populations of selected species for sustainable commercial and recreational harvest, consistent with the other ERP strategic goals.
 4. Protect and/or restore functional habitat types in the Bay–Delta estuary and its watershed for ecological and public values such as supporting species and biotic communities, ecological processes, recreation, scientific research, and aesthetics.
 5. Prevent the establishment of additional nonnative invasive species and reduce the negative ecological and economic impacts of established nonnative species in the Bay–Delta estuary and its watershed.
 6. Improve and/or maintain water and sediment quality conditions that fully support healthy and diverse aquatic ecosystems in the Bay–Delta estuary and watershed; and eliminate, to the extent possible, toxic impacts to aquatic organisms, wildlife, and people.
-

tures that describe the ERP approach. Rationales are also contained in Volume II, which clarify, justify, or support the targets and programmatic actions.

The Strategic Plan for Ecosystem Restoration was not originally envisioned to be part of the ERPP. In 1997, CALFED convened a panel of independent scientists to review an early draft of the three other volumes of the ERPP. A key criticism by the panel was that the 1997 version of the ERPP was a menu of options without a clear strategy for implementation. The panel provided specific recommendations for preparing a concise strategy document. The resulting strategic plan was a collaborative effort of independent scientists and agency staff. It defines an ecosystem-based approach that is comprehensive, flexible, and iterative, designed to respond to changes in the complex Bay–Delta system and changes in the understanding of how this system works. The strategic plan establishes adaptive management as the primary tool for achieving restoration objectives, describes opportunities and constraints to be considered, presents broad goals and more specific objectives, and presents a stepwise procedure for selecting actions to be implemented. The strategic plan also describes how conceptual models should be used in developing restoration programs and defining information needs. Table 14.2 lists the six goals of the Ecosystem Restoration Program as presented in the strategic plan.

Throughout the planning phases of the CALFED Program, every effort was made to keep the program as balanced as possible with respect to all the major interest groups. Urban, agricultural, and environmental interests were consulted regularly and were represented on advisory councils. As mentioned above, the CALFED charge was to address four interrelated problem areas. The package of actions that was eventually developed reflected this careful topical balance. There were actions to protect and improve water quality, increase water supply reliability, maintain and improve levee system integrity, and pursue ecosystem restoration. The goal was to develop a comprehensive solution that offered benefits for all interests, and the CALFED planning documents met this goal.

Early Implementation

Despite this careful balancing, there was from the beginning a recognition that CALFED was spawned out of crisis surrounding the protection of endangered species in the Bay–Delta. This recognition led to consensus on implementation of some ecosystem restoration actions even before the CALFED plan was complete. Local and regional water agencies were some of the strongest supporters of early implementation of ecosystem restoration actions and even funded many of these actions. A bond act passed by California voters in 1996 provided additional funds for this early ecosystem

restoration effort. By the time CALFED completed its program plan and environmental documents in 2000, the program had already spent or committed \$254 million to fund 240 restoration projects.

The approach to implementation of ecosystem restoration actions that CALFED developed at that time, and continues to follow today, is remarkable for its open and inclusive nature. Rather than following the old model of tasking state or federal agencies with the job of planning and carrying out restoration actions, CALFED awards grants through an annual proposal solicitation process, or PSP, that is open to virtually anyone with an appropriate project. Successful project proponents have included grassroots citizen groups, environmental groups, local agencies, educational institutions, as well as state and federal agencies. Restoration priorities are adjusted from year to year but generally follow the ERPP. The competitive selection process includes peer review for scientific and technical merit. Funded projects are diverse, including control of invasive species, promotion of wildlife-friendly agriculture, physical habitat restoration, environmental education, and water quality improvement.

These restoration projects are not limited to the estuary but are located throughout the watershed of the Bay-Delta system. One example of restoration opportunities far up in the watershed is at Battle Creek, a Sierran tributary of the Sacramento River where CALFED has funded the removal or modification of barriers to fish passage. Battle Creek is a cold, spring-fed stream with exceptionally high flows during the summer dry season, making it the only Sacramento River tributary that is highly resistant to drought. It offers productive habitat similar to that which was lost to the system upon the completion of Shasta Dam, the centerpiece of the CVP. Battle Creek apparently once supported all four races of chinook salmon (*Oncorhynchus tshawytscha*) as well as steelhead (*O. mykiss*). At present, the main population of endangered winter-run chinook salmon spawns in the Sacramento River. During droughts, winter-run chinook suffer severe mortality from high water temperatures. Restoration of Battle Creek will provide an alternative spawning area for this race of chinook. The Battle Creek project will remove five dams and place fish ladders at others. Diversions will be screened and flows improved. These actions will result in improved water quality and access to 71 km of historical anadromous fish habitat (CALFED Bay-Delta Program, 1999).

IMPLEMENTATION CHALLENGES

By 2001, CALFED was poised to implement its plan. The years of careful planning, the unprecedented level of involvement by a spectrum of interest groups, the painstaking balancing to ensure that every interest group gained something from the program, and the collaboration among more than 20 state and federal agencies were all designed to produce an implementable program. The beginning of CALFED implementation has been marked by several challenges. For the most part, these challenges are being successfully overcome. Most of the agencies and organizations involved with CALFED are eager to see the collaborative CALFED approach succeed and want to avoid the controversy and policy stalemate that has marked California water policy development for at least a generation.

The strategy of providing something for everyone so that everyone would support the program was not completely successful. Individuals and groups that had not been directly involved in formulation of the plan questioned the level of balance in the final compromise. Some interests that had been deeply involved decided that they might improve their position through the courts, and several lawsuits were filed against CALFED and its member agencies. Remarkably, the suits were all filed by water interests and agricultural interests. The environmental community, long accused of using the courts to pursue its agenda, filed no suits against CALFED. While the lawsuits slowly work their way through the judicial system, CALFED continues to implement its plan.

What other challenges can be anticipated as the ambitious CALFED ecosystem restoration program is implemented? There will likely be some unanticipated difficulties, but some challenges

can already be foreseen. These include difficulties related to implementing new and innovative programs, maintaining a balanced program, adhering to an implementation program rooted in adaptive management, and coping with drastic change in the natural system.

Challenges of New and Innovative Programs

One of the major sources of conflict in the Bay–Delta system prior to CALFED was protection of listed species, particularly delta native fishes, and the impact of this protection on water supply reliability and the ability to export water from the Bay–Delta. The most useful tool available to regulatory agencies had been curtailment of the export of delta water supplies to farms and cities to the south, and these curtailments had a huge economic impact on water customers that received water supplies from the Bay–Delta. Water managers sometimes viewed regulatory water curtailments as being made without any regard for the economic impacts these reductions in water deliveries might have.

CALFED devised an innovative mechanism to maintain protection for aquatic species while ensuring that regulatory agencies would share the perspectives of water managers. This mechanism is called the *Environmental Water Account* (EWA). The EWA is based on the concept that flexible management of water will achieve fishery and ecosystem benefits more efficiently and to a greater degree than a completely prescriptive regulatory approach. The EWA provides assets of water, water storage capacity, money, and rights to use facilities of the CVP and SWP. Three regulatory agencies, the U.S. Fish and Wildlife Service, the National Marine Fisheries Service, and the California Department of Fish and Game, manage the EWA. When they call for a curtailment in water exports to protect fish, they compensate water customers for the loss of that water by providing alternative water supplies from the EWA.

During development of the EWA concept, a number of simulations were conducted to better understand how an EWA might have been operated in real time if it had existed during the 1981 through 1994 water years. This period included a variable hydrologic sequence of wet years and dry years to test the EWA. In each simulation, the EWA had access to a different collection of facilities, contracts, water rights, and income. Based on these simulations, the CALFED agencies agreed to test the EWA concept for 4 years. The EWA would be authorized to acquire, bank, transfer, and borrow water and arrange for its conveyance. Each year, water “deposits” would be made to the account through several complex mechanisms and formulae, totaling roughly 468 million m³ per year. Operations of the EWA were agreed to in a document of operating principles signed by the involved CALFED agencies and published as part of the CALFED Record of Decision in August 2000.

The agencies acknowledged that the EWA alone would not be sufficient to provide the water needs of species in the Bay–Delta. They envisioned three tiers of environmental water. Tier 1 is the regulatory baseline of water protections, including existing regulation and operating flexibility. Tier 2 is the EWA. Finally, Tier 3 would provide additional water only when necessary; and the CALFED agencies committed to making that water available should it be needed so that there would be no additional uncompensated loss of water by customers south of the Delta who received their supplies from the CVP and SWP.

The EWA represents an entirely new way of protecting listed species in the Bay–Delta, so it is an unfamiliar tool to all that are using it. During the simulations conducted during EWA development, there was recognition that the simulations did not and could not reflect all the variations that EWA management could encounter. The government planners devised a mechanism (Tier 3) to provide protection should EWA assets prove insufficient; but it was clear that finding the funding to acquire any needed Tier 3 water would be challenging, and reliance on Tier 3 would erode the compromise that was reflected in the innovative EWA.

By March 2001 the EWA was in operation and facing its first difficult period. A situation occurred that EWA planners had never anticipated. The outmigrating smolts of a protected species, the endangered winter-run race of chinook salmon, began showing up in fish salvage facilities in the south delta, near the giant export pumps, at unprecedented levels (Greene, 2001). To protect

them, EWA managers ordered the curtailment of project pumping and expended EWA assets at a rate that far exceeded expected use of the account. Still, EWA managers allowed some pumping so that they could save some EWA assets to protect other native fish such as delta smelt (*Hypomesus transpacificus*) later in the year. The result was a take of more than 19,000 winter-run salmon at the SWP pumps. The future for the EWA looked perilous. Only 3 months into its existence, with its water supplies already drawn down more than anticipated and most of the first year still ahead, the EWA faced the possibility of running out of assets within its first year.

Fortunately, the EWA was able to end the water year with a slight surplus of its water assets. The surprisingly large take of winter-run salmon fostered constructive discussion among biologists and regulators over the relative merits of various population estimation techniques. Finally, an independent scientific assessment of the EWA found several positive aspects of the EWA in its first year of operation (EWA Review Panel, 2001).

Maintaining a Balanced Program

Another challenge for CALFED will be maintaining a balanced program. Although painstaking CALFED efforts to achieve balance did not produce unanimous initial support, the program did attract an impressive level of support considering the contentious history of California water policy development. The support of various interests can be expected to wax or wane according to how well the program lives up to their expectations. For example, the CALFED program includes the commitment to pursue several new or expanded reservoirs. Any such effort is fraught with challenges — technical, financial, environmental, and regulatory. At the insistence of political leaders, CALFED committed to extremely ambitious work schedules. It is highly likely that planning, permitting, or construction of some of these projects will fall behind schedule.

To guard against unequal implementation, CALFED committed to annual progress reviews by the governor of California and the secretary of interior. If the schedules are not substantially adhered to, the governor and secretary will prepare a revised schedule that ensures achievement of balanced solutions in all program areas. In other words, when the reservoir projects bog down, CALFED could delay work in other areas such as ecosystem restoration. At that point, advocates of ecosystem restoration might be expected to argue that a restored ecosystem takes years or decades to become fully functional, so the ecosystem restoration program is really years behind construction projects. Unless various interest groups are patient and flexible, political leaders will then face a new conflict that could prove difficult to resolve to the satisfaction of all interests.

Implementing Adaptive Management

Additional seeds of conflict are sown in the CALFED program. A prominent feature of the CALFED program is a dedication to *adaptive management*. The ERPP includes a scholarly discussion of the topic, and the term has been used often by staff of CALFED and its agency members as they describe the way the program will be carried out. It is not clear that the parties involved have considered all the possibilities that might be presented if the program adheres to a policy of adaptive management. Continued research into the structure and function of the complex estuary and the reasons for the decline of many of its native species may lead to conclusions that are difficult for some interests to accept. If any interests are later asked to give up more and get less than they did in the original carefully crafted program, support for the program is likely to erode, and the level of conflict is likely to rise.

Coping with Unanticipated Change

Finally, the CALFED program may not be resilient to unanticipated changes in the Bay–Delta system if the type or degree of change is outside the scope of existing planning efforts. Existing

data suggest at least two scenarios that could occur, and either one would sharply increase the level of conflict among those with an interest in the Bay–Delta system. These two scenarios are global warming with a concomitant sea level rise and prolonged drought.

Exploration of sea level rise and its effect on the CALFED effort will illustrate the challenge. CALFED documents mention global warming and related sea level rise as an example of the type of situation that could be approached through adaptive management. However, it is likely that the consequences of sea level rise on the economy and environment of the Bay–Delta would overwhelm the collaborative decision-making process that CALFED has crafted. Land subsidence resulting from draining and cultivation of delta peat soils has left much of the delta below sea level. Even today, the coincidence of high flows, high tides, and wind often causes one or more delta levees to fail and the protected islands to flood. A gradual rise in sea level would result in calls for greater spending to maintain and strengthen levees, and this could tip the careful CALFED balance. A rise in sea level might also cause greater saline intrusion up into the channels of the estuary, resulting in higher salinities at the CVP and SWP intakes. There would be a call for a new channel to bring fresh water to the intakes from further upstream where salinity is lower. CALFED rejected this alternative in 2000 when it selected through delta conveyance as a component of the preferred alternative. It is not clear whether CALFED agencies and interest groups would readily accept such a fundamental change in the program, regardless of the technical or biological merits.

In conclusion, the development, adoption, and initial implementation of the CALFED program have been major accomplishments. The level of collaboration among federal, state, and local agencies, public interest groups, and other interested parties has been unprecedented in California water policy development. The well-funded CALFED Ecosystem Restoration Program, guided by science and adaptive management, is a great advance over project-by-project mitigation for environmental impacts. The CALFED future will undoubtedly be a perilous one. The program has its detractors now, and the situation will likely become even more difficult and contentious in the future. But CALFED was formed because conflict had made it impossible for any Bay–Delta interests to achieve their objectives, whether these objectives related to the recovery of endangered species or the delivery of a reliable water supply. The new way of collaboration and comprehensive problem solving is difficult, but the old way had become impossible. Ultimately, the success of CALFED and its ambitious ecosystem restoration program may depend on the ability of Californians to remember this history lesson.

Understanding the Politics of Ecological Regulation: Appropriate Use of the Concept of Ecosystem Health

John Freemuth

Unless the scientist reads outside her or his field, or takes a sociology class and learns how Kuhnian paradigms as “cultural baggage” lead humans by the nose in all they think and do, one can go through life ignorantly believing that science is detached, objective, factual, unmythic, and withal goal-setting.

Michael Barbour, 1995

Where there is certain knowledge, true science or absolute right, there is no conflict that cannot be resolved by reference to the unity of truth, and thus there is no necessity for politics.

Benjamin Barber, 1994

INTRODUCTION: ECOSYSTEM HEALTH AS POLITICAL ARGUMENT

This chapter works from a premise about our discussions of environmental management. Those who support ecosystem health as a useful way to understand the management of the natural (and to some extent the human) world are making a political argument about the use of a very powerful and appealing idea. Ecosystem health has the same emotional and intuitive appeal as words like justice, equality, and freedom.

Proponents of ecosystem health value certain things at the expense of other things. They are making claims about decision processes and who ought to make decisions. As noted by political scientist Deborah Stone, “Every idea about policy draws boundaries. It tells what or who is included or excluded in a category. These boundaries are more than intellectual — they define people in or out of a conflict or place them on different sides” (Stone, 1997).

SETTING THE STAGE

Two examples from *Ecosystem Health* (Rapport et al., 1998) illustrate this introductory point. In the first we read that society should ensure that “ecosystem health is not further compromised by human activity.” Note how a boundary is drawn here: certain human activities compromise ecosystem health, so they should probably not be allowed. My activity is acceptable, yours is not.

This act of drawing boundaries, of giving to and taking from, puts ecosystem health squarely into the middle of political talk and discussion. Someone has to draw and enforce those boundaries.

In the second example, again from *Ecosystem Health*, we learn that:

[I]ndividual values generally prevail on local scales, community values prevail on regional scales, and societal values dominate on still larger scales. Ecosystems and landscapes are regional in extent and generally involve time frames that span more than one generation. Thus, the community, which has a longer time horizon than the individual, represents the best “match” in terms of relating values to ecosystem outcomes (Rapport et al., 1998).

This is political theory, not scientific fact. It asks the reader to accept the claim that the community (which remains undefined) rather than the nation (the state? the city?) is where we should apply the ecosystem health paradigm. It also unconsciously follows a tradition that has been going on in political theory for a very long time. James Madison once argued that large republics were better than small republics. In *Federalist 10* he said: “Extend the sphere and you take in a greater variety of parties and interests; you make it less probable that a majority of the whole will have a common motive to invade the rights of other citizens” (Rossiter, 1961). Arguments about the proper size of a community, which makes decisions that allocate values, are thus political arguments, not scientific ones.

THE PROBLEM OF POLITICS: ECOSYSTEM HEALTH AND POLITICAL POWER

Those who advocate for ecosystem health need to be fully aware of how our current institutional arrangements affect the success of implementing ecosystem health as a management paradigm. Note, though, that these arrangements are based on assumptions that lead to structuring of political power relationships in a certain way. Ecosystem health proponents do this as well, as will be discussed later.

There is no better voice here than that of James Madison, who explains one of the key assumptions of the authors of the Constitution this way in *Federalist 51*:

Ambition must be made to counteract ambition If men were angels no government would be necessary. If angels were to govern men, neither external nor internal controls on government would be necessary. In framing a government of men over men, the great difficulty lies in this: you must first enable the government to control the governed and in the next place, oblige it to control itself. A dependence on the people is, no doubt, the primary control on the government but experience has taught mankind the necessity of auxiliary precautions (Rossiter, 1961).

The precautions, of course, are the commonly understood checks and balances, separation of powers, federalism, and republicanism. Power is diffused in the U.S. political system. Policy change is often difficult to achieve.

Madison also remarks in *Federalist 10* that one of the most important reasons for checking power is the existence of factions (today’s interest groups): “a majority or minority of the whole who are united and actuated by some common impulse of passion, or of interest, adverse to the rights of other citizens, or to the permanent and aggregate interests of the community”; hence the need to check Madison’s “mischief of faction” by representative government, larger political units, and so forth.

Putting all of the above in more modern terms, there is thus a designed tendency of the political system to gridlock and for policy shifts to happen rarely. But we do know that there are examples where the political system overcame the tendency for political gridlock. One example of particular interest to proponents of ecosystem health is the development of certain policies during the progressive era at the turn of the last century. Scholars and practitioners

interested in the implementation of an ecosystem health-based management regime would do well to revisit the early days of the progressive movement for clues as to how to develop and implement a management regime accepted by an entire society.

This era was the time of Gifford Pinchot, Teddy Roosevelt, and the birth of the conservation movement. The progressive era, of course, institutionalized science-based, expert-centered management as a general approach to the growing complexity of society at the time. For example, the federal bureau that best represented the progressive era in land management was the United States Forest Service. Samuel Hays, in his seminal work *Conservation and the Gospel of Efficiency*, noted that:

Conservationists were led by people who promoted the “rational” use of resources, with a focus on efficiency, planning for future use, and the application of expertise to broad national problems. But they also promoted a system of decision making consistent with that spirit, a process by which the expert would decide in terms of the most efficient dovetailing of all competing resource users according to criteria which were considered to be objective, rational, and above the give-and-take of political conflict (Hays, 1975).

In the case of the Forest Service, the expertise brought to bear on forest management questions came from the science of forestry.

What is most important about that earlier movement, however, may well be how its themes captured the public imagination. Gifford Pinchot discovered that “in the long run, forestry cannot succeed unless the people who live in and near the forest are for it and not against it” (Pinchot, 1947). Pinchot helped lead the effort for professional management of the national forests. But the key to Pinchot’s success lay not solely in his advocacy of professionalism and expertise but also in the service of both to a democratic vision.

In the words of Bob Pepperman Taylor, “For Pinchot the conservation of natural resources is of fundamental democratic value because it allows for the possibility of equality of opportunity (access to public resources) for all citizens” (Taylor, 1992). Taylor adds, “If we remove the vision of Progressive democracy from Pinchot’s work, we are left merely with the scientific management and control of nature for no other purpose than brute human survival.”

It is also true that later foresters “became progressively more narrow in outlook as a result of the kind of specialized education they [Pinchot] encouraged” (Clary, 1986). The vision may have become less successful over time because it lost its ability to speak in nonspecialized terms. The point to remember, though, is that early public land management was successful because of its link to a democratic vision accepted by the majority of society at the time, representing an underlying consensus about how a large amount, but not all, of the federal estate should be managed. The estate should be managed wisely for an ongoing supply of goods and services for the industrial society. It is clear that progressive-era public land management was centered as much on this vision of society as it was on a technical expert-centered land management regime. This, then, is part of the roadmap for proponents of ecosystem health. They should make clear how ecosystem health offers a vision for society that might link up democratic institutions and processes with economic and environmental equality. But one other component needs discussion.

THE PROBLEM OF SCIENCE AND HIDDEN VALUES

Perhaps it would be good to begin this part of the discussion with a brief look at the development of ecosystem management as a relevant case study. There appear to be two general approaches to how ecosystem management was originally conceived: the expert-centered and technically rational, and the democratic. The first approach is illustrated in one definition of the term: “Ecosystem management integrates scientific knowledge of ecological relationships within a complex sociopo-

litical and values framework toward the general goal of protecting native ecosystem integrity over the long term” (Grumbine, 1994).

This definition appears technically rational and expert-centered for several reasons. One, it seems to imply some sort of expert ecosystem manager who will integrate an established knowledge base to achieve a goal that apparently has already been defined and agreed upon. Such a stance is very similar to the expert-centered decision-making model first developed in the progressive era, without the accompanying underlying consensus that ecosystem management is acceptable to society, if its goal is protecting native ecosystem integrity.

Two, this approach appears to view the people who live within various ecosystems as another component to be managed. These people are to be studied, surveyed, and so on by the same managers who will then take whatever knowledge is discovered and include it as social data in an ecosystem management framework. There does not appear to be much need for a discourse to be established with local people who might happen to live in a defined ecosystem. Nor, even more fundamentally, do these definitions consider that the local communities may wish to, or currently do, disapprove of ecosystem management as they understand it. The people should be for it and not against it, to paraphrase Pinchot.

There are, however, other definitions and ways to look at ecosystem management that clearly take a more democratic approach. Robert Lackey moves in this direction when he asserts that, “Ecosystem management should maintain ecosystems in the appropriate condition to achieve desired social benefits; the desired social benefits are defined by society, not scientists” (Lackey, 1994). Lackey’s point can be better understood if we consider his view on biodiversity, often mentioned as a key component of ecosystem management. He asserts: “Ecosystem management may or may not result in emphasis on biological diversity as a social benefit.” Finally, Hal Salwasser has observed that “ecosystem management is about people. Other views of ecosystem management have placed goals for nonhuman biological and physical attributes of ecosystems ahead of goals for human attributes” (Salwasser, 1994).

My point in contrasting these various definitions of ecosystem management is to illustrate a fundamental difference in the approach and assumptions of the definitions. That difference centers on whether ecosystem management is a technical process best left to experts who will manage any public component of the process of implementation, or more of a democratic process requiring the development of a new and democratically derived consensus position. It has been my contention that, for ecosystem management to succeed, it must center on that democratic process.

Proponents of ecosystem health are faced with a similar choice. If they adopt the highly rationalized and democratically passive management alternative suggested above, they risk failure, as they have provided no way to show that there is any public acceptance of their new management paradigm. That then runs the risk of appearing to dismiss and disdain the opinions and values of citizens.

A second and closely related component to this analysis is the growing use of what might be termed *advocacy science*. Advocacy science can take two closely related forms. The first clearly mixes up values and science, where what are clear values preferences end up masked as scientific truths. The second works by adopting a certain value preference as a policy goal (logging is harmful or logging is beneficial) and then finding the science that demands a conclusion that turns out to be the prechosen goal (logging harms biodiversity, so we must stop logging; or forests are unhealthy, so we should selectively cut them).

Consider one example from one side of the grazing debate. In the December 1994 issue of *Conservation Biology*, a fascinating editorial was written about the role of conservation biology in range management questions. The opinion piece takes issue with the answer to a question asked and answered by Reed Noss: whether conservation biologists should “link arms with activists in efforts to reform grazing practices” (Brussard et al., 1994). The authors conclude that they should not. Worried that conservation biologists would damage their credibility by openly advocating political positions, the authors instead suggest asking a different question. That question is, “how can livestock grazing be managed to have the fewest impacts on biodiversity and ecosystem

integrity?” The authors claim that a special symposium on grazing, which precipitated their editorial, offered no help on this question.

In a powerful conclusion to their editorial they express concerns about:

... the inherent flaw of deductive reasoning which asks one simply to accept “that range management must be dramatically reformed” ... how can we hope to advance the Society’s mission to preserve biological diversity if our audience of policymakers assumes that we intend to “prove” a presumed conclusion (Brussard et al., 1994).

Lackey also does a good job with his discussion of the values vs. science problem. Writing about the increasingly contentious issue of salmon recovery in the Pacific Northwest, he urges:

... those of us who are technocrats, scientists, biological resource managers, or scientific advisors should remain humble in our dealings with the public and elected officials and overcome the tendency to advocate political choices driven by strong personal interest and packaged under the guise of a scientific imperative (Lackey, 1997).

The success of ecosystem health as the leading paradigm for environmental management will depend on its integration with forms of democratic discussion and deliberation. As noted in *Ecosystem Health*, success will depend on whether society adopts ecosystem health as an important goal and supports the allocation of resources toward achieving that goal. A good distance remains to be traveled, however. In that same book is the assertion that ecosystem health “challenges us to identify the societal goals that are compatible with sustainable life systems, to identify and validate indicators of ecosystem function that are essential to its evolution and perpetuation, and to merge goals (societal values) with biophysical realities.” This statement is potentially unnerving. It suggests, certainly, a cadre of elites setting goals for society. It is exactly the sort of science –values confusion that Lackey and others caution against. Science cannot set goals for society, but it can inform those goals. As Gregg Cawley and I have noted:

Indeed, science strives to construct a picture of the physical world based on empirical observation. A management regime, in contrast, must remain continually attentive to the impact human values and interests have on allocating meanings to scientific observations. A rather simple example might help make this point.

Scientific observation remains more or less content with the conclusion that a sixteen-ounce container has eight ounces of fluid in it. From a management perspective, however, the crucial question may very well be whether the container is “half-full” or “half-empty.” It is this question which determines the appropriate course of action — whether or not more fluid is needed, as it were. The problem, of course, is that “half-full/half-empty” are value judgments derived from the interests of people. As such, they are open to negotiation at any given moment, and over time, unless we assume that values and interests remain constant. Scientists and managers, who center decisions solely on science, do not have any *special* position in negotiations over value questions (Cawley and Freemuth, 1993).

There is a recent indication that some of Lackey’s advice has begun to be heeded. At a recent meeting of the Idaho chapter of the American Fisheries Society, a vote was taken as to the opinion of the membership regarding the best option for salmon recovery. Some 90% of those in attendance voted that dam breaching had the best option of restoring salmon runs, but the vote was couched in the language of probability, not certainty. More importantly, according to chapter president-elect Ted Koch, “The chapter does not advocate dam breaching. It’s up to our elected political leaders to make the hard choice for the region” (Barker, 1999).

This action appears to be close to what is emerging as the proper role for science in difficult public policy debates according to many observers: informing policy debate, not making policy

decisions. Again, as Lackey and others argue, “The complete implications of each alternative policy choice should be fully and clearly explained, including the short- and long-term consequences, and especially the level of scientific uncertainty” (Lackey, 1997).

Salmon recovery is a complex issue, but it pales alongside the wholesale adoption of management paradigms for the entire society. It may well be that ecosystem health is an inappropriate paradigm to follow. Some have made that case; others disagree with that assessment. That debate will continue. What this chapter has tried to do is suggest that the strategies and arguments that are employed by ecosystem health advocates are as much about politics and policy as they are about science. They are in large part about the society we ought to envision for ourselves.

ACKNOWLEDGMENTS

The author wishes to thank the two reviewers of an earlier version of this chapter, as well as Gregg Cawley of the Department of Political Science of the University of Wyoming, for their helpful comments.

Attitudes and Their Influence on Nature Valuation and Management in Relation to Sustainable Development

Hans A.M. de Kruijf, Ekko C. van Ierland, C. Martijn van der Heide, and Jos N.M. Dekker

DILEMMAS OF VALUATION AND BIODIVERSITY MANAGEMENT

In this chapter the concept of biodiversity is viewed as analogous to the Convention on Biological Diversity: “Biodiversity is the variability among living organisms from all sources, including *inter alia*, terrestrial, marine and other aquatic ecosystems, and the ecological complexes of which these are a part: this includes diversity within species, between species and of ecosystems” (UNCED, 1992).

It is widely recognized that biodiversity is threatened and that extinction of several species occurs or may occur in the near future. Increasing population pressure and per capita income will have tremendous impact on ecosystems and the species that inhabit it (Heywood and Baste, 1995). Pressures on biodiversity are described in more detail in an OECD report (1996) and summarized in Table 16.1.

In protecting biodiversity, many policy decisions have to be made on how to protect biodiversity: creating reserves; protecting natural ecosystems by direct regulation; reducing pollution that is affecting ecosystems; constructing corridors between ecosystems; or other policy measures (Table 16.2). But first, when dealing with biodiversity, policy makers should make choices about what to protect or sacrifice, where to protect, and how to finance the protection of biodiversity (Table 16.3). Although valuations are not always directly expressed in monetary terms, in practically all cases, implicit value assessments are made in the decisions to protect or sacrifice ecosystems and manage nature.

Answering these questions involves value judgments about biodiversity and nature. Different nations have different value systems and different attitudes toward the protection of biodiversity (Furze et al., 1996; Perrings, 1995).

It would be helpful if a common framework of analysis could be developed to understand and analyze the problems of biodiversity valuation (Bateman, 1993). There are many indications that economic valuation methods are important in making explicit the values that play a role in protection of biodiversity.

Many politicians and economists agree that some of these valuation methods assist in decision making about biodiversity protection. Certainly not all valuation questions related to biodiversity can be solved by monetary valuation methods. Ethical and religious aspects are important in considering the nature of the values; the “public” good character of environmental amenities may not be automatically compatible with value judgments based on private and individual value assessments (Furze et al., 1996).

Table 16.1 Human Actions and Biodiversity

	Cause	Comment
I. Proximate Pressures		
a. Land conversion	Development for agriculture	Losses of ecosystems
b. Exploitation wild species	Over-exploitation, exceeding regenerative capacity	Ecosystem instability
c. Introducing exotic species	Changing ecosystem structures	Loss of endemic species
d. Homogenization	Competing in global agricultural markets by specialization for higher productivity	Relatively few plants account for the world's food production; serious implications for food security
e. Pollution	Pollutants from different sources	Reduce and eliminate populations of sensitive species
f. Global environmental change	Global warming, caused by greenhouse gases	Large-scale extinctions have occurred in the past; further losses in biological diversity may be expected
II. Underlying Pressures		
a. Consumption and production	Increasing and unsustainable consumption of energy and natural resources	Increased impact on resources and habitat conversion and degradation
b. Patterns of population growth and distribution	Greater need for agriculture and industrial produce	Impacts on level of biological diversity
c. Economic failure	Uncontrollable use of natural resources, conversion of land	Loss of precious habitats, valuable species

Table 16.3 Options for Protecting Biodiversity

I. At the National Levels	II. At the International level
1. Reduction of pollution	1. Reduction of pollution
2. Reduction of physical impacts	2. International treaties for protection
3. Creation of wildlife parks	3. Debt-for-nature swaps
4. Protection of habitats	4. Global environmental facility
5. Creation of ecological main structures	5. Joint implementation programs
6. Reduction of population pressure	

Data from Keating, 1993; Swanson, 1995; McNeely et al., 1995; Barbault and Sastrapradja, 1995; Turner et al., 1994; Barbier and Rauscher, 1995.

If monetary valuation methods cannot provide a full solution to dealing with biodiversity, which other methods for policy analysis are available and can be applied that take into account monetary and nonmonetary values?

This chapter analyzes basic attitudes toward biodiversity in countries and how policymakers and stakeholders with different attitudes cope with decision making about biodiversity.

ATTITUDES AND DETERMINANTS

Attitudes

Attitudes toward biodiversity are value-loaded perspectives on possible behavior with regard to biodiversity. Valuations of biodiversity are embedded in these attitudes, which connect values to possible actions, and vice versa. Attitudes are steering elements for strategies and policies.

Opinions and attitudes on biodiversity differ among people, countries, religions, political parties, and societies. People have different — even opposite — attitudes, which creates ambivalence. Moreover, attitudes can change in time. The relationship of determinants and attitudes to valuation methods and policy making is illustrated in Figure 16.1. Finally, valuation methods and policy making are needed to assess biodiversity.

Classification of attitudes toward biodiversity assists understanding attitudes and thus encourages communication about strategies and policies for the management of biodiversity. However, classifying can also restrict and close such communication. There are many different classifications; most are one dimensional with man on one side, nature on the other, and mixed attitudes in between. Then one can conceive attitudes with dominating man and rich nature, or powerless man and poor

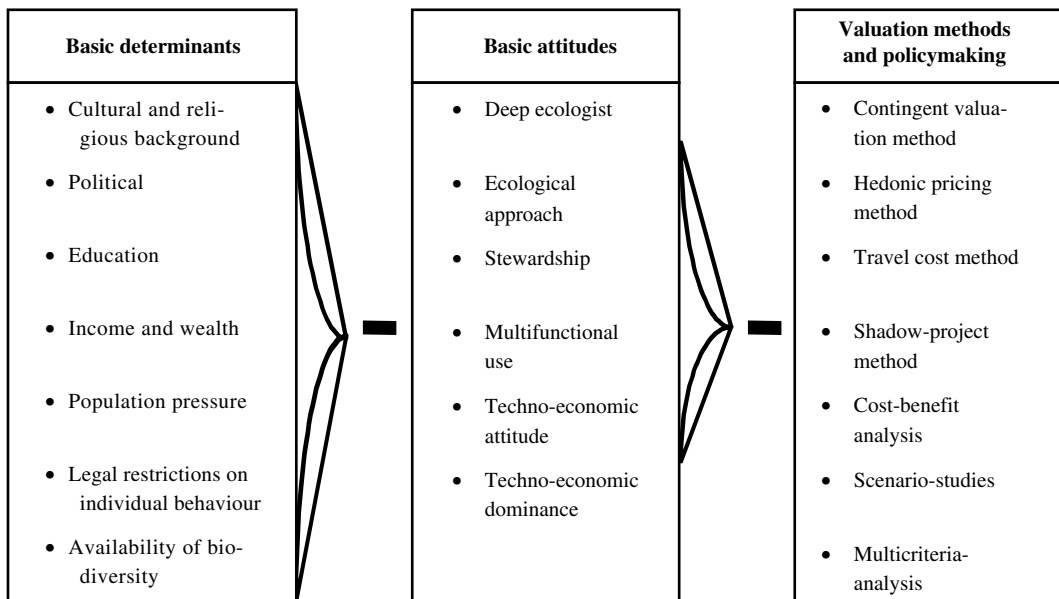

Figure 16.1 Relationship of determinants and attitudes to valuation methods and policy making. Attitudes are determined by various basic determinants. These attitudes determine the valuation of biodiversity and policy choices that can be made about biodiversity protection. Deep ecologist and techno-economic dominance are attitudes that reflect an extreme position. For these attitudes, valuation methods are not necessarily required since choices have already been made. (Adapted from Achterberg, W., *Partners in de Natuur (Partners in Nature)*, Van Arkel, Utrecht, the Netherlands, 1986.)

nature. For example, ecological restoration in the U.S. and nature development in the Netherlands are policies based on the supposition that man can produce nature in a systematic way with modern technology. However, not all people will accept this result as nature. In both developing and developed countries, poverty can result in neglecting nature. Some may appreciate this result as an enrichment of nature, while others will see it as marginalization.

The classification of attitudes (Figure 16.1) ranging from the *deep ecologist* attitude to *techno-economic dominance* will be used (adapted from Achterberg, 1986).

Societies, over time and space, can be placed on a continuum between these opposites as human attitudes change due to internal social dynamics and external influences. However, such attitudes greatly influence how humans use natural resources and, therefore, the impacts they have on biodiversity (McNeely et al., 1995).

- The *deep ecologist* gives first priority to biodiversity. Mankind should live in harmony with nature, without interfering in ecological processes through economic activity; this view limits the options for economic activity and potential for traditional economic growth. Biodiversity protection, nature conservation, and pristine landscapes have top priority.
- The *ecological approach* is also focused on biodiversity, nature conservation, and priority for ecosystems. Some impacts on the environment and the ecological system are necessary for mankind to survive and are accepted; discussion is ongoing to define the economic minimum standards and identify acceptable impacts on biodiversity and ecosystems.
- *Stewardship* can be characterized as the attitude which accepts that humankind can manipulate nature and ecosystems but that responsibility exists to deal very carefully with ecosystems in order to provide opportunities to next generations. The main question is the extent to which nature and ecosystems can be manipulated and the limits to consider.
- The attitude of *multifunctional use* focuses on the combination of economic activity and conservation of nature and biodiversity. It sacrifices large areas of ecosystems in order to provide space for agriculture, infrastructure, housing, and industrial activities. In doing so it tries to protect some areas and exploit ecosystems without destroying them. The main emphasis is on matching economic activity with protection of biodiversity and nature.
- The *techno-economic attitude* is characterized by confidence in technical solutions and confidence in the resilience and robustness of ecosystems. Economic growth is an important aspect. Sometimes technological devices and technologies are applied to maintain biodiversity artificially, e.g., by constructing dikes or manipulating water tables. In this context ecological engineering is considered a useful tool to combine economic activity and protection of biodiversity.
- *Techno-economic dominance* is characterized by full dominance of the drive for economic growth and technological development and is negligent of nature conservation, biodiversity, or ecosystems protection. Only economic issues matter; the more goods and services produced, the better it is. Techno-economic dominance is highly optimistic about self-regulation of nature and the resilience and robustness of ecosystems.

In the two extreme cases, no policy choices have to be made. *Deep ecologists* have, by definition, chosen for ecosystems protection and biodiversity. Everything is to be protected. At the other extreme, *techno-economic dominance* focuses completely on economic growth, sacrificing what is necessary to obtain these goals. All other attitudes have, in one way or another, the challenging task to decide about what, where, and how to protect, and how to finance protection of ecosystems and biodiversity. Attitudes play an important role in the decision-making process and the preparation of biodiversity policies.

A serious problem of most classifications is that they are not operationalized. Identifying concrete attitudes within the classification categories is difficult. For example, a traditional agricultural method of shifting cultivation may be identified by conservationists as an indicator of a techno-economic dominance because it reduces biodiversity. From a broader perspective, it can be seen as an indicator of multifunctional use, stewardship, or even an ecological approach. Thus, trying to classify this method and the culture clearly generates debate and disagreement.

Basic Determinants

Most losses of biodiversity are due to independent decisions of billions of individual users of environmental resources. Underlying causes of the impacts and the decisions include the objectives that motivate decisions, preferences behind the demand for goods and services, property rights that define individual endowments, relative prices that determine the market opportunities associated with those endowments, and attitudes toward biodiversity (Perrings, 1995). These attitudes are determined by a large variety of characteristics and circumstances of basic determinants as described below.

Cultural and Religious Background

Cultural and biological diversity are intimately and inextricably linked (McNeely et al., 1995). Religion is also closely related to attitudes toward biodiversity. Perrings (1995) and others (Furze et al., 1996) demonstrate that some religions (Islam and Christianity) have gone far in setting humans apart from nature; other cultures with religious traditions such as Buddhism, Jainism, and Hinduism did not go as far.

Political Conviction

To some extent the political persuasion of individuals determines the attitudes toward biodiversity. When policy influences local populations, political decision making can change the attitudes of individuals; for example, where central government agencies have established control over forests previously managed by the community, attitudes changed from the ecological approach to the multifunctional approach (Neba, 1998).

Education

The higher the level of education, the greater the awareness of biodiversity. In industrialized countries a tendency toward techno-economic attitude or techno-economic dominance can be observed. In isolated populations, where individuals have never been in school, people know intuitively how to manage biodiversity in a sustainable way. Nevertheless, proper attention to biodiversity issues in education is an important element in developing support for policies to protect biodiversity.

Income and Wealth

Income and wealth are important determinants of basic attitudes. Poverty sets priorities on economic development and exploitation of natural resources.

Population Pressure

In extreme population densities, insufficient opportunities exist to maintain biodiversity. Population pressure tends to set priorities on economic development, exploitation, and conversion of national or rural areas toward agriculture. McNeely et al. (1995) demonstrated that human population density is clearly linked to loss of biodiversity.

Legal Restrictions on Individual Behavior That Prescribe the Range of Admissible Actions

Legal arrangements can be considered an expression of certain attitudes, while at the same time they contribute to the development of attitudes. Societies with an individualistic approach will not be in favor of protective policies. Societies with a more collective attitude may be more inclined to a larger extent toward collective actions for protection.

Valuation Methods

Valuation methods can be used to some extent to establish the benefits of biodiversity protection. The contingent valuation method is an *expressed* preference method; the hedonic pricing method and the travel cost method are referred to as a *revealed* preference method. Another important valuation method, the shadow-project method, can be considered as a *nondemand curve approach*.

The *contingent valuation method* (CVM) approach relies on a direct survey in which respondents are confronted with a hypothetical market situation. Given information on a specific environmental issue (e.g., forest conservation or the presence of certain species in nature), they are asked to make bids. Thus, they reveal their values and indicate their willingness to pay or their willingness to accept. There has been much controversy concerning the philosophy and practice of contingent valuation surveys (Cameron, 1997). Nevertheless, under some conditions it seems to be a helpful method (Bishop et al., 1983; Munasinghe, 1995).

The *hedonic pricing method* (based on the assumption of hedonism as the basis for human behavior) derives a value for some aspects of environmental quality from actual market prices of certain private goods. For example, we can expect real estate prices near a national park to be higher than those in industrial areas. Other things being equal, the difference in housing prices shows the premium paid for the local environment: how the consumer values the availability of nature. Thus, the purchaser's willingness to pay is indicated (Pearce and Markanday, 1987; Hanley, 1992).

The *travel cost method* is one of the earliest methods for valuing recreational functions of the environment. Just like the hedonic pricing method, the travel cost method is based on observed behavior (Clawson and Knetsch, 1966; Knetsch and Davis, 1966; Brown and Mendelsohn, 1984; Howe, 1991). The travel cost method has been particularly useful for assessing recreational values.

The *shadow-project method* is closely linked to the names of Klaassen and Botterweg (1976). The method is based on the view that no further deterioration of natural areas should take place. The shadow-project method determines the price of a natural area by calculating the costs of reproducing such an area at another location or by calculating the costs of an alternative project that avoids the damage.

Finally, valuation of the benefits of biodiversity and nature are far from trivial. The valuation methods can be separated into two basic approaches — those which value biodiversity following a demand curve and those which do not. The former approach consists of two kinds of methods: expressed preference method and revealed preference method.

ANALYSIS

Better understanding of attitudes, values, and biodiversity can only be gained when functions of biodiversity are recognized and valuation methods are appraised.

Functions of Biodiversity

Quality of life (well-being) and human welfare depend directly or indirectly on the availability of environmental goods and services. Early recognition of the functions and the role ecosystems play in maintaining these functions is essential for ensuring the long-term integrity of biodiversity. Four functional categories can be distinguished (Table 16.4; de Groot, 1992).

1. *Regulation*: the capacity of natural and seminatural ecosystems to regulate essential ecological processes and life-support systems that, in turn, contribute to the maintenance of a healthy environment by providing clean air, water, and soil.
2. *Carrier*: natural and seminatural ecosystems provide space and a suitable medium for many human activities, such as habitation, cultivation, and recreation.

Table 16.4 Functions of Natural Environment

Regulation Functions	
1.	Protection against harmful cosmic influences
2.	Regulation of the local and global energy balance
3.	Regulation of the chemical composition of the atmosphere
4.	Regulation of the chemical composition of the oceans
5.	Regulation of the local and global climate (including the hydrological scale)
6.	Regulation of runoff and flood prevention (watershed protection)
7.	Water catchment and groundwater recharge
8.	Prevention of soil erosion and sediment control
9.	Formation of topsoil and maintenance of soil fertility
10.	Fixation of solar energy and biomass production
11.	Storage and recycling of organic matter
12.	Storage and recycling of nutrients
13.	Storage and recycling of human waste
14.	Regulation of biological control mechanisms
15.	Maintenance of migration and nursery habitats
16.	Maintenance of biological (and genetic) diversity
Carrier Functions	
	<i>Providing Space and a Suitable Substrate for:</i>
1.	Human habitation and (indigenous) settlements
2.	Cultivation (crop growing, animal husbandry, aquaculture)
3.	Energy conversion
4.	Recreation and tourism
5.	Nature protection
Production Functions	
1.	Oxygen
2.	Water (for drinking, irrigation, industry, etc.)
3.	Food and nutritious drinks
4.	Genetic resources
5.	Medicinal resources
6.	Raw materials for clothing and household fabrics
7.	Raw materials for building, construction, and industrial use
8.	Biochemicals (other than fuel and medicines)
9.	Fuel and energy
10.	Fodder and fertilizer
11.	Ornamental resources
Information Functions	
1.	Aesthetic information
2.	Spiritual and religious information
3.	Historic information (heritage value)
4.	Cultural and artistic inspiration
5.	Scientific and educational information

Adapted from de Groot, R.S., *Functions of Nature*, Wolters Noordhoff, Groningen, the Netherlands, 1992.

3. *Production*: nature's many resources range from food and raw materials for industrial use to energy resources and genetic material.
4. *Information*: natural ecosystems contribute to the maintenance of mental health by providing opportunities for reflection, spiritual enrichment, cognitive development, and aesthetic experience.

Functions of ecosystems can be mutually exclusive or competitive; one function cannot be fulfilled if another function is dominating (Holling et al., 1995; Mooney et al., 1995). This competition can be qualitative (polluted water reduces the regulation function) or quantitative (habitation requires space that is not available for other purposes).

Also, there are probably many unknown goods and services (functions) with considerable (potential) benefit to human society (De Groot, 1992). Table 16.5 describes 37 separate functions of nature; a complete listing and division of functions may be impossible to produce.

Closely related to the functions of nature are the categories of value distinguished in economics.

Value Categories

The economic taxonomy of the value of biodiversity distinguishes between direct and indirect use values and adds the so-called non-use value (Perrings, 1995). The components of value are illustrated schematically in Figure 16.2. This figure illustrates the use and non-use values provided by a multiattribute environmental asset such as a woodland (Bateman and Turner, 1993). By definition, *use value* refers to the direct value individuals attribute to the services an ecosystem provides, e.g., recreational value or production value relating to hunting, fishing, and collecting plants or fruits. Use value is a measure of willingness to pay for goods and services, backed up by utility and purchasing power (Kadekodi and Ravindranath, 1997). For production value we can usually measure the market price of the goods and services. For values without market prices such as recreational values, we need to use other valuation methods (Clawson and Knetsch, 1966; Douglas and Johnson, 1992).

Option values based on Turner et al. (1994) need further explanation. They are essentially expressions of preference: a willingness to pay for the preservation of environmental systems or components of systems against some probability that the individual will make use of them at a later date. Provided the uncertainty concerning future use relates to uncertainty in the availability or *supply* of the environment, economic theory indicates that this option value is *likely* to be positive (Weisbrod, 1964). A related form of value is *bequest value*, a willingness to pay to preserve the environment for the benefit of one's children and grandchildren. It is not a use value for the current individual value but a potential future use or non-use value for his or her descendants.

Finally, there are *non-use values*. They suggest noninstrumental, anthropocentric values in the real nature of the thing, but not associated with actual use or even the option to use the thing. "Instead such values are taken to be entities that reflect people's preferences, but include concern for, sympathy with and respect for the rights or welfare of non-human beings" (Bateman and Turner, 1993). An example of these non-values is the *existence value* or intrinsic value (Krutilla, 1967; Pearce and Turner, 1990). It refers to the value that the public attributes to the ecosystems just because of their presence, without making direct or indirect use of them. It includes a recognition of the value of the very existence of certain species or whole ecosystems. *Total economic value*, then, is made up of actual use value plus option value plus existence value.

The non-use values of ecosystems are, in general, very difficult to establish. Non-use values typically have a public good character for which no market prices are available.

If biodiversity is important to the functioning of some ecological system, it will not automatically be valuable to society, or vice versa. Economic assessments of biodiversity are also influenced by ethical judgements. They merely make explicit something that is currently implicit. However, there remains a gap between the market price of biodiversity and its value to individuals and societies (Perrings, 1995).

Trade-Offs

Trade-offs are benefits from one decision that are bought at the expense of another. If conserving biodiversity conflicts with economic activity, the question is which view should

Table 16.5 Overview of Characteristics of Attitudes, Valuation, and Nature Management in Six Countries

Country/ Region	Dominant Religious Background	Dominant Attitude	Example of Values	Consequences for Nature Management	Value and Valuation Method
Bali	Balinese culture endowed by the Hindu religion	Humans have use of, not ownership of or dominance over the environment Urban: multifunctional use Rural: ecological approach	Great value on continuity of customary belief and community behavior	Few constraints to fell forests, few protected areas	Bequest and existence value CVM ^a , MCA ^b
Benin	Urban: Christian, Islamic; Rural: animism	Urban: multifunctional use Rural: ecological approach	Holy forests with religious and cultural functions	To be strongly protected, preferably by reinforcement of traditional laws	Option and existence value CVM, MCA
Bhutan	Buddhism	Compassion and respect to all forms of life, a deep ecologist view	Forest Act (1959 and adapted 1997)	Protection of nearly all forests of Bhutan, strong control	Existence and indirect use value CVM, MCA
Cameroon	Urban: Christian Rural: animism	Ecological approach supported by taboos	Conservation of forests in sud-Cameroon	Proposed restrictions for protection of forests in favor of local communities	Existence and indirect use value CVM, MCA
Costa Rica	Christian	Multifunctional approach; stewardship	Originally forests being converted into land for cattle	Laws for protecting remaining forests and other biodiversity assets	Direct use, option and bequest value CVM; travel cost, market prices
The Netherlands	Christian	Diverse, but dominant: stewardship	Wadden Sea, strong clashes on ecological and nature issues by groups with different attitudes, slight movement toward ecological approach	National: results in the development of ecological main structures Local: management of the Wadden Sea	Direct use, existence value; market price, hedonic pricing and CVM

^a CVM: Contingent valuation method.

^b MCA: Multicriteria analysis.

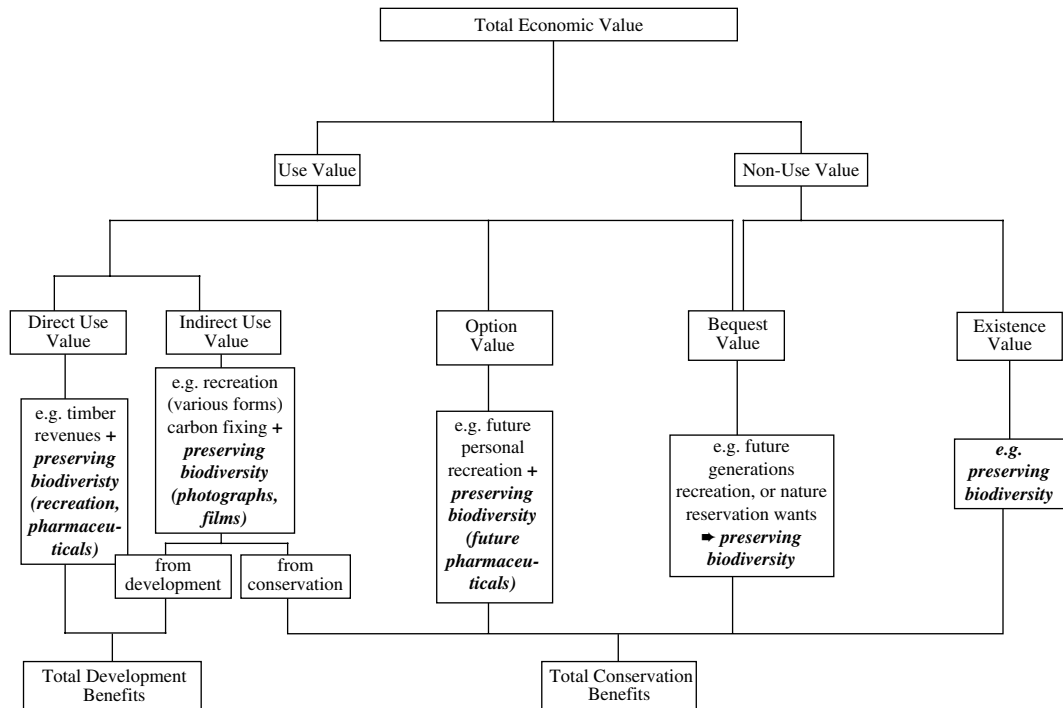

Figure 16.2 The total economic value of biodiversity. (Adapted from Bateman, I.J. and Turner, R.K., *Sustainable Environmental Economics and Management; Principles and Practice*, Belhaven Press, London, 1993, pp. 120–191.)

prevail? Decision making is based on the idea that we do only those things that yield us net gains. In other words, where we have to choose between alternatives, we choose the one that offers the greatest net gain. This is the foundation of the cost–benefit analysis (Turner et al., 1994). If the cost and the benefits of biodiversity protection are known, economic decisions on biodiversity protection can be made.

Local and Global Benefits

The benefits of biodiversity can be separated into local and global benefits. These benefits often have no market; but when they can be estimated, they are often global in nature (Turner et al., 1994). A good example is given by Costanza et al. (1997), who estimated the current economic value of 17 ecosystem services, such as water regulation, soil formation, biological control, genetic resources, cultural assets, etc.

The Costs of Protection and Sharing the Burden

Biodiversity protection implies a cost to society: the opportunities forgone by society by protecting such diversity. Protection of biodiversity also includes direct operating and capital costs. When the benefits of biodiversity protection can be classified as global benefits, it will always be in the interest of any one country to see that all other countries, except itself, pay for such a protection. The global existence value of biodiversity (Figure 16.2) often accrues to rich nations but does not have a cash flow.

Removing Barriers for Protection

One way to encourage protection is for countries possessing biodiversity to appropriate the global benefits they are providing the rest of the world (Turner et al., 1994). Further, mental barriers can be removed by changing the basic attitudes on biodiversity.

Many economic activities are subsidized or encouraged in some way by governments. Whereas conservation is not subsidized (generally), alternative land uses are. Therefore, biodiversity conservation has to face unfair competition. Conservation of biodiversity should be evaluated along with other goods and services provided by environmental resources and should form an integral part of land use and management. The aim of conservation should be to optimize the provision of ecological and other services, and this does not necessarily imply the preservation of the existing resource in all its facets (Perrings, 1995).

For making cost-effective solutions, it is fundamentally important to know what is being traded off against what. The basic rule is that, for conservation to be *economically* justified, the benefit of protection minus the cost of protection should be larger than the benefit of economic activity minus the cost of economic activity. But, as already mentioned, “biodiversity often has no market price tag and a considerable amount of uncertainty can surround their true value and significance” (Turner et al., 1994).

Since not all value categories of biodiversity can be valued and expressed in monetary units, it is essential to develop consistent policy plans for biodiversity protection. These plans are based on scenario studies for biodiversity that describe and analyze past and existing situations and sketch a future situation and how to arrive at it.

To develop scenarios it is essential to describe and analyze options for biodiversity protection and include the economic costs of carrying them out. Next, the policy measures can be ranked according to cost effectiveness, and choices can be made for the priorities in biodiversity protection.

The scenarios can be analyzed by partial cost–benefit analysis, assessment of indicators, and by multicriteria analysis, which rank alternative policy plans on the basis of explicit weights attached to the various criteria. These criteria may include economic costs, quality of landscape, protection of biodiversity (expressed by means of indicators), and impacts on employment.

Once scenarios have been developed, it is possible to analyze their impacts and discuss the distribution of costs and benefits among various stakeholders, including local producers and consumers, national economic agents, and the international community. At the same time, one can analyze how biodiversity protection can be financed from domestic or international sources. The scenario studies can be supported by geographical information systems, decision support systems, and expert systems that document the present situation and make it possible to analyze future developments.

Research along these lines can contribute to developing national and international policy for biodiversity protection that is cost effective and clearly indicative of how well-defined targets for biodiversity protection can be reached in various regions of the countries concerned (de Kruijf and van Vuuren, 1998).

OVERVIEW OF CASE STUDIES

This section gives an overview of the background and attitudes to nature and biodiversity of selected populations and communities. Based on the foregoing discussion, we indicate the values of and consequences for nature management. For Bali, we used an extensive review by Martopo and Mitchell (1995) and some personal observations; for Cameroon, we used a thesis and some personal observations; for the other countries we used different reports and publications (see van Ierland et al., 1998).

Bali

In Balinese society, human ecological relationships are governed by philosophies and cosmologies that place humans in a *middle* world between spirit worlds *above* and *below*. Life revolves

around finding and maintaining harmony and balance among gods, humans, and the environment. Nevertheless, although there are small areas of protected forests, there seem to be few constraints on felling forests. Still, the possible presence of spirits slows the rate of attrition. Protection and use of natural assets typically are conflicting activities. In Balinese culture, based on Hinduism, there seems to be a delicate equilibrium between the ecologist view and the multifunctional approach (Boehmer and Wickham, 1995; Whitten, 1995).

Benin: The Holy Forests

Small, isolated forests near villages are set apart by local and regional authorities for religious and cultural rites. Only initiated men are allowed to enter. Values of the forests are considered only from religious perspectives. The forests are still very well protected but face challenges from the population due to conversion to Islam and Christianity. Another problem is the exchange of endangered, but in principle protected species (e.g., the pythons), as these forests are quite isolated. Reinforcement of traditional law is the best option, but it is difficult to achieve. Creation of corridors between the holy forests is not feasible because agricultural areas would have to be taken from the population. A clash exists between traditional — animism — and modern ways of management.

Bhutan: Biodiversity and Nature

In Bhutan 72.5% of the land is covered by forest (26% is protected), and nearly all of it is protected by law and religious conviction (Buddhism). Ethical and aesthetic roles and values of biodiversity are integral components of the culture, as rooted in the Buddhist philosophy of “compassion and respect to all forms of life.” What is taken away should be given back. The intrusion of modernity has not, until now, disrupted the ancient equilibrium of a hierarchical, well-ordered, agricultural, and pastoral society, under which evolved a way of life, architecture, and art firmly rooted in the philosophy of Buddhism and exceptionally well related to its natural environment. Bhutan is practicing an ecological approach in the management of its environment nearest to the deep-ecologist attitude. Opening to modern lifestyle will in the long run challenge this view, approach, and decision-making system.

Cameroon

In Southern Cameroon, as in Benin, taboos form the basic drive for local management of forests. This approach determines the way the autochthone population is allowed to use and manage the forests. The forests are multifunctional and, therefore, extremely valuable to the local people. The intention to develop nature reserves in these areas demands an approach that considers these views. Traditional views are in conflict with the technical management views of the government, which tries increasingly to limit the use of forests by the riverine people. Cameroon represents the typical conflict between the original multifunctional approach and the modern ecological approach of nature management (Neba, 1998).

Costa Rica

Christian tradition has governed the use and management of nature in the last few hundred years. Exploitation was governed by the needs of the population and economic demands. This is the typical stewardship approach. Serious changes can be observed in the last decade, partly initiated by the UNCED and other comparable activities; these changes have led to a more multifunctional approach of the management of nature and biodiversity. Judicial systems are not yet sufficiently developed, nor is the population fully aware of these changes of philosophy in managing nature.

The Netherlands: The Wadden Sea

The open connection of the Wadden Sea to the North Sea has an enormous importance for wildlife as a breeding area for North Sea fisheries and as a sanctuary for migratory birds twice a year. The presence of large, economically interesting mineral resources, as well as the commercial exploitation of some areas within the Wadden Sea, has led to heated discussion about the management of the Wadden Sea. Attitudes ranging from ecologist to techno-economic are present in these discussions. Policy measures most related to the ecologist view have been taken to protect the area, but they are constantly challenged on the basis of economic welfare.

OBSERVATIONS AND CONCLUSIONS

Attitudes

Attitudes toward biodiversity and nature differ among policy makers, individuals, and stakeholders and range from deep ecologist to techno-economic dominance. The examples show that attitudes of the more relevant policy-making institutions range from ecological approach to techno-economic attitude. At the local level, decision makers or responsible local authorities tend to the more extreme end of the classification. It is unclear when and how the local attitudes will prevail or influence decision making on biodiversity protection, use, or exploitation because these attitudes may well differ from the national views.

In addition to socioeconomic and political considerations, traditions, religions, and culture are important in defining the values and uses of biodiversity, especially at the local and regional levels. Therefore, these factors were considered in decision-making processes in biodiversity. In spite of strong influences of attitudes and religions in Benin and Bhutan, trade-offs between biodiversity protection and economic development can and are being made under highly specific circumstances. People accept that some negative impacts on biodiversity may occur, if they are sufficiently compensated by economic gains and if extensive cultural explanations are allowed. It was also shown in the case studies that attitudes toward biodiversity and nature conservation can be influenced by education, religion, practical use of the natural goods, and experience.

Classification of Economic Values Related to Biodiversity

The classification of economic value categories (direct use, indirect use, option, bequest, and existence value) is considered to be an anthropocentric, mainly economic classification, acceptable in principle to many decision makers. Besides direct and indirect use values, option, bequest, and existence values make explicit that other value categories (related to ethical, cultural, and religious perspectives) are important in decision making on biodiversity conservation. How to assess option, bequest, and existence values remains a complicated issue. Further studies and practical experience should reveal to what extent actual monetary valuations for these latter values can be made.

Valuation Methods and Their Applicability

Economic valuation methods are considered useful tools to assess the above-mentioned value categories but should not be considered a panacea for all valuation questions related to biodiversity. Different valuation methods can be applied to various functions of biodiversity or value categories (see Table 16.5).

Table 16.5 shows that most methods for monetary valuation can only be used for a limited number of value categories. The CVM method is, in principle, applicable for all value categories; but a scientific debate is going on about its validity, strengths, and drawbacks.

It is recommended that the relevant valuation methods in practice for the appropriate value categories (Table 16.5) be applied to obtain the best information about the monetary value of various functions of ecosystems and biodiversity. Valuation methods make it possible to pay attention explicitly to the various functions of biodiversity and ecosystems. However, not all value categories can be captured by monetary valuation methods.

Monetary valuation methods can only be usefully applied if the policy makers and other stakeholders support their use. In countries with a strong neoclassical economic tradition, such as the Netherlands and Costa Rica, the application of economic valuation methods are more likely to be accepted. In Bali, Benin, and Cameroon, an interest also exists in the application of monetary valuation methods. For Bhutan it remains to be discussed whether and how economic valuation methods can be applied. Valuation is an essential tool to support the policy-making process, e.g., at the local level and in land use planning, agriculture, and infrastructure activities. Monetary valuation is an additional step that may provide relevant information. More experience is necessary to assess to which cases to apply monetary valuation.

Analytical Tools for Biodiversity Protection

If economic valuation methods cannot contribute to proper decision making on biodiversity protection, what other methods are available? Decision making on biodiversity protection can be supported by means of scenario studies, land use planning, and environmental impact assessment that show how various functions of ecosystems will develop over time under different policy scenarios. The scenarios can suggest implications for the international aspects of biodiversity, and national, regional, and local impacts. In this way the global and national benefits of various plans for biodiversity protection can be assessed, at least qualitatively. Policy makers and other stakeholders can then express their preferences for various scenarios, thus implicitly indicating how they value the various characteristics of the scenarios. Ranking the scenarios can be established by multicriteria analysis.

Research is then required to analyze, describe, and sketch future developments. Good indicators are required for describing the developments and the state of biodiversity. Values based on attitudes and well-documented information should be obtained to sketch the various scenarios and implications for biodiversity at the level of ecosystems, species, and genetic material. In addition to valuation, other essential tools to assist in conservation and sustainable use of biodiversity include scenarios, protection plans, environmental impact assessment, and spatial planning. They must also be applied on the basis of data and should consider the different values and attitudes of stakeholders. Knowledge derived from continuous data collection and inventory of biodiversity and its components largely determines the effectiveness of the application of these tools. Therefore, a continuous scientific effort must determine:

- Inventory of ecosystems, species, and genetic information
- Qualitative description of functions
- Quantitative analysis

A thorough decision-making process, based on sustainable land use planning that includes local participation and the application of tools such as valuation, will provide elements for sustainable use and conservation of biological resources.

Economic Benefits from Biodiversity Protection

Biodiversity protection will result in many economic benefits attributable to the various functions of ecosystems, species, or genetic information. Economic benefits include carbon sequestration, watershed protection, water supply, hydropower, and development of genetic potentials for

pharmaceuticals, agricultural use, recreation, and tourism. Still, numerous economic benefits are underutilized and need further attention if they are to be taken into account in the economic decision-making process. Attitudes are very important in these processes as shown by the case studies. For further development to be long-lasting, successful, and inclusive of many views, information about attitudes is essential.

Protection of property rights, particularly for benefits sharing, is essential. Well-designed laws and relevant human resources are also essential in this regard.

International Aspects

When applying valuation of biodiversity, it is important to recognize that values may differ among stakeholders. At the international level, attitudes and values may differ from those at the regional and local levels. The difficult issue of when international interests, national interests, regional interests, or local interests receive priority certainly cannot be solved by means of monetary valuation. Harmonization of legislation on transboundary biological resources and adequate enforcement are needed both between countries and between relevant international agreements (e.g., with CBD and CITES). Enforcement of existing regulation should be strengthened.

The international community should support conservation measures that consider peoples' attitudes and values and provide global as well as local benefits through financial means and appropriate technological transfers.

ACKNOWLEDGMENTS

We are grateful to a number of colleagues who participated in workshops trying to get hold of the complicated aspects of values, attitudes, and nature. In particular, we thank Gaetan Agbangla and Fulbert G. Amoussouga from Benin; Edmundo Castro, Luis Gamez, and Erick Varga from Costa Rica; Karma C. Nyedrup and Kunzang Norbu from Bhutan; and Jacob-Jan Bakker, Arthur Eijs, and Chris Enthoven from the Netherlands. Also we acknowledge the help of WWF in Cameroon. The Foundation Ecooperation supported part of this study.

Humane Values as a Basis for Ecosystem Health

John W. Grandy and Allen T. Rutberg

INTRODUCTION

Humane values have broad public appeal. Care and compassion for our fellow creatures are deeply rooted in our emotional makeup and in our fundamental human abilities to understand and empathize with the experience of other people and animals (Kellert and Wilson, 1993). The emotional connections we form with the dogs or cats in our households, the horses in our pastures, and the many other animals in our lives are real and profound, and spring from the same sources as our loving connections with family and friends.

More and more people now recognize and appreciate the fundamental rightness of humane values and that the quality of life for all of us will be improved if these values guide our actions. As a result, charitable organizations such as The Humane Society of the United States (HSUS), which advances the values of care and compassion for all creatures, have experienced tremendous growth. In the last decade of the millennium, the constituency of the HSUS grew more than fivefold and now exceeds over 7 million concerned citizens. Other organizations dedicated to advancing humane values have also thrived.

This growth in membership and support base, which we believe is underestimated even by these growth levels, represents both a sea change in public support for animal protection and conservation programs and an unparalleled opportunity to make significant progress in meeting our shared objectives for ecosystems, habitats, and animals that are affected by humans.

The lives of wild animals and humans have become increasingly entangled. People have always affected and been affected by wildlife: as prey or predators, as competitors, as codependents, and as biological signposts in our attempts to map our world. All these relationships remain intact today; but now, more than ever, the fate of wild animals will depend on how they are treated by humans. The modification, fragmentation, degradation, and destruction of wildlife habitat by people are now, at least in the short run, the most important forces determining where, how, and whether wild animals live on Earth.

To cement the link between humane values and wildlife protection, and ultimately to ecosystem protection, we focus our efforts on that large segment of the public that lives in cities, towns, and suburbs. That is where the heart of public opinion lies. (According to the 2000 U.S. Census, 80% of the population now lives in metropolitan areas of 50,000 or more.) It is also where most people encounter wildlife most frequently. These people know, and want to know, the beauty of wildlife first-hand. They are not concerned about whether wildlife is deemed feral, native, or nonnative; rather, they understand it as beautiful, majestic, and awe-inspiring. For many, wildlife still sleeps

in back yards; feeds in gardens, flower beds, and berry bushes; burrows under the front steps; forages in the vacant lot across the street; and fills the park near the outskirts of town. Even in the heart of Washington, D.C. and in its densely settled suburbs, our yards are home to raccoons, opossums, voles, salamanders, woodpeckers, crows, and chickadees. We and others are richer for each encounter with these wonderful creatures and for the increasing level of interaction with Canada geese and white-tailed deer in the larger community.

ENHANCING PUBLIC APPRECIATION OF WILDLIFE

We believe that if people appreciate and enjoy wildlife in their lives, even vicariously, they will want to help improve the welfare of wildlife, improve and save wildlife habitat, and support local, national, and international programs and policies that benefit wildlife. This is an ascending cycle of understanding, concern, and involvement. Consequently, we have put into place a number of programs that promote appreciation for wildlife, help people solve any conflicts that may arise with their wild neighbors through humane and effective techniques, and simultaneously build concern and encourage involvement in wildlife protection.

Our urban wildlife protection program is the centerpiece of these efforts. The HSUS Urban Wildlife Program started (and continues) with a series of 1- and 2-day workshops, held all over the country, aimed at animal control officers, shelter staff, nuisance wildlife control operators, and others who deal directly with wildlife conflicts experienced by the public. Participants are trained in the latest techniques in humane wildlife conflict resolution and receive information on wildlife diseases and legal constraints. Information presented in each workshop is tailored to the region in which it is conducted.

From these origins, the HSUS Urban Wildlife Program grew to include publication of brochures and two books. The first book was the very successful *Pocket Guide to the Humane Control of Wildlife in Cities and Towns* (Hodge, 1991), which was then expanded into *Wild Neighbors* (Haddidian et al., 1997). HSUS personnel regularly attend and present at wildlife damage control meetings and work closely with government personnel, wildlife rehabilitators, nuisance wildlife control operators, and others to explore new techniques and set standards for handling wildlife.

Our latest urban wildlife program is the HSUS Urban Wildlife Sanctuary Program. Born out of the National Institute of Urban Wildlife's urban sanctuary program, led by Dr. Lowell Adams, our backyard sanctuary program is a powerful educational tool for encouraging appreciation of backyard wildlife, disseminating practical information on the humane resolution of wildlife conflicts, and providing guidance on how to improve backyard habitat for wildlife. Landowners who apply to the HSUS for urban sanctuary designation receive a copy of *Wild Neighbors*, a subscription to the quarterly newsletter *Wild Neighbor News*, and access to a variety of other helpful resources. This enterprise engages not only small private landowners but also neighborhood associations, planners, developers, corporate landowners, and even whole municipalities. We see unlimited potential here to influence the urban landscape and to preserve the opportunity for people to see and appreciate wildlife.

Complementing the Urban Wildlife Sanctuary Program is the HSUS Wildlife Land Trust. Although only a few years old, the land trust now protects 46,296 acres on 35 properties in 17 states as well as one foreign country, and it is growing rapidly. As with many conservation-oriented land trusts, the Wildlife Land Trust uses donations of land, land purchases, and conservation easements to restrict further use and development on properties valuable to wildlife. But the HSUS Wildlife Land Trust is different from others. While there are hundreds of land trusts in the U.S. (the Land Trust Alliance reports that it works with over 1200 such groups), from organizations with a national or international focus, like the Nature Conservancy, to the smallest local trust, the HSUS Wildlife Land Trust is the only national land trust committed to conserving land under principles of *humane stewardship*. For the HSUS, humane stewardship means that the animals

living on land trust properties are protected in perpetuity from commercial and recreational trapping and hunting; that wildlife conflicts arising on trust properties are solved humanely; and that management is directed toward the benefit of the animals themselves, not toward human use. Moreover, the HSUS Wildlife Land Trust makes one additional commitment: if it agrees to take a parcel of land, it will protect or insure its protection *in perpetuity*. It will either keep it fully protected under its ownership, or, if the land is donated to another protected use, it will insure that protective covenants are maintained in perpetuity.

Thus, in addition to the direct and immediate benefits to wildlife of protecting their homes forever, the HSUS Wildlife Land Trust serves another function: to send a message to land managers everywhere that wildlife is worth preserving for its own sake, not just for its utility to hunters, trappers, or even bird-watchers. The HSUS Wildlife Land Trust takes a critical step in inserting humane values into the preservation of ecosystem health by demonstrating that conservation and protection of wildlife habitats can be mutually reinforcing of humane values.

BUILDING HUMANE VALUES INTO SCIENCE

Securing the health of ecosystems requires good science, as is demonstrated by the other chapters in this volume. The HSUS maintains, however, that the science of wildlife and land management itself must, for the future, be founded on humane values. After all, the role of science is to describe nature by collecting and organizing observations of the natural world. But the choice of questions that scientists ask about nature, what observations are made, and how those observations and questions are organized are guided by values as well as by the observations themselves (Rutberg, 1997). We believe that science founded on humane values such as kindness, compassion, and reverence for life will better inform and guide wildlife management policies in a progressive and positive direction.

In the 20th century, wildlife management was founded on and steeped in killing — sport hunting, “management hunting,” commercial and recreational trapping, predator control, and other lethal forms of animal damage control. To increase deer numbers, state wildlife agencies sold licenses to shoot bucks; they then used the revenue to disrupt the habitats of other creatures to create more deer habitat, pushing up the reproductive rates of the does. To increase waterfowl numbers, state and federal wildlife management agencies inhumanely trapped raccoons, foxes, and other nest predators — again using the revenues generated from the sale of hunting licenses. Until the passage of the Endangered Species Act (ESA) in 1973, nongame species were largely ignored. Even including ESA-driven programs, government expenditures on nongame species were still, at the end of the century, dwarfed by hunting- and trapping-related expenditures (Hagood, 1997). In FY 1995, for example, approximately \$30 million were appropriated by Congress to implement the ESA; by contrast, \$209 million of federal Pittman–Robertson money were channeled to the state wildlife agencies to support hunting-related activities. Expenditures by the states are even more lopsided in favor of hunting.

But the restoration and preservation of healthy, sustainable ecosystems cannot be based on an ethical system indifferent to the value of life and to the well-being of our fellow creatures. For the next century, we must develop new methods and new technologies that intrude as little as possible into the lives of wildlife, thereby recognizing the value of all life.

For wildlife, the other side of the deteriorating habitat problem is increased conflicts with people where wildlife and people come together. The HSUS believes that tolerance for wildlife and modification of human behavior are the appropriate first responses to wildlife conflicts. However, it has become clear in the last decade or so that, in some locations, densities of wildlife are so high as to cause conflicts intolerable to the majority of people and injurious to the animals themselves (Conover et al., 1995). In the eastern U.S., dense populations of white-tailed deer are involved in many thousands of collisions with vehicles, with fatal consequences to the deer and trauma and

sometimes injury to the occupants of the vehicle. In other situations, high densities of deer, wild horses, pigs, and other species may result in harm to habitat, biodiversity, and other wildlife that is deemed unacceptable (DeCalesta, 1997; Mac et al., 1998).

Recognizing that wildlife overabundance can be a genuine concern, but insisting that the traditional method of dealing with wildlife overabundance — killing — is ethically bankrupt, the HSUS has committed itself to leading a major research program in wildlife immunocontraception. By helping to develop a safe, effective, and humane nonlethal method to control wildlife populations, we hope to help ease the conflicts that develop where wildlife and people meet as neighbors, and thereby to help engender public tolerance for wildlife. At the same time, the act of applying immunocontraception to wild animals carries with it a message of concern for the lives of the animals we meet, disturb, and sometimes displace, and acknowledges our responsibility for humane stewardship.

The immunocontraception program is one of the largest carried out by the HSUS. We collaborate in this endeavor with at least half a dozen major universities, including the University of California, Davis; with zoos and aquaria around the world; with the National Park Service, the U.S. Fish and Wildlife Service, the Bureau of Land Management, the Department of Commerce, and Navy; with South Africa National Parks; and numerous state and local agencies. Our research focuses principally on white-tailed deer, wild horses, and African elephants; but it also encompasses dozens of species in zoos and a handful of other species in the field (Kirkpatrick and Rutberg, 2001).

Since our program began in earnest in the early 1990s, we have made extraordinary progress. The National Park Service is using immunocontraception to control wild horse populations on several East Coast barrier island beaches, most notably Assateague Island National Seashore, where immunocontraception has been the management tool of choice since 1995 (National Park Service, 1995). Our research team, in cooperation with the Bureau of Land Management, has treated over one thousand wild horses on public lands with immunocontraceptive vaccines and is testing it for large-scale management use across the west (Turner et al., 2001). We have learned much about the vaccine itself (Thiele, 1999; Naugle et al., 2002; Walter et al., 2002) and are testing prototypes of an effective tool — a one-shot, remotely delivered vaccine — for the management of white-tailed deer. Research we supported has even shown that the vaccine can be effective in wild African elephants when delivered remotely from helicopters in Kruger National Park in South Africa (Fayrer-Hosken et al., 2000). Possible applications appear enormous.

Moreover, immunocontraception has kindled the imagination of the public. Even without an effective management tool, the HSUS annually receives hundreds of requests for access to the technology from constituents, communities, land managers, and the public. They ask us: We have a deer problem; can we use your birth control method to help solve it? Does it work on beavers, on raccoons, on pigs, on goats, on bison? And the interest is confirmed in public opinion surveys. When asked what their preferred method for controlling wildlife populations is, the public consistently places birth control at or near the top.

Immunocontraception is not, of course, the ultimate answer to wildlife overabundance. As we assert above, the fate and welfare of wildlife depends ultimately on changing human behavior. Still, we are heartened and gratified by the outpouring of public demand for its use. It means we are right; the public cares deeply about wildlife and would like to see wild animals managed with kindness and compassion.

CONCLUSION

Ecosystems are slippery things. They are of intense interest to scientists, but the public has trouble understanding what ecosystems are, let alone supporting their protection. Ecosystem health, likewise, is of intense interest to scientists, as evidenced by this volume and participation in the conference upon which it is based. However, from this and other efforts must come the recognition

that conservation and humane communities must increasingly come together to support protection for wildlife, its habitat, and the ecosystems upon which it depends. In 1938, the National Council of Parent Teacher Associations urged nationwide programs for the education of children emphasizing four fundamental humane values: kindness, compassion, justice, and reverence for all life. These are the values that drive the HSUS and its constituents today. And these are the values that drive the true conservation and animal protection communities. Clearly, what we must build for the future is a better world based on these core values and the healthy ecosystems they will support.

Healthy ecosystems will need healthy values. Care, compassion, and acknowledgment of the value of all life are, we believe, the right medicine for healthy ecosystems.

The Role of the Water Education Foundation in Creating Factual Awareness and Facilitating Consensus in Western Water Issues

Rita Schmidt Sudman

When the Western Water Education Foundation was incorporated as a California nonprofit foundation in 1977, few expected it to become a major force in water education. After all, there were many groups espousing the same goal of water education for Californians. The exact goal of the founding board of directors, a group largely aligned with water agencies in California, was to implement public information programs on water conservation, reclamation, reuse, and development. The founding board of the foundation believed in presenting unbiased information and allowing the major sides of the water debate to air their differences in the foundation's main vehicle for information, *Western Water* magazine. Some of the board members were confident that the public would support more water development if the facts were known. All board members were fair-minded people who believed in open discussion of the issues. This spirit of open discussion formed the basis of the growth of the Water Education Foundation to become a trusted source of information and a major credible organization.

The first issues of the magazine were distributed to several thousand people around California. Today it is distributed to over 20,000 — a list that includes reporters, interest groups, schools, libraries, and public agencies. This nonpartisan discussion of the issues in *Western Water* magazine immediately set the foundation apart from other water interest groups. One of the foundation's first projects was a "white paper" format, the *Layperson's Guide* series. It was designed to explore a particular water issue in more depth. The first guide in the series was Auburn Dam; some things never change. Today the series includes 16 guides. The guides are distributed similarly to *Western Water* magazine, but to a smaller audience.

At the time the foundation began, many groups were representing themselves as unbiased, and the foundation spent the early 1980s establishing credibility from all sides of the water debate. Funding was modest (about \$30,000 the first year) and came from many sources, including subscriptions to the fledgling magazine, sales of a newly produced California Water Map, small contributions from those involved in the water business, and even a raffle to fund the water map. *Western Water* was written about a hot water topic, as it is today. In the early years, some pioneering work — such as the new topic of water marketing and agricultural water conservation — was analyzed for the public for the first time in the magazine's pages. Other topics, which gained public attention for the foundation, included the fight over the waters going into Mono Lake and state board hearings on water quality and conservation. A briefing for the business community and other

forums for discussion were established as a regular part of the program. The reporters' briefings and other events to educate journalists about water issues were begun. We also established an award for the best water reporting in small and large newspapers. School education outreach was begun with packets of materials for teachers and students — a program that now reaches over 500 teachers and more than 650,000 students yearly. We began to diversify our board of directors to better reflect the major points of view in the water world — agricultural, urban, environmental, and public interest. And we changed our name to the Water Education Foundation to reflect better our broader view of water issues.

Additionally, we developed the first in a series of field trip tours to major water facilities and rivers. These were established to bring decision makers to see the controversial areas of the state. Typically two buses of water directors, city council members, reporters, legislative aides, and state and federal agency staff would travel on 3-day tours. These tours greatly facilitated discussion among people sufficiently involved in water issues to spend 3 days touring and analyzing the issues. The early tours covered the Bay-Delta and Northern California. Also in the 1980s we developed funding and support for the statewide Water Awareness campaign with state and local agencies. This annual program, carried out in the month of May, today reaches millions through public events, television and radio spots, and school programs.

By 1990 we were positioned to move into more multimedia education to reach a wider audience. During the height of the early 1990s drought, we obtained grant funding from a private foundation, the Hans and Margaret Doe Charitable Trust, to partner with public television to produce a documentary on California water issues, "To Quench a Thirst," with Roger Mudd as host. This important program brought a thoughtful discussion on water and the visualization of the problems into the homes of 3 million Californians. We updated the program several years later, and it is still being shown on cable television and distributed by the Water Education Foundation. Shortly after the program aired, Governor Wilson, who was looking for a forum cosponsor to announce his 1992 statewide water policy framework in San Diego, chose the nonpartisan Water Education Foundation.

Also in the early 1990s, recognizing the connection of California to the other Western states, the foundation began outreach to the other six Western states that share the Colorado River. The goal was to educate a wider group about Western water issues and seek resolution of these problems. We changed the mission of the foundation to reflect that change. No longer were we going to report only on these issues; we were also going to facilitate solutions through stakeholder conferences, public forums, published papers, and leadership training. This newer work would still be done within our continuing role as a nonpartisan organization.

Our first work in Western issues began with the publication of the Colorado River map, a three-state tour of the lower Colorado region, speaking engagements in the west, and a special issue of *Western Water* on Western drought. In the early 1990s we responded to hundreds of inquiries from the press and public on information on the drought. We also began a major involvement with two national information organizations: The National Geographic Society and National Public Radio. We assisted the reporters and photographer to produce the special issue of *National Geographic* magazine (November 1993) on water in California and reviewed the article for factual content. Also we assisted in the production of National Public Radio's "Radio Expeditions" series on Western water issues. Since politics tends to be local, we decided to develop a series of town hall meetings on local water issues. The purpose of the town hall meetings would be to (1) disseminate information and (2) facilitate solutions. During several summers we traveled to five different towns annually to present forums on specific local water issues and worked with the local media to cover those forums.

During this time revenue grew to several hundred thousand dollars, and funding was roughly divided as one third from grants, one third from contributions, and one third from tours, briefings, and publications. By 1992, when the foundation was 15 years old, our work on television documentaries increased. Our ability to bring groups together on issues led to the foundation's selection by the Hewlett Foundation to assist in coordinating and becoming the fiscal agent for

the loose coalition of interest groups called the Three Way Group — a group representing agricultural, urban, and environmental groups. This group met at the height of the early 1990s drought, when pressures from the Endangered Species Act were causing pumping restrictions and water shortages among agricultural and urban users and when drought was putting more pressure on the environment. It was the first attempt to have formal and informal meetings among these diverse interest groups. In this age of political consensus, the Three Way Group seems archaic; but at the time it was a revolutionary means of changing policy. It failed because there was no leadership to force a decision or compromise. Also, there was no crisis point until 1994, when the Bay–Delta Accord was agreed upon by all sides under the threat of federal government implementing water quality standards for the state of California. During both the Three Way Process and the Bay–Delta Accord, our main role continued to be to cover the story. Our coverage of the issues, particularly in *Western Water* magazine, helped the decision makers themselves to see points where there may be compromise and today continues to be the basis of factual information for all interested people.

After our involvement with the Three Way process and the Bay–Delta Accord, the Water Education Foundation became involved in a number of consensus-based meetings and discussions. In 1996, the foundation was a member of the planning committee and the conference coordinator of the California Assembly Process on the Bay–Delta issues. Dwight Eisenhower had established the Assembly process when he was president of Columbia University. In this particular process, members of diverse interest groups debated concerns about the new CALFED process. About 300 stakeholders participated in the 3-day process. We assisted the group to develop a final document by compiling the voting results of the general discussions and breakout groups. The results were sent on to CALFED and formed a basis for its early discussions.

For us, the larger outreach for Bay–Delta education came with the development of our public television documentary on the issue. We have convinced a number of well-known actors to host these water documentaries, and their involvement seems to bring us wider attention and more coverage on public television stations. Tim Busfield hosted this 1-hour special on the history and current issues of the Bay–Delta area. In developing the documentary, we involved the interest groups in an advisory committee and therefore continued our involvement in the collaborative process of seeking solutions.

Another consensus process we became involved in was the search by the Sacramento area water interest groups for a way to share local water resources. Although this was a fully facilitated process lasting several years, the foundation cosponsored and moderated panels for the 1996 Water Forum. Our materials, again, were used as a basis for discussion, and we have analyzed the results of the forum process through the years.

Also in the 1990s we made a significant addition to our water education program by emphasizing groundwater education. Groundwater accounts for at least one third of the water used in California. It is a hidden resource but vital to the economy and ecosystem stability of the state. We began our groundwater work with a poster map of the groundwater basins in California. By 1995, we had added groundwater school programs, videos, a groundwater table flow model, and a statewide groundwater tour. We joined forces with the national Groundwater Guardian program to help communities gain recognition for local work to protect the resource. In several communities we staged community forums seeking solutions to overdraft and contamination.

In our continuing search for factual information, we developed a water input study with the University of California to study the amount of water associated with food production. For example, we analyzed how much water it takes to produce a hamburger. This figure takes into account the water to produce the feed for the cow, produce, and package the hamburger. There have been quick studies by groups who released certain numbers on water input in food production, but this joint foundation and University of California study was the first methodical study of its kind. Needless to say, the results were quite controversial. We were threatened with a

lawsuit by an agricultural producer and criticized by some environmental interests. We survived the storm and stood by the numbers.

Through the years, we have coordinated a series of exclusive in-depth personal interviews in the pages of *Western Water* and in the television documentaries. Top state and federal officials such as Interior Secretary Bruce Babbitt, Environmental Protection Agency Administrator Carol Browner, California Governor Wilson, and, recently, California Resources Agency Director Mary Nichols were interviewed in *Western Water*. We have also reached out to specific professional audiences. We have even tried to educate attorneys. We began the Continuing Legal Education program in 1994. And in our attempt to raise the level of knowledge of young professionals who may work in water issues, or at least be impacted by them, we began the water leaders mentor program in 1995. There have been four classes of 10 to 20 young professionals each year in our water leaders class. They have set aside some of their time to attend our tours, briefings, read our publications, interview top leaders in the water world, and produce a class report on a specific water issue.

Another group we have worked with in recent years is teachers; we provided high-quality water education materials that fit into established curriculum guidelines. By conducting teacher training seminars, we have increased the acceptance of our materials statewide.

As water issues in California intensified, we were asked to assist water education on an international level. In 1993, we assisted the city water department of Barcelona, Spain, in setting up a public education campaign to convince the Spanish people to value and conserve water. Shortly afterward, we sponsored a major conference on similarities in the problems and solutions of California's Bay-Delta, the Netherlands, and Chesapeake Bay, Maryland. In 1995, we began a series of trips to Sweden, at the request of and with some expenses paid by the Swedish government, to discuss strategies for educating the public and specific audiences. We are now involved with the American advancement of the Junior Swedish Water Prize, a program to educate high school students about water and science. In 1997, we assisted the University of California with the meeting of the Rosenberg International Forum on Water Policy. The Water Education Foundation was the coordinator of the scientific field tour for the visiting professors from the world's arid countries.

In addition to publishing our own material, in 1996, the foundation's chief writer, Sue McClurg, was selected to prepare a study for Congress and the administration of the Sacramento-San Joaquin basin for the Western Water Policy Review Advisory Commission. This was one of several such basin studies developed for the commission. McClurg and the foundation were selected because of the commission's respect for our unbiased writing about Western water issues. Another basin report described the issues around water use of the Truckee River and Pyramid Lake. In an Emmy-nominated public TV program, seen by millions around the country, the struggle over the water of Pyramid Lake for the Paiute Indians, farmers, growing cities, and States of California and Nevada were chronicled in the foundation's documentary, "Healing the Water." Hosted by actor Robert Conrad, the history and recent negotiations were analyzed. The diverse funding and reputation of the Water Education Foundation are part of our success in getting our programs on public TV. Another program, now in production, covers issues in the Klamath basin and involves similar interest groups and the States of California and Oregon. The message of all these documentaries is basically the same: what is at stake in the ecosystem and the economy if people of good will do not come together and try to find compromise and solutions to these Western water problems?

That search for solutions and consensus led us, in 1997, to use the 75th anniversary of the Colorado River Compact, the document that divided the water of the Colorado River between the upper and lower basin states, as a pretext for a major symposium of invited stakeholders and top policy makers. At the symposium, the first draft of a California plan for the state to live within its 4.4 million acre-feet water limitation was formulated. Of the 125 invited stakeholders, 60 were involved and the current interior secretary and a former interior secretary addressed the group. A 200-page proceedings of the symposium was published in the conservation-style format of the conference and has been used by reporters and others interested in river issues. A similar symposium was scheduled in Keystone, Colorado.

One of the groups not included in the original division of the Colorado River was the American Indian tribes living along the river. We are now writing more about tribal water issues. Also, with a grant from the U.S. Environmental Protection Agency, we are developing a tribal workbook to help tribes assess and protect their water quality. The results will be placed on the EPA and our Web pages.

The World Wide Web has taken us around the world. It has allowed us to make briefings on water issues free to public. We also sell our materials on our Web site, and sales generate revenue to continue our work. By the end of the 1990s, our budget grew to \$1.4 million, with funds continuing to come from diverse sources. Our tour agendas and upcoming events also are publicized on the Web. We see the huge potential to use the Web in water education. It is certainly a way that our small staff, ten people, can reach millions.

Our latest project is a literature and photography book on California water. It is meant to be a beautiful book, one to inspire the next generation and maybe even a few of today's folks, to care about these issues. Finally, the foundation's History Project brings us full circle. In an attempt to learn from our past, in the last few years we have sponsored a series of exhibitions, historical reenactments, and publications on how other generations made decisions on their water problems and how those decisions affect us today. Yes, we are still following Bay-Delta issues, and we even look at the proposed Auburn Dam when it periodically gets discussed.

As we enter the 21st century, we hope the Water Education Foundation will continue to be a reliable source of unbiased information on water issues. We hope this information and our work in the collaborative process will help Westerners become good stewards of our water systems and encourage care for our ecosystem.

Addressing Threats to the Health of Coastal and Near-Coastal Ecosystems — The Gulf of Mexico*

James D. Giattina

INTRODUCTION

The diversity of the Gulf of Mexico, from the hypersaline waters of the Laguna Madre to the mangrove swamps of south Florida, contributes to the variety and productivity of life and human custom that characterize this sea. When a Spanish fleet sailed into the Gulf waters in 1497, the human diversity and culture of the region already paralleled the physical diversity. From the Colusa of Florida's southwestern coast to the empire of the Aztecs, the depth and complexity of the native civilizations was largely unappreciated by the Europeans. In the 500 years since its discovery by Spain, the Gulf of Mexico has become the Americas' "Mediterranean" — a wellspring of commerce and transportation as well as an area of strategic military importance (Gore, 1992). The Gulf region has flown under many flags, and that diverse political and cultural heritage is still evident in the architecture, linguistics, and political structure of the area.

It is that vastness and diversity that often precludes us from seeing the fundamental relationships between the living and nonliving workings of this magnificent ecological system. As a result, the vastness of the Gulf is both its strength and its weakness. Its size and diversity contribute to its productivity, yet they also lull us into a sense of complacency with regard to our day-to-day actions and their potential impact on the Gulf.

ENVIRONMENTAL AND PUBLIC HEALTH THREATS TO THE GULF OF MEXICO

A closer look at more specific areas and issues within the Gulf ecosystem reveals that many of the effects of human action are threatening the health and well-being of the Gulf. Those effects range from the localized, but ubiquitous, closure of shellfish-growing waters after heavy rains to a larger area of low dissolved oxygen on the Louisiana inner continental shelf, known as Gulf hypoxia. The former problem results from ineffective or inappropriate sewage treatment. The latter results from the cumulative effects of myriad human actions within the Mississippi River basin — a basin that covers over 40% of the continental U.S.

Throughout the Gulf natural processes combine with human actions in ways that are detrimental to the economy as well as to the ecological stability of the Gulf region. For example, today 85%

* Portions of this chapter were published in *The Coastal Society Bulletin*, 20(3):8–12.

of our nation's remaining coastal wetlands are in the southeastern U.S., with a significant portion of those in coastal Louisiana. Yet we are continuing to lose portions of coastal Louisiana at a rate of approximately 25 square miles every year. This is due to a combination of factors, including natural subsidence that has been exacerbated by the leveeing of the lower Mississippi River. Levees, while providing vital flood protection, have also cut off the river from its natural floodplain, reducing the essential flow of nutrients and sediments needed to replenish the marshes. This effect, in turn, has been further accentuated by channeling of the coastal marshes to allow for oil and gas exploration and production and improved transportation. The dissection of the coastal marshes, which was essential to the energy policy of the day, both caused physical destruction and allowed the introduction of saltwater into previously freshwater marsh areas, hastening their demise. Finally, we cannot ignore the impact on the coastal marshes of nutria, a nonindigenous species. These voracious, beaver-like rodents are making their own contribution to the loss of Louisiana wetlands because of their propensity for eating marsh grasses — roots and all.

The conversion of land and marsh to open water in coastal Louisiana is resulting in the tragic loss of a unique American place — one that is rich not only biologically but also culturally and historically. Furthermore, these wetlands serve as important protection from tropical storms; thus, this loss also increases the risk to billions of dollars of infrastructure — homes, schools, roads, towns, cities, ports, businesses, industries, and storage facilities — even from storms that are less than Category 5 catastrophes. Coastal marshes are essential to various life stages of over 90% of commercially and recreationally important species. The Louisiana marshes alone account for over 40% of the commercial landings in the U.S. waters of the Gulf, and marsh loss will continue to impact this sector of the economy and a way of life for many people.

As further evidence of the potentially destructive combination of natural and human forces, an unprecedented red tide occurred in the Gulf during the fall of 1996, impacting beaches and shellfish waters from Florida to Texas. Red tides — blooms of tiny organisms, known as dinoflagellates — have occurred in the Gulf for many years. In the past these events were confined to the waters of the western and northwestern Florida continental shelf, the east coast of Texas, and the Bay of Campeche, Mexico. The unusual 1996 event caused large-scale mortalities in fishes and invertebrates and significant mortalities in the endangered Florida manatee. In addition, as these blooms approached shore, the toxic by-products of the bloom organisms contaminated shellfish, causing closures and harvest limitations. In some areas wave action generated toxic aerosols, causing respiratory problems, eye irritations, and allergic reactions for beachgoers. The linkage of the 1996 red tide event and land-based pollution, particularly excessive nutrient enrichment of Gulf coastal waters, is speculative at this time. The hope is future research will shed additional light on the causes of these blooms and those environmental factors that contribute to their persistence and movement.

GULF OF MEXICO PROGRAM — OFFERING LEADERSHIP BEFORE CRISIS

At the 1998 National Ocean Conference, the Honorable Leon Panetta observed that, “in a democracy you get things done either through crisis or leadership” (National Ocean Conference, 1998). The warning signs we can already see reinforce the need for leadership in both protecting and fostering the sustainable use of resources of the Gulf. Leadership requires foresight, and foresight is contingent on our ability to evaluate our current state, assess and predict trends in key indicators (social and economic indicators, as well as ecological ones), and act to prevent those actions that will lead to crisis in both ecological and economic terms. The way to prevent a systematic crisis in the Gulf of Mexico is to redouble our efforts to remediate the problems of today. These problems are harbingers of impacts to come as the underlying stresses of population, coastal development, energy production, and transportation continue to expand on the Gulf — the nation's second fastest growing coastline.

In the 1980s, a variety of factors and events culminated in the formation of a multiagency leadership forum on Gulf environmental and natural resources issues — the Gulf of Mexico Program. Citizens were becoming more vocal in their concerns over the environmental changes they were witnessing on the Gulf coast — habitat losses, endangered species, and toxic pollution. The latter concerns were most vividly expressed in 1983 at a public hearing on ocean incineration of hazardous waste conducted by the U.S. Environmental Protection Agency (USEPA). This single hearing drew approximately 6000 people. Citizen opposition from the Gulf, Atlantic, and Pacific states was massive and adamant and contributed to the cancellation of the ocean incineration program in 1988 (*Rachel's Hazardous Waste News*, 1988).

The ocean incineration issue galvanized public concern for the Gulf and served as a lightning rod for public frustration with what many saw as duplicate and conflicting policies both within and among government agencies. Recognizing the need for coordinated policy development and implementation as well as increased financial and technical assistance, citizens called for the formation of a program capable of addressing those concerns and responsible for taking a Gulf-wide perspective on problems and their solutions. Federal and Gulf state agencies responded and, under the leadership of the USEPA, formed the Gulf of Mexico Program in 1988.

The Gulf Program was modeled after the organization and management concepts embraced by the National Estuary Programs. Founded on the threefold principles of partnership, science-based information, and citizen involvement, the Gulf Program joined the Great Lakes and Chesapeake Bay Programs as flagships of the nation's efforts to apply an adaptive management approach to large coastal freshwater and marine ecosystems.

From its inception, the Gulf Program was envisioned as a multiagency partnership endeavor based on the simple premise that no one agency or institution alone had the technical skills, financial resources, or legislative authority needed to resolve the environmental or natural resource problems confronting an ecological system the size of the Gulf. Lacking a specific legislative mandate, the program was structured around a policy review board and a technical advisory committee composed of representatives from the major federal and Gulf state agencies concerned with environmental protection and natural resource management, as well as representatives from business, industry, the environmental community, and academia. Eight subcommittees were formed to characterize both the effects and the causes of key problems confronting the Gulf and to develop action agendas that could be implemented by the partnering agencies to resolve those problems. The issues included living marine resources, public health, habitat loss, freshwater inflow, shoreline erosion, nutrient enrichment, marine debris, and toxic substances. The program was bolstered by two support committees — one addressing public education and outreach, and the other data and information transfer among agencies.

Also key to the early momentum of the program was a citizens advisory committee appointed by the governors' offices. The committee was composed of five representatives from each state, with each of the five representing a different interest — environmental, fisheries, tourism, business and industry, and agriculture.

Throughout the program's development, the principles of involving a broad constituency, building consensus, and basing decisions on technical information and science have been followed. The Gulf Program was established under the general authority of the Clean Water Act and operates under the guidelines and procedures of the Federal Advisory Committee Act (FACA). Day-to-day administration and facilitation of the various program committees and teams has been the responsibility of the Gulf of Mexico Program Office, which is underwritten by the USEPA.

Over its 10-year history, the Gulf of Mexico Program has assisted in characterizing some of the most difficult environmental issues confronting coastal waters and has implemented a variety of demonstration projects and studies that offer solutions to those problems.

PROGRAM IN TRANSITION — A PARTNERSHIP WITH A PURPOSE

Beginning in 1996 and stimulated by concerns over the program being “federally intrusive” and fostering a regulatory agenda, the Gulf Program’s policy review board recommended a series of changes to the program’s organization and management to accomplish three objectives: (1) increase the involvement of key nongovernment interests; (2) enhance the opportunities for greater Gulf state leadership; and (3) focus the efforts of the partnership on a narrower range of environmental objectives in order to achieve demonstrable progress and measurable outcomes. Specific changes were instituted, while the fundamental principles of partnership, science-based decision making, and public involvement were reinforced.

The program has streamlined federal agency representation on the policy review board to improve the opportunities for strategic leadership by the Gulf state agencies and the nongovernment interests. At the same time, the management committee has been expanded to embrace a broader constituency so that key organizations and agencies are engaged more effectively in the operational aspects of the program. Three key interest groups have also been brought into leadership positions on the board and are involved in all activities of the program: business and industry, represented by the Gulf of Mexico Business Coalition; production agriculture, represented by the American Farm Bureau Federation’s Gulf of Mexico Committee; and environmental and social justice interests, represented by the Gulf Restoration Network.

Finally, the program has targeted four “focus areas” for concerted action: (1) public health (specifically shellfish and recreational water contamination and hazardous algal blooms); (2) excessive nutrient enrichment in numerous bays and estuaries and in the Gulf hypoxic zone on the Louisiana inner continental shelf; (3) habitat loss and degradation, with initial emphasis on emergent coastal wetlands and submerged aquatic vegetation; and (4) nonindigenous species introductions, principally targeting shrimp viruses and ballast water releases from commercial vessels. Focus teams have been formed for each area and charged with establishing measurable goals and objectives, working with the management committee and policy review board to implement those actions, and identifying the key indicators for measuring progress.

The program’s focus teams are supported by three operational committees: the two noted earlier — public education and outreach and data and information transfer — and a new modeling, monitoring, and research committee. Finally, a scientific review committee has been established to oversee technical peer reviews of specific program products and plans.

THE CHALLENGE OF SCALE

Kai N. Lee, director of the Center for Environmental Studies at Williams College, noted in his seminal work *Compass and Gyroscope: Integrating Science and Politics for the Environment*:

Social learning is most urgently needed in large ecosystems: territories with a measure of ecological integrity that are divided among two or more governing jurisdictions. Large ecosystems present some of the most difficult problems of environmental science and policy. They are complex, often badly damaged, riven by deep-rooted rivalries among several jurisdictions, and essential to the well-being of large populations.... Large ecosystems provide opportunities for learning from and about the real world. Their governance presents challenges of science, management, and politics, often entangled in ways that resist simple approaches. But without some degree of simplification there can be no learning and no transfer from one case to others” (Lee, 1993).

Even though the ecological problems confronting the Gulf are complex and enormous on a geographic scale, these sometimes seem to pale in comparison to the institutional barriers fostered by the legal, regulatory, and organizational landscape we have created. Those barriers are founded

on the very real challenges associated with human relationships, including our ability to effectively communicate and to develop not only shared goals but also common and complementary approaches to achieving those goals. Governance of the Gulf of Mexico truly encompasses the challenges and opportunities in the areas of science, management, and politics noted by Lee (1993). But however great the challenges, the opportunities for learning and taking positive actions are even greater.

To successfully seize those opportunities and achieve measurable improvements in the quality of life for the Gulf's citizens and in the quality of the Gulf's ecological foundation — its water, land, air, and living resources — the Gulf Program must form effective working partnerships — partnerships with a purpose. The institutions and interests now at the table must be willing and capable of taking decisive action to resolve existing and emerging problems before they lead to systemic crises that cannot be ignored. In essence, the Gulf of Mexico Program must be viewed by all partners as an integral forum for identifying and resolving environmental issues in the Gulf ecosystem. Ultimately, the sphere of influence generated by the current partners will have to be broadened to embrace and invite the leadership of our international counterparts in Mexico, Central America, and the Caribbean.

CONCLUSION

If we can bring to light the recognition that the Gulf is one resource shared by all, then there is very likely the possibility that the experiment in governance we call the Gulf of Mexico Program will provide the leadership needed to avoid crisis. As former Administrator of the USEPA William K. Reilly observed, the challenges and opportunities presented by the Gulf of Mexico “call upon us as never before to look beyond isolated pollution problems to chart a course of action broadly based on the health of the entire ecosystem, a course drawing together the creative energies of all levels of government, academia, business, environmental groups, and private citizens” (Weber et al., 1992). The Gulf program is doing just that in order to create a future Gulf that continues to flourish in all its natural richness and variety while embracing the needs and desires of its people. Both are inextricably linked and essential to the cultural fabric of the region and to the economic well-being of both the region and the nation.

SECTION I.4

Setting Goals and Objectives in Managing for Healthy Ecosystems

Overview: Setting Goals and Objectives in Managing for Healthy Ecosystems

Robert T. Lackey*

Section I.4 focuses on policy goals and objectives — the explicit policy targets that provide meaning and definition to the platitudes that typically dominate much of the political discourse on ecological policy. To move beyond the realm of policy platitudes (e.g., protect our planet, assure sustainable development, embrace smart growth, implement community-based environmental protection, perpetuate our cherished natural legacy, restore degraded ecosystems, achieve ecosystem health) and toward policy evaluation and implementation requires that society, through its mechanisms of governance, decide which societal values and preferences to adopt. Societal values and preferences are the criteria society uses to select from among opposing policy goals and objectives.

Scientific input is important in selecting policy goals and objectives because not all goals are feasible. Even among the goals and objectives that are ecologically feasible, decision makers, and especially the public, rarely understand the ecological consequences of each option. Ecological policy goals typically conflict, may be mutually exclusive, and have ecological consequences, each of which are known with varying levels of certainty.

Ecological goals and objectives are often cast in terms of ecosystem *restoration*, but exactly what ecological feature does society wish to restore and to what extent? What makes one ecosystem more important to society than another? For example, if society wishes to receive the benefits of a roadway, should the adverse ecological effects of highway construction be mitigated? If so, how should they be mitigated? As Zedler and Callaway illustrate in Chapter 21, not all ecological restoration efforts replace what was lost, nor can even the trajectory for restoration be predicted in advance.

Many discussions about goals and objectives end up enmeshing values and preference within the scientific information essential to evaluate the consequences of policy options. For example, scientists providing technical information in policy discussions are often accused of offering *normative science* by implicitly advocating policy and value judgments under the banner of impartial science. Normative science is science based on implicit policy preferences. An example of normative science is the use of adjectives such as *degraded* or *healthy* in describing the condition of a particular ecosystem. Such terminology under the guise of “science” conveys the message as to which ecological state is (or should be) desired and which is not. Often scientists are unaware that they have moved from science devoid of a policy preference to science that

* The views and opinions expressed do not necessarily represent those of any organization with which Dr. Lackey is affiliated.

implies that a particular policy option is preferred. The notion of ecosystem health is often criticized because of its tacitly derived value and preference character. In Chapter 22, I review the characteristics of normative science and propose a proper role for scientists to play when providing information in policy deliberations.

Debates over goals and objectives often become the crux of approaches to addressing ecological policy problems. For example, ecosystem management has burst on the land management agencies in North America as the policy approach for this century. What exactly is ecosystem management and how does it differ from past approaches to implementing ecological policy? Does it only apply to publicly owned lands, or are private lands within its scope? Is ecosystem health sufficiently robust to underlay implementation of ecosystem management? Fitzsimmons provides a critical review of the concept of ecosystem health as a basis for managing lands in North America in Chapter 23.

Most governmental policy favors, even encourages, economic development, but how do such policies relate to concepts of ecosystem health? Do healthy ecosystems imply that human populations are prospering? In some sections of the world, it appears that relatively pristine ecosystems support (by Western standards) a very unhealthy human population. If an organization such as the World Bank has alleviating poverty as one of its central policy goals, how is this goal reconciled with “healthy” ecosystems? Anderson (Chapter 34) explores the often confusing and contradictory worlds of *ecosystem health* and *economic development*.

Food security is of widespread concern and a feature of many governmental goals and objectives, but how does it relate to ecological policy? For many years agriculture operated by reducing biological diversity and channeling photosynthesis through a few plants and animals. Few would argue that biological diversity, at least in a general sense, is important to past and continuing agricultural development, but what should be the relationship between biodiversity and agriculture given that the amount of “natural” ecosystems being converted to farming continues to increase? Thrupp (Chapter 35) evaluates the relationship of biological diversity and agriculture from the perspective of assuring a long-term food supply.

Ecological goals and objectives deal with more than producing food and fiber. How does a person’s perception of quality of life relate to ecological policy? There does appear to be, at least for some people, a connection between what are often described as healthy ecosystems and their perceived quality of life. Is this relationship true only under circumstances where people are relatively affluent? In Chapter 24, Ewert explores the connection between perceived quality of life, recreation in natural ecosystems, and individual policy preferences.

Traditionally, economic development has been predicated on the natural resource development model. Early in the development of a country, its economy tends to be extractive. As the economy develops and expands, the economy generally shifts toward manufacturing and possibly toward a “service” economy. Is this the most desirable trajectory? Are concepts of *natural capital* useful in describing more effective approaches to economic sustainability? In Chapter 25, Collados provides a critical look at natural capital and ecological sustainability and their implications for developmental policies of nations.

The chapters in this section attempt to move beyond the platitudes so typical of ecological policy discourse. Each author critically evaluates the nature and character of potential goals and objectives and, in some cases, how such goals might be achieved. Some of the chapters also document what are clearly inappropriate goals because they rely on the values and preferences of scientists, rather than reflecting the values and preferences of society.

Adaptive Restoration: A Strategic Approach for Integrating Research into Restoration Projects

Joy B. Zedler and John C. Callaway

INTRODUCTION

The San Francisco Bay–Delta and the southern California coast are both highly populated regions (over 16 million people in southern California and nearly as many in the Bay area), and both have experienced substantial impacts on natural wetlands. The Bay–Delta, however, had large wetland resources historically, whereas southern California never had large wetlands; and less than 10% of the historical extent has survived coastal development. Thus, efforts to restore lost wetland habitat and ecosystem functions (services) are relatively advanced in southern California, and experiences and recommendations in this rapidly developing region may be useful to efforts in northern California and other coastal areas.

The San Diego Association of Governments predicts that southern California's population will double by 2040. As human pressures continue, opportunities for wetland restoration occur both as mitigation for the filling and dredging of wetlands and as habitat improvement measures supported by resource agencies. In an earlier paper, Zedler (1996) recommended that restoration and mitigation activities be undertaken within a regional context. The Southern California Wetlands Recovery Project has taken a bold step toward implementing that recommendation. In a recent state budget, California targeted approximately \$6 million for wetland restoration along the region's coast, following a regional inventory of coastal wetlands (<http://www.coastalconservancy.ca.gov/index.html>).

Recent experiences with habitat restoration and planning in southern California are relevant to the California–Federal (CALFED) program for the San Francisco Bay–Delta. First, we explore how a 13-year mitigation program at San Diego Bay became a model of adaptive management; next we describe how modular restoration at Tijuana Estuary was planned to incorporate scientific experiments. The experiments were planned to learn how subsequent modules should be restored. That is, there was insufficient knowledge to decide exactly how to restore habitat so that objectives would be achieved quickly and efficiently. For both San Diego Bay and Tijuana Estuary, project managers were amenable to accommodating research at the restoration sites, but the information needs developed at different times. At San Diego Bay, the studies developed along the way — an example of adaptive management, in that needs suggested research and results from the studies led to management recommendations (Table 21.1). At Tijuana Estuary, the questions were clear in advance, and research formed the basis for the restoration design (adaptive restoration). The term

adaptive restoration has been coined to describe projects designed as large-scale restoration experiments; that is, the site itself is divided into replicate subareas where different treatments are applied.

Compared with the San Francisco Bay–Delta, southern California has few opportunities for restoration and small areas available for experimentation. San Diego Bay’s two excavated wetlands, Connector Marsh and Marisma de Nación, total 28 acres (12 ha) and are a significant part of the overall opportunity for restoration at the U.S. Fish and Wildlife Service (FWS) Refuge. At Tijuana Estuary, the Tidal Linkage and Model Marsh are the initial steps of a 500-acre (200-ha) planned tidal restoration program. With large areas at Tijuana Estuary (and even larger for CALFED), it is possible to experiment early on to develop and improve methods for future restoration.

To direct research toward the most pressing issues, an assessment of the ecosystem in question and its potential for restoration is needed. With basic understanding of how reference systems operate and a list of questions about how natural resources can best be restored, restoration experiments can be developed and prioritized.

THE SAN DIEGO BAY ADAPTIVE MANAGEMENT EXPERIENCE

Although San Diego Bay is large, the remaining wetland habitats are tiny. Plans to widen Interstate 5 and construct an interchange for a new highway with a major flood control between its west- and east-bound lanes were, thus, highly controversial. These three federal projects were, nevertheless, approved and construction began in 1984. However, mitigation for phase 1 was not undertaken on schedule, and phase 2 construction was begun in violation of environmental agreements. The Sierra Club and League for Coastal Protection sued three federal agencies and won. The lawsuit reopened the Endangered Species Act’s Section 7 Consultation, in which the FWS is

required to identify endangered species whose populations are jeopardized by federal projects and to identify suitable mitigation measures. These were determined to be the excavation of about 12 acres (4.8 ha) of fill from a degraded wetland and the excavation of 17.1 acres (6.9 ha) of fill from a dredge spoil deposit (sediments previously removed from shipping channels in San Diego Bay). The sediments removed from both sites were designated for use in constructing highway ramps at the edge of the site.

The lawsuit was settled by a federal judge in 1988; this marked the beginning of a 10-year association of unlikely teammates: the California Department of Transportation and the U.S. Army Corps of Engineers (Caltrans and CoE, the mitigators); the U.S. Fish and Wildlife Service (FWS, the resource agency and regulator); and the Pacific Estuarine Research Laboratory (PERL, the monitoring and research group, headed by J. Zedler). This team worked together to evaluate the results of ecosystem monitoring and to identify shortcomings of habitat designed for three endangered species. The field studies are the subject of numerous scientific papers (Table 21.1). The aim here is to describe the adaptive management process and its outcome.

FWS established a set of criteria that were to be met for Caltrans to be relieved of habitat construction work and monitoring. Some criteria required that specific standards be met over a 3-year period, which was an innovation at the time; previous monitoring requirements were for set 1- to 2-year periods. Other standards required self-sustainability during a 3-year period; in other words, mitigation efforts would need to continue until self-sustainability was demonstrated for 3 years in succession. We knew of no other mitigation requirements that were as open-ended as these.

PERL was hired by Caltrans to begin monitoring the Connector Marsh in 1989. Caltrans selected the attributes that we should evaluate, as compliance was not expected until some time after excavation of Marisma de Nación was completed in 1990. We began by assessing the use of channels by fishes and invertebrates (required as forage for endangered birds) and the growth of cordgrass (*Spartina foliosa*, required as nesting habitat by an endangered bird). We also began sowing seeds of an endangered plant (*Cordylanthus maritimus maritimus*), which was to be reintroduced to the site as part of the mitigation requirement.

In our field studies, it became clear that the standards were not written clearly enough to specify monitoring protocols; that the endangered plant (an annual species) was not setting sufficient seed; and that the cordgrass was not growing as tall as in natural marshes. After conferring with Caltrans, we met with representatives of the management team to clarify both the requirements and the information needs. That meeting established what became our adaptive approach. We agreed to make the standards more clear; i.e., we recorded our perceptions of what was initially intended and achieved concurrence from the management team. For example, the requirement that fish and invertebrate species densities be 75% of those in natural channels was interpreted to mean densities of *native* species, not exotics. We agreed that the designated site for plant reintroduction be changed from an island that had been created by dredging channels around it (and which seemed to be too isolated from pollinators to yield adequate seed) to a remnant natural marsh where the plant had historically occurred. We further agreed that we could begin experimenting with soil amendments in the newly excavated 17-acre (6.5 ha) site to find ways to grow taller cordgrass. Caltrans agreed not to plant the entire site until we had results from the 1990 field experiment. In 1991, Caltrans implemented our recommendation that nitrogen-rich fertilizer be added to holes where plugs of cordgrass were transplanted. Later, when we saw that one-time additions were insufficient to sustain tall cordgrass (Gibson et al., 1994), we were permitted to undertake additional experiments (Boyer and Zedler, 1998) in the Connector Marsh. Independent funding was obtained for much of the research that went beyond routine monitoring. Support came from the California Sea Grant College, the NOAA Coastal Ocean Program, and the FWS Biological Resources Survey (now the USGS Biological Resources Division). The infusion of research money, although difficult to obtain and of short duration, was critical to the adaptive management program.

Gradually, we institutionalized the following process: PERL sampled as directed, with frequent interaction with the Caltrans biologist. Results were provided in a draft report to Caltrans before being distributed to the full team. Included in the report were findings from associated research projects and recommendations for work the following year. PERL then organized an annual meeting of all team members, who had received copies of the draft report in advance. At the annual meeting, PERL presented results relevant to each set of criteria (i.e., for each of the three endangered species deemed jeopardized by the project). At the end of each presentation, PERL called for decisions as needed. For example, when we had evidence suggesting that the criteria for the endangered California least tern (*Sterna albifrons browni*) had been met, we called for a decision from FWS that Caltrans was in compliance for that species. When we proposed to apply soil amendments in large-scale plots (400 m²), that decision was agreed upon by all team members as an appropriate follow-on study from experiments in 4-m² plots. We recommended using remote sensing to assess the area of cordgrass and of high marsh in both excavated wetlands, and suggested that Dr. Doug Stow, an expert in remote sensing, be brought in to apply the technique to restored wetlands. Such decisions were recorded and added to the draft report; the final report was then distributed to team members. The budget for monitoring and assessment was also discussed annually, as duties changed and some approaches were more costly than anticipated by Caltrans. Each year, the budget for monitoring was negotiated, with PERL suggesting what *could* be done, FWS indicating which tasks *should* be done, and Caltrans indicating what constraints there were on funding. Negotiations were facilitated by a sincere interest by all parties to learn what was needed to restore the site to levels that would support endangered species.

As various students undertook studies related to the project, we asked them to incorporate their findings into the annual report and to contribute to the annual presentations. Stuart Phinn was a frequent contributor, because his dissertation involved the remote sensing of different habitat types; and only he could explain where the imagery was most reliable and why digital maps of the sites were not perfectly matched with regular photographs. The oral presentations personalized the information and helped team members see the broader value of the work.

By 1996, criteria for the endangered California least tern and for the endangered plant had been met, but the site was clearly slow to produce tall cordgrass required for the endangered light-footed clapper rail (*Rallus longirostris levipes*). As much of the research on cordgrass had been paid for by funding agencies that required broad dissemination of results, our finding that the restoration was not achieving its target became widely known. Among the magazines that publicized stories based on our research were *National Geographic*, *National Wildlife* magazine, *Scientific American*, *Time* magazine, and *Science*. An April 17, 1998, headline in *Science* read, "Restored Wetlands Flunk Real-World Test." Understandably, Caltrans administrators were not happy with this publicity. Reporters and editors tended to pay more attention to the "flunking" than to the years of sincere effort and the compliances for two out of the three endangered species whose habitat was jeopardized.

Several observations in the field led us to conclude that the site would not achieve compliance for clapper rail nesting habitat in a timely manner. The large-scale experiments with nitrogen addition gave results counter to those of small-scale plots, and it appeared that fertilizing the marsh would aid its conversion to succulents, rather than lead to self-sustaining tall cordgrass (Boyer and Zedler, 1999). We summarized our long-term data on key variables (soil organic matter, soil nitrogen levels, and tall stems), and the quickest to match reference sites was soil nitrogen, which we predicted would match that of the reference site after 40 years (Zedler and Callaway, 1999). The number of tall cordgrass stems was shown to be declining, rather than increasing, as the site gradually accumulated sediments and nutrient status remained inadequate. Our prediction that compliance would be unlikely in the near future was critical to ending the mitigation program. We recommended that the FWS select an alternative penalty and end the mitigation program. Our recommendation was probably made more credible by the fact that implementing it would end our annual monitoring contracts; that is, it was clear that PERL recommendations were not biased

to continue funding. The recommendation was accepted, and FWS asked Caltrans to remove sediments from a nearby site to complete the mitigation program. Many details are avoided in this summary, but the process was fairly simple once all players were familiar with the annual routine. Absolutely key to the achievement of consensus on all decisions were the dedicated team members (essentially the same individuals from about 1990 on) and their shared goal of providing habitat for endangered species.

THE TIJUANA ESTUARY RESTORATION PLAN

At Tijuana Estuary, PERL played a major role in designing an overall restoration plan (Entrix et al., 1991) for some 500 acres (200 ha) of habitat improvement that would be implemented in 10 to 20 modules, with each module incorporating scientific experiments in the design. This approach was accepted by numerous participating agencies (FWS, NOAA Sanctuaries and Programs Division, National Marine Fisheries Service at the federal level, California Department of Fish and Game, and California Coastal Commission at the state level), and it passed public review at various hearings during the environmental impact analysis phase. The State Coastal Conservancy paid for the planning effort and guided the environmental impact statement (EIS) through the review process. As at San Diego Bay, the dedication and long-term involvement of a few individuals made this plan a reality.

Key to planning and implementing the two projects at Tijuana Estuary has been the existence of a National Estuarine Research Reserve, a resident research group, long-term research funding, managers who facilitate scientific involvement, and the long-standing assistance of the California State Coastal Conservancy. The outcome will be answers to questions that are needed to proceed with the full 200-ha restoration program at this National Estuarine Research Reserve. An award from Earth Island Institute supported several years of research. The importance of a funding base to fill in between short-term awards cannot be overstated.

Adaptive Restoration at the Tidal Linkage

The first restoration module, just 1.74 acres (0.7 ha), was excavated in 1997. This *Tidal Linkage* site has a channel that supports native fishes, invertebrates, and birds, a northern marsh plain that was planted with salvaged marsh plugs, and a southern marsh plain that was devoted to an ambitious field experiment. Because of our understanding of salt marshes, we knew that some eight halophytes would potentially grow at the site. Previous restoration efforts, however, included few species and mostly those grown from rhizomes. We hypothesized that low species diversity would slow the development of marsh functions. Hence, we designed an experiment that would show how many of the native salt marsh species needed to be planted to achieve desired ecosystem functions.

Because the question (does diversity matter?) was of broad scientific interest, the National Science Foundation funded three of us (J. Zedler, J. Callaway, and G. Sullivan) to evaluate the field experiment. As is often the case, funding was not obtained on first request, and we had to revise our proposal; hence, funds were not in hand in time to support our experimental planting of the site. If PERL had not had an award from Earth Island Institute for improving restoration methods, we would not have been able to produce the 6000-plus seedlings nor to pay helpers to plant them in the 87 field plots. Although the site was small, we designed a large uniform marsh plain to allow planting of 87 plots, each 2×2 m, as both a native plant-dominated salt marsh and a field experiment. Admittedly, it did not look like a natural marsh for the first few years, because the plots and paths between them gave it a patchwork quilt appearance. What might have been a negative feature became an advantage for public interpretation, as a nearby footbridge offered an overlook that allowed visitor center staff to describe our work and its importance to the National Estuarine Research Reserve.

Preliminary results show that species richness does little to affect seedling recruitment — the process is mostly restricted to three opportunistic species, and their seedling distributions are mostly determined by physical factors, such as elevation and open space. However, plots with diverse plantings have more complex canopies (which benefit wildlife) and more biomass belowground. Analyses of nitrogen accumulation rates are under way. We also see species-specific effects. In general, our preliminary conclusion is that species richness, species composition, and abiotic factors act together to influence the development of ecosystem structure and function. This finding supports three sides of a debate that is receiving considerable attention in the ecology literature.

Adaptive Restoration at the Model Marsh

The second module is larger (20 ac; 8 ha) and has a more ambitious experiment. Again, knowledge of how the natural ecosystem functions and observations of constructed or restored salt marshes played a central role in prioritizing the experimental approach. Whereas most natural marshes are riddled with small tidal creeks, marshes were constructed as round or square basins with perhaps a round, mounded island to provide habitat heterogeneity. It seemed reasonable to hypothesize that tidal creeks would affect nearly every aspect of marsh functioning, including plant composition and productivity, algal growth, invertebrate abundance and composition, fish use, and bird use. Hence, the model marsh was designed to compare ecosystem functioning in replicate areas with and without tidal creek networks.

Although designed in 1988, it took 10 years to obtain the engineering designs, provide the necessary supplementary impact analyses, develop sediment-control measures upstream, gain permits, and identify sources for \$3.1 million needed to excavate the site. Construction began in late 1999. PERL has added a number of experiments concerning how to prepare the site, and we will evaluate several hypotheses about how tidal creeks affect ecosystem structure and functioning. Again, the Earth Island Institute award made the planning and implementation of these adaptive restoration experiments possible.

LESSONS FOR THE BAY–DELTA PROGRAM

The CALFED program is designed to be adaptive. Although many of the restoration measures concern alteration of flows and other off-site measures, there are many opportunities for restoration site-based experiments, e.g., restoration of tidal emergent vegetation and riparian vegetation, levee setbacks, and channel dredging. Using the terminology introduced here, these efforts could be undertaken as adaptive restoration, that is, with subareas established as replicated treatments in scientific field experiments.

We have several general recommendations that may be helpful in establishing adaptive restoration modules:

- Develop an adaptive management team that meets annually, identifies priority research needs, prioritizes sites where adaptive restoration might take place, reviews research results, and recommends future actions.
- Design the restoration site to facilitate experimentation and to test alternative approaches to restoration. We emphasize the need for careful consideration of experimental design, replication of treatments, data gathering, and statistical analyses.
- Using the general goals that have been established for the Bay–Delta Program, set site-specific goals with appropriate assessment criteria so that projects can be evaluated as part of the adaptive process. While it may be necessary to modify goals during the process, an initial target is desirable and suitable for the adaptive process.
- Establish priorities for research questions based on management concerns and current knowledge; this is an area where there is much opportunity for interaction between researchers and resource managers.

- Carefully consider the scale of experimentation. We recommend that experiments be conducted along a series of scales, from mesocosms to large-scale experiments, so that specific cause–effect relationships can be identified at the small scale, while general and more diverse response patterns can be characterized at the large scale.
- Because the Bay–Delta Program offers large areas for restoration and adaptive management, it is important to phase the work and the research so that information gained in early modules can be used in subsequent modules. Initial experimentation should help improve restoration methods.
- Provide backup funding for research teams that are dedicated to adaptive restoration projects, while encouraging researchers to obtain additional competitive grants. Adding studies reviewed by the National Science Foundation will help the research gain credibility and aid in information dissemination.
- Include scientists in the adaptive management team and reward them for publishing peer-reviewed research as well as for writing guidelines for future restoration implementers and managers.

SUMMARY

At San Diego Bay, a project designed to mitigate damages due to highway and flood channel construction evolved into a model adaptive management program based on restoration. For approximately 10 years, the California Department of Transportation and the U.S. Army Corps of Engineers (mitigators), the U.S. Fish and Wildlife Service (resource agency and regulator), and the Pacific Estuarine Research Laboratory (monitors and researchers) worked together to evaluate the results of ecosystem monitoring and to identify shortcomings of habitat designed for endangered species. Multiple attempts to improve habitat based on field research were followed by the prediction that some mitigation standards would not be achieved for ≥ 40 years. The finding that habitat for the light-footed clapper rail could not be provided in a timely manner was critical to ending this phase of the mitigation program (an alternative penalty was agreed upon by all parties).

At Tijuana Estuary, an improved adaptive restoration approach has scientific experiments built into the first two modules of a 200-ha restoration plan. The first module (the 0.7-ha Tidal Linkage) has one half of its marsh plain devoted to an experiment that shows which and how many of the native salt marsh species need to be planted to achieve desired ecosystem functions. The second module (an 8-ha model marsh) is designed to compare ecosystem functioning in replicate areas with and without tidal creek networks.

Key to adaptive restoration is the willingness of managers to facilitate scientific involvement, availability of funding for restoration and research, and interest of researchers. An additional helpful condition is the ability to restore large sites as phased modules, with results from early efforts informing the planning and implementation of later modules. Given these attributes and sufficient time, the adaptive restoration approach should be able to answer critical questions about how to implement even the largest and most ambitious restoration projects.

ACKNOWLEDGMENTS

We are grateful for the support of the National Science Foundation (DEB96-19875) and the Earth Island Institute. We thank Dick Daniels for inviting this contribution.

Appropriate Use of Ecosystem Health and Normative Science in Ecological Policy

Robert T. Lackey*

INTRODUCTION

Complex, challenging, and important ecological policy issues confront society (National Research Council, 1997; Rapport et al., 1998; Science Advisory Board, 2000). Significant improvements in some aspects of the environment have been realized. Many of the more egregious forms of pollution in North America have been reduced, but the continuing increase in the human population and associated human activities have created a tangled array of ecological policy challenges (e.g., land use alteration, hydrologic modification, climate change, change in biological diversity, introduction of nonnative species [also called exotic or alien species], concern about ecological sustainability, cumulative effects of man-made chemicals, etc.) (U.S. Environmental Protection Agency, 1999). Further, the fact that commerce is increasingly international in scope complicates already befuddled ecological policy issues. Recent treaties, for example, address climate change, biological diversity, waste transport, and environmental equity — and the directives contained in such legally binding agreements must be considered when addressing domestic ecological policy issues.

Traditional approaches to implementing ecological policy typically follow the *command-and-control* (*promulgate-and-police*) paradigm (Carnegie Commission on Science, Technology, and Government, 1990). With the command-and-control approach, a narrow (e.g., water, air, chemical, or effluent), technically based standard is promulgated as a surrogate for a larger, often nebulous ecological or public health policy goal. Adherence to achieving the standard is enforced by a regulatory bureaucracy (Elliott, 1997). In practice, the typical result is a centralization of political power.

This strategy may be characterized in simple terms as relying on an elaborate system of planning in which a central administration imposes production quotas on different plants and industries through directives specifying the amount of pollution allowed to escape into the air, water, and land (Carnegie Commission on Science, Technology, and Government, 1990).

Command-and-control approaches to implementing ecological policy tend to be reductionist, thereby limiting the kinds of policy problems that can be addressed effectively (Science Advisory

* The views and opinions expressed do not necessarily represent those of any organization with which Dr. Lackey is affiliated.

Board, 1990). Attempts to correct one environmental problem sometimes create or exacerbate others (National Research Council, 1997). The command-and-control approach fits reasonably well for comparatively narrow policy problems (e.g., water quality and air quality), but it does not mesh well with complex policy problems such as the consequences of land-use changes, maintenance of biological diversity, nor the impacts of the introduction of exotic species.

The command-and-control approach to implementing ecological policy is criticized frequently as ineffective or insufficient in addressing the most important ecological concerns. For example, the U.S. Environmental Protection Agency's Science Advisory Board (1990) concluded a decade ago:

... controlling the end of the pipe where pollutants enter the environment, or remediating problems caused by pollutants after they have entered the environment, is not sufficient.

In some cases, command-and-control approaches have been effective (although perhaps not efficient cost-wise) at ameliorating the most conspicuous forms of pollution, but important ecological concerns today are not easily nor efficiently amenable to end-of-the-pipe and command-and-control approaches (Science Advisory Board, 2000).

Another criticism of the command-and-control approach is its tendency to polarize the public and rouse strong opposition to the proposed policy or regulation (Elliott, 1997). The very nature of the command-and-control approach engenders centralized decision making, top-down policy making, and public resistance (Carnegie Commission on Science, Technology, and Government, 1990). The U.S. Environmental Protection Agency (1998) has concluded:

In the past, there has been a "command and control" approach to regulation.... As with centralized decision making, the regulations have been made clear, unbending, and applicable nationally.

Lack of public support is understandable, even predictable, because ecological issues and socio-economic issues are intertwined. There are winners and losers in policy choices, so the prospect of authentic win-win solutions is illusory. Even so, many perceive that command-and-control approaches to implementing ecological policy create excessive societal strife.

Another widely voiced perception is that many command-and-control regulations are excessively intrusive, especially when the ecological benefits are not obvious or are of only local concern. Some efforts to comply with the U.S. Endangered Species Act, for example, can be expensive and socially disruptive for little apparent benefit to society or even the species being protected.

Other critics assert that command-and-control approaches do not effectively use new scientific and technical information (Elliott, 1997). Current understanding of the functioning of ecosystems, for example, has moved away from the assumption that the natural or climax condition of an ecosystem is fairly predictable, e.g., the old *balance of nature* idea (De Leo and Levin, 1997). Current thinking is that the state of ecosystems is less circumscribed (e.g., "chaotic" events are often decisive). Although rarely explicitly stated, much of the command-and-control approach to implementing ecological policy has been predicated, in part, on the balance of nature worldview.

Command and control, characteristically narrowly focused (e.g., policy reductionism), often reinforces the proclivity of many scientists to simplify science and research (e.g., science reductionism). That is, many scientists prefer to reduce complex policy problems into small, compartmentalized research pieces that can be addressed in scientifically credible ways. Thus, for scientists working in a command-and-control bureaucratic environment, there is a propensity for *both* scientists and policy makers to fall victim to the reductionist snare. Research reductionism results in excellent science that withstands rigorous scientific scrutiny, but it is not necessarily useful to policy makers in selecting from among policy options. Many scientists tend to eschew research problems that deal *directly* with complex policy problems, because such problems tend to be scientifically intractable: the results of such research would be unlikely to weather the scrutiny of other scientists.

ALTERNATIVE APPROACHES

Because the limitations of the command-and-control approach are widely recognized, many experts contend that effectively resolving complex, divisive ecological policy issues requires a different approach (Carnegie Commission on Science, Technology, and Government, 1990; Science Advisory Board, 1990). Issues in ecological policy are now less focused on relatively isolated questions, such as whether it is safe to license a certain chemical, whether it is good policy to build a particular dam, or whether we ought to spend resources to control exotic species such as the zebra mussel. Alternative and competing approaches are widely discussed in the professional literature (Norton, 1995; Gaudet et al., 1997). For example, as the National Research Council (1997) concluded:

... efforts to solve a specific problem must be considered within a broader context. This is particularly true of the growing number of regional- and global-scale problems associated with population growth, industrial development, and the corresponding pressure on limited natural resources.

Specific but disparate examples of popular modifications and permutations of the command-and-control approach are ecosystem management, community-based environmental protection, the Precautionary Principle, bioregional management, watershed management, and imposition of overarching public policy goals such as ecological sustainability, ecosystem integrity, or ecosystem health. Each alternative is championed, sometimes energetically, by its partisans.

In some alternatives (e.g., ecosystem management and community-based environmental protection), command and control is often viewed as one of several possible policy *tools* to help achieve the overarching policy goal. Other alternatives (e.g., bioregionalism) are the antithesis of the centralized, bureaucratic command-and-control philosophy. Taylor (1991) portrays the political propensity of adherents to bioregionalism as one of devolved decision making:

Bioregionalism envisions communities of creatures living harmoniously and simply within the boundaries of distinct ecosystems. It criticizes growth-based industrial societies preferring locally self-sufficient and ecologically sustainable economies and decentralized political self-rule.

It is easy to dismiss as scholarly quibbling the arguments about which of the competing approaches for implementing ecological policy or natural resource management ought to be adopted, but that would be a mistake. It is unfortunate that the discussion about the competing concepts has the flavor of “a battle of buzzwords” (Noss, 1995), because the discussion is more than a mere scholarly debate; the future direction of ecological policy will be determined, in part, by which concept wins.

ECOSYSTEM HEALTH

Ecosystem health is the most popular of the emerging modifications of command and control (Gaudet et al., 1997; Belaousoff and Kevan, 1998; Rapport et al., 1998). Many of the popular alternatives and modifications to command and control (e.g., ecosystem management and ecosystem sustainability) have notions of ecosystem health at their core (Lackey, 1998). Adoption of ecosystem health as a public policy goal could have major, although often unclear, ramifications:

... an ecosystem health focus sets the stage for a new environmental ethic — one in which actions may be judged by their contribution to maintaining or enhancing the health of the regional ecosystem (Rapport, 1995).

Ecosystem health enjoys a wide following, especially in the popular press and with some environmental advocacy groups (Gaudet et al., 1997). Part of the appeal is that it appears to be a

simple, straightforward concept (Ryder, 1990; De Leo and Levin, 1997). Applying the human health metaphor to ecosystems, it proposes a model of how to view ecological policy questions. By implication, the metaphor also defines what types of scientific information are essential to help decision makers (Shrader-Frechette, 1997).

Ecosystem health, especially in the 1970s and 1980s, was often defined in nebulous terms — definitely not as clearly articulated constructs (Steedman, 1994). It was typically depicted as a broad societal aspiration rather than a precise policy goal or management target. Lacking precise definition, it was difficult to consider the concept as a practical public policy goal. As the concept emerged from semantic ambiguity with more precise definition and description, it became a serious topic for discussion and, predictably, a lightning rod for conflict.

The most alluring feature of the human health metaphor is that most people have an inherent sense of personal health (Ryder, 1990). By extension, many proponents argue that most people almost instinctively envision a “healthy” ecosystem (e.g., a forest, lake, or pastoral landscape) as pristine or at least appearing to be minimally altered by human action.

Most concepts of human health focus on the *individual* human, whereas ecosystem health treats the *ecosystem* as the unit of policy concern, not the individual animal or plant (Schaeffer et al., 1988). Concerns about *individual* animals or plants — the typical focus of animal rights and animal welfare policy — are usually not the level at which *ecological* policy is debated.

There remains considerable variation in the concept conveyed by the words *ecosystem health* (Calow, 1992; De Leo and Levin, 1997). Karr and Chu (1999), for example, reflect a common, but not universal, position that concepts of ecosystem *health* and *integrity* are fundamentally different. They define ecosystem *health* as the *preferred* state of ecosystems modified by human activity (e.g., farmland, urban environments, airports, managed forests). In contrast, ecological *integrity* is defined as an *unimpaired* condition in which ecosystems show little or no influence from human actions. Ecosystems with a high degree of integrity are natural, pristine, and often labeled as the baseline or benchmark condition. *Natural* ecosystems would continue to function in essentially the same way if humans were removed (Anderson, 1991).

Others make no such clear distinction and may describe ecosystem health and integrity as different words for the same general concept. Regier (1993), for example, concludes that:

... the notion of ecosystem integrity is rooted in certain ecological concepts combined with certain sets of human values.

and, thus, a desired ecosystem condition:

... other than the pristine or naturally whole may be taken to be “good and normal.”

Hence, if one accepts that there are multiple (and equally acceptable) benchmarks for ecosystems with integrity, then the terms *ecosystem health* and *ecosystem integrity* would be conceptually the same. However, for the remainder of this chapter, I will use the concepts and definitions of ecosystem health and ecosystem integrity used by Karr and Chu (1999), where the two notions represent different but related intellectual constructs.

The majority of ecological policy debates concern ecosystem *health* rather than ecosystem *integrity* (Westra, 1998). Such an emphasis on health (altered ecosystems) is understandable because the vast majority of ecosystems are not pristine; hence, according to the definitions used here, altered ecosystems lack at least some integrity. Westra (1998) clearly describes the relationship between the two concepts:

... an ecosystem can be said to possess integrity when it is wild — that is, free as much as possible from human intervention today, and “unmanaged,” although not necessarily pristine. This aspect of integrity is the most significant one; it is the aspect that differentiates the wild from ecosystem health, which allows support and manipulation.

NORMATIVE BASIS

The concept and implementation of ecosystem health are surrounded by controversy (Jamieson 1995; Wicklum and Davies, 1995; Callicott, 1995; Belaoussoff and Kevan, 1998). Addressing questions of ecosystem health might appear to be a fairly scholarly, perhaps even arcane, activity, free from the policy intrigue that dominates much of the science and policy underlying environmental management, but such is not the case. Concepts of ecosystem health are seldom afforded the luxury of dispassionate discussion because, as Wicklum and Davies (1995) observe:

The phrases ecosystem health and ecosystem integrity are not simply subtle semantic variations on the accepted connotations of the words health and integrity. Health and integrity are not inherent properties of ecosystems.

Wicklum and Davies (1995) realize that the words *health* and *integrity* elicit powerful, positive images even if their meanings are ambiguous. Therefore, they argue, a precise understanding of these words is essential because they are likely to be used, and given a variety of meanings, by policy advocates, politicians, bureaucrats, and the general public. In practice, it may fall to scientists and other technocrats to provide operational clarity to these perplexing, value-laden, normative concepts that appeal on an intuitive level to nearly everyone. Unfortunately, but typically, normative ecological concepts, such as ecosystem health, become general perceptions, perhaps useful in general conversation but impossible to quantify (Ryder, 1990).

Ecosystem health and other normative concepts have become highly charged political terms (Jamieson, 1995), often to the extent that they have become shorthand descriptors for one faction in political debates. Even in the relatively isolated venues of academic and government laboratories, an assertion that ecosystem health and integrity are not intellectually sound concepts may be sufficient to have the perpetrator branded as a political reactionary. Conversely, proponents may be categorized as zealots whose political aspirations have corrupted the sanctity of the scientific method. As Callicott et al. (1999) maintain, “partisans of a single normative concept try to make it cannibalize or vanquish all the rest.”

Some (Shrader-Frechette, 1997; Kapustka and Landis, 1998) have counseled against using the concept of ecosystem health to communicate to the public about environmental issues. To be sure, thoughtful discussions about ecosystem health and similar concepts are usually abstract, often contentious, and rarely lead to consensus; but is the use of the health metaphor, even as a heuristic tool, ill-advised? Kapustka and Landis (1998) exhort against the metaphor because it is misleading and based on the chosen values and judgments, not an *independent* scientific reality. Conversely, Callicott (1995) concludes that ecosystem health is intellectually defensible and heuristically valuable; but he concedes that the *value*, thus the calibration, of ecosystem health is subjective. Indeed, Callicott et al. (1999) classify it as an “ill-defined normative concept” that reflects the “occurrence of normal ecosystem processes and functions;” but most discussions rarely explain clearly how current policies would change if attainment of ecosystem health became a public policy goal. Perhaps one way to make progress would be to move discussions beyond policy platitudes and definitional nuances and toward assessments of the specific *implications* for individuals and society of implementing the concept.

Most frustrating to some critics of the health metaphor is the charge that they have rejected a concept but not offered an alternative. Even many supporters of the utility of the notion of ecosystem health concede that it is easy to identify its conceptual limitations (Callicott, 1995). Developing alternatives that overcome the shortcomings has been much more difficult. If critics end up spurning ecosystem health, what do they offer as an alternative? Better alternatives are not obvious.

Regardless of the merit and direction of the scholarly debate, notions of ecosystem health frame important public policy issues (i.e., sustainability of agriculture, overuse of marine ecosystems, scarcity of water for domestic and agricultural use, and ecological consequences of introduced species) (Shrader-Frechette, 1997). Ecological policy issues are not mere abstract intellectual concerns, but matters that affect people’s daily lives.

IMPLICIT ASSUMPTIONS

At the core of the debate over ecosystem health is a number of implicit but highly contested assumptions. First and foremost is the long-debated assumption that ecosystems are *real* (Calow, 1992; Callicott, 1995). Kapustka and Landis (1998), however, assert that “no human has ever seen an ecosystem” because it is not a discrete unit like individual birds, trees, or worms, or even populations of organisms. When a science or policy problem is specified (i.e., a “salmon” issue), then the ecological boundaries (i.e., the *ecosystem*) follow intuitively. Thus, ecosystems are context-specific because they cannot be delimited without a science or policy concern or issue; therefore, they may have heuristic and problem-solving value but are not analogous to the patient in medicine (Suter, 1993).

Although rarely stated explicitly, in most formulations of ecosystem health there is a premise that *natural* systems are healthier than human-altered systems (Wicklum and Davies, 1995). For example, consider a defined geographic location and, given the alternatives of a pristine woodland, a housing subdivision, or an industrial complex, which is the healthiest? The subdivision may be necessary, even somewhat aesthetically pleasing, and the industrial complex may serve a worthy purpose; but almost everyone implicitly considers the “unaltered” woodland to be the *healthiest*. Tacitly, the assumption is that pristine, or the less altered, is good and preferred; highly altered ecosystems, in contrast, are less desirable, if not *degraded*. Thus, recognizing the normative basis for ecosystem health, Fairbrother (1998) concludes: “use of the term ecosystem health as a definition of an idealized state is not an appropriate paradigm.”

Another common assumption involves the importance of biological diversity to *society*. Biological diversity is certainly an important element in understanding the structure and function of ecosystems, but the key policy assumption revolves around the level of importance *society* assigns to biological diversity or its constituent elements. For example, some argue that biological diversity is such a core (i.e., societal) policy value that scientists should actively lobby for it. As Meffe and Viederman (1995) bluntly recommend:

Scientists can take a clear stand that biodiversity is good, that functioning and intact ecosystems are good, that continued evolutionary change and adaptation are good, and that diversity and variation in general is good. Scientists cannot and should not remove themselves from these usually unstated value judgments.

Meffe and Viederman (1995) assert that values in science are always present, whether admitted or formally expressed by scientists, and that the policy process merely focuses values more clearly and honestly. Therefore, scientists should drop the facade of policy neutrality and lobby for those policies they deem to be in the best interests of society.

Invariably, concepts of ecosystem health implicitly assume that certain ecosystem features such as biological diversity have an *inherent* policy importance (Schaeffer et al., 1988). Ecosystems are complex, typically in both structure and function, and the diversity of species within an ecosystem is important to determining how that particular ecosystem functions; but biological diversity is *inherently* no more important to ecosystems than are nutrient cycling, carbon storage, or the rate of photosynthesis. As a public policy priority, and apart from its ecological function, society collectively may ascribe high (or low) value to preservation of certain, perhaps all, species based on *human* values and preferences.

Although not universally assumed, a common implicit assumption is that there is a *natural* ecosystem state (i.e., balance of nature) akin to the simple homeostatic dynamics of physiological systems (Anderson, 1991). The existence of such a natural state is appealing because disruption of ecosystem balance — deviation from the natural state — could be used to define and measure health. Unfortunately, this idealized view of ecosystems does not typically exist. Ecosystems may not predictably approach single-point equilibrium but may oscillate over time in a fairly indeterminate manner.

Another assumption concerns the degree to which human activities should be considered *natural*. Many proponents of ecosystem health contend that a fundamental goal of managing ecosystems is to maintain or restore their *natural* structure and function (Hunter, 1996). Outside of ecosystem reserves, some deviation from natural would be tolerated to meet human needs, but the benchmark would be the *natural* state of the ecosystem in question (Anderson, 1991). Even defining the *natural* state of an ecosystem is *de facto* an implicit policy preference when used in policy discussions. For example, in North America, is the natural condition that which existed at the time of initial human arrival (~13,000 to 15,000 years ago) or at the time of European and African arrival (~500 years ago)? To a dissimilar degree, both groups of immigrants and their offspring altered ecosystems (Hunter, 1996). Selecting which of these two benchmarks (or another one) is *natural* is a value-based decision.

NORMATIVE SCIENCE

Few challenge the assertion that societal aspirations drive the environmental management goals inherent in implementing ecosystem health, but the question remains: Which societal aspirations will be selected (Gaudet et al., 1997)? Society is not a monolith, and there are many competing opinions of what is important.

The language and discussion of ecosystem health is value laden (Jamieson, 1995), but how are societal values and preferences to be incorporated when using ecosystem health in public policy? The crux of the policy challenge is deciding which of the diverse set of societal preferences is to be adopted. Resolving policy issues always consists of trade-offs, partially or entirely exclusive alternatives, winners and losers, and plenty of compromises.

Consider any specific ecological policy issue and ask: Who are the stakeholders and how would their input be used to define ecosystem health? The task is relatively easy when policy problems are defined narrowly, such as licensing a particular chemical or authorizing a timber harvest rate for an individual forest, but what about for achieving a broad societal aspiration (like ecosystem health)? For example, are the stakeholders for a national forest local or national? Obviously, local residents are most directly affected by policy decisions, but the land is “owned” by everyone in the nation. The policy preferences of local residents are likely to differ from those with a national perspective.

What role should science and scientists play in defining ecosystem health? Scientific information is important, even essential, but it is only part of what is needed (Gaudet et al., 1997). Most important ecological policy issues involve coarse scales. Unfortunately, most scientific information is finely scaled and narrowly focused, thus not directly relevant to many ecological policy questions. Further, political institutions (legislative and regulatory agencies) must balance competing values and preferences, so scientific information is merely one facet of decision making. For adjudicating conflicts over values and preferences, science offers no moral or ethical guidance (Kapustka and Landis, 1998).

An argument is sometimes advanced that, because ecosystem health shrouds difficult and painful trade-offs under the guise of science, its use inhibits incorporation of societal values and preferences by not forcing an explicit selection from competing policy options. As Suter (1993) observes in evaluating various attempts to implement ecosystem health:

Use of unreal properties (particularly unreal properties with imposing names) in environmental regulation obscures the bases for decision making; increases the opportunity for arbitrariness; and decreases the opportunity for informed input by the public, regulated parties, or advocacy groups.

Toll (1999) unequivocally concludes that “environmental problems cannot be solved without applying some sort of value system.” Shrader-Frechette (1997) charges that the concept of ecosystem

health does little, in spite of the volume of rhetoric, to improving decision making because proponents have failed to:

... clarify the precise respects in which the term yields additional scientific explanation beyond those provided by assessments of production, biodiversity, and so on.

APPROPRIATE USE

Regardless of the precise notion of ecosystem health asserted, it is important to understand its use in implementing ecological policy. The most redeeming feature is its ability to help clarify complex policy questions (Calow, 1992). The metaphor of health applied to ecosystems is simple whereas ecological policy problems are complex; the decision options are many and sometimes counterintuitive; and the consequences of implementing each option are rarely certain.

Although not essential, concepts of ecosystem health *may* help explain to the public the ecological consequences of policy choices, thus potentially reducing the likelihood (to the public) of *unexpected* consequences. Helping avoid surprises that result from policy decisions is a useful characteristic of any decision-support tool; but unfortunately, surprises are a common trait of ecological policy decisions (National Research Council, 1997). If society decides, for example, to have a dam constructed which causes an *unexpected* (to the public) loss of a migratory population of fish, then society lacked the appropriate scientific understanding of the consequences of the decision. If, on the other hand, loss of the fish population was *expected* (by the public), then the benefits of dam construction were judged by the public to be sufficient to warrant the loss of the fish population.

Another feasible use of ecosystem health is that it potentially allows society to understand more easily complex ecological policy questions (Shrader-Frechette, 1997). If the ecological information is complex, as is often the case, it is difficult to provide helpful, understandable information to decision makers unless there is a relatively simple intellectual organizing framework such as ecosystem health. However, excessive simplification of scientific information has the risk of misleading decision makers. Thus, the complexity of ecological systems should not be overlooked in an attempt to provide helpful information to decision makers (National Research Council, 1997).

There are properties of ecosystem health that make it prone to misuse. Misuses may be intentional and done in an effort to achieve advantage in policy debates, or simply be due to ignorance of the fact that the concept has a normative basis.

The most pervasive misuse of ecosystem health and similar normative notions is insertion of personal values under the guise of *scientific* impartiality. Most concepts of ecosystem health require a benchmark (i.e., a *desired*, *preferred*, or *reference* condition) of an ecosystem. Often, the implicit assumption is that an undisturbed or natural ecosystem is somehow superior, thus preferable to an altered one (Anderson, 1991). An ecosystem, once altered by human activity, is different from the previous state, but there is nothing *scientific* that compels any ecological state to be considered preferred or better (healthier). Lele and Norgaard (1996) caution those searching for scientifically derived benchmarks for ecosystems: "Naturalness as the benchmark is neither value-free nor logically or practically usable."

Practical expressions of ecosystem health and ecosystem integrity should reflect societal values and preferences (Gaudet et al., 1997). A misuse of the concepts is the situation in which professionals, usually operating from bureaucratic positions, *de facto* determine healthy (i.e., preferred) target ecosystems conditions. Concepts of ecosystem health or ecosystem integrity are normative because someone must decide what ecosystem condition or function is *good* (Sagoff, 1995). Ecosystems have no preferences about their states; thus preferred states or *benchmarks* must come from the individuals doing the evaluation (Jamieson, 1995). One common approach is to arbitrarily select reference sites to serve as the benchmarks for the ecosystems in question. Kapustka and

Landis (1998) conclude that the principal danger for scientists attempting to define healthy ecosystems comes from the incorporation of beliefs, morals, values, and ethics as *properties* of ecological systems.

Another less obvious but disconcerting use of the concepts of ecosystem health and integrity is defining a public policy goal in vague terms that engender broad public support, labeling it ecosystem health or ecosystem integrity, but camouflaging the ramifications of its adoption. Indeed, there is general public support for the idea of maintaining ecosystem health, but few members of society grasp the consequences of such a policy approach. The implications for democratic processes are rarely revealed, much less debated. Westra (1996), for example, candidly stated some far-reaching political consequences:

... no country's unilateral decision, no matter how representative it might be of its citizens' values, should be permitted to prevail, unless it does not conflict with the global requirements of the ethics of integrity, thus with true sustainability.

Another inappropriate use of the concept of ecosystem health is pejoratively categorizing opposing policy choices. After all, the competing policy choices must, by definition, not be appropriate for achieving ecosystem health. One policy choice then becomes identified as promoting *health*, with the alternatives struggling to avoid being dismissed as arguing for *sickness*. For example, a policy decision to drain a wetland to create a cornfield might legitimately be categorized as appropriate to maintain ecosystem health. Either the wetland or cornfield could be healthy, depending on the societal preferences embraced. Because *health* conveys a positive political connotation, the common practice in policy debates is to capture the high ground by labeling *your* policy choices as necessary for health and those of your opponents as leading to sickness or ecosystem degradation.

Environmental managers are culpable, often unintentionally, of misusing the concept of ecosystem health. Understandably, those responsible for making difficult, controversial policy decisions may be reluctant to define their goals clearly; so they sometimes, perhaps unintentionally, embrace ecosystem health in the belief that it is a scientifically operational term. After evaluating the potential uses of the health metaphor in environmental management, Suter (1993) concludes:

... environmental managers are active agents, translating the inchoate norms of the current generation and the poorly predicted needs of future generations into specific actions to protect or restore real, valued properties of actual ecosystems.... Hence, the decision to abandon ecosystem health as a goal is not just a matter of semantics.

As Kapustka and Landis (1998) admonish: "If we are to manage the environment, it should be done with the clear knowledge that choices will have to be made, not fueled by misplaced desires or myths."

ALTERNATIVES

Ecological policy issues such as managing the consequences of human land use, reduced biological diversity, or the cumulative effects of chemical use, are real and demand serious attention by society (Science Advisory Board, 2000). Concepts based on normative science can be compelling, but even most proponents concede that there are serious conceptual or operational difficulties with such concepts. What are the alternatives, if any?

The most direct alternative to using normative science is to cease using words such as ecosystem health and simply describe what is proposed. More specifically, rather than propose a policy objective of managing a forest for health, express exactly and clearly the management objective.

Another alternative is to demand coherent, clear definitions of the normative concepts of ecosystem health. There are multiple definitions for the same words, so consensus on the exact meaning is essential to focusing policy debate on societal trade-offs, not semantic niceties. The Environmental Protection Agency (1998), for example, defined ecological *integrity* as the “ecosystem structure and function characteristic of a reference condition deemed appropriate for its use by *society*” (emphasis added). Thus, by adopting this definition, the appropriate ecological reference condition — the benchmark for normative evaluation — is decided by society, not by scientists applying their own policy preferences.

Regardless of whether normative concepts are used in ecological policy deliberations, public involvement (even as fractured as the public often appears to be) is essential because *values* drive policy. Public involvement should be at the essence of using normative concepts because of their requirement for *inherent* value judgments. As Rykiel (1998) explains:

In a simplistic sense, science deals with true and false, whereas society deals with good and bad. Science can delineate the possibilities and describe the system that is likely to result from a policy, but it cannot decide if the resulting system is good or bad.

Thus, policy *decisions* are, by definition, normative because values and preferences were used by the decision maker to select a particular option.

Another alternative to using ecosystem health is to treat ecological policy issues as yet another complex public policy question and not to rely on any metaphor. Other policy issues (e.g., welfare, education, energy, transportation) are also complex and challenging, but overarching, explicit heuristic models or metaphors are not typically used.

CONCLUSION

Ecology has become much more than a scholarly discipline; it has impacts far beyond simply enhancing our understanding of ecosystems. Many uses of ecology have a strong normative flavor. As Worster (1990) observes:

The science of ecology has had a popular impact unlike that of any other academic field of research. Consider the extraordinary ubiquity of the word itself: it has appeared in the most everyday places and the most astonishing, on day-glo T-shirts, in corporate advertising, and on bridge abutments.

The future role of normative science (and ecosystem health in particular) is uncertain. At the ideological extreme, there are stark opinions. Some argue that normative science is desirable — even essential — for implementing ecological policy. Scientists, they assert, have an obligation to incorporate *policy* value judgments into ecology, even to the point that such *science* concepts as ecosystem health should be adopted as the cornerstone of ecological policy (Callicott, 1995). Some scientific disciplines and professions (e.g., conservation biology, restoration ecology) unapologetically embrace normative science postulates as the core of their trade (e.g., biological diversity is inherently good; extinction of populations and species is inherently bad; ecological complexity is inherently good; evolution is good; biological diversity has intrinsic value) (Soulé, 1985).

Others, however, assert that normative science (e.g., ecosystem health) hides, under a veneer of science, the reality of trade-offs involving competing personal and societal values and preferences (Kapustka and Landis, 1998). The proper role of science is to help lay out options and assess the consequences of various choices, and it is only part of the needed input (Tingey et al., 1990; Shaw et al., 1999).

Scientists and scientific information will continue to play an important role in resolving ecological policy, but the role, in my opinion, should be carefully circumscribed (Lackey, 1999). Often, even among scientists, ecology has been treated more as a belief system than a science. It is easy,

even encouraged, for scientists to abuse privileged roles in ecological policy debates by surreptitiously labeling personal values and policy preferences as “science” (Salzman, 1995).

Understanding the values and preferences of society is crucial to appropriately implementing concepts of ecosystem health, but obtaining such understanding credibly is difficult. Political institutions do not provide such understanding or guidance in efficient ways. To assert that concepts of ecosystem health are merely scientific constructs is incorrect. As Russow (1995) concludes, “the claim that scientific descriptions in general or measures of ecosystem health in particular are value neutral is simply false.” The likely alternative to public involvement is that the values of scientists and other technocrats will be used as surrogates for societal values and preferences.

Perhaps the term *ecosystem health* has already become a political term, a code word for a particular policy or political position. Even now, invoking ecosystem health often is equated with a green political position. Becoming identified as a political term is unfortunate because the word and concept lose usefulness in serious policy, public, and scientific debate.

A different risk for the future of ecosystem health is that it becomes co-opted and, ultimately, marginalized. For example, if everyone adopts the term and becomes an advocate of ecosystem health, then the term and concept have lost their usefulness. In policy deliberations the terms are now political rhetoric — encompassing a suite of meanings that everyone readily accepts as reflecting each’s individual, though divergent, policy positions.

The ecological policy concerns that engender widespread debate over ecosystem health and other normative constructs will not disappear. These concerns need to be addressed because of the increasing demand on limited ecological resources (Salwasser et al., 1997). The resolution of ecological policy is likely to become increasingly challenging because interactions among the planet, its nonhuman inhabitants, and its large and still expanding, human population constitute a dynamic system of increasing complexity (National Research Council, 1997). Whether one finds intellectual sustenance in the notion of ecosystem health, the policy concerns it attempts to confront are genuine.

Ecosystem Health: A Flawed Basis for Federal Regulation and Land-Use Management

Allan K. Fitzsimmons

INTRODUCTION

In the U.S. many scientists, politicians, environmentalists, and others see ecosystem management as the path to a correct relationship between people and nature. They argue for the new paradigm of ecosystem management because, wrote Carl Reidel and Jean Richardson (1995), “Put simply the old paradigms are no longer scientifically or politically valid.” The traditional anthropocentric approach to natural resource policy that blends multiple use, conservation, preservation, and protection of human health leads to “collapse of life and living as we know it” and must be replaced by “ecocentrism ... and ecosystem management” according to Roderick Nash (1994). In the new paradigm world of ecosystem management, protection of ecosystem health, integrity, and sustainability replaces concern for improvement in human well-being at the core of government environmental and natural resource policies. Government must use regulations, permitting, planning, and other means to control land use on public and private lands to see to it that ecosystems remain healthy or are restored to a state of health. In 1998 former President Clinton’s last chief of the U.S. Forest Service (FS), Mike Dombeck, said, “Our first priority is to maintain and restore the health of our ecosystems.” Dale Bosworth (2001), the new FS chief under President Bush, echoed Dombeck, “Today, the role of the Forest Service is to restore and maintain healthy ecosystems to meet the needs of present and future generations.”

In this chapter, however, I argue that the ecosystem concept itself and the notion of ecosystem health are too arbitrary and ambiguous to provide a viable basis for prudent public policy or land use management.

VAGUENESS OF THE ECOSYSTEM HEALTH CONCEPT

Researchers vigorously debate the validity of the ecosystem health concept and its value for public policy making, but observers of all stripes generally agree that the idea remains imprecise (Shrader-Frechette and McCoy, 1993; Goulden, 1994; Jamieson, 1995; Callicott, 1995; Lackey, 1996; Sagoff, 1997; De Leo and Levin, 1997; Rapport, 1998; Wilkins, 1999; Karr, 2000; Lancaster, 2000; Levin, 2001; Lackey, 2001). David Rapport (1998), a strong advocate of making the protection of ecosystem health “a super societal goal,” nonetheless pointed out that, “The

question of what constitutes ecosystem health remains somewhat perplexing and controversial.” Benjamin Haskell, Bryan Norton, and Robert Costanza (1992) found that there is no “clear conception of the term” and that it has “never been defined well enough” to make it useful for policy purposes, while Peter Calow (1995) concluded that the search for a definition “has proved somewhat elusive.” After reviewing the work of his colleagues, Rapport (1995) observed that there “are a plethora of attempts to define ecosystem health ... [that] range widely from very broad definitions which incorporate biophysical, human, and socioeconomic components to definitions focusing primarily on the biophysical aspects to definitions which focus on a single indicator within the biophysical domain.” The public can rightly ask why protection of ecosystem health should become the centerpiece of natural resource policy when its proponents cannot even agree on a definition of the term.

Citizen perplexity will only increase with further investigation of the idea. I will not review the variety of definitions offered for ecosystem health, but a look at some thoughts of notable scholars working in the field is instructive. For Bryan Norton and Robert Ulanowicz (1996), “The capacity for creativity constitutes the crux of what is normally referred to as ecosystem health.” But what is *creativity*? In their view it is the ability of an ecosystem to solve problems and that in turn requires the ecosystem to possess “a requisite amount of ordered complexity” and an adequate level of “internal incoherence.” And what is *ordered complexity*? For them, an ecosystem must contain enough “apparatus” to respond to events via “a channelized sequence of reactions.” And what is *internal incoherence*? That is the presence of “dysfunctional repertoires” not normally used by the ecosystem but that serve as reservoirs of “stochastic, disconnected, inefficient features that constitute the raw building blocks of effective innovation.” This sequence of fuzzy ideas led them to accept the Haskell et al. (1992) view: “An ecological system is healthy and free from ‘distress syndrome’ if it is stable and sustainable; i.e., if it is active and maintains its organization and autonomy over time.”

Let me apply these ideas to a specific ecosystem: a whale carcass. (Norman Christensen and his fellow members of the Ecological Society of America’s Ad Hoc Committee on Ecosystem Management, 1996, told us, “A dung pile or whale carcass are ecosystems as much as a watershed or lake.”) We can all understand how the whale, when it was alive, was active and maintained its organization and autonomy over time. The brain directed purposeful actions to secure the whale’s continued existence. Various organs and other parts of the whale performed specific functions that combined to sustain its life. While alive, the whale consciously sought to maintain itself.

A moment after the whale’s demise, however, what had been a whale became an ecosystem made up of large amounts of now-dead tissue plus various biota that had found the once-living whale a nourishing habitat. With no brain or central nervous system, what now supervises the effort to keep the carcass-as-ecosystem stable and sustain its presence on the beach over time? How does this supervisory entity do its job? Or, if there is nothing in charge of maintaining the carcass, how do separate players or forces residing within it collectively decide that keeping the carcass together is a good idea? How do they coordinate with each other to achieve their common goal? In short, what allows the carcass to be creative in defense of itself as an organized whole? We know that agents of other ecosystems — crabs, seagulls, a host of other living things, and physical components of the environment — will make short work of the carcass, thus dooming efforts of the new ecosystem to maintain itself. At the very least, therefore, we must conclude that either carcasses-as-ecosystem are inherently unhealthy or that the notions of stability, sustainability, and purposeful action over time by an ecosystem to maintain its organization and autonomy are poor criteria of ecosystem health.

How do ideas in the Norton and Ulanowicz view of ecosystem health and those in the Haskell et al. definition square with other aspects of current ecological understanding? For example, most ecologists renounce the equilibrium model in favor of a nonequilibrium model (Hagen, 1992; Rapport et al., 1995; Christensen et al., 1996; De Leo and Levin, 1997). The ideas of stability and

sustainability, however, flow from the rejected equilibrium model; so what are their meanings here? The nonequilibrium model makes it clear that the landscape constantly changes; therefore, how can an ecosystem's health depend on its ability to achieve the impossible goal of maintaining itself over time?

Can ecosystems have properties like creativity, or be capable of innovation, or actively seek to perpetuate themselves? Together these attributes assume that ecosystems exist as real and discrete organizational entities above the species level that have inventoried themselves so that they know what they should look like and what they should be doing. It suggests that ecosystems deliberately gather and evaluate information to determine what combination of factors are harmful to their self-preferred state and subsequently plot a course to avoid or overcome injurious changes. Such attributes presuppose consciousness, the ability to be aware of external happenings and take purposeful action to achieve a particular goal. Yet such abilities are characteristics of living things, which most researchers now steadfastly maintain ecosystems are not. Ecologists widely agree that the discipline abandoned superorganicism in decades past. As Frank Golley (1993) wrote, the ecosystem concept itself is properly criticized "when ecosystem scientists propose that ecosystems are self-regulated superorganisms with the purpose of maintaining stability." The preface to the proceedings of a NATO advanced research workshop on ecosystem health includes the finding, "All who have been involved in this Workshop reject the concepts of ecosystems as superorganisms and as homeostatic systems" (Rappaport et al., 1995). One cannot reconcile the abandonment of the equilibrium paradigm and superorganicism with claims that ecosystems are creative, innovative, and seek to maintain themselves over time.

Given the nebulous nature of the ecosystem health idea, one should not be surprised there is little agreement on its measurement. Shrader-Frechette and McCoy (1993) pointed out that people know the norms of human health but comparable norms for ecosystems do not exist. Why the difference? The medical community knows about diseases that attack various components of the human body and their respective threats to the body's ability for continued functioning. When considering human health, a real and living patient is before the doctor. Every other physician who enters the examination room would instantly recognize the exact same patient. They would agree about function, structure, and placement of the patient's component parts as well as generally concur about the relative importance of each. They understand that the individual parts do not have life separate from the whole and that the parts perform their functions to serve the central purpose of maintaining the patient's life. Doctors can differentiate between life and death of the patient.

In contrast, when considering ecosystem health, the ecodocor's patient is neither real nor alive. Other ecodocors view the same landscape and may see quite different patients. Even if they can agree on the presence of a particular ecopatient, ecodocors may or may not concur on the patient's parts or their functioning or their relative importance. They may or may not share the same views regarding what conditions represent the patient's death. Perhaps the only thing they may agree on is that, unlike the medical doctor's patient, separate parts of the ecosystem-as-patient possess life without any regard to the whole.

A landscape in constant flux confronts scholars seeking to give substance to the ecosystem health notion. Biota continuously redistribute themselves in space. Populations wax and wane. Rates of change vary from species to species and place to place and over time. Physical processes likewise vary though space and time at different rates. How can we objectively proclaim some changes as healthy but label others as indicators of disease for public policy purposes? Jill Lancaster (2000) concluded, "Ecological health (and its synonyms) cannot be defined or measured objectively and that claims to the contrary are essentially fraudulent." Vagueness and internal contradiction render the ecosystem health concept inappropriate as a guide to better environmental policy making. But these flaws, while fatal in their own right, do not get to the heart of the matter; and that is the nature of the presumed patient, ecosystems themselves.

NATURE OF ECOSYSTEMS

Ecosystems are mental constructs, heuristic devices, rather than tangible landscape units possessing intrinsic characteristics like health or integrity. Ecosystems represent geographic conveniences fabricated by researchers, not objective reality. They are but portions of the landscape — regions — that researchers arbitrarily label as this or that ecosystem. What some people call the Greater Yellowstone Ecosystem is no more a discrete, organized entity seeking to maintain itself against external or internal threats than is the Great Plains region a physical totality defending itself against the Midwest region to its east or from a growing greater Denver region within its borders.

The study of landscapes and regions is the cornerstone of one of our oldest fields of knowledge, geography. More than half a century ago, after a lengthy and spirited debate, geographers abandoned the notion that the regions they studied were actual objects. They recognized that regions are tools that may play an important role as intellectual devices for organizing, analyzing, and presenting information in a spatial context while rejecting the idea that regions are present on the landscape awaiting discovery by suitably diligent and well-informed researchers (Hartshorne, 1959; Hart, 1982). Scholars can say the same, but not more, about ecosystems.

Scientists do not discover ecosystems on the landscape via the application of theory and diligent fieldwork; instead, they arbitrarily label a portion of the landscape as an ecosystem to suit the needs of the project at hand. Simon Levin (2001) observed that ecosystems “are better thought of as idealizations rather than real entities.” He goes on to note, “What we call an ecosystem is an operational convenience, a loosely defined and ephemeral assemblage of co-occurring organisms ... [whose] ... boundaries are defined by the investigator for convenience of description.” Ecosystems are “temporary conveniences,” wrote Norton (1992) “to be discarded and replaced at will.” James Agee and Darryll Johnson (1988) found that an ecosystem is “any part of the universe chosen as the area of interest, with the line around that area being the ecosystem boundary.” Bruce Hannon (1991) agreed, saying, “The delimitation of the [eco]system is strictly up to the observer; i.e., the system boundaries and the list of internal elements may be chosen at will.” Ecologists Lawrence Kapustka and Wayne Landis (1998) pointed out, “No human has ever seen an ecosystem.” These observations confirm Robert Ricklefs’ (1987) conclusion that ecosystems “have no boundaries in space or time — they are not discrete, identifiable units like organisms.” Efforts to identify the Greater Yellowstone Ecosystem (GYE) illustrate these points.

The idea of the GYE emerged in the 1970s. Grizzly bear researcher Frank Craighead, Jr., produced the first published map of the GYE in 1979. His version covers roughly 5 million acres enclosed within a seven-sided polygon, determined by the range of the grizzly bear population roughly centered on Yellowstone National Park. Others latched on to the idea of the GYE but took different approaches to its construction. The first edition of *The Greater Yellowstone: the National Park & Adjacent Wildlands* appeared in 1984. Author Rick Reese, a founder and first president of the Greater Yellowstone Coalition, wrote that the GYE extended over “8 to 10 million acres.” In the second edition he estimated the size of the GYE at 18 million acres (Reese, 1991). The fire of 1988 notwithstanding, during the interval between the first and second editions, the landscape underwent no fundamental change; the GYE doubled in size simply because those doing the labeling changed their minds. “How we define the geographic extent of the Greater Yellowstone,” Reese said, “depends on which of its characteristics we use as criteria for delineating boundaries.” He and his colleagues at the Greater Yellowstone Coalition invoked a bewildering array of criteria to consider when determining the GYE, including climate; actual vegetation; potential natural vegetation; hydrography; topology; geothermal features; and ranges and habitat requirements of grizzlies, elk, deer, bison, and other biota (Glick et al., 1991). Each one of these separate spatial variables has its individual (and often shifting and imperfectly known) distribution. The coalition did not say what these patterns were or tell us how they combined them into their version of the boundary for the GYE. Meanwhile, the Congressional Research Service (1986) prepared a map that largely followed existing administrative boundaries and enclosed some 14 million acres.

Confusion surrounds the GYE. Law professor Robert Keiter (1991) observed that the Greater Yellowstone Ecosystem “cannot be defined by boundaries of any lasting significance.” Fellow student of the GYE, Duncan Patton (1991) said that “the GYE has no definite boundaries” while simultaneously claiming it “is bound by its ecological cohesiveness.” Tim Clark and Steven Minta (1994) — who, like Keiter and Patton, are advocates for protection of the GYE — wrote “Some definitions in currency are ... clearly at odds with one another ... there is disagreement on the location and extent of the GYE ... [which simultaneously] cannot be 5 million and 19 million acres.” No agreement exists on which spatial variables analysts should use in delimiting the GYE or how they should meld those variables into a single boundary. No wonder Jonathon Taylor and Nina Burkhardt (1993) opined, “Clear designation of the boundaries of the greater Yellowstone ecosystem remains somewhat vague.”

Over 20 years have passed since the GYE surfaced in print, but its students cannot agree on where it is, how to define it, or what shape it has. They cannot agree on how big it is, how much public land it includes, or how much private land it covers. They cannot tell you where it begins or ends, describe its core characteristics, or classify it with respect to other ecosystems. “Boundary definition,” wrote John Freemuth (1997), “is stunningly problematic.” He concluded that the debate about boundaries “is no mere quibble, and may lie at the core of problems in both defining and implementing ecosystem management.” That is because sound land management policy cannot be built on geographic uncertainty, yet what we see with the GYE is typical of what happens when researchers move the ecosystem concept from the textbook to the landscape.

Mark Sagoff (1997) pointed out that one area of intellectual enterprise vital to the growth of a science is the ability for practitioners to classify the objects they study. The National Research Council (1993) likewise emphasized the importance of classification. “Ecological classifications,” they wrote, “are extremely important for the management of biological resources on an ecosystem ... basis.” Classifications “are needed for recognizing and mapping” ecosystems “and for communicating about their status, distributions, and trends.” Ecosystem maps, in turn, are “a prerequisite to planning for, budgeting, authorizing, and appropriating funds for, and ultimately managing activities on the basis of ecological units” according to the U.S. General Accounting Office (1994) in a report to Congress on ecosystem management. Yet more than 60 years after Sir Arthur Tansley (1935) proposed the ecosystem concept, after decades of dominance in graduate schools, after the publication of thousands of articles, books, and studies, researchers still have not developed a recognized classification system for ecosystems (Sagoff, 1997). As the National Research Council (1993) concluded, “There are currently no broadly accepted classification schemes for ... ecological units above the level of species.”

Nebulousness reigns. Scholars cannot agree on what constitutes the core characteristics of ecosystems which, after all, can be anything from a drop of water to a dung pile to a whale carcass to the entire planet (National Research Council, 1993; Christensen et al., 1996). Kurt Jax et al. (1998) observed considerable disagreement about the basic features of ecosystems. They go on to say that no agreement exists on how to define and measure the “spatiotemporal continuity of an [ecosystem] through time, during which the essential characteristics of the [ecosystem] are retained.” Sagoff (2000) concurred, writing that researchers cannot agree on ways to define ecosystems and to redefine them through time and change. Put another way, scholars cannot objectively determine if an ecosystem remains itself in space and time or clearly establish when or where it becomes a different ecosystem. Yet such capabilities are indispensable to answering questions about the status and trends of an ecosystem’s health, integrity, and sustainability — the presumed attributes of ecosystems which champions of ecosystem-based policies want to make the centerpiece of federal land management.

Essentially researchers, policy makers, land managers, and the public are left with idiosyncrasy from which not even the most knowledgeable and energetic among us can fashion a cogent and verifiable ecosystem classification system or the definitive ecosystem maps necessary to direct the application of laws and regulations intended to restore or maintain ecosystem health, integrity, or sustainability.

Let me review. Scholars cannot classify ecosystems or point to their core characteristics. They cannot determine where ecosystems begin or end in space or time. People can label any portion of the Earth's surface they choose as an ecosystem, using whatever criteria they select. They can draw its boundaries wherever they please using methods of their own choosing so that on the landscape the ecosystem concept represents a geographic free-for-all. Ecosystems are mental constructs, not living entities seeking to sustain themselves either spatially or temporally. How, then, can ecosystems form a rational basis to organize the landscape for the purpose of governance? They cannot, as two recent efforts by the federal government to implement ecosystem-based land use management make plain.

EFFORTS TO IMPLEMENT ECOSYSTEM MANAGEMENT

On November 9, 2000, the U.S. Forest Service (2000) announced a final rule to govern planning for the 191-million-acre national forest system. When the proposal was first announced, then-Agriculture Secretary Dan Glickman (1999) heralded it as a fundamental change in philosophy. It proclaimed, "The first priority for planning to guide management of the National Forest System is to maintain or restore ecological sustainability." That required the Forest Service to "put greater emphasis on maintaining and restoring ecosystem health in order to promote" sustainability. The rule reflects the uncertainty and confusion inherent in the ecosystem concept and in the notion of ecosystem health.

The entire rule rests on the idea that ecosystems are discrete, knowable, and real entities on the landscape, possessing attributes that the government should restore and protect as its first order of business. The rule offers no justification for such contentions and fails to define either ecosystems or ecosystem health. This is especially disturbing in light of the substantial literature arguing that ecosystems are nothing more than *ad hoc* spatial conveniences and that the notion of health cannot be properly applied to ecosystems. The final rule tacitly acknowledges that the landscape contains a limitless number of ecosystems (the proposed rule freely admitted there are an infinite number of ecosystems on the landscape), but it does not specify how managers are to select the relatively few ecosystems whose maintenance and restoration will become the focus of agency efforts. It establishes no procedures for determining ecosystem boundaries in space or time; instead it simply directs managers to choose "appropriate spatial and temporal scales." Spatially, these scales may range from a few acres to millions of acres and, temporally, from decades to centuries, depending on agency opinion. Guesswork abounds.

How people are to judge the success of plans developed according to the rule is equally obtuse. The rule defines ecological sustainability as "the maintenance or restoration of the composition, structure, and processes of ecosystems including ... the productive capacity of ecosystems." Productive capacity is said to be "the ability of an ecosystem to maintain primary productivity including its ability to sustain desirable conditions" that encompass the ability for ecosystem self-renewal after disturbance. But as we have seen, the scientific community has no agreed-upon way of judging when an ecosystem system ceases to be itself and becomes a new ecosystem. Further, because the nonequilibrium model makes it plain that the landscape constantly changes, the idea of maintaining composition and structure appears to be a fruitless exercise that does not offer a rational basis for assessing the success of government programs.

When one examines the rule more closely to see how people are to judge plan success, things become even more confusing. Section 219.20 (b) tells "responsible officials," when making decisions "that will affect ecological sustainability," they must consider "ecosystem diversity," "species diversity," and "Federally listed threatened and endangered species." The measure of sustainability, and therefore plan success, rests heavily on the idea of protecting ecosystem diversity. The rule offers no definition of this nebulous idea, describing it in terms of maintaining an ecosystem within its natural range of variation which is "the expected range of variation in ecosystem composition

and structure that would be expected under natural disturbance regimes in the current climate period.” The agency does not tell us how one is to measure, predict, and evaluate the natural range of variation. More importantly, the FS offers no justification for why deviation from the arbitrary and wholly unscientific standard of *nature knows best* should guide management of public land (Peters, 1991).

In short, the agency wants to make application of undefined standards to protect unclear values found in unspecified places to be determined later by unnamed means the basis for managing the nation’s national forests. This is not the stuff of sound land use management.

The Interior Columbia Basin Ecosystem Management Project (ICBEMP) provides a second example of a regulatory effort at making ecosystem protection the centerpiece of federal land management. A combined effort of the FS and the Department of the Interior’s Bureau of Land Management (BLM), it aims at making protection and restoration of ecosystems the fundamental management goal for some 75 million acres of public land from Oregon and Washington to Montana. Like the FS planning rule, it reflects all the vagueness embodied in the ecosystem concept and its associated ideas like ecosystem health.

The project began in 1993 with a directive from former President Clinton to develop an ecosystem-based strategy for federal land use management in the region. Its purpose is to “restore and maintain long-term ecosystem health and ecological integrity” and, while human use of the area is permitted, it must be “consistent with maintaining healthy, diverse ecosystems” (U.S. Department of Agriculture, 2000a). Yet, after 7 years of effort and over \$40 million in project costs, the agencies still cannot tell us which ecosystems will be protected or restored (U.S. General Accounting Office, 1999). The Draft Environmental Impact Statements (which, with appendices, exceed 2000 pages) contain over 100 maps, but none shows the ecosystems of policy interest (U.S. Department of Agriculture, 1997a,b). The Supplemental Draft Environmental Impact Statement contains 64 maps, and the Final Environmental Impact Statement has three maps; none show the ecosystems whose health and integrity the agencies intend to restore or protect (U.S. Department of Agriculture, 2000a,b). The documents also fail to specify how such ecosystems may be identified in the future. About ecosystems in general, however, they do say that we can never know for certain what a particular ecosystem contains, but we do know they constantly change and have artificial boundaries.

Project officials define ecosystem health as a “condition where the parts and functions of an ecosystem are sustained over time and where the system’s capacity for self-repair is maintained, such that goals for uses, values, and services of the ecosystem are met.” Questions arise immediately. Because ecosystems constantly change over time and space, the notions of sustainability and a capacity for self-repair have no substantial meaning. Ecosystems simply blend into one another as time passes (or one replaces another after cataclysmic events such as the eruptions on Mount St. Helens); so how can one reasonably say one sort of change is healthful and another pathologic? What do we use as a baseline to compare change against? Today’s conditions? How things were in 1900? How about conditions at the time when Europeans arrived? How do we compare different kinds of change for overall health assessment purposes? For the sake of argument, suppose we decide to place carbon sequestration and species abundance on our list of ecosystem health measures. Suppose further that after 20 years we find an ecosystem sequesters 10% more carbon but lost 10% of its species. Is it more or less healthy than it was?

ICBEMP strives to restore and protect ecosystem integrity as well as ecosystem health. In so doing, it wanders farther into a buzzword world. Admitting that “absolute measures of integrity do not exist,” project officials defined integrity as “the degree to which all ecological components and their interactions are represented and functioning; the quality of being complete; a sense of wholeness” (U.S. Department of Agriculture, 2000b). Although this view of integrity comes from within the scientific literature (Kay, 1993; Angermeier and Karr, 1994), one is hard pressed to find an objective, verifiable foundation for it. For Karr (2000) a place with maximum integrity is one that supports “a biota that is the product of evolutionary and biogeographic processes with little or no

influence from industrial society.” Again we are confronted with an arbitrary *nature knows best* standard that flows from individual likes and dislikes rather than from science. The judgment that one landscape is complete or whole, whereas another is not, does not rise above personal opinion. If wild salmon disappeared tomorrow from the ICBEMP area, would any ecosystems therein lose their sense of wholeness? If so, which ones; and were these systems complete or whole before salmon appeared in the region? Suppose, after a species of salmon disappeared from a river, three other fish species joined the community. Would the ecosystem then be more or less complete or whole than before the salmon departed?

Science cannot answer such questions because the notions of completeness and wholeness have no scientific basis. Like the ideas of ecosystem health and integrity, they are nothing more than subjective personal landscape preferences, states of mind rather than conditions of the environment. Levin (2001) noted, “The ecosystem is not an organism and has not been shaped by evolution to perform particular functions” thus undercutting “all efforts to measure ecosystem ‘health’ and ‘integrity.’” Lancaster (2000) was more direct, writing, “Ecological health is a nebulous concept that should be stricken from the vocabulary. Likewise, all synonymous terms [like ecosystem integrity] are ridiculous in a scientific context.” The ICBEMP effort, like the FS planning rule, rests on buzzwords.

A FINAL POINT ON ECOSYSTEMS AND GOVERNANCE

Americans require their government to be neither arbitrary nor capricious. Spatially, our government rests on precisely known, universally recognized, and fixed geopolitical units. Consider the states of the U.S. Only one pattern of states blankets that portion of the planet called the U.S.; that is, there are a fixed number of states whose shape, size, and location are known to all. States do not overlap other states, and there are no gaps between states. Boundaries between states are well defined, and they do not change with the seasons or the years. A given portion of the landscape lies in exactly one state. This geopolitical exactness provides citizens a certainty that, for example, officials in state A who are unaccountable to people in neighboring state B cannot dictate to people in state B. Such geopolitical exactness is a necessary condition for stability in a democratic society.

Imagine for a moment that states possessed the same spatial characteristics as ecosystems. Then, for example, people would not really know the location of state boundaries; state boundaries would change through space and time, transforming individual states into geographic amoebas oozing over the landscape; states would overlap so that a given area could, say, simultaneously be in California, Nevada, and Oregon; some states would cease to exist while new ones would appear; and several different patterns of states would simultaneously cover the U.S. No one would seriously propose giving states these characteristics because governing would become arbitrary and capricious if it were possible at all. So why, then, should we use ecosystems as the spatial guides for the application of government rules and regulations?

CONCLUSION

Sagoff (1997) wrote, “Ecological systems are the conceptual constructs of a theoretical ecology, the old equilibrium ecology, that is now defunct. Just as the smile of the Cheshire Cat survived its demise ... the concept of the ecosystem haunts the ecological literature as an apparition without substance.” Many legitimate reasons exist for society to concern itself with land use and land management, but protecting or restoring the health of ecosystems is not among them. Nebulousness and uncertainty so surround the concepts of the ecosystem and ecosystem health that they do not provide a cogent foundation for government action.

A hundred years ago Joel Chandler Harris wrote his classic Uncle Remus stories. Through the antics and adventures of his characters, Harris continues to impart wisdom to generations of readers. Chief among his players are Brer Rabbit and his antagonists Brer Fox and Brer Bear. In the story of the “Tar Baby,” Brer Fox and Brer Bear fashion a figure from tar and dress it like child so as to ensnare our unsuspecting hero. When Brer Rabbit encounters the Tar Baby along the side of the road, he thinks he has found a new friend and says, “Howdy.” The Tar Baby, however, fails to answer and thus does not respond as Brer Rabbit hopes. After repeated “Howdies” do not get the desired response, Brer Rabbit — refusing to accept the now obvious — pounds on the Tar Baby in a fruitless attempt to force it into doing something it cannot do — talk. Eventually our rabbit friend is hopelessly enmeshed in goo, but the Tar Baby still does not speak.

It seems to me that is where we are with respect to ecosystems and public policy. The tar baby of ecosystems attracts many people. But for reasons I note here and elsewhere, defending illusions on the landscape is not a responsible goal for public policy (Fitzsimmons, 1999). Instead of continuing to try and turn the ecosystem tar baby into something it cannot become — a rational foundation for land use management — I suggest we extract ourselves and move on down the road in search of better constructs because, at least in the realm of public policy, the ecosystem concept and its attendant notions of health, integrity, and sustainability represent intellectual and evolutionary dead ends.

Quality of Life, Recreation, and Natural Environments: Exploring the Connection

Alan Ewert

INTRODUCTION

The interface between people and natural environments occurs in a variety of complex ways that affect the individual's economic, cultural, physical, and spiritual well-being. Although historically this interaction has been characterized in economic terms (e.g., commodity production) or cultural aspects (e.g., number of jobs created in a community), there is currently a trend that recognizes the physical and spiritual effects of natural environments upon individuals or communities (Driver et al., 1996; Schroeder, 1996).

Moreover, natural environments appear to play an increasingly important role in an individual's perceived quality of life (QOL). The purpose of this chapter is to discuss the connection between natural environments, outdoor recreation, and QOL issues. To discuss these and other points the following framework will be used:

- A definition and description of the construct of QOL
- A discussion of natural environments and their relationships to human health and QOL
- The connection between outdoor recreation and pro-environment behaviors and attitudes

In this chapter, ecosystem is defined as a community of organisms working together with their environments as integrated units (Salwasser et al., 1993). Natural environments are thought of as areas involving differing scales (e.g., stand, watershed, region, etc.) in which natural processes are essentially predominant and human development is minimized. Moreover, while technically not equivalent, the terms *ecosystem* and *environment* will be used interchangeably throughout this chapter.

Two issues tend to complicate any discussion about QOL. First, individuals who are part of broader social structures, such as neighborhoods or communities, often associate QOL with variables such as accessible education, affordable housing, and just law enforcement systems. Individuals who are members of natural resource management and research professions often equate QOL with living environments rich in biodiversity, sufficient wilderness, and undeveloped landscapes managed under a sustainable practices strategy. In both cases, however, QOL is ultimately associated with the life and work space of the individual and community.

A second, more fundamental issue related to discussing QOL revolves around the operational aspects of QOL. That is, QOL for many is equated with personal income, size of house, or the number of cars owned (Hatcher, 1994). Yet others think of QOL in terms of the amount and type of leisure

time and recreational opportunities available to them. For this second group QOL is related to their ability to recreate and enjoy pristine natural environments (Peterson et al., 1988; Loomis and Walsh, 1997). Indeed, while managers and scientists discuss the importance of issues such as sustainability, ecosystem restoration, and exotic invasions, a substantial portion of the public equate QOL with the ability to enjoy outdoor recreation actively on a regular basis and in relatively natural landscapes.

Consequently, a major point of this chapter is that participation in recreational activities located in natural environments may offer an effective vector for educating the public about environment-related issues and provide a direct linkage to the attitude–behavior phenomenon. In other words, if people are able to enjoy natural surroundings and environments, they will be more willing to seek protection for these areas and practice environmentally sustainable behaviors such as reduced energy consumption, reduction of littering, and less materialism. Thus, the premise of this chapter is that public education and awareness will ultimately serve to protect and promote natural ecosystems and environments.

QUALITY OF LIFE

QOL has been defined in a variety of ways using a number of different terms, including a sense of happiness, manifest joy, and some measure of self-actualization. Consistent in many of these definitions have been the terms *well-being* and *wellness*. In this chapter, well-being is considered an internal sense of satisfaction or the fulfillment of real as well as perceived health. In this instance, *health* is defined as optimal social, physical, spiritual, or emotional conditions of the individual. In a similar vein, wellness can be thought of as a function of health, with an individual's sense of wellness at any one time located on a continuum from poor to optimal health. It is worth noting, however, that the construct of health is dynamic and subject to constant reevaluation of what constitutes human health (VanLeeuwen et al., 1999).

In addition to well-being and wellness, QOL can be characterized as falling within two general approaches to treatment and intervention — one associated with the medical sciences and the other closely aligned with the behavioral sciences. Within the medical sciences, QOL is often assessed along parameters such as health status, physical functioning, energy levels, or general perceptions of health. From the behavioral sciences perspective, QOL is often linked to issues such as need satisfaction, sense of independence, competence, and a meaningful use of time. Thus, in a larger sense, QOL acquires the characteristic of a latent variable by subsuming a number of manifest or indicator variables such as a sense of wellness, security, or a sense of personal control, depending on one's perspective and situation. While it is clear that QOL is a construct highly dependent on how and by whom it is defined, there are some common human needs that are thought of as important components for most QOL indices. These common needs involve personal health, economic needs, self-esteem, social support systems, and aesthetic needs (Sirgy and Efraty, 1998).

ECOSYSTEM HEALTH AND THE INDIVIDUAL

Worldwide, significant changes in the attitudes, behaviors, and priorities concerning the management and use of natural resources among the population have been observed (Costanza et al., 1992; Bengston, 1994; Ewert and Kessler, 1996). Fundamental to these changes has been an awareness that the interface between humans and natural environments produces both benefits and costs that have significant implications for an individual's perception of QOL (Driver et al., 1991; Suzuki, 1997).

Increasingly clear is the linkage between healthy, natural environments and elevated QOL indicators. This linkage may be regarded as bidirectional in that humans not only impact natural environments, but natural environments can also significantly impact humans. In the vernacular, “we affect nature; nature affects us.”

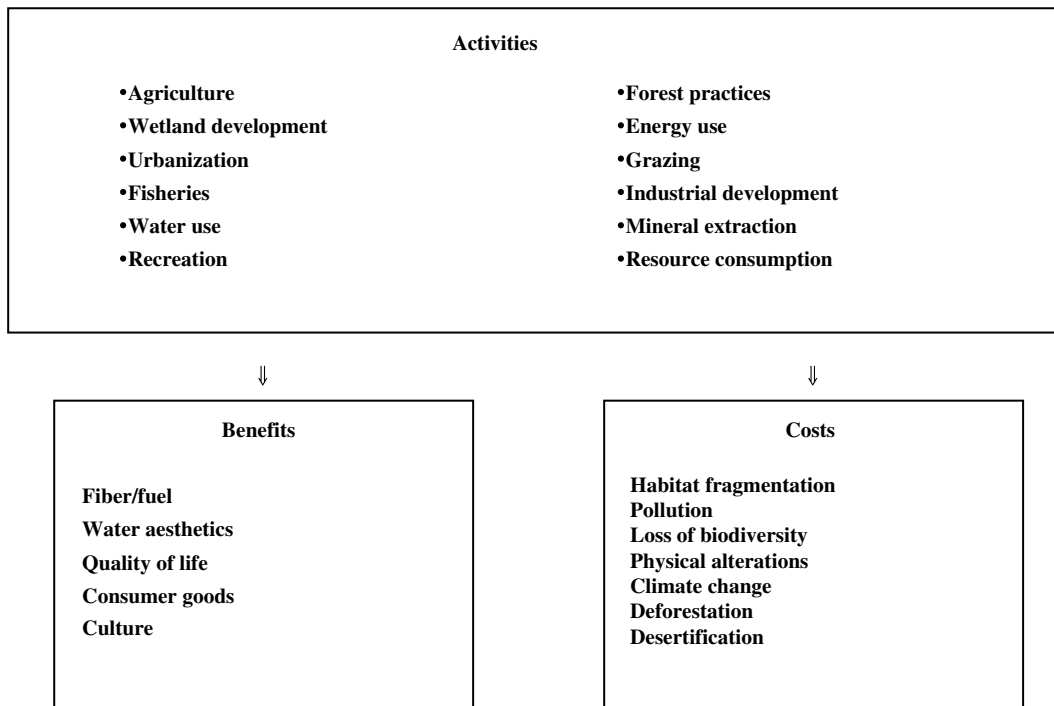

Figure 24.1 Human activities impacting the sustainability of natural ecosystems.

Human Impacts on Natural Environments

From the perspective of human impacts on natural environments, numerous human activities serve as catalysts for creating benefits from, and costs to, natural environments. Benefits, discussed in the next section, imply goods and services. As listed in Figure 24.1, sample costs include habitat fragmentation, introduction of exotic species, levels of unsustainable consumption, and alteration of physical systems such as the atmosphere. Porter and Brown (1991) suggest that some of the forces driving these negative impacts include increased population, consumption patterns, disparities in economic wealth, patterns of global trade, and national and international politics. As a result, many communities (towns, cities, countries, etc.) often embrace an orientation toward unsustainable growth and development that often leads to unrestrained parameters of consumption, instability of systems, and an increased ability to impact and modify natural environments.

Environmental Impacts on Humans

Environmental impacts on human systems can occur along three different dimensions: direct, indirect, and goods and services. Direct impacts are functionally associated with an interaction between humans and natural environments and include recreational, cathartic, and aesthetic experiences. Other direct impacts to humans are health-related and include pesticide use, water and air quality, atmospheric warming, and land use for development and recreation (Table 24.1). These issues are not only significant by themselves but are also regarded as part of a larger pattern moving from specific issues (e.g., use of dioxin) to broader concerns such as anxiety over the food supply, water quality, or air-related illness. These effects can be pervasive and have now assumed a significant level of concern among the public (Hahn, 1994; Graham and Rhomberg, 1996). Foster (1993) supports this view by suggesting four major determinants to human health: human biology, lifestyle, medical care, and the environment.

**Table 24.1 Major Health-Related Concerns
Related to Ecosystem Management**

Pesticides
Air/water quality
Toxic contaminants
Release of hazardous materials
Atmosphere warming and ozone depletion
Excessive noise
Loss of biodiversity
Psychological stress

Indirect impacts on humans encompass vicariously experienced stress reduction, restorative environments, and *existence valuation* (Krutilla, 1967; Loomis and Walsh, 1997). In this case, a benefit can be described as an improved condition or the prevention of a worse condition (Lee and Driver, 1999). Goods and services can be thought of as one form of benefit. Westman (1977) characterized goods as products derived from the natural ecosystem, while services provide a functional role representing a component or combination of components (e.g., water purification through wetlands) in a natural ecosystem.

THE RELATIONSHIP BETWEEN OUTDOOR RECREATION AND ENVIRONMENTAL HEALTH

It is in the realm of personal and health-related concerns that outdoor recreation can provide a segue between healthy, natural ecosystems and healthy humans. This role assumes two dimensions. First, the literature strongly supports something already well known: namely, that recreation and leisure can be effective agents toward improving human health in a variety of ways (Driver et al., 1991). Examples include physiological benefits, relaxation, catharsis, and sociological benefits (Figure 24.2).

Recreational activities appear to create positive benefits for humans in a number of ways: personal enjoyment, personal growth, social harmony, and social change (Wankel and Berger, 1990). In addition, two mechanisms useful in coping with life stress and developed through recreational activities involve building a sense of hardiness and internal locus of control through the enhancement of social support networks and heightened feelings of self-determination (Coleman and Iso-Ahola, 1993). Thus, participation in recreational activities in natural environments benefits the individual not only through enhancing one's level of resiliency (i.e., ability to return to baseline) through physical fitness, relaxation, and exposure to pristine environments but also by strengthening the hardiness (i.e., ability to resist negative change) of an individual through the use of social networks and a sense of personal empowerment (Driver et al., 1991).

Participation in a recreational activity in a natural setting can have beneficial effects on individual health and these benefits can have important ramifications in a QOL assessment. In a sense, natural

Figure 24.2 Recreation and leisure contributions to human health.

ecosystems become giant health machines through the goods and services they provide and the personal recreation opportunities they offer.

It is the second dimension, however, that is perhaps the most important factor in the long-term interaction between human actions and natural ecosystems. Salwasser (1999) suggests that the practice of ecosystem management will primarily be accomplished through resource management agencies, governments, and large corporations. This could be true for the management of large ecosystems on federal and other public lands, but I believe he misses the point. To paraphrase from Breslow (undated), “It is what you do hour by hour and day by day that largely determines your state of health.” The same thing could be said about ecosystem management and preservation. The day-by-day, individual-by-individual things eventually determine whether an ecosystem will be preserved or properly cared for. However, without public backing, government intervention is usually of short-term duration, at best. In a sense, our natural ecosystems are as dependent on individual actions, behaviors, and commitments as they are on large governmental bodies or corporate entities (most of whom take their lead from public trends and aspirations).

And what better way to develop public understanding and support for ecosystem protection than by allowing individuals to form connections and positive attitudes toward the natural environment through direct experience in those environments? Many authors suggest that experience-building can play a critical role in the development of solutions to environmental issues and willingness to become involved in those issues (Kraft and Kielsmeier, 1995; Glover and Deckert, 1998). Moreover, there are a number of complex cognitive schema that can be experienced and learned in an outdoor environment — competence, empowerment, symbolic interaction, and personal redirection.

Using a modification of Ajzen and Fishbein’s (1980) Model of Reasoned Behavior as an organizing framework, one possible explanation of how this experiential component through outdoor recreation may function is in the sequence illustrated in Figure 24.3. In this model, recreational experiences in natural environments provide a platform from which the individual becomes more aware of natural environments and develops a greater willingness to protect those environments. Thus, the experience acts as a mediating variable in affecting the development of a particular set of attitudes that, in turn, have direct impacts on an individual’s behaviors and actions (Vaske and Donnelly, 1999). In part, this effect may be the result of heightened levels of awareness or knowledge and a sense that individual actions can make a difference in protecting natural environments (Shepard and Speelman, 1986; Ewert, 1996). Keen and Fisher (1992) suggest that the development

Direct experience through outdoor recreational behaviors

Emotive connections and values

Development of a belief system

Alteration of attitudes and behaviors toward environmental stewardship

Figure 24.3 Model of effect of experience and environmental behaviors.

of this awareness, and concomitant attitudes and behaviors, is a necessary condition for advancing a willingness to engage in and promote sustainable practices. Orr (1995) goes so far as to suggest that traditional university curricula worldwide need to change radically in order to address the growing crisis in natural environmental degradation. This chapter has suggested that direct participation in recreational activities in natural environments, besides benefiting the individual, may help meet the challenges of environmental degradation.

In conclusion, this chapter has described the connections among QOL, natural environments, and outdoor recreation. Natural environments provide a host of products and services for human use in addition to recreational location. However, the direct experience with natural environments through recreation increases the likelihood that an individual will become more aware of the threats and impacts to an area and consequently become more willing to practice behaviors that serve to protect those environments. This approach to increasing individual action may ultimately be the true value of outdoor recreational activities because the problems of, and solutions for, natural resource management and ecosystem protection are human-centered.

Natural Capital Differentiation, Sustainability, and Regional Environmental Policy*

Cecilia Collados

INTRODUCTION

Chile is a country that has grown at a fast rate in the last two decades. This economic growth comes mostly from exporting natural resources. This growth process, which includes mining, fishing, industrial agriculture, exploitation of native forests, and the construction of hydroelectric dams, has deteriorated or destroyed important ecosystems. These actions not only have direct negative environmental, social, and economic consequences for the regions but also erode the natural capital basis of new development for the whole country. What explains the Chilean choice of a nonsustainable path of development?

QUALITY OF LIFE AND USE OF NATURAL CAPITAL: THE THEORY

The Neoclassical Model

The Chilean model of development is based on the predominant neoclassical economic paradigm that focuses on efficiency. Neoclassical economics considers the economic system to be separated from the natural and other social systems. Natural capital is only a source of materials that comes into the production process at no cost, except the cost of extraction. Development is defined as increase in gross domestic product (GDP) and can be accomplished with an efficient price system that reflects scarcity and stimulates technical improvement. This technical change counteracts depletion by substitution and by facilitating extraction. Substitution among different kinds of capital (and between capital and labor) is infinite, depending only on technological change (Bator, Cobb–Douglas analyses**). Irreversibility of damage to natural capital is therefore not an issue. The sustainability criteria derived from this view are highly influenced by the assumption of complete substitutability between the factors of production, including natural capital. Economic

* This chapter is a summary of part of Collados' dissertation work for the Ph.D. degree in City and Regional Planning, University of California, Berkeley (Collados, 1999). Part of this chapter has been included in Collados and Duane (1999).

** Bator analysis for the determination of the best configuration of inputs, outputs, and commodity distribution for a two-input, two-output, two-person situation uses land and labor as perfectly substitutable inputs (Bator, 1957). The Cobb–Douglas analysis determines value added as a function of capital stock and employment that can be substituted among themselves as long as neither input goes to zero (Heathfield and Wibe, 1987).

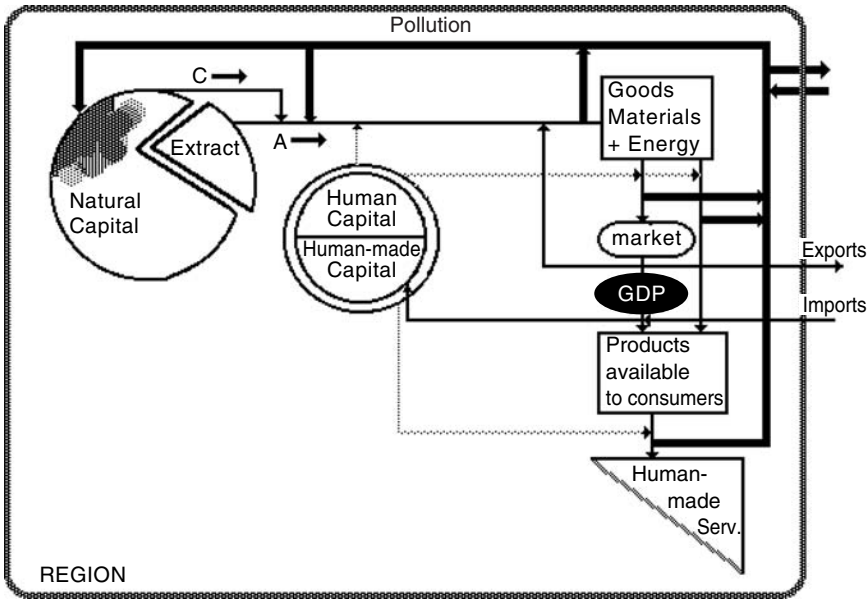

Figure 25.1 Traditional view. *Thin arrows*: processes that contain natural resources: production processes (A and C), distribution, consumption, and import-export. *Thick arrows*: waste. *Dotted lines*: processes without natural resources component. Some processes in this figure have been kept simple: *Distribution*: makes processed materials and energy, including intermediate and capital goods, accessible to consumers and producers (some occurs through the market, some does not). *Consumption*: changes materials and energy into services. *Import-export*: brings materials and energy in and out of the region. (From Collados, C. and Duane, T.P., *Ecol. Econ.*, 30:441–460, 1999. With permission.)

development is sustainable if the overall stock of assets remains constant over time. Any one asset can be reduced as long as another asset is increased to compensate for it. This is what has been called *very weak sustainability* (Turner et al., 1994).

A regional model of these views is summarized in Figure 25.1, showing the relationship of the economic system with natural capital. Natural capital includes all natural assets — everything that is not human-made. It can be altered by humans, and its reproduction can be enhanced by humans, but it cannot be created by humans. The categories of natural and human-made capital are not sharply divided. Natural capital can have human modifications, as will be discussed later. Examples of natural capital are ecosystems (forests, rivers, the water cycle). Human-made capital is always an alteration of natural capital.

According to this model, natural capital generates two kinds of production processes, A and C. Process A starts with extractive activities, while process C obtains natural resources without destroying ecosystem integrity.* Both processes can use recycled waste. After natural resources are introduced into the economic process by A or C, with the intervention of people (human capital), and human-made capital (which includes institutions and other forms of social capital), these resources are transformed in material goods and energy that are distributed, with or without the use of the market, and made available to consumers and producers. These goods and energy are transformed into human-made services through a consumption process.

This paradigm presents some strong assumptions: among others, a narrow definition of development that includes only part of human-made services; the existence of a price system that reflects scarcity accurately; and a high degree of substitution among different kinds of capital. If working

* *Extraction* is defined as any kind of destruction of the integrity of the ecosystem. It will be defined more precisely when natural capital categories are explained.

well, it allocates resources to where they are most needed, but takes them from where it is less expensive to extract in traditional cost terms, not in environmental services terms.

Environmental economists propose two variants to the neoclassical approach. The first is the Pigouvian taxes approach, which controls pollution with taxes; the second is the property rights approach, which offers a market solution to externalities. This second approach maintains that, by redefining property rights, pollution problems can be solved by polluters and sufferers through bargaining; no state intervention should be necessary. (The basis for this approach is an interpretation of the Coase theorem, 1960). This solution allocates resources efficiently but does not consider the fact that other assignments of rights can also have efficient allocations, that there are income distribution effects when assigning property rights, or that the transaction costs involved in bargaining can be very high.

Pearce and Turner (1991) use “the main body of economic thought to derive important propositions about the linkages between the economy and the environment.... Rather than looking for some different economics, we are seeking to expand the horizons of economic thought.” They do not look for alternative economics, arguing that many of the concerns of those who are motivated to search for alternatives can be accommodated within the central body of modern economics.

Most of the theoretical contributions of environmental economists deal with the effects of pollution on natural capital and the possibility of internalization of these negative externalities into the economic system. This body of theory has been the basis for the *polluter pays* principle and for policies such as tradeable pollution permits.

Another branch of environmental economics is resource economics, which applies welfare economics principles to determine optimal use and depletion of resources (Fisher, 1981). The goal is, then, the maximization of the present value of the resource to society. In the case of renewable resources, efficient use may entail depletion of the resource to extinction, or its sustained use at either higher or lower stocks than currently exist. In the case of exhaustible resources, it means finding an optimal rate to deplete a resource completely. The Hotelling model of efficient resource extraction was developed in 1931 under the assumption that resource allocators are aware of the total stock of resources, the course of technological development, and the level of demand throughout the future. This model indicates that, in the simplest case, with costless extraction, the resource should be extracted in a way that the prices rise at the discount rate (Pearce and Turner, 1991).

Another approach in the resource economics literature tries to deduce whether resources are scarce from costs and price paths. Critics of this empirical model, and in general to all economic indicators of long-run scarcity, argue that such approaches implicitly assume information about quality and total quantity of the resource in question, which is precisely what they are trying to determine (Norgaard, 1990). Other problems with this model are its absence of concern for future generations' interests (Howarth and Norgaard, 1992; Norgaard, 1992) and the implied conviction that technology and substitution will solve the problems after resources are depleted. The policies derived from this discipline recommend a better management of nature respecting the environmental linkages — economic incentives like prices, credit, and exchange rates, and changes in the tenure of land (Pearce and Turner, 1991).

Natural capital is recognized by these authors as an important contributor to human welfare, as a life support system that provides a supply of resources, as a waste receptor, and as a provider of amenities. The opportunity cost of the use of natural capital is emphasized by Krutilla and Fisher (Fisher and Krutilla, 1975). The rule for natural capital conservation is that resource stocks should be kept constant over time. The stock of renewable resources should not decline over time (understanding the waste assimilative capacity as a renewable resource), and depletion of exhaustible resources should be replaced by increases in renewable resources or human-made capital (assuming substitutability). This is what has been called *weak sustainability* (Turner et al., 1994).

These contributions have emphasized the idea that environmental services are important as a component of well-being and have introduced a general criterion of conservation of natural capital; but they do not specify the linkages between the different kinds of natural capital according to its function in producing environmental services and improvements in the quality of life.

Regional Development Theory

Regional development theory treats land and other environmental components as space, and in most cases treats space as an abstraction that does not include social or physical characteristics. The social vacuum in such theory has been analyzed by authors like Charles Gore (Gore, 1984), and many institutional and cultural aspects have been introduced by authors that come from a sociological or geographical background. But environmental degradation is still ignored or treated as a marginal consequence, and natural capital is viewed only as a source for extraction of commodities. It is not recognized as an essential component of an ecological system that has a value per se or as a factor of production of environmental services, culture, and social space.

This view impedes inclusion of sustainability issues in regional theory. The contributions of this body of knowledge to the sustainability debate are limited by its failure to recognize that regional development always involves environmental opportunity costs and that society has to deal with these costs somehow, by exporting them to other societies, by transferring them to future generations, or by paying for them locally now.

Many authors have dealt with sustainability problems from a local point of view, trying to define self-sufficient regions. These efforts have led to very diverse and interesting concepts. Examples of these concepts are bioregions, most commonly associated with water basins. The goal is “to create a society that will maintain its environment as a congenial and pleasant place to live in now and in the future” (Atkinson, 1992). The concept of agroecology is also related to bioregionalism in the context of developing countries. It proposes a comprehensive reframing of rural development strategies, with priority given to empowerment of local communities, poverty reduction, natural resource conservation, secure food supply, and promotion of self-sufficiency (Altieri, 1993).

There is also the argument that environmental quality can be an important driving force of the economy that can bring in people, and employers would follow. This is especially important in areas where extraction activities have been considered the economic engine for years. In these cases the opportunity cost in terms of quality of living environments might be too high today and needs a careful evaluation (Power, 1996). In the case of minerals, this assertion is confirmed by recent estimates of mineral supplies for the next century. Given the lack of pending crises in availability of minerals, mining can no longer presume the *de facto* claim as the best of all possible uses for land (Hodges, 1995).

Industrial ecology is another small-scale approach to environmental problems. It involves the design of industrial processes and products from the dual perspectives of product competitiveness and environmental interactions. It is a system-oriented vision with the premise that industrial design and manufacturing processes are not performed in isolation from their surroundings but rather are influenced by them and, in turn, have influence on them. It seeks to optimize the total materials cycle from virgin material to finished material, to component, to product, to obsolete product, and to ultimate disposal. Factors to be optimized include resources, energy, and capital. As in a biological system, it rejects the concept of waste and considers all possible uses of residues. These objectives can completely change the product development processes, because many variables are added to the production processes and the product definition (Graedel and Allenby, 1995). These ideas can bring about a new rationality for agglomerating industries that can use each other’s wastes and by-products.

The main problems in implementing these ideas relate to the boundaries of the regions. Political boundaries could be changed; but often the most relevant physical boundaries do not coincide with cultural differences, and these could be quite problematic. In today’s global economy it is almost impossible to refer to regions as geographically discrete places in terms of the land they depend on for their activities (the *ecological footprints**). Cities, for example, appropriate the carrying capacities of distant *elsewheres* (Rees and Wakernagel, 1994).

* The opposite idea or *environmental bleeding* could also be useful, especially from the point of view of those regions which export natural resources: determining who are the beneficiaries of the environmental damage on a particular region.

Ecological Economics and Co-Evolutionary Economics

Ecological economics represents a major challenge to neoclassical economics by making the socioeconomic system part of the ecological system and addressing the relationships between them. Within this approach it is generally recognized that environmental problems have a structural character and cannot be approached simply by using the concepts of externalities and substitution.

The materials balance approach introduces entropy limits to the economic analysis; it argues that pollution is not only the result of market failure but an inevitable phenomenon dictated by the laws of thermodynamics.

The ideas of Boulding, who introduced the relevance of thermodynamics to economics in 1966 (expanded by Nicholas Georgescu-Roegen in the early 1970s) are very important to the development of this paradigm. In very simple terms, low entropy is the ultimate means of production and exists for humans as terrestrial stock and solar flow, both limited in practical terms. Humans have almost complete control over the use of stocks (which could yield only a few days of sunlight, and could be used very quickly — 4 days [Ayres, 1950]), but almost no control over the flow of solar radiation intercepted by the Earth (Georgescu-Roegen, 1980).

Based on these concepts of limits, Herman Daly, in 1977, argued for a steady-state economics.

Steady-state economy is an economy with constant stocks of people and artifacts, maintaining some desired, sufficient levels by low rates of maintenance *throughput* — that is, by the lowest feasible flows of matter and energy from the first stage of production (depletion of low-entropy materials from the environment) to the last stage of consumption (pollution of the environment with high-entropy waste and exotic materials) (Daly, 1991).

To define the optimum stock to be maintained in a steady state, Daly first defines our dependence on the natural world:

This dependence takes two forms — that of a source of low-entropy inputs and that of a sink for high-entropy waste outputs. Services come from two sources: the stock of artifacts and the natural ecosystems. The stock of artifacts requires throughput for its maintenance, which requires depletion and pollution of the ecosystem (Daly, 1991).

From this perspective he defines an optimum stock as:

Total service (the sum of services from the economy and the ecosystem) is maximum. This occurs when the addition to service arising from a marginal addition to the stock is equal to the decrement to service arising from impaired ecosystem services that result from the incremental throughput required by the increment in stock (marginal cost or service sacrificed equals marginal benefit or service gained). This is the rule defining the optimum level of stocks to be maintained in a steady state (Daly, 1991).

Coevolutionary theory, developed by Richard Norgaard in the early 1990s, refers to an ongoing process between the social and ecological systems, through feedback loops, that determines the possible development of both. This theory considers economic development as a process of adaptation to a changing environment while being itself a source of change. Coevolution can continue indefinitely, reaching equilibriums and coming out of them as the social and ecological systems evolve. Norgaard (1994) argues that Western science and modernization break this pattern of coevolution by producing new ways of organizing and new technologies that are aimed more to control nature than relate deeply to it.

Ecological economics and coevolutionary approaches emphasize physical limits and environmental processes that are essential for human life and the uncertainty that surrounds these processes. They bring together multidisciplinary fields of study and go back to the questions classic economists

tried to answer, in a more ample context that includes social and natural systems. They are also characterized by including a view of how the world should look in the long term. These transdisciplinary fields address three main goals: first, assessing and ensuring that the scale of human activities is ecologically sustainable; second, ensuring that the distribution of resources is fair within the current generation, between future generations, and among species; and third, efficiently allocating marketable and nonmarketable resources under those limits. Natural capital, human capital, and manufactured capital are “interdependent and to a large extent complementary” (Folke et al., 1994). Natural capital consists of two major subtypes: nonrenewable resources, such as oil, coal, and minerals; and renewable resources such as ecosystems. Ecosystems are sources of raw materials, food, and a wide range of environmental services.

These authors emphasize the importance of environmental services, which include maintenance of the composition of the atmosphere, amelioration of climate, operation of the hydrological cycle, waste assimilation, nutrient recycling, soil generation, crop pollination, maintenance of biodiversity and landscape, and aesthetic and amenity services. “These services can hardly be produced by any other form of capital, and consequently are complementary to them. Depletion and pollution are making natural capital a limiting factor for further development” (Daly, 1991).

The sustainability concept for this paradigm is keeping the life-support ecosystems and interrelated socioeconomic systems resilient to change. “It is not sufficient to just protect the overall level of capital, rather natural capital must also be protected, because at least some natural capital is nonsubstitutable” (Turner et al., 1994). What is stressed in this approach is the combination of factors (e.g., irreversibility and uncertainty), not their presence in isolation. Only if this combination of factors is maintained can we have sustainability. This has been called *strong sustainability* by the authors just cited.

Because these theories are large in scope and are not very specific in establishing the links between natural capital attributes and quality of life, it is very difficult to use them as a basis for regional policy.

Table 25.1 presents a summary of how these different theories conceptualize the relationship between the economic and ecological systems, define natural capital, prevent damage to natural capital, cope with scarcity, and define sustainability.

THE PROPOSED MODEL

This model explains how the natural capital of a region contributes to its quality of life. This model is based mainly on ecological and co-evolutionary economics concepts, adapting them to the regional level. It specifically defines the relationship between the different kinds of natural capital and the quality of life of the region in an attempt to make it a framework for policy, development, and evaluation (Figure 25.2).

In Figure 25.2 natural capital is still represented as a circle (as in Figure 25.1) for analytical purposes but dispersed irregularly throughout the region as components of ecosystems. This model adds another production process to the neoclassical view presented in Figure 25.1 — process B, which generates environmental services. These services are consumed by humans directly, becoming part of the quality of life, and also go back to regenerate natural capital. Production process B does not require human participation (human capital, human-made capital, or technology). Examples of these services are pollination, climate control, natural water purification, maintenance of biodiversity, and aesthetic services. These processes do not compromise the integrity of the natural capital permanently because their waste is processed by the natural systems. Some environmental services are indispensable for the regeneration of natural capital and, in this way, critical for any kind of development.

The natural capital regeneration rate and ability to produce environmental services is diminished by the waste produced by all of these processes (thick arrows). It is also diminished by the destruction of its integrity due to the extraction or fragmentation of some of its components (process A).

Table 25.1 Five Views of the Economic System and the Environment

Views	Relationship between Economic and Ecological System		Prevention and Treatment of Damage to Natural Capital			Sustainability
	Economic System	Natural Capital	Natural Capital	Solutions to Scarcity	Sustainability	
Neoclassic economics	Separated systems	Materials source Exhaustible: (Hotelling model) Renewable: (harvest = yield)	Pollution treated as externality Taxes Market (legal system)	Technical change, recycling Allocative efficiency and substitution	Very weak = sum all assets constant	
Environmental economics	Connected systems — looks for links, interactions	Inputs Receiving media Amenities	Keep within bounds of assimilative capacity of environment	Substitute exhaustible resources by renewable ones	Weak = renewable conserved, nonrenewable replaced by renewable	
Ecological economics	Economic system is a subsystem of ecological system	Inputs Receiving media Amenities Environmental services Biodiversity Complementary to human-made capital	Carrying capacity is the limit to biophysical throughput	Recognizes limits to substitution	Strong = combination of natural capital and human-made capital constant	
Steady-state economics	Same	Same	Same	No substitution	Very strong = sum of services from the economy and ecosystems is maximum	
Coevolutionary economics	Coevolving, relationship between both	Same	Same	Substitution is part of the co-evolving process, dynamic, unpredictable	Very strong = natural capital and human-made capital maintain an evolving equilibrium	

Collados, C. and Duane, T.P., *Ecol. Econ.*, 30:441–460, 1999. With permission.

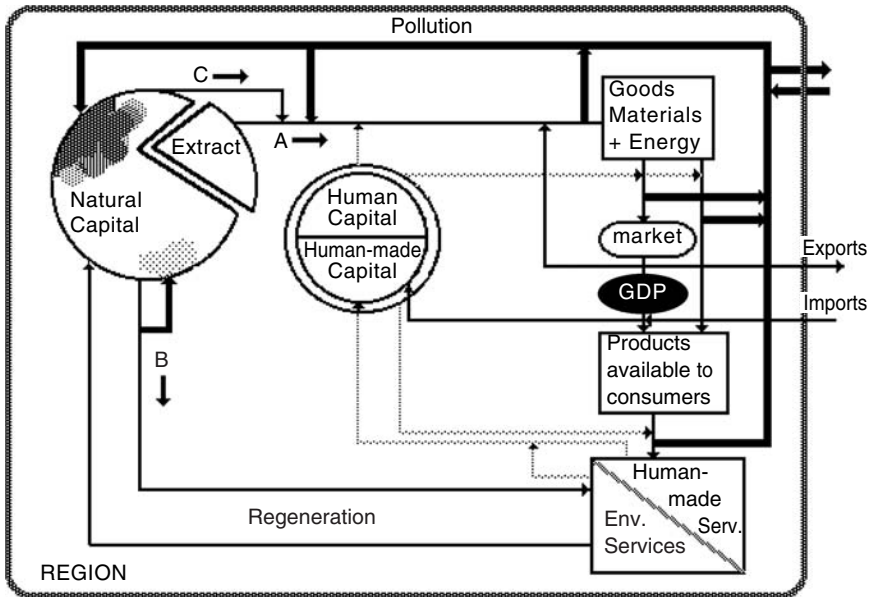

Figure 25.2 The proposed model relating quality of life and natural capital. (From Collados, C. and Duane, T.P., *Ecol. Econ.*, 30:441–460, 1999. With permission.)

From a regional point of view, if the ability of natural capital to produce environmental services is impaired by the damage caused by extraction and pollution beyond its regeneration capacity, both production processes would be affected. Goods and energy can be imported, but environmental services can only be produced locally. The boundaries of the region are permeable to environmental services, but the region does not have control over this permeability.

Natural capital contributes to the quality of life of a region in two complementary ways: first, by directly providing a flow of environmental services that cannot be imported; and second, by supplying the natural resources that, through a human-controlled production process, become valuable to humans.* Environmental services also determine of the ability of natural capital to regenerate itself. Ecosystems and other components of the regional natural capital produce environmental services that provide life-support functions necessary for natural capital reproduction. The economic process also has waste, which alters natural capital and, as a consequence, the quality of life both in the short and long term. Quality of life is determined by the combination of human-made services and environmental services.

Human-Made Services

Human-made services are the services produced directly by people and those derived from goods during the consumption process. These services can be essential — necessary for human life. There are many approaches to define what is essential for a society. These approaches are related to different theories of well-being. These theories interpret well-being as a state of mind, a state of the world, human capability, or as the satisfaction of underlying needs (Dodds, 1997). For the purpose of this study, it is important that what is essential be determined socially. For some regions, weapons or cars may be considered essential, while to others these could be nonessential goods.

* The relation between human-made services and environmental services as components of the QOL is a complex one. For a detailed analysis of increases and decreases of human-made services and environmental services, see Collados (1999).

Environmental Services

Environmental services are functions provided by natural systems. They cannot be imported; they become part of the quality of life because of their importance in the surroundings where humans live. They can be classified as:

Life-supporting environmental services are necessary for maintaining all life and for the regeneration of natural systems (e.g., the regeneration of soils, pollination of crops, maintenance of the atmosphere, waste assimilation, or purification of water). These services make ecosystems dynamic self-regulating systems that maintain their essential structures in the face of exogenous shocks (homeostatic quality), that adapt to changes in their input and output environments (adaptiveness), and are conducive to change in the species composition with time (succession) (Dryzek, 1992).*

All other environmental services are part of the quality of life but do not determine the survival or reproduction of the ecological system. They include recreational and aesthetic environmental services not provided with human intervention.

The Stock of Natural Capital and Its Differentiation

Natural capital is all that is not created by humans. It can be destroyed by human actions, and its reproduction can be influenced by human actions, such as in agriculture or plantation forests. It is the basis for the creation of most human-made capital and services. It is also the source of all environmental services, including the necessary life-support mechanisms for humans and other species, that allow for its own regeneration. Natural capital is classified in this model according to its ability to produce services and other attributes in four categories: essential, nonsubstitutable, nonreconstitutable, and life-supporting natural capital. These categories, and how they are linked to the quality of life of the region, are presented in Figure 25.3.

Essential natural capital is used by humans to produce services that are essential for human survival, such as food, shelter, and clothing, as previously defined. This subset of natural capital, determined by the need of essential human-made services, can change because population numbers or expectations change. Technology can also change and allow use of different kinds of natural capital to satisfy the same need. An example could be replacing the construction of hydroelectric plants by producing more efficient electric bulbs. In this case the same service would be obtained with a different kind of natural capital. No number has been associated with essential natural capital in this model because the *range of essentiality* should be determined by each region.

How the region is defined (and the size of it) will make a difference in determining what services are essential and, in turn, the natural capital that is essential. The size of the region will also alter the availability of natural capital to satisfy essential and other needs. When the demand of different social groups contained in a region for essential natural capital overlaps, a social problem may arise. This may be a social — not environmental — problem, but it can become an environmental problem if the conflict is resolved in a way damaging to the environment, e.g., war or destruction of crops.

Life-supporting or critical natural capital (Figure 25.2, Items 1 to 4) produces life-supporting environmental services and are necessary for life reproduction. Examples are riverine ecosystems, wetlands, and forests that provide habitat for many species. This quality of natural capital is determined by nature.

Extraction is defined in this model as any action that destroys the integrity of an ecosystem. This integrity is maintained by what has been previously defined as life-supporting environmental services that are responsible for its self-regulation. Therefore, any use of life-supporting natural capital is an extraction since it will stop the flow of life-supporting environmental services and impair the ability of an ecosystem to adapt and reproduce in the presence of exogenous stress.

* This definition of life-supporting environmental services derives from a dynamic conception of ecosystems that are perpetually changing and undergoing disturbance (natural and human). Preserving nature *untainted* or in stable balance can be, in many cases, counterproductive, impairing the self-organizing and self-recreating characteristics of ecosystems.

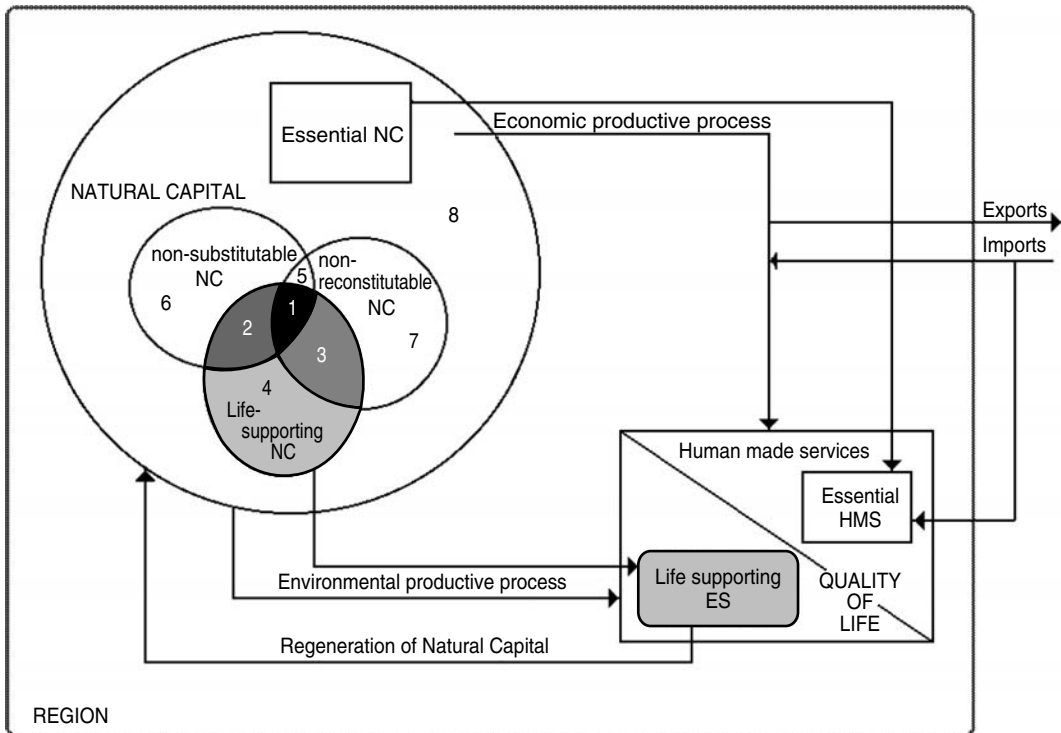

Figure 25.3 Natural capital categories. Examples of natural capital in the different categories: 1. Rivers and riverine ecosystems that cannot be reconstituted and provide nonsubstitutable support to life. 2. Artificial forests that provide environmental services necessary for life that cannot be provided with other kinds of capital but could be reconstructed. 3. Riverine fishing areas that could be substituted by non-life-supporting natural capital or human-made capital. 4. Wetlands as purifiers of water, to some extent reconstitutable, and substitutable by artificial purifiers. 5. Landscape, aesthetical natural capital, recreation areas. 6. Gardens, agricultural land. 7. Minerals. 8. Artificial lakes, pasture land with low biodiversity. (From Collados, C. and Duane, T.P., *Ecol. Econ.*, 30:441-460, 1999. With permission.)

Nonsubstitutable natural capital (Figure 25.2, Items 1, 2, 5, and 6) cannot be substituted by human-made capital. Examples are forests that regenerate soils, birds and insects that pollinate crops, and their habitats.

Nonreconstitutable natural capital (Figure 25.2, Items 1, 3, 5, and 7) does not regenerate once destroyed, or are too costly or impossible to reconstruct artificially. They include what economists call exhaustible resources, e.g., minerals and complex ecosystems like rivers, native forests, or wetlands that are impossible to create or recreate. In the case of complex ecosystems, there is not only the difficulty and cost of putting it back together, but also the lack of information once it has been destroyed. In the case of minerals, possible reconstitution is mostly a matter of cost; the energy needed to restore them in their original form is simply too high.

What is nonreconstitutable and nonsubstitutable natural capital at a given moment is determined by the evolving responses of nature and past human actions. It is discovered by humans through science or other sources of knowledge. The categories presented in Figure 25.3 are not sharply divided, they vary, and they are constantly changed by alterations in the environment and new discoveries. Such changing of categories makes planning the use of natural capital a complex task that requires constant adjustment of these categories in order to maintain a sustainable state.

Categories 1, 2, and 3, which result from the overlap of life-supporting or critical natural capital with nonsubstitutable and nonreconstitutable natural capital, are of special interest for conservation policy. Category 1 includes life-supporting natural capital for which there is no substitute or possible reconstruction. An example is riverine ecosystems. Category 2 includes life-supporting natural

capital that cannot be substituted by human-made capital, such as planted forests. Category 3 is natural capital that is life-supporting and cannot be reconstituted but could be substituted. An example could be water purification by wetlands.

Uses of Natural Capital

Figure 25.3 represents an ideal utilization of natural capital. It discriminates the use of natural capital according to its ability to provide critical environmental services and essential human-made services. It would use essential natural capital only for the production of essential human-made services and noncritical, nonessential natural capital for the rest of the human-made services.

In a market economy without environmental planning, the criteria for using natural capital is determined by the cost of extraction or accessibility of the resource in need. Natural capital is extracted in most cases without consideration of its ability to provide environmental services, obtained indiscriminately from all categories of natural capital. This practice is conducive to an erratic use of natural capital that can be unsustainable if it destroys critical natural capital.

Interrelations among critical and essential natural capital define different scenarios and planning problems that require specific approaches.

Essential and critical natural capital do not overlap: By substituting noncritical for critical natural capital to satisfy essential needs, the production of life-supporting environmental services can be increased, improving the quality of life of the region. This is a problem that can be solved with adequate environmental planning institutions that administer natural capital according to its ability to produce environmental and human-made services.

Essential and critical natural capital overlap: Where critical natural capital is the basis for satisfying essential needs, there is a problem that cannot always be solved by better administration. An example could be a region that needs wood as fuel and can take it only from native forests that are considered critical for their function as habitat. Confronting these problems could require changes in the scale by which the problem is defined, changes in values, or changes in the objectives of investments and new technologies (creating new opportunities for substitution, thereby reducing or eliminating the competition between satisfying essential needs and using natural capital).

Overlap of these two categories, without possible substitution of natural capital internally, can explain, for example, the cycles of increasing poverty in some regions without access to resources from other regions. This dilemma is illustrated by the overexploitation of forests for fuel or the clearing of land for agriculture beyond their abilities to reproduce. The traditional planning processes used in these situations tend to increase the production of human-made services by increasing productivity of labor, often damaging natural capital at a faster rate. In such cases this model shows that there would be no internal solution to the problem, and a connection with other regions should be sought to solve it. These solutions could include migration or a change in the export–import flow to correct the use of internal critical natural capital. It is often said that poverty is the main enemy of the environment. This model shows that the problem may not be poverty per se, but the isolation of poor regions which have limited access to outside sources of noncritical natural capital.

Conditions for Sustainability

Which kind of natural capital goes into the economic process has a twofold direct impact on the quality of life of the region: it determines the quantity and quality of human-made services and the quantity and quality of the flow of environmental services.

This decision also has an indirect impact on the regional quality of life in the long term: it determines the availability of life-supporting environmental services which, in turn, establish the regeneration capacity of natural capital. Since natural capital is the basic source for maintaining or increasing quality of life, its regeneration is a condition for long-term or sustainable development.

If a region uses the critical natural capital that is most essential for the production of environmental services and for its own regeneration, it will have a development path that diminishes the environmental services component of quality of life in the long term. If, instead, it uses its natural capital so that ecosystems are maintained to function and produce environmental services, it will maintain or increase this component of quality of life in the long term.

In a market economy, where an important part of natural capital is in private hands, there are economic incentives to utilize natural capital to produce human-made services. These incentives do not exist for the production of environmental services, however, because they are considered positive externalities of natural capital. This asymmetry and the goals of economic growth (increases in human-made services) drive the system in one direction: transferring natural capital from producing environmental services to producing human-made services.

Under these conditions the transfer of natural capital from producing environmental services to producing human-made services can only be done in a sustainable way without impairing the reproduction of natural capital and the production of environmental services if the economic system uses natural capital that is not critical. Besides the conditions imposed by strong sustainability criteria, a necessary condition for sustainable development is *not to use critical natural capital*.

To comply with this necessary condition, the function of environmental planning is to balance the use of essential and natural capital and strictly avoid using critical natural capital. This concept resembles co-evolution (Norgaard, 1994), in which social and environmental systems evolve and adapt to each other in a constantly changing balance; it differs, however, by limiting the changes that can occur. These limits are determined by the nonrestitutability and nonsubstitutability of some life-supporting natural capital, because the destruction of these kinds of natural capital is conducive to irreversible system breakdown, or *distress syndrome* (Haskell et al., 1992).

THE INSTITUTIONAL INTERFACE

Institutional Framework

The social decision to use natural capital is made through an institutional system that acts as an interface between natural capital and the quality of life. How the institutional system comes to play in the decision to bring natural capital to the economic process is illustrated in Figure 25.4.*

The institutional framework, composed of institutions from inside and outside of the region, may be divided in a layer of basic underlying institutions and a layer of organizations that comprise the public sector and those associated with it.

The market, the legal system, the educational system, and the political voting system are the main institutions involved in natural capital use.

The market allows for the expression of demand-and-supply forces through prices of goods, prices of natural resources, and through extraction costs. For any given income distribution and a set of preferences, it allocates resources where they are most needed. In general, the market directs the use of natural capital to where it is least expensive to extract, not where it is least costly in terms of environmental services.

An important effect of the market is that it acts as a filter of information by separating the consumer from the human, natural, and social capital that generated the product to be consumed. For example, in the furniture marketplace, advertising, labels, display announcements, and other information mechanisms communicate to prospective buyers the qualities of products; but they do not indicate whether the products were produced with child labor, native woods, or under labor laws that do not respect basic human health conditions. This filtering action becomes very important

* This model shows only the interactions among the components of the institutional system that may be significant for the design of policies affecting the use of natural capital; it is not comprehensive.

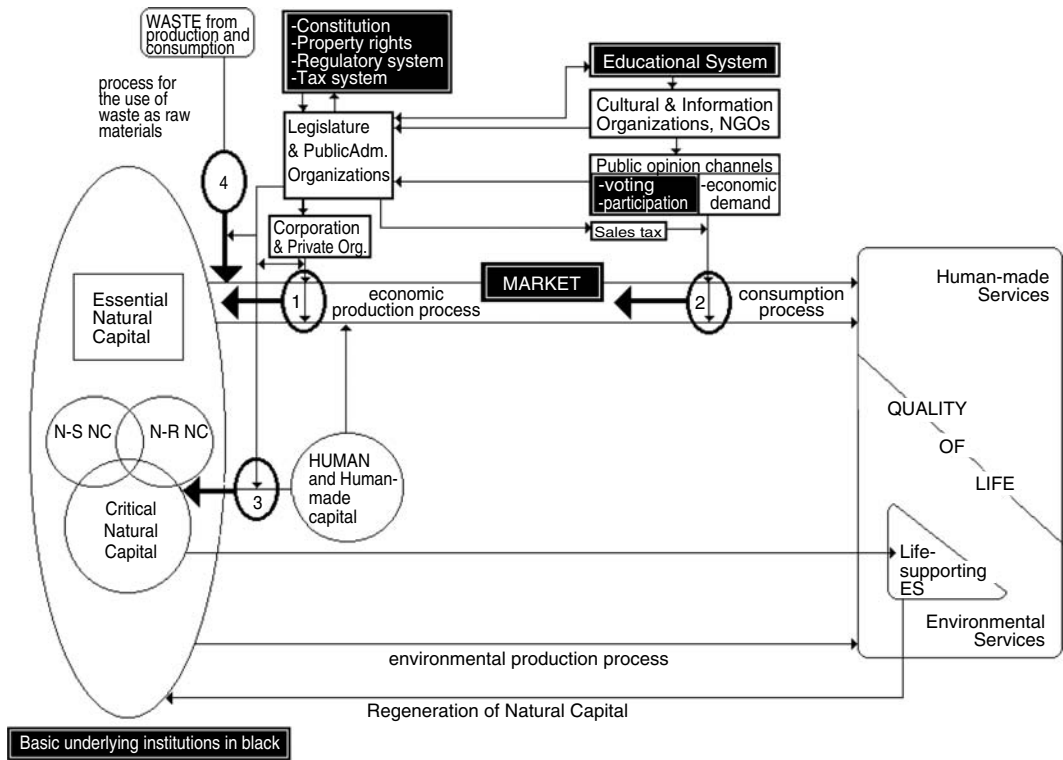

Figure 25.4 Some intersects among institutional and economic systems.

in the complicated economic relations of a global economy and the many elements that must be combined to produce some goods.

The legal system links basic institutions with organizations that implement laws. It also establishes the relationship between natural capital and people through three main mechanisms: property rights that assign natural capital to people and specify its use; the regulatory system that limits private property rights; and the tax system that directly or indirectly encourages or dissuades the use of critical natural capital.

The educational system provides social knowledge which, in turn, influences the public’s preferences and determines its economic demand, the way it votes, and how it participates in the decision-making processes.

In a democracy the political voting system elects representatives and provides a mechanism to convey preferences on social issues. For the system to be effective, the issues should be clearly defined and well known by voters. Environmental issues present a particular problem because of complexity and because information about them diffuses slowly; thus, it takes considerable time until they can be acted upon by voters.* There are other forms of public participation, such as lobbying and comments on the environmental impact assessments by nongovernment organizations or the public.

Over this first layer of basic institutions is an organizational setting consisting of government institutions that make decisions and nongovernment organizations that function in association with them. These organizations include the public administrative system, the private sector, international organizations, cultural organizations, and informational organizations.

The organizations and the basic institutions are linked and dependent on each other, thus forming an institutional structure. For example, these organizations may be related in a

* Some political systems, such as those in California, also allow direct votes either on voter initiatives or legislative action.

hierarchical structure, connected in an advisory relationship, or in conflict with each other. The institutional structure and the relative influence of each organization determine how each of them contributes to the planning process and the final decisions over the use of natural capital. Some organizational views dominate and others may be ignored, while some may not even be considered in the final decision.

Interaction of the Institutional and Economic System

There are many significant points for the use of natural capital at which the institutional system and the economic system intersect in a market economy. This chapter identifies four of these *policy points* at which the consideration of the categories defined in the proposed model could improve the design of sustainable development policy.

The first point of intersect (1, Figure 25.4) occurs before the natural resources enter the production process and the market. At this point, besides the accessibility costs, the basic underlying institutions determine the use of natural capital.

Natural capital is assigned to public, private, or joint entities through a property rights regime that allows a range of uses for natural capital (Hanna, 1994). These uses can result in the resource being destroyed or remaining virtually unchanged. In the case of water, for example, it can be taken out of the source (a river, a lake) and consumed, or it can be taken, used, and then returned to the source in the same condition in which it was obtained. The property rights regime is not necessarily related to all attributes of natural capital as defined in this research. Usually, property rights are only associated with aesthetic values, as is the case of most national parks. A possible intervention here is designing property rights that are more restricted according to the scale of priorities suggested by differentiating natural capital in the proposed model.

At this point the regulatory system also influences the decision to bring natural capital into the economy. Laws such as the Endangered Species Act, which limit exploitation rights when endangered species may be affected, are a good example of regulations that restrict the use of natural capital. Environmental impact assessments, which sometimes require reconstruction of affected natural capital, are another good example. These regulations could be guided by the priorities suggested by this research as well.

The property tax subsidy system can also modify behavior. By creating subsidies to owners of critical natural capital who do not extract it, society can foster the production of life-supporting environmental services. In the same way, taxing extraction of the most valuable natural capital can contribute to its conservation.

The second place (2, Figure 25.4), where the institutional system interacts with the economic process, is the point of consumer choice. Consumer decisions, in turn, affect the market for resource extraction, thereby determining the use of natural capital. Consumer demand is culturally determined and can be influenced by education and information.

According to neoclassical economic theory, consumer demand is utility driven and influenced by available information. Consumer decisions are made not only by the direct utility expected from the good to be purchased but also by the overall utility of the consumer. One factor that can diminish this overall utility is the decrease of environmental services from damage to the environment. For instance, buying gasoline to drive a car provides consumers a benefit from which they subtract the benefits of breathing pure air.

Awareness of these indirect effects on the environment is important when consumers decide what to buy and it is not provided by the market. Worse, the market obscures such awareness. At this point education and information systems are the institutions through which planning can influence the use of natural capital. Introducing reforms to school programs, for example, or expanding public access to environmental information will be conducive to a better understanding of production and consumption processes (from cradle to grave, or, with recycling, from cradle to cradle).

Another way to inform consumers is to introduce mandatory labels for products that identify the damages and benefits to the environment. Manufacturers and producers stress positive environmental outcomes in advertising or product labels; but other than health warnings, negative outcomes are never reported.

The third point (3, Figure 25.4) in which institutions influence the use of natural capital is direct intervention on natural capital regeneration to maintain or accelerate its reproduction.

This is an important point of action for environmental policy; it does not interfere directly with the economic process except by subtracting some human and human-made capital for the enhancement of reproducing critical natural capital. Examples of direct intervention include government initiatives such as nurseries for native plants or reproduction of native fish to be reintroduced in areas where they have become extinct or endangered. Currently only a few intervention programs that involve private parties have been implemented in India and the U.S. (Gadgil and Rao, 1995). These programs could improve the welfare of the region, not only by improving the flow of environmental services but also by creating jobs that provide income and access to imports from other regions.

The fourth point of interaction (4, Figure 25.4) is the input of waste to the economic process that replaces the extraction of virgin natural capital. This use of waste requires the development of new technologies and different kinds of investments that need government participation.

To utilize this source of materials and energy, industry (mining, agriculture, forestry, and manufacturing) has to be designed in accordance with its surroundings, following the principles of industrial ecology. The factors to be optimized include resources, energy, and capital (Graedel and Allenby, 1995). Profound changes are needed to design competitive industry that utilizes waste as inputs. An example of this kind of investment is the \$600 million recycled newsprint mill in the South Bronx. These kinds of projects face “huge economic and cultural obstacles, especially in urban settings where their environmental and social value could be greatest.”*

THE EMPIRICAL WORK

This research was designed to evaluate if the institutional recognition of the natural categories defined by the proposed model contributes to a sustainable path of regional development.

The empirical study examined the new Chilean environmental institutional system at point (1) in Figure 25.4. This is the point at which the decision to bring natural resources to the production process is made. In order to evaluate to what extent basic institutions and environmental organizations have changed in their recognition of the different kinds of natural capital, two cases were selected: the Ralco and Pangué hydroelectric dams in the Bio-Bío River in the Alto Bio-Bío region in southern Chile.

Pangué had been already constructed, and Ralco was projected to start operating in 2002. Besides their actual and potential damage to critical natural capital, the Alto Bio-Bío cases were chosen because they are separated (in time) by the creation of environmental and social institutions designed to implement environmental policy and achieve the goal of sustainable development. The first dam, Pangué, was planned and approved before the existence of any environmental laws (Collados, 1993). The second one, Ralco, has been subject to new legislation that includes an Environmental Law and an Indigenous Peoples Law.

The decisions made in both cases were compared to conclude whether there was a change toward a more sustainable use of natural capital.

* Presentation of Dr. Allen Hershkowitz, Senior Scientist, Natural Resource Defense Council (NRDC), University of California at Berkeley, March 4, 1999.

The Chilean Basic Institutions*

The basic institutions gave greater recognition to the categories of natural capital defined by the proposed model after the new environmental law (No. 19,300) was approved in March 1994. The categorization of natural capital by this law is mostly embedded in Articles 34 to 39, which refer to protected areas. Article 30 specifies the need for protection of some areas in order to “assure biological diversity, preserve nature, and conserve the national patrimony,” recognizing the value of biological diversity as an important life-support factor and the value of nature as capital. Articles 37 and 38 indicate the need to classify flora and fauna species to protect biodiversity according to the following categories: extinct, in danger of extinction, vulnerable, rare, with insufficient information, and out of danger of extinction. This classification could be associated with the nonreconstitutable and nonsubstitutable categories of the habitats of these species.

The Organizations

Those at the organizations researched who participated in the decision processes differed in their recognition of critical natural capital; however, the general tendency was to recognize the categories established by the theoretical model. Life-supporting characteristics were the most recognized, nonreconstitutability was the least recognized.

The Chilean Environmental Decision Process

The Pangué process occurred before the environmental law was in place. It was subject to environmental review only because Pangué S.A., a subsidiary of ENDESA (Empresa Nacional de Electricidad, a private enterprise) requested a loan from a foreign institution, the International Financial Corporation, to finance part of the project. In turn, the financiers requested an environmental impact assessment (EIA) and some compensation for the affected people. Part of this EIA was carried out before the loan was approved and part was not. The EIA was not publicly distributed, but it started a debate that had great public impact. Eventually the debate contributed to the creation of environmental institutions, as this was the first case to go through an EIA in Chile.

At the time the Chilean institutional framework could only impose conditions on the project when its presenter applied for water rights. Traditionally, hydroelectric projects were requested to leave a 10% minimum flow. In this case, the only requirement was to leave a 10% minimum flow in a tributary that joins the Bio-Bío River 3 km downstream from the dam (Collados, 1993).

The Ralco project was one of the first cases to go through the Sistema de Evaluación de Impacto Ambiental (SEIA) carried out by Comisión Nacional del Medio Ambiente (CONAMA). When this took place, controversies about the Pangué dam were still fresh in the public mind. Points of conflict were much greater in the Ralco case, however, because the project was bigger (seven times the inundated surface of the Pangué dam) and because the affected community was larger, had great cohesion, and had conserved its culture practically intact. The process, occasionally bumpy, was characterized by the confrontation of professional and political views and the reversal of previous decisions. The process included the removal of two political appointees from the two agencies with the most decision-making power, after the appointees changed their views in light of further study and professional opinion. In addition, the final decision was made by the Directive Commission, which is composed of 13 ministers, and this commission can reverse all previous decisions. In this case it reversed most of the environmental conditions that had been imposed by CONAMA. The way the institutions are set, the executive branch has the power to appoint the heads of the agencies involved; if that is not enough, it can impose its view at the end of the process. The SEIA is, then, mostly a political decision. In this case, the decision was dominated by the short-term goals of

* For a detailed analysis of these basic institutions, see Collados (1999).

rapid development, which are part of the political agenda. Most dominant in the process were ENDESA and top executives of the government.

Ralco followed the approval process established under the environmental law, and its construction was approved in August 1997. Its compliance with the Indigenous Peoples Law is still under consideration, but construction of roads and other complementary features has already begun despite the complaints of environmentalists and some of the Pehuenche people (40% of the investment had been done by July 1999).

The Ralco case process has fleshed out many weaknesses of the SEIA as a tool for the protection of natural capital — weaknesses that the private sector has detected and used to its advantage. Many of the necessary changes have already been pointed out by the Chilean scientific, legal, and political communities; but the will to change has to be political, and seems to be lacking.

Figure 25.5 graphically presents the Pangué and Ralco processes. The results that affect the use of natural capital differ only in the condition for the Ralco case to preserve an area equivalent to the inundated area of 1700 hectares and the obligation to maintain a minimum flow of 27.1 m³/s.

Besides the environmental law, the existence of the Indigenous People's Law as part of the approval process of the Ralco project made the procedure of this case very different from Pangué. The dam reservoir will inundate indigenous peoples' land. According to the law, these lands should be protected and cannot be taken away without consent of the owners and the National Corporation of Indigenous Development. Neither consent has been given; thus, the inundation of the land is illegal. The construction of the dam has, nevertheless, begun. The campaign to acquire the land has been long, bitter, and cruel. The economic and political power of ENDESA and the government have been used against the Pehuenche people, one of the poorest groups in the country, while the congress and most of the rest of the country watch in silence.

The Effects of the Alto Bio-Bío Dams

The construction of these dams will continue to create important social problems and considerable destruction of critical natural capital (Figure 25.6).

The environmental consequences of the inundation are severe (Goldsmith and Hildyard, 1984). First, there is a loss of the functions that a forest provides, such as water replenishment, climatic stabilization, soil renewal, air purification, and wildlife habitat. This kind of damage can also be associated with the deforestation necessary for the installation of the transition lines. The loss and alteration of habitats that are part of ecosystems rich in biodiversity are highly significant in the long term and reduce the adaptability of species to change (Jensen et al., 1993).

Second, there is a loss of riverine environment. Rivers and river banks are very rich habitats that are destroyed when a lake is created (Chapel, 1992; FEMAT, 1993; Koski et al., 1984; Erman et al., 1977). Over 75% of the terrestrial flora and fauna in semiarid climates is linked directly or indirectly to rivers (Kondolf et al., 1987). Fish and birds that nest in river banks are highly affected, since the waters are detained and the level of the artificial lake created may vary greatly and rapidly during the production of electricity.

Third, there is an interruption of water flow during dam construction. In general, ecological processes are an important attribute of ecosystems and determinants of biodiversity. They create the initial conditions that allow species to colonize an area or maintain an environment conducive to species' survival. These processes can be large-scale and dramatic, such as severe storms or wildfires, or routine, everyday occurrences, sometimes difficult to discern (Peck, 1998). Dams have downstream and upstream effects derived from the interruption of the water flow process that can be considerable. Once the river is interrupted by a dam, the ecological balance is further altered when the flow of suspended material and dissolved gases change. Fish migration is disrupted, and spawning and rearing conditions are altered. The total river population decreases substantially, and some species disappear completely. Furthermore, in the long term, the release of clear water by the dam with excess stream power erodes the channel bed and the banks

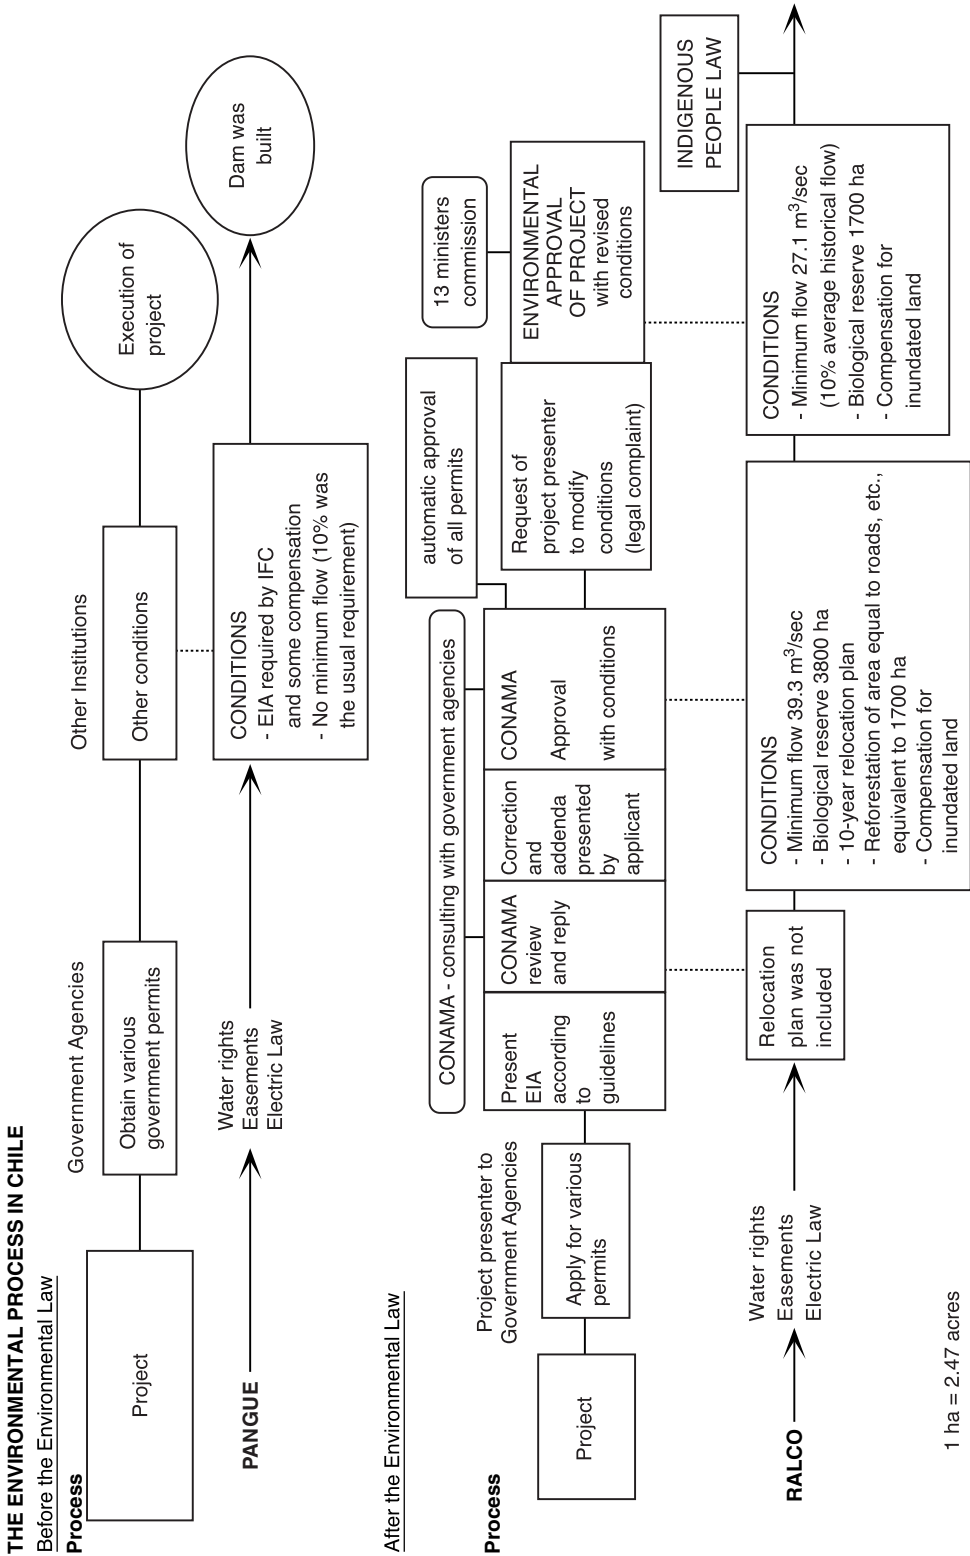

Figure 25.5 The Pangué and Ralco decision process.

downstream, and producing changes in the channel morphology that affect the living communities and riparian vegetation of the banks.

In this area, where seismicity and volcanic activity are present, the risks derived from these events are augmented by the presence of the dam. The undercutting of steep slopes by the rapid variation of the lake level makes landslides and debris flows a more probable occurrence. There is also some evidence that earthquakes could be triggered by the pressure of the immense mass of water in the lake on the geological structure (Keller, 1992). When dams are constructed for hydroelectric or irrigation purposes, it is convenient to keep the highest level of water in the reservoir; hence, the dangers of flooding can be exacerbated rather than diminished.

These factors also contribute to shortening the useful life of the projects, which is already limited because of the heavy sediment content of the rivers. The Pangué dam is estimated to trap 87% of the sediment load, an equivalent of over 4000 tons daily, thus giving an estimated life for the project of 113 years (Ecology and Environment, Inc. and Agrotec, Ltd., 1991).

Results of the Empirical Study

- The case of Ralco, when compared to Pangué, presents some evidence of a more systematic use of natural capital according to its ability to produce environmental services. The changes are minor: 1700 hectares have to be protected in exchange for the destruction of the forests that will be inundated.
- A compulsory maintenance of a minimum flow for dammed rivers was established at 10% of the annual flow average.

In the case of Chile, moderate changes in environmental institutions that allow for the recognition of critical natural capital, under the conditions of constant technology, have resulted in only

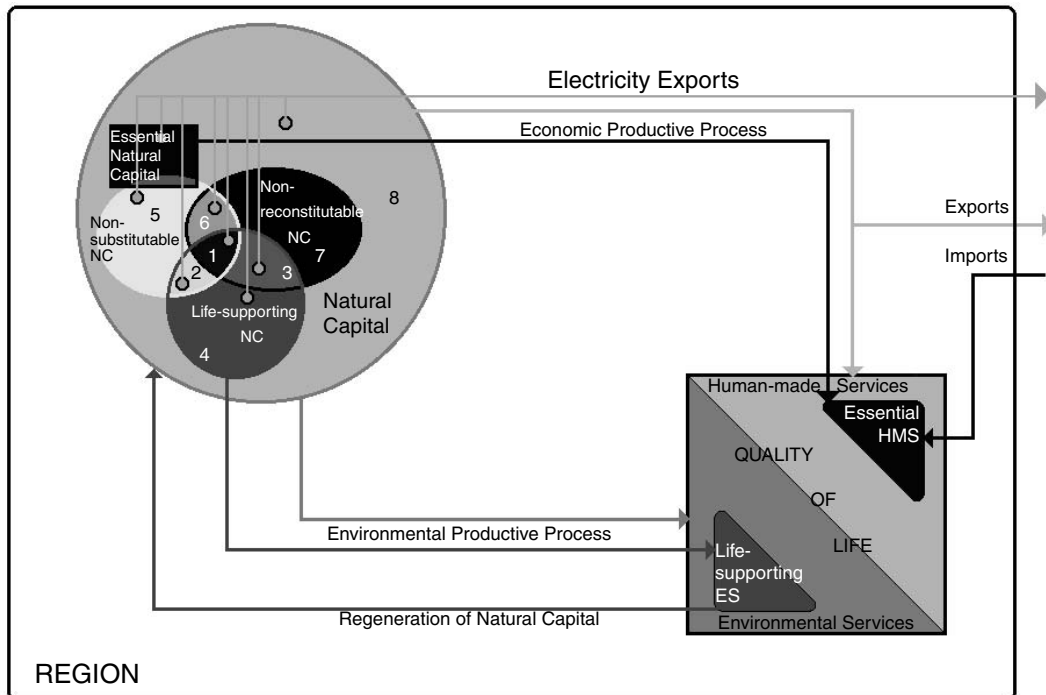

Figure 25.6 Use of natural capital by the Pangué and Ralco dams. *Critical natural capital*: 1. River bed and buffer zones. 2. Planted forests as soil regenerators. 3. Riverine fishing areas. 4. Wild fruit trees and bushes. *Noncritical natural capital*: 5. Landscape, hot springs, rapids for sports. 6. Agricultural land. 8. Pasture lands. *Local essential natural capital*: Overlap with natural capital #6.

minor changes in the use of natural capital. The recognition of these kinds of natural capital is a necessary but not sufficient condition for sustainability.

CONCLUSION

What explains the Chilean choice of a nonsustainable path of development? The analysis of the Ralco approval process shows that the short-term goals of economic development dominate decision making. The new Chilean environmental institutions are designed to allow, at many stages of the process, for the reversal of long-term decisions already made. They tend to imitate the steps and procedures followed in developed countries, and in many cases directly borrow standards and reference terms from foreign legislation. One important difference with other countries is that the process of approval includes, and is determined by, the participation of government organizations whose direction can be changed. The ease in removal of decision makers from the process keeps its control in the hands of the executive branch, making the process a completely political one in which technical considerations may have no impact at all and short-term goals may dominate.

The fact that the new environmental institutions were created in Chile mainly to comply with international demand and commercial agreements (which resulted from the increase of international exchange due to an open economy policy) has had an effect on the way these institutions were designed and the way they operate. In general they have the shape, staff, and presence of those in developed countries, but they serve only as a facade for international trade and domestic appeasement, without contributing to immediate improvements in the local use of natural capital or to a fair distribution of environmental costs. The only positive effect in the long term is creating public awareness of the environmental consequences of infrastructure projects.

In absolute terms, the approval of the Ralco project, as well as Pangué, represents an irreversible loss of critical natural and cultural capital for Chile. The new environmental institutions have had almost no impact in reducing this loss, which is their mandate. The long-term problem of reducing environmental damage has been transformed, through the decision process, into a short-term equity problem: how best to compensate immediate losers. The majority of the environmental costs are still transferred to future generations, perpetuating unsustainable development.

SECTION I.5

Finding Indicators

Overview: Can We Develop and Utilize Indicators of Ecological Integrity to Manage Ecosystems Successfully?

Gary N. Cherr

Section I.5, Finding Indicators, contains six chapters that provide thought-provoking insight into the approaches and processes used to develop suites of indicators for establishing integrity of a particular ecosystem. Along the broad scale of ecosystem integrity, environmental managers as well as the public can typically differentiate highly degraded ecosystems from those that are more toward the pristine end of the scale. However, the assessment of an ecosystem that is undergoing a slow decline in its integrity (or the often misused word *health*) over many decades, or of one which has not been characterized in its previous, more intact state, offers challenges to scientists and environmental managers. A major goal of environmental management is not only to develop a suite of indicators of ecosystem integrity but also to synthesize these indicators into technically defensible assessments of environmental health. An important part of this goal is to develop indicators of integrity for specific floral and faunal populations within an ecosystem and the health of humans who exist within the ecosystem and utilize its resources. Existing monitoring approaches, such as population assessments, epidemiology, routine collections, toxicity testing, and chemical analyses can and should all be components of an integrated approach to environmental health assessment. However, these approaches are at present not adequate by themselves to definitively address ecosystem integrity; thus, additional research is needed to define measurement endpoints and the integration of those metrics into a conceptual framework that environmental managers can directly utilize for decision making.

Understanding the impact of multiple anthropogenic stressors on ecosystems is an urgent challenge for environmental management. A major proportion of the human population lives on or near watersheds, impacts the quality of these ecosystems, and, in turn, experiences adverse health impacts due to environmental degradation. These impacts are both ecological and economic and can include altered food production and safety, with direct impacts on both wildlife and human populations. While pollution from large industrialized cities and agricultural runoff have increasingly stressed watersheds, other human-related impacts, including poor logging practices, freshwater diversions, invasive species, pathogens, and climatic change have also contributed significantly to declining ecosystem integrity. Detecting the effects of the multiple environmental stressors is particularly difficult in complex ecosystems. For example, environments such as estuaries are particularly difficult to assess given their dynamic natures and wide fluctuations in freshwater input,

tidal circulation, and biotic abundance (Breitburg et al., 1999). Developing ecological indicators for complex ecosystems is as challenging as it is essential.

The criteria for selecting and validating indicator endpoints have been discussed by numerous authors (e.g., Kelly and Harwell, 1990; Huggett et al., 1992; Karr, 1993; Peakall and Shugart, 1993; Suter, 1993; Mineau, 1998; Harwell et al., 1999; Jackson et al., 1999; Van Dam et al., 1998), and these vary with the goals to be achieved. Some of the most relevant include early warning of impact, ecological relevance, variability, specificity, selectivity, broad geographic applicability, and feasibility of implementation. For example, some indicators of ecological integrity may have the advantage of being highly relevant to managers because they measure the status of an organism or population of organisms, but lack specificity and often exhibit high temporal and spatial variability. In contrast, specific biomarker responses can have high specificity and can also provide early warning of environmental impact, but need to be applied in conjunction with other tools to be relevant for the population- and ecosystem-level problems faced by managers. Thus, it is critical that combined information from the multiple types of endpoints, expressed at different levels of biological organization and spatial and temporal scales, will provide more meaningful assessments of environmental stress than could be achieved with a less diverse suite of endpoints.

Integration of ecological indicators involves combining measurement endpoints in different ways and interpreting the results as an index of ecosystem integrity. If this can be accomplished, then the specific measurements become useful indicators for managers. As such, one cannot determine, *a priori*, which specific measurement endpoints for a particular ecosystem will be the most useful ecological indicators until they are incorporated in an environmental framework in the appropriate context that utilizes previous studies for guidance. There are several general approaches one can take in establishing an ecological framework for assessing ecosystem integrity. The assessment of a number of endpoints that relate directly to measures of ecosystem integrity needs to be conducted to determine the appropriate statistical combinations of endpoints and evaluate their applicability for different environments. These measurements can then be incorporated into process-based models that permit projections of population and ecosystem change over time in order to predict ecosystem sustainability.

The chapters in this section cover ecosystem indicators that range from aquatic and terrestrial environments to human health. The contributions in this section provide a case study for establishing a conceptual framework for selecting indicators of ecological integrity using the San Francisco Bay–Delta–River system. This estuarine system, the largest in the western U.S., is rapidly becoming one of the most managed ecosystems because of its extreme loss of ecosystem integrity. Chapter 27 discusses the opportunity to employ a conceptual framework that incorporates a suite of comprehensive indicators to provide direct ecosystem health assessment. The second contribution to this section, Chapter 28, establishes specifications of ecological indicators of sustainability. This includes the establishment of five specific requirements for developing useful indicators of sustainability. The next contribution, Chapter 29, looks at the relationship between ecological decline and human health through the power of epidemiological approaches. This is truly a holistic approach to ecosystems, where the human health element is so often given low priority in indicator integration. Chapter 30 focuses on a terrestrial index of ecological integrity with the emphasis on landscape-level indicators of entire watersheds that can be tracked over time. Chapter 31 discusses the U.S. EPA Office of Research and Development technical guidelines for evaluation of ecological indicators for monitoring programs. There are 15 guidelines presented, organized into four evaluation phases. Several examples are provided to enable the reader to see how these guidelines provide a framework for large-scale assessments. Finally, Chapter 32 addresses concepts and models as applied to forest ecosystems. Specifically, it discusses the feasibility of using a Forest Capital Index to manage forest ecosystems on a worldwide scale.

The themes that run through Section I.5 address the ideas mentioned above, including suites of indicators of ecological integrity, development of conceptual frameworks and modeling, and its utilization by managers. However, throughout this section the different contributions consis-

tently go beyond assessment of ecosystem integrity and deal with the issue of sustainability. Although an obvious issue to discuss, sustainability has often been left out of many ecosystem indicator discussions; but this section provides an overarching conceptual link among these excellent contributions.

ACKNOWLEDGMENT

The author would like to acknowledge the U.S. EPA-supported Pacific Estuarine Ecosystem Indicator Research (PEEIR) Consortium, which is part of the Estuarine and Great Lakes Indicators Research Program (EaGLE).

A Conceptual Framework for Choosing Indicators of Ecological Integrity: Case Study of the San Francisco Bay–Delta–River System

Karen Levy, Terry F. Young, and Rodney M. Fujita

Expert opinion — from scientists, managers, and policy makers alike — has begun to converge on ecosystem management as an appropriate method for managing activities that affect natural systems. The federal Interagency Ecosystem Management Task Force, created under the Clinton administration, defines the goal of ecosystem management as “to restore and maintain the health, sustainability, and biological diversity of ecosystems while supporting sustainable economies and communities” (GAO, 1994). Grumbine (1994) states that “ecosystem management integrates scientific knowledge of ecological relationships within a complex sociopolitical and value framework toward the general goal of protecting native ecosystem integrity over the long term.”

Ecosystem management programs are currently being designed and implemented across the U.S. and elsewhere (Yaffee et al., 1996; Christensen et al., 1996; GAO, 1994). All four of the primary federal land management agencies (the National Park Service, Forest Service, Fish and Wildlife Service, and Bureau of Land Management), which collectively manage all federal lands (30% of the total surface area of the U.S.), have planned ecosystem-based approaches to managing their lands and natural resources and have formed an interagency group to coordinate these efforts (GAO, 1994; Beattie, 1996; Dombeck, 1996; Thomas, 1996). Many other groups have formulated ecosystem management strategies as well, including the National Oceanic and Atmospheric Administration and even the Department of Defense (Griffis and Kimball, 1996; Goodman, 1996). The U.S. General Accounting Office states that “a consensus has emerged that ecosystem management provides a sounder approach for meeting the federal stewardship mandates of protecting natural resources and sustaining long-term commodity production and other uses on federal lands” (GAO, 1994).

The Ecological Society of America Committee on the Scientific Basis for Ecosystem Management describes ecosystem management as “management driven by explicit goals, executed by policies, protocols, and practices, and made adaptable by monitoring and research based on our best understanding of the ecological interactions and processes necessary to sustain ecosystem structure and function” (Christensen et al., 1996). The committee recognized eight essential components of ecosystem management: (1) long-term sustainability as fundamental value; (2) clear operational goals; (3) sound ecological models and understanding; (4) understanding complexity and interconnectedness; (5) recognition of the dynamic character of ecosystems; (6) attention to context and scale; (7) acknowledgment of humans as ecosystem components; and (8) commitment to adaptability and accountability.

The ecosystem management paradigm is also being applied to large-scale *restoration* programs. For example, the National Research Council (1992) concluded that restoration of an aquatic ecosystem requires coordinated, comprehensive management of all significant ecological elements, often on a watershed or other landscape scale. The Kissimmee River Restoration Project, which aims to restore the historic form, hydrology, and associated ecological resources of 70 km of continuous river channel and 11,000 hectares of floodplain in Florida (Arrington, 1995), has the explicit goal of “restoring the ecological integrity of the Kissimmee River” (Toth, 1993).

While a common vision may be emerging about the prerequisites for sound ecosystem restoration and management, however, a similar convergence of opinion has not yet developed on how to implement this new paradigm. In this chapter, we address the challenge of operationalizing the emerging paradigm of ecosystem management, using a case study of the San Francisco Bay–Delta–River system as an illustration. We propose a methodology to implement part of this challenge — describing a large system in order to evaluate its overall health or sustainable ecological integrity — and report on the experience of our case study. We also discuss issues pertaining to the decision-making processes involved, specifically our attempt to achieve broad stakeholder consensus on scientific ideas.

OPERATIONALIZING THE ELUSIVE CONCEPT OF ECOLOGICAL INTEGRITY

A common understanding of the concepts of sustainability and ecological integrity is still evolving in the scientific literature, largely because ecosystems and landscapes are highly complex entities. *Ecological integrity* and *ecosystem health* have been described in a variety of ways, from ecological persistence to resilience, homeostatic balance, increased probability of survival, and availability of habitat (Scrimgeour and Wicklum, 1996). Karr (1993) defines ecosystem health as the condition in which a system realizes its inherent potential, maintains a stable condition, preserves its capacity for self-repair when perturbed, and needs minimal external support for management.

Although these qualities are intuitively understandable, implementing ecosystem management requires that they be captured with an operational definition (Wrona and Cash, 1996). To do this, specific, measurable indicators of ecological health are needed. To use a human health analogy, we know humans *should* be able to walk and talk and recover when hit by a tennis ball, but we use specific measurements based on a scientific understanding of the human body, such as pulse and temperature, to evaluate whether the patient is in a healthy state overall. Similarly, for ecosystem integrity, it is useful to develop a model of the ecological system, and then define measurable parameters that, when taken together, report on the status of the key properties of the system. Ecological indicators, defined here as attributes of a system that can be measured to provide information about the health or integrity of that system, provide such measurements.

To successfully develop a suite of ecological indicators on a landscape scale, we advocate the use of a formal conceptual framework as an organizing tool. The framework ensures that the suite of indicators is ecologically sound and that the indicators (and the restoration or management plan) are comprehensive — that they address the integrity of the entire landscape as an ecological whole, as well as addressing each of the component parts. An additional benefit of using an explicit framework is to demonstrate to policy makers and the public the importance and relevance of each of the indicators.

CASE STUDY: THE SAN FRANCISCO BAY–DELTA–RIVER SYSTEM

As a result of a confluence of events, a major restoration effort for the San Francisco Bay–Delta–River system is currently being undertaken by a consortium of federal and state agencies, with extensive stakeholder input. The impetus for the restoration effort grew out of more than 20 years of conflict among agricultural, urban, and environmental interests regarding the appropriate

apportionment of water resources. In the latest chapter of this saga, a truce was declared in 1994, when the State of California, the federal government, and a variety of stakeholders signed the “Principles for Agreement on Bay–Delta Standards between the State of California and the Federal Government,” more commonly known as the *Bay–Delta Accord*. The accord required the parties to develop an environmental restoration program and associated long-term agreements regarding urban and agricultural water use in 3 years, providing about \$60 million annually for the 3-year period to support restoration efforts, primarily derived from assessments on water users. It also established the CALFED Bay–Delta program, a consortium of state and federal agencies responsible for developing a long-term plan for managing the Bay–Delta. Additional state funding was secured in November of 1996, when California voters approved Proposition 204, a \$995 million general obligation water bond measure containing about \$600 million to fund Bay–Delta ecosystem restoration efforts. In addition, federal funding in the amount of \$430 million (\$143 million per year over 3 years) was authorized by the passage of the “Bay–Delta Act” (California Bay–Delta Environmental Enhancement and Water Security Act, P.L. 104–333, Div. I, Title XI, 1996).

Although the restoration plan for the system is being developed by a consortium of interests not dominated by scientists, the basic premise of the program is remarkably consistent with the tenets gleaned from the scientific literature and listed above. In addition to formal acknowledgment of a whole-system management approach and broad stakeholder input, the program seeks to “take advantage of natural processes, ... restore some of the ecosystem’s natural resilience,” and “support sustainable populations of diverse and valuable plant and animal species” (CALFED, 1996a).

Few precedents exist for restoring a system this large. The San Francisco Bay–Delta–River system, as defined herein, comprises the watersheds of the Sacramento and San Joaquin Rivers, their delta, San Francisco Bay, and the nearshore ocean off the Golden Gate Bridge (see Figure 27.1). This system is commonly referred to as the San Francisco Bay–Delta; we have added the word “river” to its name to emphasize the need to think of the system as a whole, from the headwater streams in the Sierra Nevada out to the Pacific Ocean. The estuary alone supports 380 wildlife species, 22 of which are listed as threatened or endangered by the state or federal governments (SFEP, 1992).

This watershed comprises one of the most modified systems in the U.S. (Nichols et al., 1986). It provides drinking water to 20 million people — two thirds of the state of California. Water diverted from the watershed irrigates over 1.8 million hectares of farmland (SFEP, 1996) that provide 45% of the nation’s produce (CALFED, 1996a). Given the size and complexity of this system, translating the general ecological health-related goal into measurable indicators of success presents a challenge.

It is within this context that we initiated a series of meetings and workshops with CALFED staff, other stakeholders, and outside scientists to develop a suite of ecological indicators for the San Francisco Bay–Delta–River system. The purpose of the suite of indicators is to provide a scientifically valid definition of ecological integrity that can be used to help develop the restoration program and ultimately to determine whether its goal has been met. During the first phase of this effort, Environmental Defense and its partners developed and tested a conceptual framework for indicator development that has proved useful in promoting a comprehensive, whole-systems approach.

PROTOCOL FOR DEVELOPING A SUITE OF INDICATORS

In order to develop indicators that could be broadly accepted in both academic and political arenas, Environmental Defense, the Bay Institute of San Francisco, and the University of California, Berkeley, convened two workshops, in October 1995 and January 1996, whose missions were to develop a scientifically defensible suite of ecological indicators for the San Francisco Bay–Delta–River system. Participants included local experts, outside experts with experience in other systems (e.g., the Rhine, Mississippi, and Kissimmee Rivers), selected policy makers, and

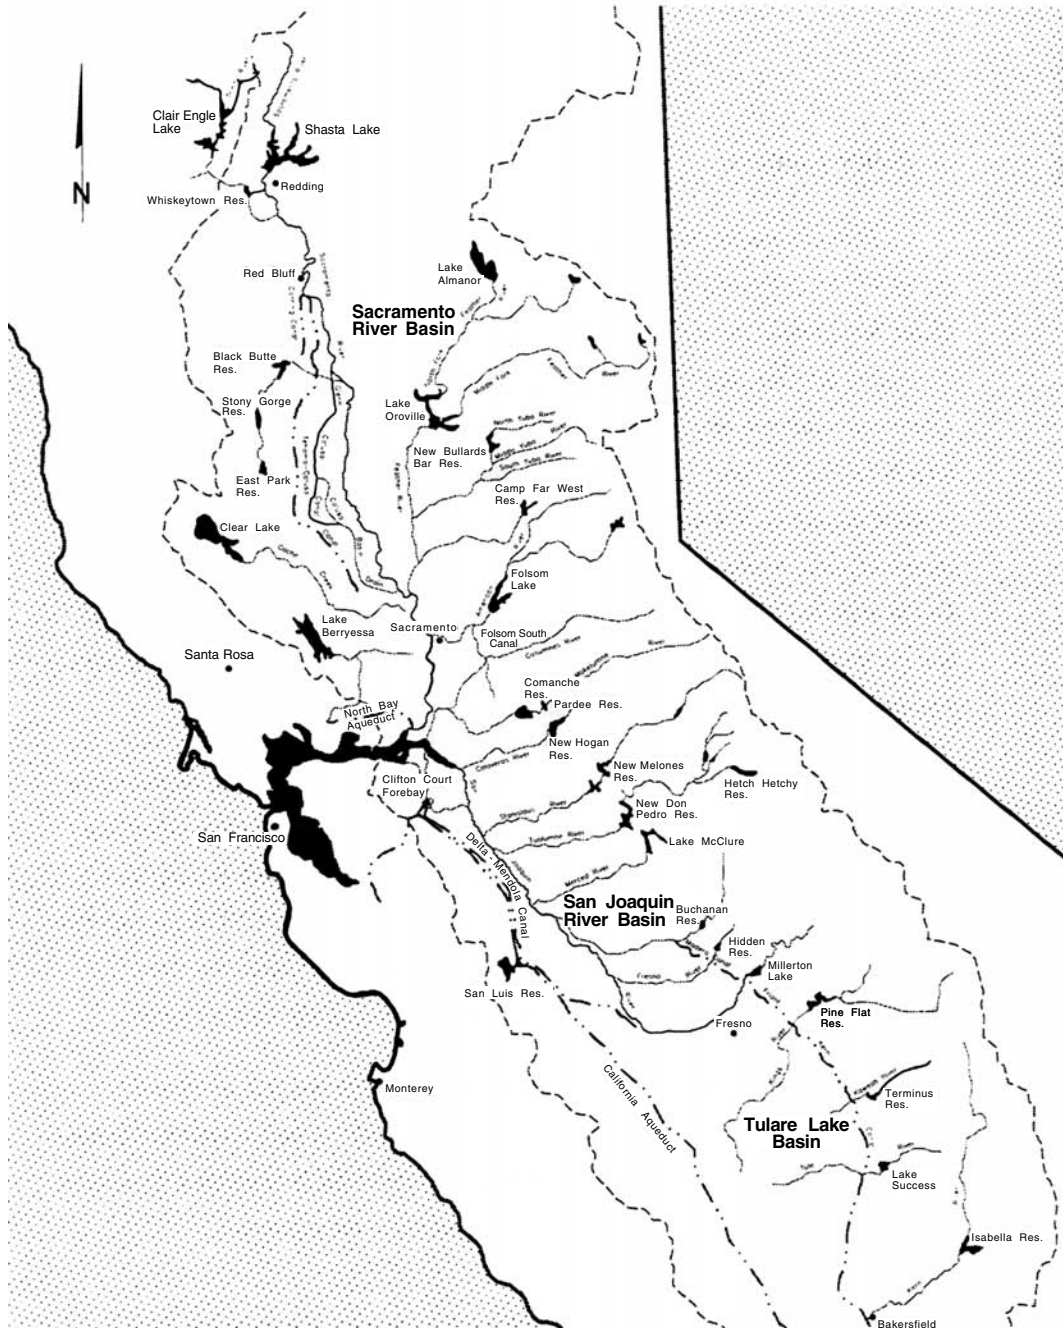

Figure 27.1 Map of the San Francisco Bay-Delta-River system. (Used with permission of the CALFED Bay-Delta Program.)

stakeholder scientists willing to check their stakeholder hats at the door. We provided background materials to the participants, including a strawman proposal for a framework and protocol for indicator development. The first workshop helped refine that framework, and the second workshop developed an initial list of indicators in accordance with the framework.

The basic procedure we undertook for indicator development followed a four-step process suggested by Keddy et al. (1993) for translating the ideas of ecosystem health into practice and establishing ecological indicators: (1) define ecological integrity or health in an operational way; (2) select appropriate indicators of health or integrity; (3) identify target levels of selected indicators; and (4) develop a monitoring system to provide feedback. The first workshop focused on step one and the second on step two; together they laid the groundwork for further refinement of the indicator system as the design of the restoration program evolved.

Step One: Define Ecological Integrity in an Operational Way

Step one — defining ecological integrity in an operational way — may begin with the development of general goals and objectives for the ecosystem management or restoration program. We distinguished between *goals*, which describe the “big picture” overview of what the restoration program is trying to achieve, and *objectives*, which are more precise descriptions of the particular steps necessary to achieve the program goal.

The workshops built on previous goal statements put forth by various government agencies and private organizations. Synthesizing these and the scientific input of workshop participants, we developed the following suggested goal statement for Bay–Delta–River restoration and management:

Establishment of a healthy system that supports a diversity of habitat types along with their resident communities of plants and animals, supports essential ecological functions, and is self-sustaining (requiring minimal intervention) and resilient to stresses.

This goal statement assumes that the system will continue to accommodate human use of natural resources.

A series of objectives also evolved from workshop discussions (Table 27.1). These objectives provide more specific descriptions of the components and processes that appear necessary to achieve the overall goal for the Bay–Delta–River system and to successfully implement the whole-system management envisioned by current law and policy. They also relate more directly to indicators than does the general goal. Note that these eight objectives are not prioritized. All must be achieved in order to support the system-wide goal stated above.

The derivation of these objectives, as well as the selection of indicators in step two, ideally should be carried out in the context of working models of the ecological system at both the landscape and smaller scales. In this case study, however, ecological models were not explicitly derived at the outset, except to the extent that a habitat typology (see below) provided a partial surrogate.

In order to take the next step — translating these objectives into a suite of indicators — an ecologically sound conceptual framework is required to ensure that the indicators include each of the key components and processes referenced in the objectives (and ideally also identified in ecological models). The framework that we propose is adapted from Noss’ (1990) conceptual model of biodiversity at multiple levels of organization. In this model, structural

Table 27.1 Restoration Objectives for the San Francisco Bay–Delta–River System

-
- A. Ensure conditions necessary to support and protect native biodiversity
 - B. Protect and/or restore conditions necessary to increase populations of valuable plant and animal species (in a manner consistent with protecting native biodiversity)
 - C. Ensure sufficient extent, diversity, quality, connectivity, and range of successional states of natural habitats
 - D. Protect and/or restore the natural trophic structure of communities
 - E. More closely approximate the natural patterns of transport of essential materials (water, sediments, nutrients)
 - F. More closely approximate the natural hydrological regime
 - G. Protect and/or restore water quality
 - H. Provide for societal uses (harvest, recreation, aesthetics)
-

(i.e., “physical organization or pattern of a system”), functional (i.e., “ecological and evolutionary processes”), and compositional (i.e., “identity and variety of elements [e.g., species or communities] in a collection”) biodiversity, shown as interconnected spheres, each encompass multiple scales of organization. The scales of interest range from the landscape to the genetic level. Although Noss’ model was developed to facilitate selection of indicators that represent the many aspects of biodiversity that warrant attention in environmental monitoring and assessment programs (Noss, 1990; 1995), it appears useful in applications beyond the context of biodiversity assessment.

Accordingly, the framework proposed here includes several elements: first, a classification scheme or typology that defines the components and scales of interest within the ecological hierarchy; second, for each component of this typology, a set of properties and corresponding measurable indicators that represents structural, compositional, and functional attributes (particularly those that relate to the restoration objectives or identified in an ecological model); and third, a set of criteria for eliciting and then screening the indicators.

Define the Components of Ecological Hierarchy: Habitat Typology

Participants at the first workshop suggested that a typology should be developed in order to divide the Bay–Delta–River system into working units for analysis and management. Typology is defined here to mean a hierarchical classification system depicting various major levels of ecological organization of the entire system. The typology we developed characterizes the Bay–Delta–River system at three basic scales: (1) *the entire landscape* (in order to consider the interactions among each of the different components of the system); (2) *ecological zones* (corresponding to major biomes at the landscape scale); and (3) *habitat types* (ecologically distinct areas within each ecological zone) (Figure 27.2). Ultimately, resolution down to the subhabitat level will be necessary to implement a restoration program.

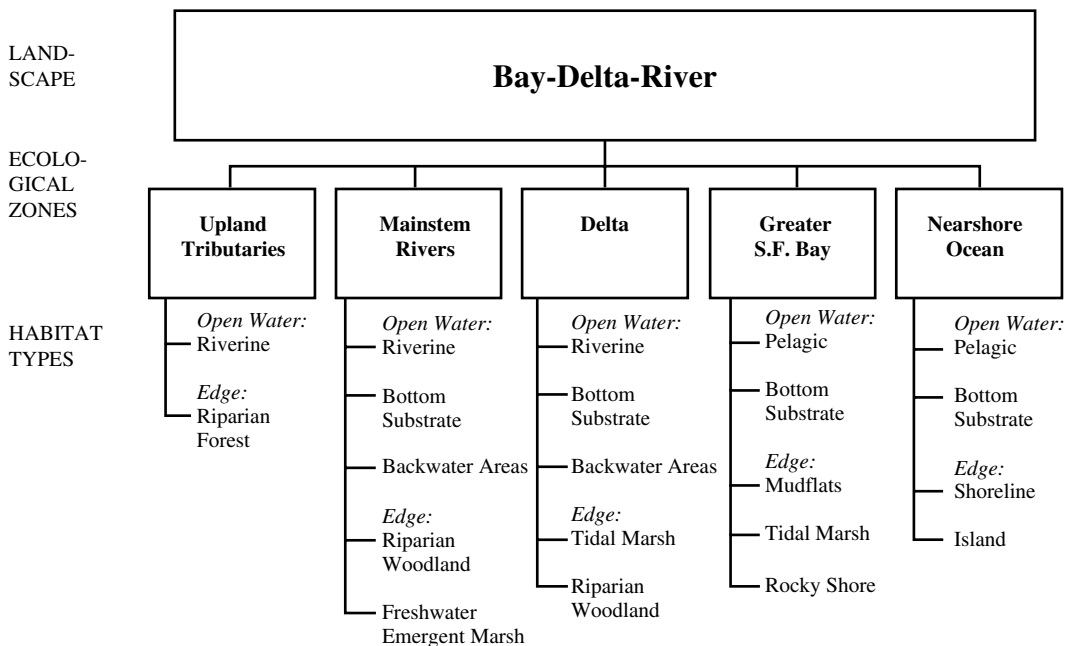

Figure 27.2 Schematic of the habitat typology used for indicator development and organization, indicating the five ecological zones upon which workshop participants came to consensus. The *suite* of indicators for the Bay–Delta–River system will incorporate a *set* of indicators for each component of this typology.

The landscape/seascape level is defined as the entire watershed of California’s Central Valley and San Francisco Bay, including freshwater, estuarine, and marine portions (see Figure 27.1). The five major ecological zones are defined as:

- *Upland Tributaries and Watersheds*: streams and rivers of the Sierra and Coast Ranges (fresh water)
- *Lowland Rivers*: the alluvial river–floodplain systems of the California Central Valley, most notably the Sacramento and San Joaquin Rivers above the tidal influence (fresh water)
- *The Delta*: the tidally influenced portion of the Sacramento and San Joaquin Rivers (estuarine)
- *Greater San Francisco Bay*: a series of embayments (Suisun Bay, San Pablo Bay, Central Bay, and South Bay) linking the delta and the ocean (estuarine)
- *Nearshore Ocean*: the corridor extending approximately 40 kilometers north and south of the Golden Gate Bridge and west to the continental shelf break (marine)

A list of habitats (e.g., riparian woodland, riverine, brackish tidal marsh) was also described for each of these zones.

Using this typology, the *suite* of indicators for the Bay–Delta–River system as a whole would incorporate a *set* of indicators for the entire landscape as well as *sets* for each component ecological zone and habitat type.

Define Attributes Relating to Structure, Function, and Composition

Because the typology organizes an extensive system like the Bay–Delta–River into components that relate to an ecological hierarchy, indicators developed for each component of the typology taken together paint a picture of the health of the whole system. We developed a template matrix for indicator development (Figure 27.3), which served as an organizing tool for developing each set of indicators. Following the Noss (1990) model, spaces were provided for both structural and functional indicators at the landscape and zone levels and, for each habitat type, structural and functional indicators at both the community and population levels. Our use of the term *structure* incorporates both the concepts of “structure” and “composition” as used by Noss; we adopted this compromise of nomenclature at the request of the workshop participants. The purpose of the matrix was to ensure completeness by providing a checklist. This device may be particularly useful in systems where reference to existing monitoring programs or a focus on particular species or habitat types might otherwise tend to dominate indicator selection.

For the Landscape and Each Ecological Zone		
	Structure	Function
	A e.g., habitat acreage	B e.g., hydrologic connectivity

For each Habitat Type:		
	Structure	Function
Community/Ecosystem	C e.g., species diversity/richness	D e.g., primary production
Population/Species	E e.g., population age structure	F e.g., fecundity

Figure 27.3 Matrix used by workshop participants to guide indicator development.

Step Two: Select Indicators According to an Organizing Framework

Based on this proposed organizing framework, participants in the second conference were asked to fill in the matrix checklist with indicators of structure or function relating to the appropriate typology component. The participants were further asked to select only indicators that met suggested criteria.

Many authors have suggested criteria for selecting ecological indicators (see, e.g., Noss, 1990; Keddy et al., 1993; Angermeier and Karr, 1994; Barbour et al., 1995; Cairns et al., 1993). Drawing on these, we developed a consolidated, short list of *essential* criteria, and a longer list of *desirable* criteria. In the former category, indicators *must* be (1) ecologically relevant and (2) scientifically defensible. An ecologically relevant indicator is closely related to or reflective of key ecological characteristics of a system or habitat. Scientifically defensible indicators are quantitative, with sufficient accuracy and precision to allow for ready interpretation. The relationship of an indicator to the property it reflects should be unambiguous and demonstrable. Exceptions to the *essential* criteria may be made if a certain indicator has significant public appeal, high economic significance, or is especially relevant to policy makers for some other reason.

Other criteria define beneficial, but not crucial, qualities of indicators. These *desirable* qualities include (1) ease of measurement; (2) sensitivity (including timely response to stress/perturbation, ability to provide early warning of disturbance); (3) existence of a historical database; (4) environmentally benign to measure (monitoring of the indicator is not damaging to the environment); (5) generality (applicable to different habitat types); and (6) ability to aid in distinguishing between natural processes and anthropogenic effects.

An inconsistency emerged from the workshops in that some participants confined their selection of indicators to measurable attributes, while others listed certain key *properties* of the system that needed to be assessed but were not in themselves directly measurable. For example, the “areal extent of wetlands” and “connectivity” of wetlands to some other habitat may both be considered key structural attributes of the system. However, while the former may be directly measured, the latter is not, but rather must be evaluated through a set of surrogate measures (e.g., amount of common boundary with another habitat; flow rates between other habitats and wetlands). We therefore distinguished between *properties* of the system that workshop participants believed necessary to assess and actual *indicators*.

For examples of properties and indicators developed at the workshops, see Table 27.2. The entire suite is reproduced in Levy et al. (1996). It provides a valuable starting point for the development of an indicator suite that can be used to assess ecosystem condition and restoration progress.

In order to further refine the indicator suite for use as an ecosystem management tool, several additional steps are required. Following the initial development of indicators, a final quality control check should be undertaken to ensure that the candidate suite of indicators meets the criteria laid out above. Also, the framework provides only an aid to ensure completeness, so it may be necessary to analyze the suite to make sure that the stated objectives will be met if the indicators all fall within the “healthy” target range. Part of the completeness check should include a determination of whether increases or decreases in the main *stressors* impacting the system will be detected by one or more indicators. Finally, the smallest number of indicators that will effectively evaluate the system is desirable.

Step Three: Develop Target Values

Once indicators are selected, a range of target values, from tolerable to desirable levels, should be developed for each. This constitutes step three of the Keddy et al. (1993) process. Because determining the target range of indicator values from first principles is difficult, comparisons with reference systems or historic states are sometimes used. In disturbed ecosystems such as the

Table 27.2 Examples of Indicators Developed at the San Francisco Bay–Delta–River Workshops^a

Scale of Interest	Objective ^b	Sample Property Assessed	Sample Indicator
Landscape	A, B, C, E, H	Connectivity of habitats (<i>Structural</i>)	Total number of barriers to anadromous fish migration
	C, E, F, G	Hydrologic regime (<i>Functional</i>)	Variability in flooding duration and frequency
Rivers	A, B, C	Extent and quality of edge habitat (<i>Structural</i>)	Length of shaded riparian bank
	E	Deviation from natural sediment budget (<i>Functional</i>)	Percentage of pre-dam supply of gravel and sand-sized sediment delivered to the reach
Delta	A, B, C, G, H	Quality of anadromous fish habitat (<i>Structural</i>)	Smolt survival through zone
	C, E, F, G	Deviation from natural hydrograph (<i>Functional</i>)	Percent of monthly inflow not diverted
Bay	A, B, C	Habitat quality (<i>Structural</i>)	Channel density
	A, B, C, D, G	Capacity to support resident fish and wildlife (<i>Functional</i>)	Habitat acreage
Ocean	A, B, C	Habitat extent and diversity (<i>Structural</i>)	Total area and proportionate amount of primary habitat types
	A, B, D	Production (<i>Functional</i>)	Average chlorophyll levels (as determined by landsat imagery)

^a The complete results of the workshops are given in Levy et al. (1996). Although lowland alluvial rivers differ ecologically from upland tributaries, we consolidated the two zones for ease of discussion.

^b Refers to objectives listed in Table 27.1.

Bay–Delta–River system, it is clearly unreasonable to strive for the restoration of pristine conditions in all parts of the system, because certain changes in the system (e.g., major dams and urban development) are not reversible within a reasonable time period. However, an analysis of historical conditions and processes can provide insights into realistic target levels (see, e.g., Steedman et al., 1996; The Bay Institute of San Francisco, 1998).

Step Four: Monitoring and Adaptive Management

Step four of the process involves monitoring the indicators to determine whether the management and/or restoration program is having its intended effect. Monitoring provides the foundation for adaptive management, whereby management actions and targets are evaluated and altered according to the results of monitoring data, and carefully designed management experiments are conducted to reduce uncertainty. Once there is consensus on the suite of indicators, monitoring can be taken up by the pertinent government agencies, although continued interaction with scientists is important.

Monitoring also allows for public accountability. It is important to communicate results of restoration projects to the general public to garner support for restoration and management efforts. Indicators that have been selected for their ability to communicate the status of the system as a whole in a way that the public can readily understand are particularly important for maintaining accountability, interest, and support.

LESSONS LEARNED

The process of developing a general goal and then translating the goal into more specific objectives (step one) provided a solid foundation for development and later refinement of the indicators. The experience from this case study highlights the benefits of involving scientists in this step — in contrast to the current trend toward maximizing involvement of stakeholders along with agency managers.

The formal conceptual framework used as an organizing tool for translating the goals and objectives into an indicator suite (step two) aided in the development of indicators that comprehensively reflect the most important attributes of the system. A secondary benefit of this formalized approach was to catalyze experienced scientists to “think outside of the box” rather than simply fall back on the elements covered in existing monitoring programs, or within their own specialties.

The development of the typology provided a tool for integrating existing, smaller-scale ecosystem management and restoration programs in the region into a larger vision for restoration on the landscape scale. The CALFED Bay–Delta Program adopted a similar typology for its ecosystem restoration planning process, in which specific restoration objectives and targets are being developed for the system.

The workshops also generated broad consensus on many indicators. It proved important to achieve this broad buy-in on metrics to describe the health of the system before trying to set the far more controversial *target ranges* for those metrics. In this way, the comprehensiveness and quality of the indicators remained the focus of discussion, rather than stakeholder issues such as economics or equity. CALFED was able to utilize the initial suite of indicators developed at the workshops immediately in the formulation of its ecosystem restoration program plan (D. Daniel, personal communication; CALFED, 1996b), although it remains to be seen whether CALFED will actually use a comprehensive indicator suite to evaluate its program.

Lack of time and failure to conduct each task in an entirely consistent way resulted in a suite of indicators that was unwieldy and somewhat internally inconsistent. In retrospect, it appears that spending additional time and resources to first develop theoretical models of the ecological system, in addition to the typology, may have paid off by providing a mechanism to focus and integrate the indicators derived for different scales. Using the formal conceptual framework for indicator selection *in tandem with* a set of theoretical models of the ecological system may well yield optimum results: the framework and the models together define the most important structural and functional elements within the system; the conceptual models display the relationships among these elements; and the framework for indicator selection provides the assurance that coverage is complete.

CONCLUSION

Increasingly, resource managers across the nation are adopting an ecosystem approach to natural resources management. The universal challenge facing any ecosystem management or large-scale restoration program is to translate the general and often amorphous goal defined by the public — e.g., a healthy system — into a set of *measurable* attributes that, taken as a whole, provide an assessment of overall ecological integrity. In the San Francisco Bay–Delta–River case study described here, we attempted to help accomplish this task by using a reproducible and methodical procedure that draws heavily on scientific literature and expert opinion, and applying this procedure in the context of the current political process aimed at forging a plan for ecosystem restoration and management. This ecologically based conceptual framework helped translate the abstract concepts of *ecosystem health* and *ecological integrity* into usable tools to guide the long-term process of large-scale restoration.

Comprehensive, operational definitions of ecological integrity also serve a broader purpose by helping to provide assurances to taxpayers and stakeholders that restoration programs will actually achieve the goals that have been set out. Because of the amount of uncertainty inherent in the science of ecology, as well as the infancy of the field of restoration ecology, a program of adaptive management will be necessary in most systems to ensure that the restoration actions (and associated dollar expenditures) are having the desired effect. Yet this flexible implementation approach may well exacerbate suspicions among stakeholders that the program will not ultimately be carried out in a way that achieves the original goal. In this context, a transparent, agreed-upon suite of indicators provides an important mechanism to ensure accountability. By providing an explicit set of perfor-

mance measures, the indicator suite can help to ensure that the adaptive management program remains on course to achieve the original goal.

Ecosystem protection and restoration goals are sometimes limited to capturing the goods and services that the ecosystem may provide (NHI, 1995). The utility of using a stepwise process and a conceptual framework, such as the one described here, is to try to make the suite of indicators — i.e., the explicit statements of the program goal and the measures of success — as ecologically relevant as possible, by capturing functional processes and major components of the system at scales that reflect the system's organizational hierarchy. Doing so will not only maximize the ultimate chances for designing and implementing a successful restoration program but also contribute to continuing public support for the endeavor.

Establishing Specifications for Ecological Indicators for the Prediction of Sustainability

Wayne G. Landis and John F. McLaughlin

INTRODUCTION

In Chapter 22, Robert T. Lackey presented in detail the difficulties in using the term *ecological health* for the management of ecological structures. Although this phrase is pervasive in popular print, radio, and television, the lack of a quantitative description of ecosystem health prevents its use in a scientific process. Lackey also states that currently an alternative model for setting the priorities of managing ecological structures does not exist. Allan K. Fitzsimmons (Chapter 23) details effectively the problems in using ecosystem health to make policy and to manage ecological structures. This chapter provides a further critique of the use of ecosystem health as a metaphor, evaluates current definitions of sustainability, and presents an alternative quantitative model, *The Box*. Finally, we present criteria for the development of indicators to facilitate the management of sustainable ecological structures.

Ecological Health and Integrity

Attempts to define ecological health and integrity have foundered. To date, health and integrity have been described vaguely: these words mean different things to different people, and explicit criteria have not been provided to explain how these terms should be applied to environmental decisions and setting policy. Two definitions of ecosystem health illustrate our point. Haskell et al. (1992) offered the following working definition:

An ecological system is healthy and free from “distress syndrome” if it is stable and sustainable — that is, if it is active and maintains its organization and autonomy over time and is resilient to stress.

In this definition, *distress syndrome* means “the irreversible processes of system breakdown leading to death” (Costanza, 1998). Karr (1992) provided a more explicit definition:

A biological system, whether individual or ecological, can be considered healthy when its inherent potential is realized, its condition is stable, its capacity for self-repair when perturbed is preserved, and minimal external support for management is needed.

The utility of these definitions is diminished by controversies over the terms *ecosystem stability* and *resilience*” (Pimm, 1984) as well as the use of terms that elude practical use and measurement. How can one measure ecosystem *autonomy*, *inherent potential*, or *capacity for self-repair* in ways that would seem objective to stakeholders with divergent values?

We have three main concerns about use of the term *ecosystem health*. First, the term *health* suggests that ecosystems are homeostatic, although they are nonequilibrium systems (De Leo and Levin, 1997).

Second, even if *health* were an appropriate term to describe ecosystem status, it would be related indirectly to the system properties of concern. Management decisions are made relative to specific entities and processes; discussion would be clearer if those properties were addressed directly and explicitly. Even in medicine, where health clearly is an appropriate concept, the term rarely is used in practice to make diagnoses, to determine treatments (for preventative or corrective purposes), or to monitor progress. Instead, direct measures of the properties or functions of concern are used. Similar approaches should be adopted for ecosystems; direct references to properties of concern are even more important to managing the status of ecosystems than they are to managing the status of individuals. Just as vague allusions to individual health ignore progress in medicine this century, reverting to ideas of ecosystem health disregards advances in knowledge about ecosystem function won by ecosystem science.

Our greatest criticism of the term *ecosystem health* is that it has very limited practical application to management. Because health is a metaphorical model, it cannot be measured directly. Advocates of the terminology suggest measuring surrogate variables. Instead, we offer an alternative term that more clearly addresses the same concept, while meeting Brooks’s (1992) criteria for an operational definition.

Our alternative defines *sustainability* for ecosystems quantitatively using an *assessment hypervolume*. This approach bases assessments on the variables themselves rather than on surrogates. This involves defining the desired ranges for various ecosystem functions and/or structural characteristics and then determining if a given system falls within or exceeds those ranges. Management goals and actions can be directed explicitly at those variables explicitly rather than at vague descriptions of system health. In this way, assessments about system status relate directly to properties of concern.

SUSTAINABILITY DEFINED

Next we present a contrast to the previous descriptions of health and integrity. These paragraphs set the context for listing specifications for parameters that lead to predictive indicators useful for management decisions.

Assessment Hypervolume (The Box)

Landis et al. (1994) originally defined the assessment hypervolume for risk assessment, and this concept provides the basis of our approach to defining sustainability. Kersting (1988) and Johnson (1988a,b) also proposed multidimensional models for assessing impacts to ecological systems. Here we apply the assessment hypervolume quantitative definition for sustainability.

Ecosystem response variables related to stakeholder values define the axes of an assessment space. These values can be derived from surveys, stakeholder meetings, or established management goals as represented by legislation. Examples of such values are presented in Table 28.1. These values were derived from the Willamette Valley Livability Forum, a group established by the Governor of Oregon with a charge of establishing management goals for the ecological services provided by the Willamette River and its tributaries. The process was driven by consensus for the time up to 2050. The first column lists the goals as defined by

Table 28.1 Subset of Values for the Construction of an Assessment Hyperplane for the Middle Willamette and McKenzie Rivers^a

Stakeholder Values	Assessment Endpoint
Fisheries	
Summer steelhead	Population meets Oregon Department of Fish and Wildlife basin fisheries plan: maintain a potential sport catch of 250 in the mainstem above Willamette Falls ⁵ Maintain an annual catch of 1200 on the McKenzie River ⁴ Maintain a return of 2400 to the McKenzie subbasin ⁴
Native Fish Populations	
River sustains thriving populations of native fish	Populations of spring chinook, rainbow trout, cutthroat trout, and winter steelhead meet ODFW basin fishery plans ¹⁻⁶
Spring chinook	Increase production to 100,000 fish entering the Columbia River ¹ Increase the number of wild spring Chinook to the McKenzie River to 10,000 ¹
Fish Organismal Health	Less than 5% of the mountain whitefish (<i>Prosopium willamsoni</i>) and large-scale suckers (<i>Catostomus macrocheilus</i>) show either external or internal anomalies
Potentially Conflicting Values	
Floodplain management for human health and safety	Flow is controlled to prevent damage to human lives or property in urban areas
Water quantities sustain human communities	Crop irrigation and human consumption
Maintaining reservoirs for fishing, boating, and windsurfing	
No loss of recreation including boating	
Fishing	e.g., Summer steelhead

^a Note the conflicting values.

this group. The second column is the quantitative measure that we used to define this goal. In some areas there are conflicts where two desired goals appear incompatible, but our goal is to be as inclusive as possible. This process provides the limits of our hypervolume, which are tied directly to stakeholder values.

Within this space, the tolerable limits to each ecosystem response define the assessment hypervolume (Figure 28.1a) (Landis et al., 1994). Thus, the boundaries of the assessment hyperplane are social constructs, determined by stakeholder values. The stakeholder values can be derived by expressions of limits set by regulatory agencies, public forums, or scientifically based surveys.

The numerical range of criteria of the stakeholder values for a given system determine its position within the assessment space. One can follow the trajectory of a system relative to stakeholder values by plotting the position of the system through time. All judgments regarding the

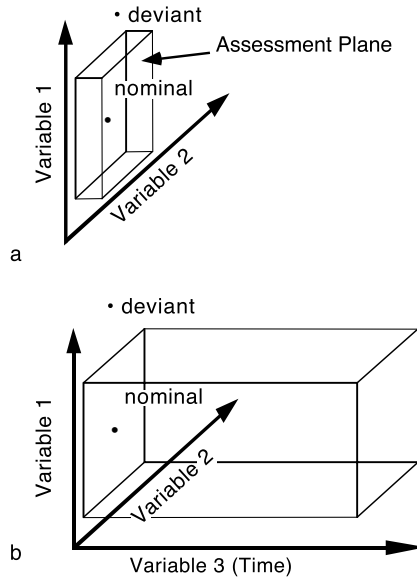

Figure 28.1 Creation of an assessment hypervolume.

success of environmental management or the suitability of management goals should refer to the system trajectory relative to the assessment hypervolume.

The time frame for defining sustainability should be considered as a separate axis (Figure 28.1b). Time horizons need to be specified to make predictions and provide boundaries for management goals. The time horizon must be finite, because no system can be sustainable indefinitely (Chapin et al., 1996; Costanza et al., 1998). Construction of the assessment hypervolume is complete after the time horizon is determined (Figure 28.1b). Then developing operational definitions for sustainability becomes straightforward.

Operational Definitions

Sustainability: Management, development, or use is sustainable if it maintains system responses within the assessment volume during a specified time period. Societal values determine the response variables, their limits, and the time horizon that delimit the assessment volume.

Ecological Nominality: A system is nominal if it is within the assessment hyperpolygon, that is to say, if it is in the Box. (Ecological integrity can be thought of as the state of being within the assessment hyperpolygon.) The system is deviant if it falls outside the hyperpolygon or is out of the box. These states are depicted in Figure 28.2. This definition meets the criteria stated by De Leo and Levin (1997): “Measures of integrity must reflect the ability of ecosystems to maintain services of value to humans” because the assessment hypervolume represents societal values.

Indicators of Sustainability: These are variables that predict whether a system will persist within the assessment volume during the specified time period, whether an initially nominal system will depart from the assessment volume, or whether a deviant system will enter the assessment volume within the assessment time.

These definitions satisfy Brooks’s (1992) requirement for an operational definition: the assessment volume provides an objective and measurable set of criteria against which ecosystem responses can be judged. They also suggest how sustainability or its loss can be predicted, subject to the degree that ecosystem stressor–response relationships can be quantified.

Figure 28.2 Trajectories of a sustainability evaluation.

SPECIFICATIONS FOR INDICATORS OF SUSTAINABILITY

Most monitoring programs are conducted to determine the current status of an ecological system (Usher, 1991). This status, or state, represents a point within the assessment hypervolume (Figure 28.2a). Since trajectories passing through a given point rarely are determined, monitoring programs often ignore system dynamics unless monitoring continues over long periods. Even with long-term monitoring, the focus on current status makes predicting trajectories difficult.

Management for sustainability, however, requires predictions. Three different kinds of predictions are needed, depending on a system’s initial position relative to the assessment volume (Figure 28.2b). First, restoration or recovery is predicted (Figure 28.2b, arrow “A”) when the system starts outside the assessment volume and the forecast trajectory moves into the volume within the time horizon. The second prediction is sustainability: the system will remain within the assessment volume throughout the specified time (Figure 28.2b, arrow “B”). Anthropogenic or nonanthropogenic factors may affect system dynamics, but these changes do not force the system outside the box. The third prediction is that the system is not sustainable: it will exceed the boundaries of the assessment volume because of widely fluctuating responses or prolonged trends caused by anthropogenic or nonanthropogenic impacts (Figure 28.2b, arrow “C”). Each kind of prediction should be made probabilistically because stochastic factors affect all ecological systems.

The assessment hypervolume approach also has three clear characteristics that are important in making predictions and managing ecological structures. First, the approach is inherently multivariate. Even if the assessment box is reduced to one variable over time, several factors determine the outcome of that parameter. Approaches that do not recognize this inherent property of ecological systems are not accurate models of ecological reality. So-called multimetric approaches do not take into account the sample or intrinsic distribution of ecological parameters. Second, the assessment hypervolume implicitly recognizes the dynamic nature of ecological systems. No assumptions are

made about unimpacted control or reference states. Finally, prediction is implicit and central to this strategy. To implement the assessment hypervolume approach successfully, the characteristics of ecological measurements need to be examined.

Measurement of Ecological Parameters for the Prediction of Sustainability

Classical measures of health and sustainability deny the inherent dynamics of ecological systems. Point measures such as species presence or absence, the index of biological integrity and its derivatives, species diversity, and the wide variety of water quality indices (reviewed in Matthews et al., 1998) all fit into this category. Each of these measures may have utility for describing the position of the ecological system within the assessment box, but none is tied implicitly to social or cultural values.

What are the goals of ecological measurements in the context of the assessment hypervolume? The measures need to place the ecological system being managed along the axes and make predictions about the future trajectory. We will now examine the properties of measurement variables and the importance of the stochastic features putting the system in a landscape context. Finally, we introduce the interaction between landscape and the timescale of the prediction.

Measurement Variables

It has been demonstrated that the variables that best differentiate between impacted and non-impacted systems change during the time course of the experiment or field study. This property of variables has been examined in a series of microcosm experiments (Landis et al., 1993a,b; 1994; 1996; 2000; Matthews et al., 1996) and in a field study (Shubert, 1997).

Several clustering methods were used in each report. Cosine and Euclidean metric clustering and nonmetric clustering and association analysis (NCAA) were performed on each sampling date. Patterns were examined to test the hypothesis that the four treatment groups within each experiment could be identified. In other words, could a microcosm treatment replicate be placed properly into its treatment group? In each experiment the variables that were best at correctly identifying the treatment of each replicate changed over the course of the experiment. In back-to-back replicate experiments (Landis et al., 2000), there was little correspondence among important variables on the same dates. Although the algal, daphnid, blue-green, and ostracod dynamics had similar patterns overall, the intrinsic variability of the system precluded an exact correspondence. Of course, microcosms change dramatically over the course of each experiment. At the beginning, systems were dominated by green algae and the daphnids. At the end of these experiments, ostracods were the most plentiful invertebrate and the systems had changed to a detritus economy.

Shubert found a similar variability in several plots in Prince William Sound following the 1989 oil spill. Some sites were oiled, some oiled and steam cleaned, and other sites were never oiled. The best variables for determining treatment group using NCAA changed from year to year.

Upon reflection, these findings are not surprising. Each system, whether microcosm or Prince William Sound, changes dramatically over time. When responding to a disturbance, ecosystem change can occur at an even more rapid rate. Colonization and growth of new organisms have a large stochastic component that has an important role in determining the composition of an ecological community.

These microcosm experiments and the field research demonstrate the persistence of effects. In each case the treatment group of the replicate or study site was correctly identified throughout the duration of the studies. This characteristic has been labeled *community conditioning* (Matthews et al., 1996; Landis et al., 1996) and is a fundamental characteristic of ecological systems. Community conditioning recognizes that ecological systems are historical and complex structures. Information about past events remains within the system for extended periods and perhaps for the temporal extent of the system. Complex systems also have the property of being nonequilibrium systems. Of course, ecological systems have stochastic features and exist within a spatial context.

Stochastic and Deterministic Variability as a Predictor

Variation, due to both deterministic and stochastic processes, is important in determining the future trajectory of an ecological system. The importance of understanding variation can be illustrated using a simple difference equation:

$$N_{t+1} = N[1 + r(1 - N/K)],$$

where

- N = population size at time t
- N_{t+1} = population size at the next time interval
- K = carrying capacity of the environment
- r = intrinsic rate of increase over the time interval

In our simulations K is allowed to vary as a random number selected between the specified boundaries. The rate of increase is 2.1, which does not put the system in a chaotic domain but is in a region where a simple bifurcation in the dynamics occurs when the carrying capacity is held constant. The output from such simulations is presented in Figure 28.3. In each instance the figure portrays the outcome of five replicate simulations. The simulation portrayed in the top of the figure is the result of letting K vary from 8000 to 10,000. All five populations remain extant and exist between 11,000 and 3000 as the upper and lower bounds. The lower panel represents a simulation with K varying from 7000 to 10,000. Extinction of all five populations occurs before iteration (time interval) 70. Different distributions of the variation within K will give different probabilities of extinction over the period of the simulation.

In summary, temporal variability is an important measure if prediction is a goal. Variability can be measured and analyzed and forms an important part of a suite of predictive indicators. In the case of ecological systems there is an important spatial component to consider.

Spatial and Temporal Considerations in Landscapes

There is an extensive literature, mostly theoretical, on the distribution of organisms within a landscape. McLaughlin and Landis (2000) have reviewed this literature with regard to the effects of contaminants and other disturbances upon populations. We would like to summarize some of the critical features of how stressors affect spatially dispersed populations.

One of the critical features of spatially dispersed populations is that an impact upon one patch can affect sites with no direct exposure to the stressor. This feature of dispersed populations, "action at a distance" (Spromberg et al., 1998), has been demonstrated by computer simulations and experimentally by L. Macovsky (1999). This research and further investigation (Landis and McLaughlin, 2000; McLaughlin and Landis, 2000) have demonstrated that the impacts of a disturbance, natural or anthropogenic, can be affected by a variety of spatial factors. The size and distribution of the population patches, the relative arrangement of patches to the stressor, and the migration rates between patches affect the magnitude and type of effects upon a dispersed population. The magnitude of indirect effects generally decreases with distance. Because stressor exposure and organismal dispersal have large stochastic components, in certain regions of the initial state space, several distinct outcomes can occur within the population patches. Probabilities can be assigned to achieving carrying capacity or becoming extinct.

One of the other critical features of spatially dispersed populations is the destruction of the reference site construct. Since the effects of a stressor can be transferred throughout a landscape by migration, no site is unaffected. Once the distance is so great that an effect does not occur, then other historical and geological factors will also be different.

The dynamics of the impacts are therefore complicated by spatial structure. Contaminant effects can be transmitted to populations not exposed. Blockage of dispersal pathways can cause extinction

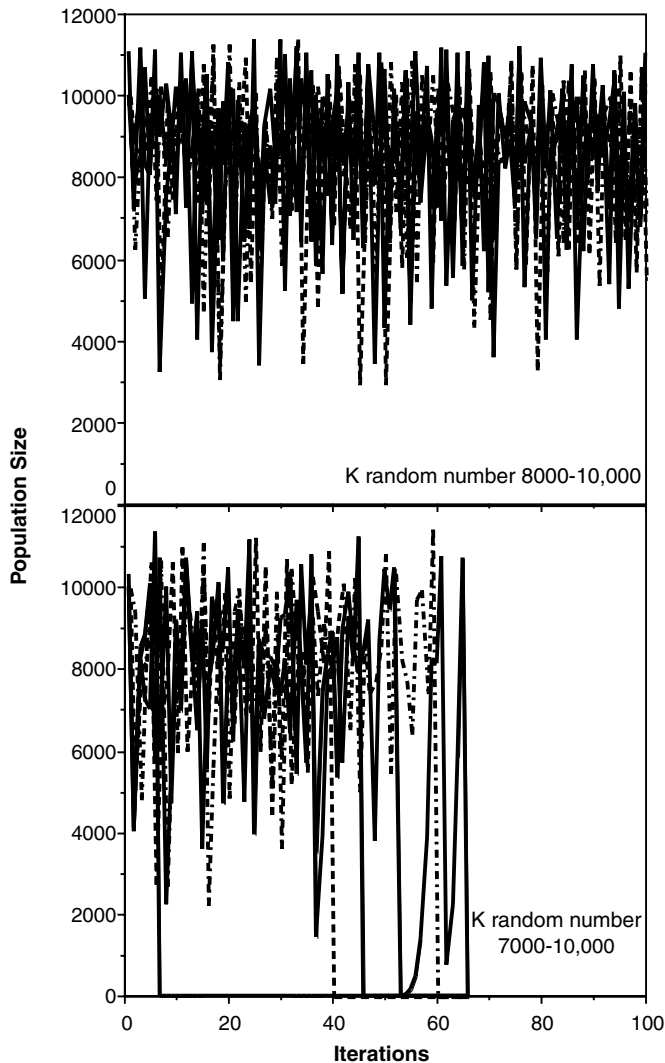

Figure 28.3 The importance of variability in the prediction of dynamics. Five replicate simulations are plotted in each graph. A change in the variability of the carrying capacity (K) results in the extinction of the model population.

of a population within a patch by not allowing migration from surrounding patches to reestablish the population. A mere census of populations within patches cannot reflect the dynamics of spatially structured systems. Populations in all patches may be similar, but one may be increasing due to migration while another is decreasing as outmigration rescues an affected population. Only an understanding of the stochastic and deterministic features of a spatially structured system will allow accurate assessment and prediction.

Other features of a landscape are also critical in understanding the potential impacts of stressor event in an ecological structure. We will use a section of the Willamette and McKenzie Rivers in central western Oregon to illustrate these features. In a regional risk assessment conducted by Matt Luxon and W. Landis, the area has been broken down into specific risk regions depending on characteristics such as the type of stressors, land use, morphology of the rivers, and urbanization. The risk assessment focuses upon impacts to the main channel due to industrialization, effluents, dams, and land use within the study area. One of our findings to date is the non-Euclidean nature of distances within the watershed to the main channel. In several instances potential stressors that

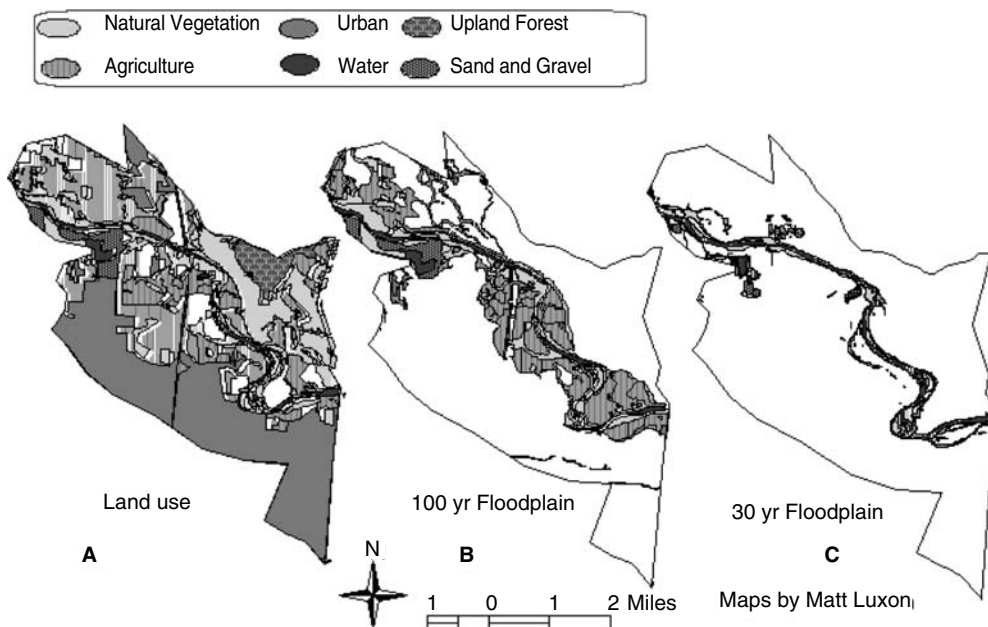

Figure 28.4 The effects of temporal specifications upon the area to be considered in the sustainability of an aquatic resource. The land use types to be considered for a direct impact on the mainstream of the river depends on the specified time frame of the assessment.

are nearly adjacent within the watershed have impacts in the main channel kilometers apart. This contradiction is because the potential sources of stressors are along different tributaries, and these tributaries feed into the main channel at very different sites.

The second critical feature is the importance of time in determining what part of a landscape may have an impact on the main channel of a river. Figure 28.4 illustrates the importance of time frame in assessing impacts. Figure 28.4A depicts the land use types along one reach of the watershed of the Willamette as it passes through Eugene–Springfield, Oregon. However, in judging the risks to the river posed by that landscape because of flooding, a different picture emerges. If the time frame is 100 years (Figure 28.4B), about half of the region will be flooded, with very little of the urban area included. If the time frame is 30 years, only those lands adjacent to the main channel will be flooded (Figure 28.4C). The number of land uses in this area is similarly limited. The time horizon of an assessment must be specified if the outcome is to be accurate and useful.

In review, the measures that best determine the current and future state of an ecological structure change over time. Stochastic and deterministic variability are important features to quantify if prediction is a goal. The distribution within and utilization of the landscape by populations has to be understood to predict the dynamics of change from a stressor event. Finally, the temporal extent of the assessment has to be specified. Each of the measures needs to be incorporated into an assessment of sustainability and with it a recognition of the temporal and spatial dynamics of ecological systems. Unlike a *health* approach, there is an explicit recognition of these features in a dynamic nonequilibrium system.

In summary, there are five specific design requirements for developing a useful set of indicators regardless of the ecological system.

1. The indicators must be placed in the context of the assessment hypervolume and tied to cultural values of the stakeholders.
2. Because projections cause the loss of information, a variety of methods with different assumptions about the nature of the system must be used.

3. The best attributes to measure alteration of the system change over time. To use just one set may miss the dynamic complexity of the system and subsequent impacts.
4. Ecological systems are both deterministic and stochastic. Each property is important to represent in an evaluative or predictive context.
5. Spatial context must be known and use of the landscape by the biota understood.

Comparisons and Damnations

In the introduction to Section I.4, Lackey described the failings of the *ecosystem health* approach to assessing and managing ecological systems. He lamented that no alternative was currently available. The assessment hypervolume is a workable alternative.

In contrast to the ecosystem health model, the assessment hypervolume approach clearly ties stakeholder values to the dynamic processes of ecological structures. The goals of the assessment and ecological management process are specified and quantified in the formulation of the assessment hypervolume. Reference sites are not required. The assessment hypervolume explicitly recognizes the dynamic nature of ecological systems and embraces measurement of dynamics. Recognizing that ecological systems and their management are multivariate discourages the use of indices to estimate risks of impacts. None of these features is an aspect of the ecosystem health model. Also, note that classic features of ecosystem health such as integrity, recovery, resilience, or unimpacted reference are not required by the assessment hypervolume approach.

Furthermore, the assessment hypervolume approach works. We have used the assessment hypervolume and the relative risk model tools successfully in assessing risks in the fjord of Port Valdez (Wiegers et al., 1998; Landis and Wiegers, 1997) and sections of the Willamette and the McKenzie Rivers in Oregon. We have started a similar assessment for Codorus Creek in Pennsylvania. Other research groups have assessments under way in New Zealand (G. Lewis.), Australia (Walker et al., 2001), and a Brazilian rain forest (Moraes et al., in press).

Ecosystem health and related ideas of integrity have been long recognized as constructs with severe problems (Suter, 1993; Lackey, 1996). The idea of ecosystem health is not necessary in the performance of assessments and management plans. In fact, ecosystem health is a misleading, unobservable, and inaccurate model of ecological systems. However, its use as witnessed by this symposium persists.

An argument often employed for using health, integrity, and values such as “good” in describing ecological systems is that these are terms the public readily understands; they can therefore be used to advance the cause of environmental stewardship. Kapustka and Landis (1998) published a response to this practice:

We contend that this is wrong on both ethical and practical grounds. The ethical component is that misrepresenting scientific issues undermines the foundation of the scientific process. In science the experiment defines reality, not public opinion or fashionable morality. Scientists have an obligation to present reality as best they know it, independent of funding source, home institution, or other cultural constraints.

The outcomes of the assessments and management of ecological systems have deep personal, economic, and social impacts. In our view, this requires us to use the best predictive methodologies available and to communicate effectively with the public. The use of misleading or incomplete descriptions reduces our credibility and the importance of the field. Given the obvious problems with the use of ecosystem health as a model, we must abandon it.

ACKNOWLEDGMENTS

We would like to thank Matt Luxon for the preparation of the maps of the Willamette and for the compilation of stakeholder values for the Willamette Valley. This project was supported in part by a grant from the National Council for Air and Stream Improvement (NCASI).

Measuring the Impact of Ecological Disintegrty on Human Health: A Role for Epidemiology

Colin L. Soskolne

INTRODUCTION

For several decades, ecologists and biologists have been warning of the extinction of various species, of declines in both the quality and extent of ecological capital, and of general and specific environmental degradation. More recently, climate change as a consequence of global warming has been added to the list of environmental concerns worldwide. The concerns arise from the view that global ecological integrity — simply interpreted as the ability of nature's life-support systems to withstand perturbations and continue to provide their usual life-sustaining services — is a first-order principle for the sustainability of life on Earth (Soskolne and Bertollini, 1999). Two texts in the early 1990s served to bring these concerns to epidemiologists' attention (World Health Organization, 1992; McMichael, 1993).

Global ecological disintegrty, the converse of *global ecological integrity*, is a function of three factors: over-consumption, population growth, and the inappropriate applications or misuses/abuses of technology. All three of these factors are, in fact, human-induced and are therefore potentially controllable. Thus, human influence in perpetuating the current course of environmental degradation is at the core of this chapter. It is posited that if it could be demonstrated that current socioeconomic policies indeed are associated with negative human health impacts, then alternative policies likely would be introduced that could serve to steer humanity from a course of nonsustainability.

In essence, environmental degradation is impacting those ecological systems upon which human beings depend for their well-being and their survival, including the life-support systems of air, water, soil, forests, fisheries, and climate. If life-support systems indeed are collapsing, the need for any of the sciences to bring the seriousness of the problem to the attention of those responsible (i.e., humans) for causing the negative environmental impacts is paramount. If inherently anthropocentric human beings could be shown scientific evidence that escalating environmental degradation is having, or could have, negative human health consequences of epidemic proportions, then those sciences could play a critical public health role by impacting policies to avert potential disasters from occurring. Thus, this chapter is based on the belief that if negative impacts on human health and well-being could be associated with environmental degradation, then adequate justification would be at the disposal of policy makers to change the course of human development toward one of sustainability. Sustainable development has been defined as development that meets

the needs of the present without compromising the ability of future generations to meet their own needs (United Nations World Commission on Environment and Development, 1987).

Because epidemiology is the applied science basic to public health policy formulation, it is proposed that this discipline has a major role to play in bridging those concerns noted by the ecologists, biologists, and climatologists with the appropriate endpoints of human health and well-being. The definition of epidemiology (Last, 2001) is: "The study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to control health problems." As such, epidemiology is the science that is basic to public health. Of all the sciences, epidemiology is the applied science that provides the rational basis for policy formulation. It is the science that informs the policy process. Its goal is to protect the public's health through preventing disease, disability, and premature mortality.

If catastrophic events of epidemic proportions are even potentially preventable through reducing the risk of environmental collapses, then epidemiologists would have a significant role to play in bridging the ecological and biological assessments to human health. Epidemiologists thus must join the ranks of the ecologists and biologists in making recommendations to prevent such collapses. In this way, the public's attention would be directly focused on human concerns related to their health and well-being and, hence, with a potentially more immediate and urgent effect on policy. After all, it is one thing to be concerned about the extinction of flora and even fauna; but the motivation for the present work lies in the public's attention being more directly gained if human life itself is recognized as being demonstrably at risk.

EPIDEMIOLOGIC METHODS IN POPULATION RESEARCH

Epidemiologic researchers have at their disposal a broad array of methods for determining the distribution and determinants of diseases in populations. The methods range from experimental (i.e., randomized controlled trials) to observational studies that fall into the class of either *descriptive studies* (e.g., disease patterns, or the distribution of diseases over time) or *analytical studies* (e.g., etiologic studies, or studies of disease determinants). These include several designs: ecological/correlational studies; cross-sectional studies; case-control studies; and cohort studies (Beaglehole, et al., 1993). An appropriate study design must be selected to best address the health question of concern; the choice will depend on the available resources and on the existing body of knowledge to justify one design over another. The question of concern in traditional etiologic research is one that aims to link a proximate exposure to the development of a particular disease. While this falls into the broad rubric of applied science, its analogy lies in basic science with its reductionist approach of relating a specific cause to a particular outcome.

The question of a health concern is one of applied science, and it usually finds its way to the desk of the epidemiologist. These concerns are identified not so much from the basic sciences through, say, the conduct of toxicological experimentation that then must be tested in human studies, but often through anecdotal evidence that is brought to the epidemiologist's attention. Anecdotal evidence could come to the epidemiologist in the form of an astute observation by a layperson who might observe that a particular disease or type of death is occurring among the person's peer group with unusual frequency. Perhaps it will be presented by an astute professional practitioner who will report in the scientific literature a cluster of events/cases, or a series of events/cases that have come to light through a narrow time frame. Such anecdotal evidence has led to epidemiologists entering the scene to scientifically quantify the problem suggested by the anecdotal reports. Thus, in the more traditional reductionist paradigm and the one that has led to many worthwhile scientific discoveries, anecdotal evidence often has provided the justification to invoke the scientific method.

If environmental degradation were to be negatively impacting human health, then epidemiology, in order to fulfill its traditional role, should be able to demonstrate that, over time, as the environment is degraded, human health and well-being decline (or suffer some loss). The latter would usually

be measured in terms of increasing rates of disease, disability, and death. If such a pattern were discernible epidemiologically, then no threshold effect would be operating. On the other hand, if such trends could not be demonstrated, then a threshold effect is the most likely scenario. If epidemiologists were to wait for threshold limits to be exceeded, then their preventive role would be nil; under the threshold model, health indicators would remain stable and even show signs of improvement. But these improvements would continue only until such time as the life-support systems failed, followed by rapidly acting processes with dramatic and massive impacts on human health and well-being. For epidemiology to play a useful preventive role, access to appropriate indicators of a sensitive and specific enough nature will be needed to maximize the detection of health trends well in advance of allowing declines to approach threshold-bearing levels.

UPSTREAM DETERMINANTS OF HEALTH AND WELL-BEING

Because disease prevention is at the core of maintaining public health, there have been appeals to epidemiologists to focus more on the so-called upstream (or distant) determinants of public health (Pearce, 1996; Susser and Susser, 1996; Shy, 1997; Susser, 1998; Porta and Alvarez-Dardet, 1998; Pearce and McKinlay, 1998; Pearce, 1999). This would require that epidemiologists make a paradigm shift in their conception of both the models and methods used in their research. That is, epidemiologists would need to move from reductionist approaches to more systemic or holistic approaches in their research. Accomplishing this shift will require transdisciplinary approaches to health research.

Transdisciplinary approaches to human health are approaches that integrate the natural, social, and health sciences in a humanities context and, in so doing, transcend each of their traditional boundaries. Emergent concepts and methods are the hallmark of the transdisciplinary effort. This approach will be essential if models are to take variables related to overconsumption, population growth, and abuses of technology into account while simultaneously controlling for the potential confounding effects of economic development as measured by, say, gross domestic product (GDP). Epidemiology is a discipline that is accustomed to inter- and multidisciplinary collaboration. The challenge will be to move into the realm of transdisciplinarity.

All of this is not to suggest that funding should be shifted from reductionism to holism; it is rather to say that some funding should be made available to stimulate systemic (or holistic) research. To help make this shift, training programs and continuing education courses will be needed to equip people with skills in complex systems analysis. Understanding the distinction between poverty and wealth and between growth and development will be needed. Integrating moral philosophy into the recommendations arising from epidemiologic research and directed at informing policy will be needed for understanding the relevance of the Precautionary Principle and future generational issues. Skills will be needed for conducting integrative risk assessments that are scenario based. The latter may require working closely with experts in the area of futures studies. Finally, understanding mass behaviors will be critical for designing interventions to promote paradigm shifts in social policy.

PAYING ATTENTION TO ANECDOTAL EVIDENCE

Many of the indicators from research to date point to dramatic declines in numerous life-support systems. Indeed, indicators of environmental decline, independently derived, show as much as a 50% reduction in biodiversity associated with selected living systems over the 15-year period 1982 to 1997 (Soskolne and Bertolini, 1999). While there is an inherent level of uncertainty associated with any scientific assessment or projection, there are some assessments for which minimal uncertainty exists.

The uncertainty associated with climate change, the associated extreme weather events, and the reemergence of some infectious diseases are a reality. The rate of species extinction continues to escalate while biological diversity declines. Fisheries are collapsing and fish stocks are depleting worldwide. Existing freshwater scarcity and increased desertification make the issue of access to fresh water the most serious threat to the security of the planet in the next 10 years. Nonrenewable resources continue to be consumed at increasing rates. The number of ecorefugees exceeded the number of war refugees in 1998, for the first time in recorded history. All indicators, independently derived, point to declines in ecological integrity.

World population continues to grow, having exceeded the 6 billion mark in October 1999. For the first time in human history, some 50% of the world's population now resides in cities. Threats to safety abound through the inappropriate uses of technology. For example, bioterrorism poses ever-greater threats to human security, while nuclear reactors and waste disposal present growing problems of pollution. The transportation of hazardous products and wastes results in accidental spills (e.g., oil, gas blowouts). Transboundary movement of pollutants and the movement of species high on the food chain have resulted in contamination of every part of the planet by some aspect of human activity.

If classical public health epidemiology has successfully paid attention to anecdotal evidence to justify studies that have led to preventive health programs, then, in the presence of the evidence pointing to declines in ecological integrity, surely epidemiology should explore ways to address the issues presented in this book in order to play its part in averting potential catastrophe.

AN INITIAL ATTEMPT TO MEASURE HUMAN HEALTH IMPACTS

As noted earlier, epidemiology is as much an exploratory, descriptive science as one that contributes to the establishment of causality. An exploratory, cross-sectional aggregate data study at the international level has been undertaken (Sieswerda, 1999). In this study, we examined the relationship between some available measures of ecological (dis)integrity and some selected general health indicators using aggregate data from 203 countries. Measures of ecological disintegrity served as *exposure* in the epidemiologic sense; our variables were chosen according to their plausibility as measures of *intactness* or *wildness* of ecosystems. The lack of an integrated ecological model means that we had no objective criteria for the validity of these choices.

Drawing on our experience with the definition of ecological integrity from the Global Ecological Integrity Project (noted in the acknowledgments), we selected the following variables as indicators of ecological disintegrity:

- Percent of land highly disturbed by human activity
- Threatened species (%) (total for mammals, birds, higher plants, reptiles, and amphibians)
- Partially protected areas (International Union for the Conservation of Nature, IUCN, categories IV to V) as a percentage of total area
- Totally protected areas (IUCN categories I to III) as a percentage of total area
- Forest remaining since preagricultural times (%)
- Average annual deforestation (%)

We modeled these indicators of ecological disintegrity against three health outcomes: life expectancy at birth, infant mortality rate, and percent of low birth weight babies.

In addition, to ensure that any potential relationships among the exposure variables and the health outcomes were not attributable to socioeconomic factors, our analyses controlled for several socioeconomic variables:

- Carbon dioxide emissions per capita (a surrogate for industrial activity)
- Percent urbanization

- Population density
- Gross Domestic Product (GDP) per capita (adjusted for cost of living)
- Gini Index coefficient (a measure of income distribution inequality)
- Adult male literacy

Despite the shortcomings of having to deal with population-based averages, variable data quality, uncertain causal mechanisms, and the necessity of using surrogates of ecological disintegrity instead of direct measurements, we found a few associations between some of our ecological disintegrity variables and the three human health outcomes that we considered. In the extremely narrow time frame of this cross-sectional study, the conversion of land to permanent human use has a small but stable association with improving health outcomes. Deforestation appears to have an unstable association with improving health. Neither biodiversity nor land protection had any association with our health indicators. Industrialization was important, but its association varied depending on whether countries were low, middle, or high income. In low- and middle-income countries, industrialization appears to be associated with improvements in the health indicators examined. In high-income countries, further industrialization appears to be associated with negative health impacts.

The main result of this study may provide some answers as to why the environment is often a secondary consideration for policy makers. This study showed that ecological disintegrity appears to be disconnected from human health in that, based on the available metrics, countries that tend to be ecologically impoverished tend to perform best on the health indicators that we used. There may exist a trade-off between improving conditions for human life and depleting or destroying the environment. So far, that trade-off has favored continued development at the expense of the environment. Thus, this study could not demonstrate directly that human health is at risk from ecological degradation. Indirectly, however, it reveals much information that is, at least, strongly suggestive.

In many ways, these findings should not come as a surprise. The interpretation given has arisen based on evidence of our species' ability to survive, and even thrive, in "islands" of ecological disintegrity, such as major cities. This perpetuates the view that humans can survive and achieve high levels of public health, independent of nature. In reality, this level of health is maintained by drawing on healthy or productive ecosystems elsewhere. In other words, trade and technology serve to distance human life from its very life source. Here lies the disconnect. Future epidemiologic studies of this issue will necessarily need to incorporate not only improved methods, data, and an integrated ecological model for human and public health; they must also recognize the realities of global technology and trade in masking the true connectedness of human health and ecological integrity.

The models developed for this study were based on past events and are inadequate for predicting catastrophic events. With the help of an integrated ecological model, our model could perhaps be refined with additional variables. Results from this initial foray into studying these questions should therefore be interpreted with great caution (Soskolne et al., 2000; Sieswerda et al., 2001).

QUESTIONS THAT EMERGE

We have conducted (Sieswerda, 1999) a correlational analysis examining associations between broad measures of ecosystem health and the current health status of human populations involving 203 countries around the world. This study revealed that, likely owing to world trade, the health of human populations (as measured by life expectancy, percent low birth weight, and infant mortality) improves as ecological capital is lost. Two serious questions emerge from such a finding:

1. How long can the health of human societies be sustained while continuing to draw down ecological capital (i.e., exploit nonrenewable resources) from other regions of the world?
2. Are the measures used from among those available the most sensitive and specific to assess human health impacts from declines in ecological integrity?

RECOMMENDATIONS: A STRATEGIC FRAMEWORK FOR PUBLIC HEALTH RESEARCH AND PRACTICE

Government offices tend to plan on the basis of 4- to 5-year horizons, or until the next election. Yet, when considering ecological degradation from human activity and the potential to measure these impacts on human health and well-being, longer time periods are needed. A list of research priorities is proposed. The time frame for these proposed priorities is longer than a 5-year horizon, starting immediately, but extending to a more appropriate long-term horizon of, say, 30 to 60 years. The framework that follows is based on a 10-year time frame.

- Provide incentives for gathering more directly relevant data/variables from which to derive indicators for modeling earlier health impacts (e.g., mental health, endocrine disruption, indicators of personal and societal well-being). Ecoregions (as opposed to geopolitical boundaries) will provide needed information against which to make meaningful comparisons of rates of disease and well-being associated with ecosystem declines, both within and across countries. Distinguish between sensitive and specific indicators of global changes and measurable human health impacts. The routine monitoring, surveillance, and assessment of global change-related variables is needed. Full participation in global observation systems' technologies is encouraged.
- Provide incentives for the development of methods capable of distilling the complex array of multidisciplinary inputs about ecosystem degradation into a risk assessment paradigm that better helps in guiding policy. Standardized metrics are essential for integrating both current and needed data into models to assess the likelihood of collapses in life-support systems and their consequences for human health and well-being. Classical risk assessment is inadequate for handling more than one variable at a time. New methods would need to be scenario based.
- Educate professions in the adaptation (i.e., adjustment strategies and approaches) and mitigation (i.e., preventative) measures needed for future projected environmental scenarios in the presence of global change. In particular, global change warrants public health involvement. Incentives for collaboration with others globally that have considered these matters would be an advantage.
- Enhance infrastructure to cope with demands under the more likely future scenarios consequent to environmental degradation. For instance, emergency and disaster relief services will need to be strengthened.
- In Canada, infrastructure includes organizations such as the Canadian Association of Physicians for the Environment (note their work to date on "Implications for Human Health of Biodiversity") and nongovernmental organizations such as the David Suzuki Foundation. Public discourse will facilitate needed shifts in policy that have yet to be considered. Effective engagement (including communication) of all stakeholders will be essential to effect needed shifts in policy.
- Build local, regional, national, and international partnerships for addressing both mitigation and adaptation measures.
- Integrate the *Precautionary Principle* into economic, social, legal, and other thinking.
- Revisit this framework continually, especially as more data become available.

ACKNOWLEDGMENTS

An international pilot workshop took place at the European Centre for Environment and Health, Rome Division of the World Health Organization, December 3–4, 1998. This event arose from the findings and collaborative efforts of a 3-year Social Sciences and Humanities Research Council of Canada Grant 806-96-0004, entitled: "Global Ecological Integrity: The Relation between the Wild, Health, Sustainability, and Ethics" (1996–1999), with Professor Laura Westra as the principal investigator. This grant included several co-investigators from various disciplines, and I was the epidemiologist on the research team. The product of the workshop is a 74-page discussion document (Soskolne and Bertollini, 1999), the most downloaded document on the WHO Euro Web site to date. In this chapter, I have distilled the conclusions of the workshop from the epidemiological and

public health perspectives. These conclusions were reached with the extensive inputs of the workshop participants and, in particular, other co-investigators on the original grant, including William Rees and Orié Loucks. James Karr, and Anthony McMichael also provided substantial input. The content of this chapter flows from the referenced discussion document (Soskolne and Bertollini, 1999).

Development of a Terrestrial Index of Ecological Integrity (TIEI), a New Tool for Ecosystem Management

James K. Andreasen, Reed Noss, and Nicholas C. Slosser

INTRODUCTION

Ecological systems are inherently complicated, interacting systems composed of biological and physical components that are so complex that some ecologists believe they cannot be understood (Egler, 1977). However, management and policy decisions require information on the status, condition, and trends of these complex ecosystems and their components. Scientists often become mired in the details about what exactly should be measured, what spatial scale should be studied, how frequently measurements should be taken, and how much data should be accumulated before recommendations are presented to decision makers. Those ecologists who are more oriented to problem solving point out that every detail of an ecosystem does not have to be understood in order to make reasonably intelligent decisions about how to manage and conserve sensitive or valued resources.

The objective of this research is to investigate whether an index, or indices, can be developed that will summarize the condition of ecosystems or watersheds so that changes can be tracked over time and this information utilized as a tool to support environmental decision making. The index might also be used to prioritize management options in watersheds so that those systems in the poorest condition could receive attention first, or that those in more pristine condition could be preserved from further degradation. Indices of integrity can function both in assessments (i.e., snapshots of the condition of a particular site or region) and in monitoring (i.e., periodic measurements used to track changes in condition over time).

There are two research questions to be answered: (1) is it possible to construct an index of ecological integrity for a given region that takes into account ecological and biological phenomena at the relevant levels of organization and spatiotemporal scales, and (2) what are the requirements for such an index?

WHAT IS ECOLOGICAL INTEGRITY?

The first reference to integrity in the environmental literature was Aldo Leopold's (1949) statement in his essay on land ethics: "A thing is right when it tends to preserve the integrity, stability, and beauty of the biotic community. It is wrong when it tends otherwise." Leopold did

not explain what he meant by integrity, and it was several decades before the concept appeared again in the environmental literature. Other ecologists consider ecological integrity merely a convenient way to describe and summarize the condition of a biological community or ecosystem. However, integrity is a key concern in several policies of the U.S. and Canada. For instance, the U.S. Water Quality Amendments of 1972 called for the restoration and maintenance of “the chemical, physical, and biological integrity of the Nation’s waters.”

It was not until Karr and Dudley (1981) offered the following insight that a definition finally gained wide acceptance. Biological integrity describes the:

... ability of an aquatic ecosystem to support and maintain a balanced, adaptive community of organisms having a species composition, diversity, and functional organization comparable to that of natural habitats within a region ... the summation of chemical, physical, and biological integrity can be equated with ecological integrity. A system possessing integrity can withstand, and recover from, most perturbations imposed by natural environmental processes, as well as many major disruptions induced by man.

The problem is how to measure ecological integrity, monitor its change through time, and describe the results to people — to the individuals who make decisions about resource management and environmental regulation and to the general public. Ecological integrity is concerned not only with ecological services for humans but also with the condition of the ecosystem for its own sake and for the sake of the other species that are dependent on it.

WHAT ARE THE COMPONENTS OF INTEGRITY?

Stability or Resilience

Ecosystems with high integrity should be relatively resistant to environmental changes and stresses and should be able to recover their original conditions or trajectories relatively quickly after a perturbation. As suggested by Holling (1996), “On the one hand, destabilizing forces are important in maintaining diversity, resilience, and opportunity. On the other hand, stabilizing forces are important in maintaining productivity and biogeochemical cycles, and even when these features are perturbed, they recover rapidly if the stability domain is not exceeded.” A resistant system is one that undergoes small changes in a state or flux variable after disturbance, whereas a resilient system is one that returns to the reference state following disturbance (DeAngelis et al., 1989).

Sustainability

As related to integrity, a holistic concept of sustainability focuses on sustaining ecosystems and all their components and processes in a condition such that they continue to provide all the goods and ecological services of which they are capable, or that managers want from that ecosystem.

Naturalness

Natural is one of the most difficult concepts to define, but it signifies something of great aesthetic and spiritual importance to people. Natural areas are generally assumed to have greater ecological integrity than human-modified habitats. Although naturalness (like integrity) is often assumed to be unmeasurable, some researchers have attempted to formalize criteria for its assessment. Bonnicksen and Stone (1982), for example, argued that:

A natural system is defined as one that portrays, to the extent feasible, either the same scene that was observed by the first European visitor to the area or the scene that would have existed today, or at some time in the future, if European settlers had not interfered with natural processes.

Angermeier (2000) states the naturalness of most ecosystems or ecosystem alterations can be assessed objectively despite imperfect knowledge if evolutionary limits and natural ranges of variability are carefully considered. Most conservationists value naturally evolved biotic elements such as genomes and communities over artificial elements. This judgment, which is not shared by society at large, is based on intrinsic and instrumental values, including respect for nature and recognition that many amenities stem from natural processes. Although sometimes difficult to assess, naturalness is a more reasonable guide than are other ecosystem features such as diversity, productivity, or evolution.

SOME REQUIREMENTS OF A USEFUL TIEI

Comprehensive and Multiscale

As broadly defined, ecological integrity encompasses ecosystem health, biodiversity, stability, sustainability, naturalness, wildness, and beauty. As more narrowly defined, but more easily measurable, it encompasses chemical, physical, and biological integrity. By most definitions, integrity suggests wholeness, completeness, and intactness, and an adequate index should capture these qualities.

An index of ecological integrity should incorporate all the components and phenomena of interest in the defined ecosystem (Karr, 1993; Fore et al., 1996). The boundaries of the ecosystem must be determined by the questions that are being addressed, but within those boundaries there will be many subsystems. These are often organized as a nested hierarchy (Allen and Starr, 1982; Angermeier and Karr, 1994) but also can be seen as a mosaic of subsystems with varying degrees of interaction and dependence on one another (Norton, 1991). Furthermore, natural communities are influenced by surrounding terrestrial, freshwater, estuarine, and marine ecosystems, by the airshed, and by invasive exotic species. An adequate index of ecological integrity must account for all these communities, their ecotones, and the interactions among them.

Although an index must be multiscale, not every conceivable spatial and temporal scale needs to be covered. Holling (1992) suggested that the behavior of ecosystems can be understood by paying attention to a relatively small number of dominant processes operating at definable scales of time and space. For most assessments of ecological integrity, data from 1-m² plots and global carbon models can be ruled out as being directly informative. Nevertheless, the landscape and intermediate temporal scales cover a lot of ground, and a useful index of ecological integrity should cover these thoroughly.

Grounded in Natural History

The importance of grounding an index of ecological integrity in natural history cannot be overstated. The process of selecting appropriate indicators, identifying and measuring them properly, and interpreting what they tell us depends on expert judgment. Expert judgment, in turn, must be based on a thorough understanding of the natural history and autecology of the organisms selected as indicators, their habitat affiliations and interactions with other organisms, and their roles in the broader ecosystem.

Relevant and Helpful

An index of ecological integrity must be applicable for measuring trends of concern to the public and decision makers in relevant landscapes, not just trends interesting to scientists. Indicators

that relate to specific trends and inform people about the status of resources they value must be part of any acceptable index. Perhaps the general public does not have to understand every component, but the overall index or suite of indicators must be interpreted and presented in a way that is understandable (Fore et al., 1996).

Able to Integrate Concerns from Aquatic and Terrestrial Ecology

The integrity of aquatic habitats is closely tied to the condition of the entire watershed, which is composed mostly of terrestrial features (Schlosser and Karr, 1981; Hunsaker and Levine, 1995). There is a great need to integrate aquatic and terrestrial ecology in environmental monitoring, assessment, regulatory, and conservation programs. Maintaining and restoring ecological integrity will require that landscapes are viewed and managed as a whole.

Flexible

Ecosystems are in a dynamic, constantly shifting state of change; and the metrics used in the index also should change as needed to properly capture these changes. In addition, the availability, type, amount, and quality of scientific information are constantly changing. An index should be able to incorporate any new and relevant information that may enhance the understanding of ecosystem function and biotic integrity. For example, certain ecosystem components that were not previously considered important, and thus were left out of an index, may, after further research, turn out to be critical factors. In such a case, flexibility would ensure that the index could be altered to reflect this new understanding. Development and application of any index should be responsive to both ecological dynamics over space and time and the generation of new scientific information.

Measurable

To be useful, an index must be measurable. Many authors have provided guidelines for selection of ecological indicators. Among the more common and useful criteria for narrowing the field of potential indicators to a workable, measurable set are (1) a relationship to the phenomenon of interest; (2) convenience, ease, and cost-effectiveness for repeated measurement; (3) ability to provide an early warning of change; (4) distribution over a broad geographic area or otherwise widely applicable; (5) capability of providing a continuous assessment over a wide range of stress; (6) relative independence of sample size; and (7) ability to distinguish changes caused by human activity from natural changes (Cook, 1976; Sheehan, 1984; Munn, 1988, 1993; Noss, 1990; Marshall et al., 1993; Woodley, 1993; Barbour et al., 1995; Fore et al., 1996; de Soyza et al., 1997).

COMPONENTS OF A POSSIBLE TIEI

If indicators of ecological integrity should be comprehensive, multiscale, grounded in natural history, relevant and helpful, able to integrate terrestrial and aquatic environments, flexible, and measurable, then what ecological components fit these criteria that might be selected for inclusion in the TIEI?

Composition (what is there?), structure (how is it arranged?), and function (what does it do?) are equally important attributes of ecosystems, and a list of indicators should include representatives of all these, ideally at several levels of organization. However, the interdependence of composition, structure, and function suggests that indicators in one group might be surrogates for the others. For instance, information on the structure and function of the ecosystem might be provided by monitoring the biota. Conversely, it might be faster and cheaper to measure habitat structure directly, especially at the landscape scale, where remote sensing and geographic information system (GIS) technology permit rapid quantitative measurements.

Composition

The various forms of existing aquatic indices, such as the Index of Biotic Integrity (IBI), are compositional (biological) measures of integrity; that is, they focus on individuals, populations, functional groups, and communities and do not consider habitats (structure) or processes (function) at any scale directly. Possibly the most important step for compositional measures is selecting the biological entities (species, functional groups, etc.) to use as metrics for the index. This step generally has been accomplished by using expert biological knowledge, and some amount of expertise in natural history is necessary for making appropriate judgments (Karr and Chu, 1999).

Because compositional indices for terrestrial ecosystems are mostly in the early stages of development and have not been well tested, the taxonomic groups, functional groups or guilds, and species most appropriate to use as metrics are unknown. Choices are highly context dependent and must vary from region to region and ecosystem to ecosystem. The taxonomic groups should be selected based on the nature of the biotic community, available expertise, ease of sampling, and other ecosystem-specific factors.

Structure

As noted earlier, the IBI in its many forms focuses directly on the biota, not on their habitats. Nevertheless, in many cases indices built on habitat measurements — either on a site or landscape scale — might be more cost-effective than indices based on organisms. Landscape metrics are in common use today, but often they do not have a close tie to the biota.

The major components of landscape spatial structure are (1) amount of habitat in the landscape, (2) mean size of habitat patches, (3) mean interpatch distance, (4) variance in patch sizes, (5) variance in interpatch distances, and (6) landscape connectivity. In a hypothetical landscape of fixed size, the components of habitat amount, mean patch size, and mean interpatch distance cannot be varied independently of one another, a limitation that complicates their use in developing the TIEI.

Habitat fragmentation is one of the best-studied problems in landscape ecology; and effects at population, community, ecosystem, and landscape levels of organization have been documented (Burgess and Sharpe, 1981; Noss, 1983; Harris, 1984; Wilcove et al., 1986; Franklin and Forman, 1987; Saunders et al., 1991; Noss and Csuti, 1997). In real landscapes, fragmentation involves both a reduction in the amount of habitat (habitat loss) and the apportionment of remaining habitat into smaller and more isolated pieces (fragmentation *per se*). Hence, fragmentation is often confounded with habitat loss and is difficult to study rigorously. Indices of fragmentation might be applicable to ecological integrity in landscapes that have passed some threshold of fragmentation. This threshold will be species specific, as species vary tremendously in their sensitivity to fragmentation.

Function

In the long run nothing is more crucial to the health and integrity of the ecosystem than the continued operation of natural biogeochemical, hydrological, ecological, and evolutionary processes. Key processes are biotic (e.g., predation, herbivory, competition) and abiotic (e.g., weathering, hydroperiod), as well as mixtures of the two (e.g., decomposition, disturbance, succession). The sensitivity of organisms to the rate, magnitude, and other characteristics of natural processes suggests that measuring processes directly without information from the biota may not be helpful for assessing integrity. However, direct measures of processes combined with information on responses of process-sensitive or process-limited species may be worthwhile to incorporate into an index of ecological integrity (Lambeck, 1997).

WHAT CAN BE LEARNED FROM PREVIOUS AND ONGOING RESEARCH?

Defining ecosystem integrity and choosing indicators for it would be a relatively simple task if the science of ecology were able to provide us with simple, rigorous models for describing and predicting these states of ecosystems. Unfortunately, a major problem in modern ecology is that we do not know which state variables are important and which ones are not. Neither do we have simple quantitative models to describe relationships among these state variables (Keddy et al., 1993).

A number of approaches to developing indices of ecological integrity have been suggested, but the only reasonably well accepted index is Karr's index of biotic integrity, the IBI (Karr and Chu, 1999). Application and testing of the IBI, however, has been confined almost entirely to aquatic ecosystems, especially streams. Although the aquatic biota reflects the condition of watersheds, no well-tested and direct index of biotic or ecological integrity exists for terrestrial ecosystems or for entire landscapes comprising terrestrial and aquatic habitats (Slocombe, 1992).

Early attempts to develop an IBI for terrestrial communities were not successful, in large part because of the enormous number of confounding variables in terrestrial systems (Karr, 1999). Applying multimetric concepts to terrestrial environments has so far been limited, and there has been less emphasis on understanding and documenting broader biological responses to human influence. Most relevant studies have examined individual biological attributes rather than a set of metrics.

Although there is no thoroughly tested terrestrial IBI, several recent studies using birds as indicators of ecological integrity are promising (Blair, 1996; Bradford et al., 1998). O'Connell et al. (1998) developed a bird community index (BCI) modeled on the IBIs previously developed for aquatic communities. The BCI is a landscape-scale index based on songbird response guilds, defined as groups of species with similar requirements for habitat, food, or other elements for survival. A high-integrity condition was indicated by a bird community associated with structural, functional, and compositional elements typical of the study region in the absence of human disturbance. It should be noted that the BCI addresses only the dominant natural vegetation of the region — eastern deciduous forest — and not wetlands, grasslands, streams, and other special communities. Hence, it is not a complete landscape IBI.

Another promising attempt to develop a terrestrial, single-community IBI is in progress at the Hanford Nuclear Reservation in Washington. This work, by J. Karr and colleagues at the University of Washington, is examining species, taxa, and ecological groups of invertebrates and plants in the shrub steppe to determine their utility as indicators of varying levels of disturbance.

CRITICISM OF INTEGRITY AND INDICES

Although widely accepted and applied, multimetric indices in general have received criticism. Suter (1993) suggested several potential problems, including ambiguity, eclipsing (i.e., component scores offsetting each other when combined into an index), arbitrary combining functions, arbitrary variance, unreality, *post hoc* justification, unitary response scales, lack of diagnostic results, disconnection from testing and modeling, nonsensical results, and improper analogy to other indices such as economic models. Wicklum and Davies (1995) argued that integrity is an ill-defined concept and "not an objective, quantifiable property of ecosystems." Furthermore, the authors contended that both health and integrity carry with them connotative baggage that does not necessarily apply to ecosystems.

These criticisms have been answered by Simon and Lyons (1995) and Karr and Chu (1999) among others. For example, multimetric indices lose information only if the information on individual metrics is discarded. IBI-type indices retain this information and condense, integrate, and summarize individual metrics into an index that enables quick, practical comparisons among sites (Karr and Chu, 1999).

In evaluating potential structural, functional, and compositional metrics of ecological integrity, it will be important to avoid confounding stressors and responses in the same index. For example, measures of habitat fragmentation and measures of bird species composition should not be combined in a single index, as the latter responds directly to the former. Confounding stressors and responses could lead to a tautological (circular) index that is difficult to interpret (Gerritsen, 1999).

CAUTIONS THAT NEED TO BE CONSIDERED

Ecoregional Characteristics

Ecoregions are defined by climate, geology, physiography, soils, vegetation, and biogeography. Natural processes also vary among ecoregions and among the many natural communities within ecoregions. An index of ecological integrity developed for one ecoregion should not be applied to a dissimilar ecoregion without substantial modification to reflect the particular characteristics of the region. Individual indicators and metrics must correspond to the natural history of each case.

Community Type

Even within an ecoregion, different aquatic and terrestrial communities will require different kinds of metrics. A landscape or regional-scale index that spans many community types must account for the unique characteristics of each system.

Disturbance History

Ecosystems with different disturbance regimes, or examples of the same kind of ecosystem at different times since the last disturbance, can be expected to diverge in many ways. Appropriate metrics for communities in early stages of succession will differ from those suited for later stages. Selection of reference sites to match the successional stages and natural disturbance history of altered sites will be important for addressing the major challenge of separating effects of human perturbations from natural variation in ecosystems.

Impacts of Exotics

Introduced plants and animals can alter the characteristics of a biological community or ecosystem radically. Exotics have proven to be a highly reliable metric in aquatic IBIs (Karr and Chu, 1999) and have increased in bird communities along an urbanization gradient (Blair, 1996) and in plant communities at the Hanford site (Hawk, 1999). Many exotic plants have been documented to alter ecological processes (Gordon, 1998), and, in some cases, systems heavily invaded by exotics may shift irreversibly to an entirely different condition.

Spatial and Temporal Scale

Indices of biotic and ecological integrity have been and are being developed at many different spatial scales. The implicit temporal scale of interest also varies widely. Studies at a local or site level will require very different metrics than those at landscape, regional, or continental scales. The “best” scale depends on the particular scientific and management questions being asked.

The terrestrial IBIs under development may turn out to be reliable and informative indices for the particular communities involved. However, it is doubtful that such IBIs could be adapted to other vegetation, habitat types, or regions without substantial modification. Furthermore, IBIs (terrestrial or aquatic) developed at the scale of a given site may not be informative of the condition

of the landscape at watershed, regional, or broader scales unless a large sample of site-level IBIs exists. Even then, the emergent properties of ecosystems at higher levels in the ecological hierarchy (Allen and Starr, 1982; O'Neill et al., 1986) will require measurements of their own.

Reference conditions and measurements from areas with minimal human disturbance are critically important for evaluating sites. More research is needed into how to define and choose reference sites or reference conditions for a variety of landscape and ecosystem types.

CONCLUSION

A terrestrial index of ecological integrity will be a useful tool for ecosystem managers and decision makers. The requirements of the TIEI are that it be comprehensive and multiscale, grounded in natural history, relevant and helpful, able to integrate concerns from aquatic and terrestrial ecology, and flexible and measurable. However, much research remains to be completed before a well-functioning index will be available. Deciding which indicators or variables should be included, how they will be measured, combined, and interpreted will not be trivial tasks. After the TIEI is developed, it will have to be thoroughly tested and evaluated in the field.

U.S. EPA Office of Research and Development Guidelines for Technical Evaluation of Ecological Indicators

William S. Fisher, Laura E. Jackson, and Janis C. Kurtz

INTRODUCTION

Worldwide concern over environmental threats and sustainable development has led to increased efforts to monitor status and trends in environmental condition. In the past, environmental monitoring focused on obvious, discrete sources of stress such as chemical emissions. It became evident that remote and combined stressors, while difficult to measure, can also significantly alter environmental conditions. Consequently, monitoring efforts began to examine valued ecological components that reflected effects of multiple and sometimes unknown stressors. To characterize the condition of these components, national, state, and community-based environmental programs increasingly explored the use of ecological indicators. These are biological, chemical, or physical measurements, indices or models used to characterize or summarize a critical, and usually complex, component of an ecosystem. Indicators are signs or signals that relay a complex message, potentially from numerous sources, in a simplified and useful manner. Indicators are essential when it is implausible to measure and interpret all the factors that comprise an ecological issue.

There are several types of ecological indicators, and they may serve several purposes. Indicators reflect biological, chemical, or physical attributes of ecological condition and may be used to characterize status, to track or predict change, or to identify ecosystem stress. They are used in environmental risk assessments (Simon and Davis, 1992; EPA, 1992; 1998), environmental management actions (EPA, 1990; 1995) and a variety of monitoring programs, such as the U.S. Environmental Protection Agency (EPA) Environmental Monitoring and Assessment Program (EMAP) (EPA, 1990), that are intended to establish status and trends in environmental condition.

Selection of an indicator is driven by the objective of the assessment. Under the EPA Framework for Ecological Risk Assessment (EPA, 1992), indicators must provide information relevant to specific assessment questions, which are developed to focus monitoring data on environmental management issues. The process of identifying environmental values, developing assessment questions, and identifying potentially responsive indicators is a challenge that must be met through close collaboration of scientists, risk assessors, and resource managers (Bardwell, 1991; Cowling, 1992; EPA, 1994a, b). The importance of appropriate assessment questions cannot be overstated; without well-considered assessment questions, an indicator may provide accurate information that is ultimately useless for management decisions. In addition, development of assessment questions

can be controversial because of competing interests for environmental resources. Issues may include multiple social values that cross resource types (e.g., forest, stream, estuary) and political boundaries.

Because of the variety of environmental issues and the complexity of environmental data and management decisions, there must be a broad array of available indicators. An indicator may be required to elucidate status, trend, risk, vulnerability, or restoration success. It may be needed to describe past, present, or possible future conditions, or to identify an environmental stressor. It must work at a geographical scale determined by the extent of the resource at risk, whether that is local, watershed, ecoregion, or global. And it must ultimately be applied within a monitoring design (landscape, representative subsample, or index site) selected to best address the issue of concern. Each of these factors enters into the development and selection of a successful ecological indicator.

ORD ECOLOGICAL INDICATORS WORKING GROUP

The Office of Research and Development (ORD) within EPA formed an Ecological Indicators Working Group to guide indicator research and facilitate indicator application, particularly in the EMAP program. The working group consisted of researchers from all of the ORD National Research Laboratories — Health and Environmental Effects, Exposure, and Risk Management — as well as the ORD National Center for Environmental Assessment. Interactions of the working group with industry (Stahl et al., 2000) and the National Research Council (NRC, 2000) identified the need for a common set of criteria to serve as a basis for selection and comparison of ecological indicators. Since the measurable characteristics of an ecosystem are essentially limitless, so are the number of possible indicators. And, whereas many different indicators can be proposed for a variety of purposes, not all will meet the program objectives.

Numerous sources have developed criteria to evaluate environmental indicators (e.g., Macek et al., 1978; Hammons, 1981; Suter, 1989; Kelly and Harwell, 1990; Kerr, 1990; Cairns et al., 1993). The working group assembled those factors most relevant to ORD-affiliated ecological monitoring and assessment programs, drawing heavily from early guidance developed for EMAP (Messer, 1990; EPA, 1991; 1994a). The resulting document, *Evaluation Guidelines for Ecological Indicators* (EPA, 2000), presents 15 guidelines in a format intended to facilitate consistent and technically defensible indicator research and review. Consistency is critical to developing a dynamic and iterative base of knowledge on the strengths and weaknesses of individual indicators; it allows comparisons among indicators and documents progress in indicator development. The evaluation guidelines will be used primarily to examine indicators for their suitability in ecological monitoring and assessment programs, but may also serve technical needs of users who are evaluating ecological indicators for other programs, including regional, state, and community-based initiatives.

The working group elected a phased approach to indicator evaluation, a concept originally suggested by Barber (EPA, 1994a). The phases describe an idealized progression for indicator development that flows from fundamental concepts to methodology, then to examination of data from pilot or monitoring studies, and last to consideration of how the indicator serves the program objectives. The guidelines are presented in this sequence because progression from one phase to the next can represent a large commitment of resources (e.g., conceptual fallacies may be resolved less expensively than issues raised during method development or a large pilot study). However, in practice, application of the guidelines may be iterative and not necessarily sequential. For example, as new information is generated from a pilot study, it may be necessary to revisit conceptual or methodological issues. Or, if an established indicator is modified for a new use, the first step in an evaluation may concern the indicator's feasibility of implementation rather than its well-established conceptual foundation. Each phase in an evaluation process will highlight strengths or weaknesses of an indicator at its current stage of development. Weaknesses may be overcome through further indicator research and modification. Alternatively, weaknesses might be overlooked if an indicator has strengths that are particularly

important to program objectives. The evaluation guidelines may be customized to suit the needs and constraints of many different applications. Certain guidelines may be weighted more heavily or reviewed more frequently. The phased approach described here allows interim reviews as well as comprehensive evaluations. Finally, there were no intended restrictions on the types of information (journal articles, data sets, unpublished results, models, etc.) that could be used to support an indicator during evaluation, so long as they were technically and scientifically defensible.

FIFTEEN GUIDELINES FOR EVALUATION OF ECOLOGICAL INDICATORS

Phase 1: Conceptual Relevance

The indicator must provide information that is relevant to societal concerns about ecological condition. The indicator should clearly pertain to one or more identified assessment questions. These, in turn, should be germane to a management decision and clearly relate to ecological components or processes deemed important in ecological condition. Often, the selection of a relevant indicator is obvious from the assessment question and from professional judgment. However, a conceptual model can be helpful to demonstrate and ensure an indicator's ecological relevance, particularly if the indicator measurement is a surrogate for measurement of the valued resource. This phase of indicator evaluation does not require field activities or data analysis. Later in the process, however, information may come to light that necessitates reevaluation of the conceptual relevance, and possibly indicator modification or replacement. Likewise, new information may lead to a refinement of the assessment question.

Guideline 1: Relevance to the Assessment

Early in the evaluation process, it must be demonstrated in concept that the proposed indicator is responsive to an identified assessment question and will provide information useful to a management decision. For indicators requiring multiple measurements (indices or aggregates), the relevance of each measurement to the management objective should be identified. In addition, the indicator should be evaluated for its potential to contribute information as part of a suite of indicators designed to address multiple assessment questions. The ability of the proposed indicator to complement indicators at other scales and levels of biological organization should also be considered. Redundancy with existing indicators may be permissible, particularly if improved performance or some unique and critical information is anticipated from the proposed indicator.

Guideline 2: Relevance to Ecological Function

It must be demonstrated that the proposed indicator is conceptually linked to the ecological function of concern. A straightforward link may require only a brief explanation. If the link is indirect or if the indicator itself is particularly complex, ecological relevance should be clarified with a description or conceptual model. A conceptual model is recommended, for example, if an indicator is comprised of multiple measurements or if it will contribute to a weighted index. In such cases, the relevance of each component to ecological function and to the index should be described. At a minimum, explanations and models should include the principal stressors that are presumed to impact the indicator, as well as the resulting ecological response. This information should be supported by available environmental, ecological, and resource management literature.

Phase 2: Feasibility of Implementation

Adapting an indicator for use in a large or long-term monitoring program must be feasible and practical. Methods, logistics, cost, and other issues of implementation should be evaluated before routine data collection begins. Sampling, processing, and analytical methods should be documented for all mea-

surements that comprise the indicator. The logistics and costs associated with training, travel, equipment, and field and laboratory work should be evaluated; and plans for information management and quality assurance should be developed.

Guideline 3: Data Collection Methods

Methods for collecting all indicator measurements should be described. Standard, well-documented methods are preferred. Novel methods should be defended with evidence of effective performance and, if applicable, with comparisons to standard methods. If multiple methods are necessary to accommodate diverse circumstances at different sites, the effects on data comparability across sites must be addressed. Expected sources of error should be evaluated.

Methods should be compatible with the monitoring design of the program for which the indicator is intended. Plot design and measurements should be appropriate for the spatial scale of analysis. Needs for specialized equipment and expertise should be identified.

Sampling activities for indicator measurements should not significantly disturb a site. Evidence should be provided to ensure that measurements made during a single visit do not affect the same measurement at subsequent visits or, in the case of integrated sampling regimes, simultaneous measurements at the site. Also, sampling should not create an adverse impact on protected species, species of special concern, or protected habitats.

Guideline 4: Logistics

The logistical requirements of an indicator can be costly and time-consuming. These requirements must be evaluated to ensure the practicality of indicator implementation and to plan for personnel, equipment, training, and other needs. A logistics plan should be prepared that identifies requirements, as appropriate, for field personnel and vehicles, training, travel, sampling instruments, sample transport, analytical equipment, and laboratory facilities and personnel. The length of time required to collect, analyze, and report the data should be estimated and compared with the needs of the program.

Guideline 5: Information Management

Management of information generated by an indicator, particularly in a long-term monitoring program, can become a substantial issue. Requirements should be identified for data processing, analysis, storage, and retrieval, and data documentation standards should be developed. Identified systems and standards must be compatible with those of the program for which the indicator is intended and should meet the interpretive needs of the program. Compatibility with other systems should also be considered, such as the Internet, established federal standards, geographic information systems, and systems maintained by intended secondary data users.

Guideline 6: Quality Assurance

For accurate interpretation of indicator results, it is necessary to understand their degree of validity. A quality assurance plan should outline the steps in collection and computation of data and should identify the data quality objectives for each step. It is important that means and methods to audit the quality of each step are incorporated into the monitoring design. Standards of quality assurance for an indicator must meet those of the targeted monitoring program.

Guideline 7: Monetary Costs

Cost is often the limiting factor in implementing an indicator. Estimates of all implementation costs should be evaluated. Cost evaluation should incorporate economy of scale, since cost per

indicator or cost per sample may be considerably reduced when data are collected for multiple indicators at a given site. Costs of a pilot study or any other indicator development needs should be included if appropriate.

Phase 3: Response Variability

It is essential to understand the components of variability in indicator results to distinguish extraneous factors from a true environmental signal. Total variability includes both measurement error introduced during field and laboratory activities and natural variation, which includes influences of stressors. Natural variability can include temporal (within the field season and across years) and spatial (across sites) components. Depending on the context of the assessment question, some of these sources must be isolated and quantified in order to interpret indicator responses correctly. It may not be necessary or appropriate to address all components of natural variability. Ultimately, an indicator must exhibit significantly different responses at distinct points along a condition gradient. If an indicator is composed of multiple measurements, variability should be evaluated for each measurement as well as for the resulting indicator.

Guideline 8: Estimation of Measurement Error

The process of collecting, transporting, and analyzing ecological data generates errors that can obscure the discriminatory ability of an indicator. Variability introduced by human and instrument performance must be estimated and reported for all indicator measurements. Variability among field crews should also be estimated, if appropriate. If standard methods and equipment are employed, information on measurement error may be available in the literature. Regardless, this information should be derived or validated in dedicated testing or a pilot study.

Guideline 9: Temporal Variability within the Field Season

It is unlikely in a monitoring program that data can be collected simultaneously from a large number of sites. Instead, sampling may require several days, weeks, or months to complete, even though the data are ultimately to be consolidated into a single reporting period. Thus, within-field season variability should be estimated and evaluated. For some monitoring programs, indicators are applied only within a particular season, time of day, or other window of opportunity when their signals are determined to be strong, stable, and reliable, or when stressor influences are expected to be greatest. This optimal time frame, or index period, reduces temporal variability considered irrelevant to program objectives. The use of an index period should be defended, and the variability within the index period should be estimated and evaluated.

Guideline 10: Temporal Variability across Years

Indicator responses may change over time, even when ecological condition remains relatively stable. Observed changes in this case may be attributable to weather, succession, population cycles, or other natural inter-annual variations. Estimates of variability across years should be examined to ensure that the indicator reflects true trends in ecological condition for characteristics that are relevant to the assessment question. To determine inter-annual stability of an indicator, monitoring must proceed for several years at sites known to have remained in the same ecological condition.

Guideline 11: Spatial Variability

Indicator responses to various environmental conditions must be consistent across the monitoring region if that region is treated as a single reporting unit. Locations within the reporting unit that are known to be in similar ecological condition should exhibit similar indicator results.

If spatial variability occurs due to regional differences in physiography or habitat, it may be necessary to normalize the indicator across the region, or to divide the reporting area into more homogeneous units.

Guideline 12: Discriminatory Ability

The ability of the indicator to discriminate differences among sites along a known condition gradient should be critically examined. This analysis should incorporate all error components relevant to the program objectives, and should separate extraneous variability to reveal the true environmental signal in the indicator data.

Phase 4: Interpretation and Utility

A useful ecological indicator must produce results that are clearly understood and accepted by scientists, policy makers, and the public. The statistical limitations of the indicator's performance should be documented. A range of values should be established that defines ecological condition as acceptable, marginal, and unacceptable in relation to indicator results. Finally, the presentation of indicator results should highlight their relevance for specific management decisions and public acceptability.

Guideline 13: Data Quality Objectives

The discriminatory ability of the indicator should be evaluated against program data quality objectives and constraints. It should be demonstrated how sample size, monitoring duration, and other variables affect the precision and confidence levels of reported results, and how these variables may be optimized to attain stated program goals. For example, a program may require that an indicator be able to detect a 20% change in some aspect of ecological condition over a 10-year period with 95% confidence. With magnitude, duration, and confidence level constrained, sample size and extraneous variability must be optimized in order to meet the program's data quality objectives. Statistical power curves are recommended to explore the effects of different optimization strategies on indicator performance.

Guideline 14: Assessment Thresholds

To facilitate interpretation of indicator results by the user community, threshold values or ranges of values should be proposed that delineate acceptable from unacceptable ecological condition. Justification can be based on documented thresholds, regulatory criteria, historical records, experimental studies, or observed responses at reference sites along a condition gradient. Thresholds may also include safety margins or risk considerations. Regardless, the basis for threshold selection must be documented.

Guideline 15: Linkage to Management Action

Ultimately, an indicator is useful only if it can provide information to support a management decision or to quantify the success of past decisions. Policy makers and resource managers must be able to recognize the implications of indicator results for stewardship, regulation, or research. An indicator with practical application should display one or more of the following characteristics: responsiveness to a specific stressor, linkage to policy indicators, utility in cost–benefit assessments, limitations and boundaries of application, and public understanding and acceptance. Detailed consideration of an indicator's management utility may lead to a reexamination of its conceptual relevance and to a refinement of the original assessment question.

APPLICATION OF THE GUIDELINES

The evaluation guidelines were generated both to guide indicator development and to facilitate indicator review. Researchers can use the guidelines informally to find weaknesses or gaps in indicators that may be corrected with further development. Indicator development will also benefit from formal peer reviews, accomplished through a panel or other appropriate means that bring experienced professionals together. It is important to include both technical experts and environmental managers in such a review, since the evaluation guidelines incorporate issues from both arenas. It is recommended that a review address information and data supporting the indicator in the context of the four phases described. The guidelines included in each phase are functionally related and allow the reviewers to focus on four fundamental questions, adapted from Barber (EPA, 1994a) and Fisher (1998):

Phase 1 — Conceptual Relevance: Is the indicator relevant to the assessment question (management concern) and to the ecological resource or function at risk?

Phase 2 — Feasibility of Implementation: Are the methods for sampling and measuring the environmental variables technically feasible, appropriate, and efficient for use in a monitoring program?

Phase 3 — Response Variability: Are human errors of measurement and natural variability over time and space sufficiently understood and documented?

Phase 4 — Interpretation and Utility: Will the indicator convey information on ecological condition that is meaningful to environmental decision making?

It is important to recognize that the evaluation guidelines do not determine indicator applicability or effectiveness. Users must decide the acceptability of an indicator in relation to their specific needs and objectives. The evaluation guidelines document was developed to evaluate indicators for ORD-affiliated monitoring programs, but it should be useful for other programs as well. To increase its potential utility, this document avoids labeling individual guidelines as either essential or optional and does not establish thresholds for acceptable or unacceptable performance. Some users may be willing to accept a weakness in an indicator if it provides vital information. In other cases, the cost may be too high for the information gained. These decisions should be made on a case-by-case basis. The evaluation guidelines document (EPA, 2000) provides three example indicators to illustrate application of the guidelines. The examples include a direct measurement (dissolved oxygen concentration), an index (benthic condition), and a multimetric indicator (stream fish assemblages) of ecological condition. All three examples employ data from EMAP studies, but each varies in the type of information and extent of analysis provided for each guideline as well as the approach and terminology used. The authors of these chapters present their best interpretations of currently available information.

ACKNOWLEDGMENTS

The authors wish to thank the many people in the ORD Ecological Indicators Working Group for the development and evaluation of the ecological indicator evaluation guidelines. This is Gulf Ecology Division contribution 1096.

Toward a Forest Capital Index

Bruce A. Wilcox, K. Shawn Smallwood, and James R. Kahn

INTRODUCTION

A significant effort has been under way since the 1992 Earth Summit to develop an international indicator framework for monitoring trends and conditions in forests and forest management. The effort, which has focused on “criteria and indicators for sustainable forest management” (FAO, 1999), has produced a set of remarkably comparable indicator frameworks (Wijewardena et al., 1997). Recently, the World Commission on Forests and Sustainable Development (WCFSD) proposed the development of a “uniform numerical indicator for each nation’s current forest capital” (WCFSD, 1999), suggesting that a “Forest Capital Index” (FCI) could be developed that would permit evaluation of progress in sustaining forest capital for each country; serve as a benchmark for assessing whether forest capital is increasing or declining; facilitate a global framework for valuation of forest ecosystem services; and create market mechanisms to compensate countries for ecological services.

It will require nearly another decade before national programs based on the criteria and indicators presently agreed upon are widely implemented. The WCFSD proposal would add another dimension to the international forest indicator challenge. This begs several technical questions beyond those relating to the policy implications of developing another global forest indicator program: What would such an indicator look like? How would we approach its development? And what kinds of data would be required?

Advances in forest ecology, ecological economics, environmental indicator approaches, and in the information technology necessary to gather and analyze forest data (particularly spatial data) remotely suggest at least the outline of an indicator framework that will achieve the above objectives. This framework would draw mainly on concepts of ecosystem health and sustainability, natural capital, the Pressure–State–Response model (P-S-R) for environmental policy indicators, and Geographic Information Systems (GIS).

In this chapter we describe these concepts and models as they apply to forest ecosystems, provide examples of the kinds of indicators and approaches that may be useful for a forest capital index, and discuss the data requirements. We conclude that while much remains to be learned about forest function, forest ecosystem goods and services, the linkage between them, and the effect of detectable forest change, an adequate understanding exists to develop an FCI. Like many of the economic indicators in use, developed despite the lack of a precise understanding of economic systems, it could prove highly useful as both a policy and management device.

BACKGROUND

Since the Rio Earth Summit of 1992 first focused world attention on the importance of forests in achieving sustainable development, more than 150 countries have become actively involved in seven regional or ecoregional initiatives to define national-level “criteria and indicators for forest management” (FAO, 1999). Taking place largely outside the normal U.N. negotiating framework, the general approach is described as follows (Wijewardana et al., 1997):

“Criteria” define the essential components of sustainable forest management. These include vital forest functions such as biological diversity and forest health, the multiple socioeconomic benefits of forests such as wood production and cultural values and, in most cases, the legal and institutional framework needed to facilitate sustainable forest management. “Indicators” are ways to measure or describe a criterion and over time can demonstrate trends.

Many indicators are quantitative, such as the percent of a country’s forest cover. Others are qualitative or descriptive, such as indicators related to forest planning, public participation, and investment and taxation policies. Both are important to assessing sustainable forest management at the national level.

Criteria and indicators are tools for assessing national trends in forest conditions and forest management. They provide a common framework for describing, monitoring and evaluating, over time, progress toward sustainable forest management. As such, they help provide a common understanding and implicit definition of what is meant by sustainable forest management.

In view of the diversity of nations involved in the development of criteria and indicators, the degree of similarity or comparability among initiatives is striking. Indicators that Wijewardana et al. refer to as quantitative can be viewed as focusing on forest characteristics. Indicators referred to as qualitative or descriptive can be viewed as focusing on factors affecting forest utilization. The different initiatives across countries incorporate both types of indicators, and all incorporate to some degree the following seven fundamental elements:

1. Extent of forest resources
2. Biological diversity
3. Forest health and vitality
4. Productive functions of forests
5. Protective functions of forests (e.g., soil and water conservation)
6. Socioeconomic benefits and needs
7. Legal, policy, and institutional framework

It is important to have a wide array of indicators, as individual indicators can be misleading. For example, an indicator such as the percent of forest cover would include not only land area covered by pristine forest but also land area covered by second-growth forest or forest plantations. These three different types of forest, however, will be associated with very different levels of ecological services such as biodiversity or watershed protection. Thus the need for additional indicators.

However, the devil is in the details — that is, the scientific and conceptual specifics. The indicator development efforts are in the early stages, and the development of the institutional infrastructure and technical protocols to gather the indicator data is nonexistent in all but a few countries. In particular, as Wijewardana et al. (1997) point out, there is a significant need to improve scientific understanding of a number of indicators, particularly those that go beyond traditional sustained yield factors to capture more recently recognized dimensions of sustainable forest management, including forest fragmentation, nonmarket benefits, and social aspects.

While this international effort has been progressing, three other lines of pursuit dealing with policy-relevant environmental indicators or other measures applicable to ecological systems have been developing in parallel. One is the effort to create national environmental policy indicators that address the environment very broadly, focusing primarily on pollution, waste, and consumption and less on the “life support system” (Adriaanse, 1993; Schulze and Colby, 1994; Hammond et al., 1995). A second is research activity, largely within the ecological health field, addressing the problem of indicators and indices of health or biotic integrity of ecosystems, with the most progress made for aquatic ecosystems (Rapport et al., 1985; Costanza et al., 1992; Davis and Simon, 1994). However, some important steps have been taken more recently toward developing an understanding of ecological patterns and processes and conceptually framing ecosystem health indicators at the landscape scale (Karr, 1994; Rapport et al., 1998). The third has been the development of valuation approaches based on ecosystem functioning, particularly the development of the concept of natural capital in terms of ecosystem goods and services (Costanza and Daly, 1992; Costanza et al., 1992). These ideas, concepts, and methodologies collectively emerging mainly from the field of ecological economics have not yet, as a whole, played a significant part of the international dialogue on sustainable forest criteria and indicators.*

Integrating the above developments within a single indicator framework would be highly desirable, especially given the need to strengthen the scientific understanding of forest indicators. Improved understanding of ideas like natural capital and ecosystem health applied to forests is needed, particularly their role in conceptually framing the indicator challenge and operationalizing indicator methods. This should help accelerate international harmonization of national-level forest indicators, perhaps the implementation of national indicator programs, and, most important, begin reversing many of the current trends in forest degradation globally.** The point of this chapter is to attempt, at least preliminarily, to consider forest indicators in light of the Pressure–State–Response (P-S-R) approach and the natural capital and health of ecosystems, while addressing the technical feasibility of a global Forest Capital Index.

PRESSURE–STATE–RESPONSE INDICATOR APPROACH

The P-S-R model has been adopted by many developed countries as the basis of the conceptual framework for policy-relevant environmental indicators. As shown in Figure 32.1, the model combines the measurement of the pressures (stresses) on the ecosystem, the biophysical criteria that measure the state of an ecosystem, and criteria that address policy actions and their efficacy on mitigating the pressures or improving the state (or health) of an ecosystem. First developed by the Organization of Economic Cooperation and Development, based on work by Canada and subsequently the Netherlands, several variations of the model exist in which an *effect* or *impact* term is added between State and Response (Schulze and Colby, 1994). The model represents both a biophysical cause–effect chain and a sociocultural response.

The P-S-R framework addresses the need for indicators that answer three basic questions relating to environmental change and social responses. First, what is happening to the environmental or a natural resource? Second, why is it happening? Third, what is being done about it? Indicators of state and change address the first question; indicators of pressures or stresses the second; and

* An area of resource valuation that probably has had more reach in these forest management policy circles is that dealing with natural resource depletion in terms of national income accounts (e.g., Repetto et al., 1989). However, this work focuses on natural capital that is utilized directly in the production of economic output. Therefore, this discussion does not necessarily involve the ecosystem functions that underlie resource values and have a more indirect (but extremely important) impact on economic output.

** Harmonization does not necessarily imply an identical set of indicators, but it would suggest indicators in the same general area. For example, in temperate forests nutrients are stored in the soil, while in tropical rain forests they are stored in the living biomass of the trees. Although one would want an indicator related to the integrity of the nutrient cycle in both tropical and temperate forests, in each case a different variable must be chosen to measure this characteristic.

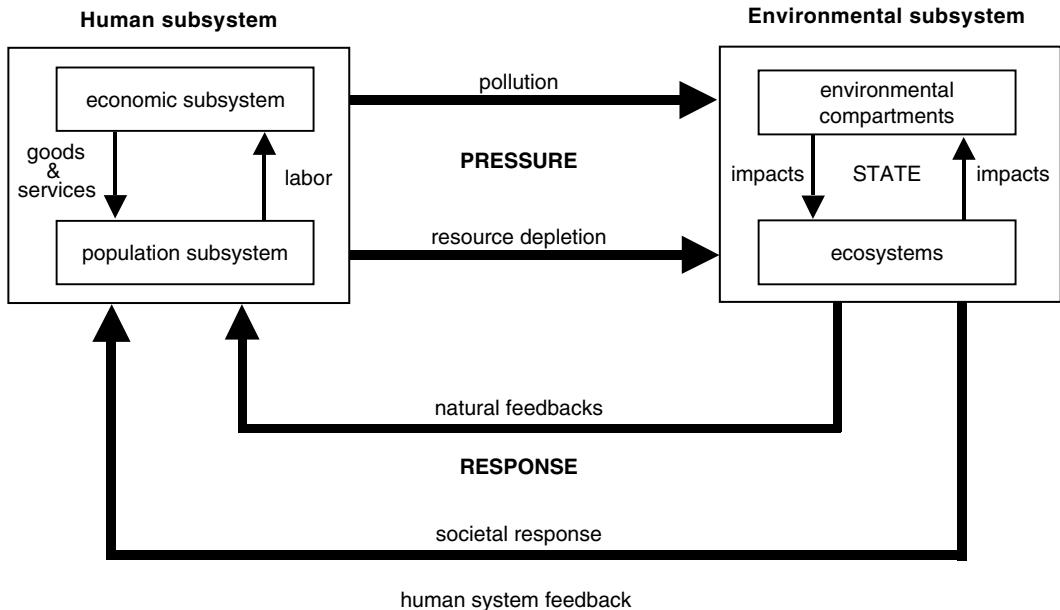

Figure 32.1 P-S-R framework for indicators.

indicators of policy response measure the third (Hammond et al., 1995). The development of national environmental indicators has focused mainly on pollution emissions, or waste generation, and depletion of natural resources. The data employed are national statistics in weight, volumetric, or aerial units. For pollution indicators such as greenhouse gas emissions, for example, emission of carbon dioxide (in units of mass) and the atmospheric concentration of greenhouse gases are recorded as pressure and state indicators. For land quality, the proportion of land having different levels of human-induced soil degradation and soil-climatic zone constraints are proposed for pressure and state indicators. For forests, measures of total forest cover and the rate of loss of forest cover typically serve as pressure and state indicators. A weakness recognized in this existing framework and set of indicators is they do not address the issue of sustainability in terms of the viability of “ecosystems to provide life-supporting goods and services,” nor do they provide “adequate measures of the state of ecosystems, such as ecosystem health” (SCOPE, 1994).

DEFINING FOREST CAPITAL

Costanza et al. (1997) refer to natural capital as the ecosystem *infrastructure* necessary to provide the numerous categories of services ranging from the regulation of atmospheric gases, climate, disturbance, and water regimes to the provision of water, food, raw materials, genetic resources, waste treatment, recreational experiences, and others (see Table 1 in Costanza et al., 1997). It should be noted that many economists define natural capital merely as nature’s extractable resources, that is, goods — not both goods and services (sometimes referred to as *environmental services*). Franceschi and Kahn (in press) differentiate between *natural capital* and *environmental capital*. Since many neoclassical economics treatments of natural capital view it as consisting solely of extractive resources, Franceschi and Kahn use the term *environmental capital* to refer to our stock of environmental resources that yield a flow of ecological services. The concept of natural capital provides a useful way of framing the issue of ecosystem sustainability and for deriving indicators that address viability in terms of ecosystem goods and services and ecosystem health.

When we utilize natural capital, we withdraw a portion of the stock, whether it is renewable or nonrenewable. However, when we utilize environmental resources, we consume the flow of ecological services such as nutrient cycling, maintenance of global climate, flood protection, or biodiversity. It is interesting to note that some types of resources can be viewed as both natural capital and environmental capital. For example, since trees are a source of wood, they can be viewed as natural capital, but the forest itself is environmental capital that yields ecological services.

Another important distinction between natural and environmental capital has to do with their substitutability with other forms of capital. For example, artificial capital and human capital are good substitutes for natural capital such as oil or coal deposits. If we run out of oil in 30 or 40 years, it won't matter, because substitutes (such as battery-powered cars charged with electricity from solar power) will be developed. However, it is unreasonable to assume that artificial or human capital can provide ecological services on the same level as an ecosystem. This has been demonstrated in the Midwest, where the engineering of flood-control systems of the Mississippi River has not been able to compensate for the flood-control services of the wetlands that have been eliminated.

Another way of distinguishing between the two is related to biophysical and geophysical properties. Extractable resources include nonrenewable resources, such as minerals, and renewable resources such as trees. Though ecosystems include minerals and processes involving their transformation and flux, the capital represented by ecosystems is, by definition, living and therefore renewable. In other words, goods produced by or associated with geophysical processes do not qualify as ecosystem capital, while those of biophysical processes do.

Forest capital can, therefore, be operationally defined in terms of biophysical attributes, the ecosystem infrastructure providing the goods and services derived from forests. Globally, according to the latest U.N. figures, this infrastructure is represented by about 3.5 billion hectares, or one third of the area of terrestrial ecosystems worldwide, and it is declining at an average rate of about 3% annually (FAO, 1999). Costanza et al. (1997) estimate that global forest capital accounts for 38% of all ecosystem goods and services. However, measurement of the decline of natural capital in these terms could be highly misleading. Coverage measures have limited meaning in the absence of further information on how the spatial pattern, location, and other factors affect ecosystem functioning and goods and services.

The forest ecosystem infrastructure providing the basis of these goods and services can be comprised of functional, structural, and compositional elements. Major functional elements are simply those processes corresponding to many of the services enumerated above: regulation of atmospheric chemical composition, global temperature, and hydrological flows (Costanza et al., 1997). Compositional elements are represented by the biophysical components — what generally is thought of as biological diversity. These are the constituents at different hierarchical levels of organization (Wilcox, 1984; Solbrig, 1991) — genes, populations, species, and finally, communities (or local ecosystems). *Structure* is represented by the spatial or geometric patterns or arrangements of the constituents. Later we describe the measurement of these elements in terms of ecosystem health and forest capital.

There are two major parts to the problem of measuring state and change of this infrastructure in terms of capital. First, there is an economic part that is considered goods and services; thus, natural capital provided by a particular ecosystem is socioculturally determined. In particular, the stock of natural capital is related to the uses we generate for the resources, the price of the resources, and the technology that is available to discover, produce, utilize, and consume the resources. For example, if the price of energy rises, or technological innovation in drilling methods occurs, the measured stock of natural resources will increase. Second, there is the ecological problem of determining the relationship of the ecosystem infrastructure to the provision of ecological services. This is a particularly difficult problem, as the relationship between social welfare and the level of ecological services is likely to be a nonlinear function (increasing at a decreasing rate), as depicted

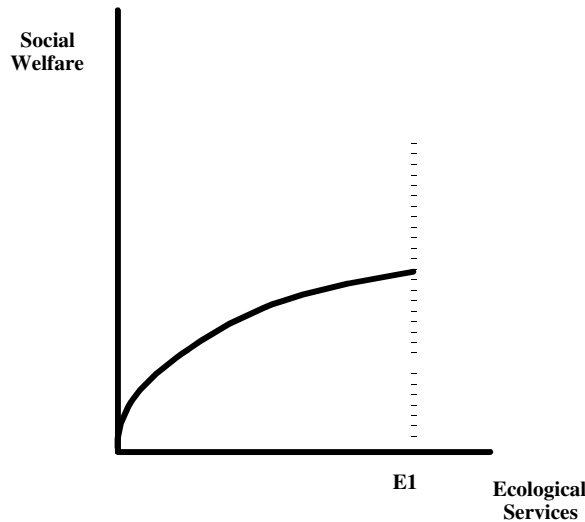

Figure 32.2 Functional relationship between social welfare and ecological services.

in Figure 32.2. This means that the value of a unit of ecological services (or the value of the stock of environmental capital from which the ecological services flow) depends on the current location on the function.

The Relationship of Ecosystem Health and Environmental Capital

How do the concepts of ecosystem health and environmental capital relate? As initially conceived, the ecosystem health model applied the idea of health in holistic medicine and physiology to ecosystems (Rapport et al., 1985). The application was to ecosystems in biophysical terms, with particular regard to state and change and emergent properties such as resilience and physiological cause and effect (i.e., stress and response). Thus, the condition of *health* of an ecosystem can be described as free of distress syndrome, stable, sustainable, maintaining organization and autonomy over time, and resilient to stress (Costanza et al., 1992). The ecosystem health field has increasingly entered the realm of the humanities and social sciences, becoming a transdisciplinary effort involving consideration of the interrelations between human activity, ecological change, ecosystem services, and economic and human health risks (Rapport et al., 1999).

As the disciplinary boundaries of this pursuit become more blurred, discussion of such issues as the role of values in determining condition and trends in the health of ecosystems can be confusing. In fact, what constitutes the condition of health as perceived by both the general public and experts in the fields of medicine or public health is a normative issue. However, the attributes of ecological health described above can, at least potentially, be characterized largely independent of cultural values and based on biophysical attributes that underlie the emergent properties equated with ecosystem health.

One possible solution to this dilemma is to define ecosystem health as a set of physical outcomes related to fundamental health properties such as stability and resilience. The recognition of values can take place in terms of social valuation of the alternative sets of outcomes. In myriad fashions, these outcomes will influence social welfare through the provision of clean water, recreational opportunities, aesthetic values, and so on. Although this approach has potential, one difficulty that will be encountered with the valuation process is that the path by which ecological services influence an individual's welfare is less direct than other services such as recreational opportunities. Thus, valuation processes could bias decision making toward these more direct use values.

Figure 32.3 Functional relationship between ecological services and ecosystem health.

By contrast to the concept of ecosystem health, the value of the capital represented by ecosystems is a function of society's preferences for alternative states of the environment and for the mix of outputs that are produced. An important determinant of value in this regard is scarcity. As the value of particular ecosystems and ecological services increases, the scarcer these ecosystems and services become. Approaching value in this way suggests that some trade-offs are permissible, even desirable. However, the scarcer a resource, the greater value the alternative must have to justify the trade-off. For example, in the U.S., old-growth forests have become so scarce that the loss of social value from further harvesting is extremely high. On the other hand, eastern second-growth forest is very abundant, so its marginal value is low. The distinction between marginal and total value is extremely important when value is used to inform policy decisions. However, this marginal decision making can conflict with systems of value that do not arise from the neoclassical economics paradigm. For example, the concept of ecological integrity, as articulated by Karr and others (Karr, 1994) is reserved for the notion of *pristine* — that is, the condition of being *intact* with regard to a pre-disturbed or non-disturbed reference state.

Given what is currently the generally accepted meaning of these concepts, we can reasonably state that the health of the system increases as its ability to provide ecological services increases. As a system becomes less and less healthy, it eventually crosses a threshold and collapses; and the capacity to provide ecological services is lost completely. This functional relationship is approximated graphically in Figure 32.3.

INTEGRATING THE PRESSURE–STATE–RESPONSE AND ECOSYSTEM MODELS

Although the P-S-R model is applied to environmental systems (i.e., countries), it has not been adapted to ecosystems (natural or human) as spatially discrete entities. Here we describe how the P-S-R and ecosystem models can be readily integrated. The P-S-R models and the ecosystem ecologist's view of ecosystem behavior both follow a systems scheme of causal relations in which external factors affect a system, the system responds, and the potential outcome is a new state. It can be useful to distinguish driving variables from controlling variables among the external factors, as shown in Figure 32.4. Driving variables include the size of the human population and the nature of both public and private decision making, including decisions related to land use, waste disposal, pollution emissions, and other impacts called *pressures* in the P-S-R model and *stress* or *stressors* in the ecosystem health model.

Controlling variables are useful to acknowledge because they affect the decision-making process, which leads to a multiplicity of indirect effects, particularly in terms of the kind of land,

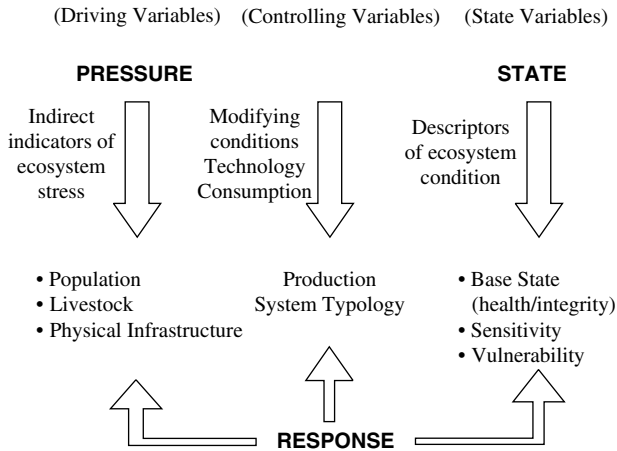

Figure 32.4 Ecosystem indicators model.

cultural, or economic production system through which the pressure is mediated. For example, the decision to clear forests is related to a set of variables including income (Brown and Pearce, 1994), the definition of property rights (Repetto and Gillis, 1988), the level of technical information (Caviglia–Harris and Kahn, 2001) and the external indebtedness of a nation (Kahn and McDonald, 1995). State variables are the *descriptors* describing the condition of an ecosystem. They include the biophysical attributes that provide measures of health or integrity.

The ecosystem health model can be integrated within this framework by employing the four major categories of stress as pressures and relating each to classes of state variables (or indicators): harvesting of renewable resources, physical restructuring, pollutant discharges, introduction of exotics, and extreme natural events (Rapport et al., 1985). Finally, effect or impact and response variables can be related to these stresses in a complex and nonlinear fashion.

Thus, ecosystem indicators can be seen to represent a special case of environmental indicators in that they reflect attributes characterizing a particular geographic area constituting an ecosystem, whether it is a local ecological community or a region. This provides the opportunity to employ a GIS for the management, analysis, and communication of information, including that on the indicator approach itself. Also, GIS, with remotely sensed data, provides a powerful method for analyzing spatial patterns, particularly fragmentation patterns. Figure 32.5 illustrates how these land-based ecosystem indicators can be implemented using spatial data consisting of zones and boundaries representing ecological and human land use characteristics. These data layers can correspond to the major variable categories in the above ecosystem indicator model.

Figure 32.5 Georeferenced data layers for ecosystem-based indicators.

DERIVING FOREST CAPITAL INDICATORS

The size of the land units to which P-S-R descriptors can be meaningfully applied is, of course, another critical issue in indicator development. Rapport et al. (1998) provide a useful overview of why the landscape is the appropriate scale for ecosystem health indicators. They give three reasons: at this ecosystem scale, values tend to focus on processes that contribute to the resilience of regional ecosystems; biophysical, sociocultural, and economic factors or processes meaningfully integrate; and the concept of the intergenerational community applies.

Thus, they further conclude, assessment of landscape health depends upon identification of societal values and the nature of biophysical processes. Both aspects provide criteria for management of human activity in specific regions. Health in the landscape is dependent on simultaneously meeting two primary goals: (1) providing ecosystem services undiminished in quantity and quality by human activity; and (2) maintaining future management options so as to accommodate changes in societal values. Both are constrained by biophysical limitations. These biophysical processes include, for example, the sequestering, dispersion, and inactivation of toxic substances, conservation and recycling of water, maintenance of soil quality and prevention of erosion, and maintenance of biodiversity.

Implementation of Indicators

Indicators of health, such as forest capital, can be distilled to three aspects of ecosystems: resilience, productivity, and organization (Mageau et al., 1995). These aspects, in turn, can be drawn from measures related to the attributes of structure, function, and composition described earlier. For any such measure, the information ultimately required is the functional relationship of health to the measure. For example, we need to know for a given change in a forest characteristic, such as soil moisture or species richness, how resilience, productivity, and organization are diminished, and, given this loss, what the reduction is in the flow of ecological services. While this answer will be unique to each measure and ecological context, and the data necessary for quantifying these relationships are not generally available, it is possible to postulate very general properties for a system of indicators.

First, we can assume ecological services increase at a decreasing rate for a given ecological characteristic. Thus, the relationship between ecological characteristics and ecosystem services has the functional form shown in Figure 32.6. This form, of course, ignores the nonlinearity that characterizes the complete collapse of a forest ecosystem and its “flip” to a different stability domain represented by another ecosystem type entirely.

Figure 32.6 Relationship between an ecological characteristic and ecosystem health.

Second, while such dynamics are inherently unpredictable, threshold levels can be roughly approximated, assuming a linear relationship for a particular characteristic and ecological and economic context. While this is far from an exact science, we believe forest ecologists could, for a range of measures (e.g., forest cover, hydrological features, soil parameters, species abundance), reasonably approximate or at least bracket threshold values. These thresholds could be narrowed by considering the pattern of forest loss, type of forest, and various measures of forest quality (e.g., soil condition, age structure, health of individual trees).

In fact, for the ecological characteristic species richness, the functional form and approximate threshold range are well established. The well-known species–area relationship fits a linear proportionality function whose parameter values are known universally to fall within a particular range. Thus, it can be shown in general that significant species losses will begin to occur when the loss of total habitat area reaches a level approximately 70 to 90%. Obviously there will be exceptions, based mainly on the spatial (fragmentation) patterns of remnant forest in relation to the distribution of species richness and the population biology of the species involved. There also is the issue of unequal value of species in terms of ecological services. However, these exceptions potentially can be taken into account.

Spatial scale also is an issue. What may represent a catastrophic collapse of ecological services locally may or may not impact forest capital at the landscape level; and a collapse at this level may or may not have an impact at a regional scale, depending on the mosaic and condition of landscapes. In this regard, it is noteworthy to consider the effect of forest cover loss on ecosystem functioning and the cumulative effect of local habitat loss and fragmentation on the biota at a regional scale. In Amazonia, for example, a large percentage of rainfall originates as water vapor from the forest itself. Thus hydrological and meteorological functions may be so altered that the climate, fire regime, and overall ecological character of the forest ecosystem, including its species composition, is changed (Nepstad et al., 1996).

Ultimately, a Forest Capital Index will require models that incorporate the behavior of ecosystems at local, landscape, and regional scales and integrate processes across scales in terms of the hydrological cycle, species composition, and other factors described by Rapport et al. (1998). Although the state of knowledge about forests in this regard is fragmentary at best, we believe enough is known to begin formulating an FCI.

Fragmentation Measures as Indicators of Ecosystem Health

We believe measures of ecosystem fragmentation — slope, terrain, riparian data, along with simple ground measures to calibrate the remotely sensed data — offer the best way to develop meaningful national level indicators. Broadly defined, fragmentation represents one of the five general classes of stress on ecosystems (Rapport et al., 1985), namely, physical restructuring, and, conveniently, it is highly amenable to mapping and measurement for use as a landscape scale indicator.

Fragmentation is a disruption of the linkages among patches that exchange ecologically important resources, but the critical linkages among patches occur at various scales (Karr, 1994). From the perspective of physical resources such as soil and water, fragmentation occurs when land conversions disrupt flows and storages of materials, energy, or landscape functions that are vital to the maintenance of soil and water qualities at particular places (Dynesius and Nilsson, 1994). Habitat fragmentation can be defined as the process in which the removal or alteration of vegetative cover produces remnant areas of smaller average size and greater isolation than were originally present (Wilcox and Murphy, 1985). In general, fragmentation is the loss of contiguity of accessible landscape from the perspective of the organism or some other ecologically important element.

Three major kinds of forest functions are affected by fragmentation: (1) hydrological and meteorological processes; (2) species' population processes; and (3) disturbance regime. These functions and the changes in these functions associated with fragmentation pattern are described as follows.

Components of the water cycle, including precipitation, runoff, infiltration, transpiration, and evaporation — and associated geomorphological processes including erosion, transport, and deposition of sediment — are strongly influenced by the spatial pattern and character of the vegetation cover. Context, in terms of geology and geomorphology, is critically significant. Climate and fire regimes are, in turn, influenced by the water cycle of a landscape, particularly where precipitation is continental in origin, as is largely the case for the Amazon Basin, for example.

Population processes, including demographics, dispersal, and, ultimately, the persistence of a regional population of a species — and so-called metapopulation dynamics — are largely determined by the spatial pattern of habitat. Some populations, particularly large vertebrate carnivores and herbivores, influence the habitat in terms of its structure, community structure, and species composition. Thus, alteration of the spatial pattern of forest habitat can significantly alter species persistence and, in turn, the integrity and health of a forest landscape.

Patch dynamics, which are driven by disturbance factors like wind, fire, or disease outbreaks, are an integral component of the dynamics and spatial patterning of closed canopy temperate and tropical forests. These disturbance dynamics are key to maintaining ecosystem resilience and biological diversity and, thus, to the integrity and health of forests (Holling et al., 1995). Therefore, fragmentation alters forest health by contracting forest area and creating remnants too small to “support” natural disturbance regimes, and allowing human disturbances larger and more frequent than natural regimes.

Some Candidate Components for Indicator Development

We will discuss two areas of applied ecological research that are particularly promising as key indicator components of an FCI: hydrologic function and vertebrate umbrella species. In both, relatively recent syntheses have substantially increased understanding of their provision of ecological functions or services, their impairment from physical alteration or fragmentation, and their possible detection and measurement using spatial analysis. The disruption and measurement of hydrological function recently has been gaining attention, and we will briefly summarize its indicator possibilities. Less well appreciated, perhaps, is the potential for developing an indicator component based on the population biology of large vertebrates serving as *umbrella* species, to which we give more attention.

Hydrological Indicators

Human activities disrupt natural hydrological functioning in multiple ways (Gleick, 1998). Dams, especially large dams which in some river systems have a combined storage capacity that exceeds annual runoff, alter flow, sediment loads, river chemistry and channel processes. In extreme cases surface flow no longer reaches the sea in normal precipitation years. Land use, including the conversion of forested to agricultural land and the increase in impervious surfaces in urban areas, changes flow pathways and often results in more frequent extreme events, including floods and droughts. Channel alterations, including navigation dams, levees, and dredging to increase shipping, constitute another major class of human alterations to natural hydrologic functioning. Flow regime is increasingly being viewed as a *master variable* that influences virtually all aspects of the physical, chemical, and biological functioning of river ecosystems (Poff et al., 1997). Thus, the integrity of the water flow regime is a key component of a forest landscape health.

We believe it is feasible to develop an index of hydrologic function (or dysfunction) applicable at the national level and scaled to economic benefits. The following characteristics, in particular, are candidates for inclusion in such an index: (1) hydrologic variability, which can be quantified using an existing and tested Index of Hydrologic Alteration (Richter et al., 1996); (2) flooding periodicity for floodplain rivers, which can be assessed using SAR imagery; and (3) change analysis of channel sinuosity and extent of flooding derived from bankfull estimates, which can be assessed

using Landsat imagery and aerial photography where available. The development of the hydrological component of a forest capital index would require testing a large suite of candidate indicators to gain as full an understanding as possible of hydrologic function, and then settling on a subset of measures to apply widely.

Umbrella Species

The capacity of a patchwork or forest to support a community of large vertebrates, particularly carnivores, is a reasonable surrogate for forest health. For example, the absence of top predators from neotropical forests has been linked to changes in the abundance of seed-dispersing herbivores — which, in turn, influences the composition of forest canopy trees (Dirzo and Miranda, 1990; Terborgh, 1992). Large-bodied vertebrates are generally more vulnerable to habitat fragmentation and therefore represent good surrogates for the vertebrate biota; their habitat requirements can serve as an *umbrella* for other species. Thus, assuming a careful selection of such species, determination of the degree to which spatial and habitat requirements are adequate to support viable populations should be a reasonable measure of a biota's intactness and resilience and, thus, ecosystem health at the landscape level (Smallwood et al., 1998).

Ecologists can now estimate the spatial areas critical for viability of larger-bodied animal species. Holling (1992) studied body size relationships in different ecological communities to identify robust scale domains within which terrestrial mammalian carnivore populations function. Smallwood and Schonewald (1996, 1998) integrated population estimates of terrestrial mammalian carnivores and found that most of the variation in density was explained by the size of the study area. Moving away from densities and log transformations, Smallwood (1999) identified scale domains in which species' populations likely occur, with an average of 52 individuals per population among species of carnivora. Based on these findings, the effect of habitat fragmentation on the capacity of a landscape to support different levels of vertebrate species richness can be approximated empirically for any ecosystem. Figure 32.7 from Smallwood (unpublished data) shows the fitted relationship of fragmentation to mammal species richness for the Headwaters Forest region in California. This figure essentially represents a surrogate curve relating ecosystem health and

Figure 32.7 Example of an empirically determined relationship between an indicator of forest ecosystem health (Forest Fragmentation Index) and an ecological characteristic (habitat area).

ecological characteristics. Because these curves can be estimated on the basis of body size alone, they can be generated for any mammalian fauna.

CONCLUSION

This chapter suggests an approach for developing indicators of forest capital. It describes how such an indicator approach could be conceptually framed and what ideas, methodologies, tools, and kinds of forest data could be used to develop an indicator system. We suggest that the understanding of the ecological and economic aspects of forest ecosystems has a level now that makes possible an indicator system adequate for decision making at the national level — and for policy prescriptions at regional and international institutions. This understanding results from the relatively recent emergence of concepts like ecosystem health and natural capital; a more comprehensive understanding of the effect of pattern and scale of forest cover and hydrological functioning in relation to the flow of ecological services; and from remote sensing and computer-based information technology for generating and handling geospatial data. Our chapter, however, represents only a preliminary step in designing and implementing a system of indicators of forest capital. Research into the design and implementation of indicators must be complemented by research that focuses on ways to use these indicators to inform the decision-making process.

SECTION I.6

Monitoring, Learning, and Adjusting

Overview: Monitoring, Learning, and Adjusting

David Waltner-Toews

Monitoring indicators, learning from changes observed, and adjusting policies and actions based on an assessment of those indicators are the hallmarks of the kinds of learning organizations we must create if we wish to learn our way into a sustainable, healthy future. Furthermore, one of the fundamental insights gained from the successes and failures of the past several decades of managing agroecosystems has been that indicators of health or sustainability cannot be derived or understood without referring to goals, and that goals are necessarily embedded in specific historical socioecological contexts. Thus, it should come as no surprise that the authors of this chapter have identified the characteristics of this process as (1) participatory, grounded in local communities but multiscalar; (2) embracing multiple perspectives among which trade-offs may need to be negotiated; and (3) rooted in a complex understanding of reality in which various components affect each other, often in surprising and sometimes disconcerting ways, through feedback loops across various timescales.

Two major perspectives, both historically and socioecologically rooted, are offered in this chapter on how one can view and assess the health of agroecosystems. The socioeconomic perspective, described by Jock Anderson in Chapter 34, views agricultural activity primarily from the perspective of its role in general economic development and its potential for achieving poverty alleviation. Lori Ann Thrupp, on the other hand, brings to the fore the deep interactions between agricultural activities and biodiversity (Chapter 35). As might be expected, given the different perspectives, they differ on what should be monitored and what might be viewed as success. Nevertheless, both authors clearly see the connections between their views and identify some key contradictions, such as the high water demand of some high-yielding crop varieties (one tool, perhaps, to alleviate poverty) and the severe water constraints faced by many developing nations. They also agree that the way forward lies through integrated, participatory, and multiscalar approaches.

The other two chapters in this section examine two broad, integrative approaches, again from slightly different perspectives and with different scalar foci. In Chapter 36, Dumanski et al., drawing on a definition of “sustainability as opportunity,” focus on sustainable land management as a way to capture a complex set of goals, and they point the way toward optimizing trade-offs in evolving “resilient production systems that are well suited to local socioeconomic and physical conditions.” In Chapter 37, Van Vuuren et al. take a specific integrative assessment tool — the Ecological Footprint — and apply it to four countries on four continents. In the spirit of this chapter, they use this assessment as an opportunity for learning not only about the performance of these countries but also about the strengths and limitations of the assessment tool and the nature of sustainability itself.

Anderson, echoing an OED assessment, suggests that there is as yet no integrative strategy for understanding rural development. Nevertheless, the characteristics identified, and many of the tools and concepts used by the authors in this section, are all features of what has been called *The Ecosystem Approach*. This approach, recently explored by the UNDP as a way to operationalize its Sustainable Livelihoods Program, is rooted in adaptive environmental management, complex systems theories, and what has been called *postnormal science* — that is, the science of extended peer groups (Ravetz and Funtowicz, 1999). This “new science” is necessary to resolve issues in which the decision-making stakes and the scientific, ethical, and epistemological uncertainties are high (Kay et al., 1999). Clearly, agroecosystem health management, with its central role in producing food and thus making possible all human development, both rural and urban, as well as its implications for socioeconomic justice and environmental sustainability, is such an issue. In practice, the ecosystem approach leads to integrative research and management methods that are iterative, participatory, multiscalar, and systemic — precisely the characteristics sought by the authors of this chapter (Waltner-Toews et al., 2003). For anyone interested in agroecosystem sustainability and health, it is reassuring that the empirical and the theoretical explorations converge in such a remarkable manner.

Ecosystem Health and Economic Development: Rural Vision to Action

Jock R. Anderson

Globalization and localization are transforming many aspects of the human experience — so many that only a comprehensive, multilayered response of policy and institutional reform will be adequate. If we fail to meet this challenge, we will condemn the world's poor to a cycle of instability, hunger, and despair. By seizing the opportunities presented by the dawn of the 21st century, together we can turn our dream into a reality — a world free of poverty (World Bank, 1999, p. 174).

INTRODUCTION

Rural development must be a central element of economic development in much of the developing world. Of the nearly 1 billion poor identified in some 60 poverty profiles completed by the World Bank, over 70% live in rural areas. Despite rapid urban growth, a majority of the poor will continue to live in the countryside until at least 2015. Without a major sustained effort to reduce rural poverty, global efforts in poverty reduction cannot be successful. Thus, policy makers and development bureaucrats must pay more attention to the poor who live in rural areas.

But there is more to rural development than only alleviating poverty. The rural environment is compromised in many places to the point where the ecosystem can hardly be described as healthy. Connectivity to the world economy is poor in many rural areas distant from urban centers and often effectively disconnected from trade opportunities.

Global interdependence of nations increased phenomenally in the past three decades because of rapid growth in international capital markets, the adoption of flexible exchange rates, and the explosion of information technology. In the realm of trade, successive rounds of the General Agreement on Tariffs and Trade (GATT) negotiations have substantially reduced trade barriers. In the most recent Uruguay Round, agriculture and textiles, long heavily protected sectors, were finally brought under GATT rules. The new World Trade Organization (WTO) should provide for better enforcement of rules and more effective dispute settlement. However, some trade policies still discourage what should be facilitated growth and investment, as well as better environmental management.

These and many other aspects of economic development are dealt with quite comprehensively in the World Bank's *World Development Report 1999/2000 (WDR99)* (World Bank, 1999). There is little explicitly rural in this report, but there is much discussion of ecosystem maladies, and

reference will be made to some of these that link to the rural sector. A companion chapter in this section (Dumanski et al., Chapter 36, this volume) takes up in more detail the global issues of direct relevance to the rural sector, also addressed by the World Bank (1997b).

Hundreds of millions of private farmers, large and small, men and women, are stewards of the vast majority of the globe's renewable natural resources. Most recognize the importance of maintaining and enhancing resource productivity and have shown that they can do so, given proper incentives. But the resources are severely undervalued by inappropriate accounting methods, policies, and institutional frameworks. Of the world's fresh water used directly by people, agriculture uses (or misuses) more than 70% for irrigation. Many water-linked ecosystems are not in good health (Water and Nature, 1999). Unsustainable agricultural practices are major contributors to nonpoint-source pollution. Deforestation remains a critical issue (Sharma, 1992). The global challenges of climate change (Alexandratos, 1995; World Bank, 1997b) and loss of biodiversity (Thrupp, 1998) require major efforts. If production per unit of land is nearly to double in the next 30 years, the policy and institutional failures that cause or contribute to the negative environmental impacts of agriculture must be reversed, and sustainable production systems developed, encouraged, and applied (Pannell and Schilizzi, 1999).

There is growing recognition (*WDR99*; World Bank, 1999) of the diverse contributions that forest resources make to development and to the global commons; forests provide not only wood but also nuts, fruits, soil and water protection, flood control, recreational opportunities, carbon sequestration as a means of offsetting global warming, and perhaps the most complex and extensive source of biodiversity habitat. However, capture of the benefits from forest cover — especially by people living in or near forests — is frequently impeded by tenure and forest-use policies (Anderson, 1987; Sanchez, 1994b; von Amsberg, 1998). The lack of effective mechanisms to transfer compensation from those who benefit from sustainable use and conservation of forests, including the international community as a whole for carbon sequestration and biodiversity preservation (Dumanski et al., Chapter 36, this volume), to those who can gain more from conversion of forest land, compromises sustainability. In far too many countries, forests remain severely undervalued because of the combination of strong rent-seeking behavior by commercial users and forest officials and highly centralized and bureaucratic forest services. This leads to poor forest management and protection and a stifling of local communities' participation in the use and protection of the resources. Regrettably, the measurement of deforestation and forest degradation, and the valuation of biodiversity and carbon sequestration, are matters that have not yet been satisfactorily addressed.

IMPORTANCE OF RURAL DEVELOPMENT IN BROADER ECONOMIC DEVELOPMENT

Early development economists tended to disregard the contribution of the rural economy to development. In the 1950s and later in many countries, the emphasis was on industrial investment to foster economic growth, usually with a strong urban bias. At best, rural areas were seen as merely the source of underemployed labor that could be redeployed in industrial enterprises. The many failures of this model led to an eventual reconsideration of possible agricultural contributions to development, particularly after the successes of the green revolution, and especially so in South Asia.

This extensive literature has been analyzed by many (Hayami and Ruttan, 1984; Hoff et al., 1993; Carruthers and Kydd, 1997). Notwithstanding the lessons of the past (e.g., Vasey, 1992), in most of these and earlier development discussions the environment generally, and rural ecosystems specifically, seldom featured prominently or at all (until the late 1980s, as noted by Staatz and Eicher, 1998), except in those notorious cases of highly obvious land degradation, such as the eroded slopes of Nepal. Ironically, contemporary perspectives on some of these cases is that much

of the most dramatic cases of erosion are more geological than anthropogenic (Biot et al., 1995), and thus lead to overstatement of the extent of land degradation (Anderson and Thampapillai, 1990; Leach and Mearns, 1996; Scherr, 1999). Another example of changing perspective is given by *WDR99* in its overview of changed thinking in development economics. The World Bank notes that in the 1950s and 1960s, large dams were seen as synonymous with development, whereas in more recent times, the sharpened appreciation for the human and ecological problems that are associated with some of these schemes have led to much greater emphasis on the adverse effects that tend to go with large dams.

As is outlined in following sections, the new World Bank rural strategy (World Bank, 1997a, hereafter *VtoA*) departed from the earlier tradition of mainstream development economics and gave rural development a central place in economic development of agrarian countries. Rural development is seen not only as an engine of growth but also as a primary focal point of poverty alleviation and responsible (to present and future generations) use of the natural resources underpinning agriculture and the rural landscape (e.g., Crosson and Anderson, 1993; Dumanski et al., Chapter 36, this volume). The new vision of better resource management is now widely shared among key players in rural development such as the Food and Agriculture Organization (FAO), bilateral donors, nongovernmental organizations (NGOs), and the multilateral development banks (Alexandratos, 1995; Lutz et al., 1998).

RETHINKING RURAL DEVELOPMENT STRATEGY AT THE END OF THE CENTURY

As rural development moved up in the development agenda during the 1960s and early 1970s, analysis of problems in the rural sector, and project interventions therein, identified issues of ownership, design, implementation, and supervision, many of which applied also to those of the integrated agricultural or rural development era. The era of Integrated Rural Development Projects (IRDPs) had emerged in the early 1970s. Fortunately, there has been a good deal of reflection on the experiences of this era in the World Bank, donor, NGO, and academic communities.*

Several basic concerns drove the IRDP approach to rural development (Ruttan, 1984). The multiplicity of constraints faced by smallholders were felt to be inadequately addressed in projects with a piecemeal approach to selected weaknesses in local institutions and infrastructure. In preparation for Robert S. McNamara's famous 1973 Nairobi speech, there was a renewed interest in the Bank to strive to deliver project benefits to the poor. Explicitly addressing human development aspects such as health, nutrition, and education along with directly productive aspects of the agricultural environment were (and still are) felt likely to be both socially vital and synergistically productive. Special efforts are needed to reach the weakest and most remote members of society, who seldom benefit from trickle-down effects of interventions not directly targeted to them. Active participation by *all* potential beneficiaries in change processes was desired to move marginalized members of society out of oppressive dependency structures. Designing project interventions to reflect these constraint-removing desiderata proved difficult from the outset, dating from U.S. Agency for International Development (USAID) efforts in North Africa and elsewhere in the 1950s and 1960s (Kumar, 1987). Activity levels and project preparation between the donor community and the bank increased in the 1970s, when enthusiasm for broad-based projects of this type reached a high pitch.

Critical scrutiny of many aspects of implementation grew rapidly in the 1970s (Lele, 1975, 1979; Klitgaard, 1981; Korten and Alfonso, 1981; Moris, 1981; Chambers, 1983), and, more recently, an Operations Evaluation Department** (OED) study in Brazil (Tendler, 1993) was part of a proliferating literature on key design issues. Among many concerns was the consistent tendency

* For example, Tendler, 1993; and the Bank's (1978) Rural Development Projects: A Retrospective View of Bank Experience in Sub-Saharan Africa, Report No. 2242.

** The World Bank's Operations Evaluation Department is a relatively independent unit that reviews completed activities.

for underperformance in the planned monitoring and evaluation work designed in the projects, because the same inherent complexity in scope of project activities led any effective monitoring to be similarly complex, difficult, and expensive.

With this history, it was inevitable that the OED would review experience in this area of rural project work, and a study began in 1987. The draft report was discussed and contrasted to the experience of other donors in a Development Assistance Committee of the Organization for Economic Cooperation and Development (OECD) meeting of June 1988. A synthesis was eventually made by Binnendijk (1989).

The OED review of Bank rural development experience was critical of many design elements including setting up enclave projects outside regular administrative structures, excessive reliance on expatriate technical assistance, and a tendency to upscale projects before adequate pilot experience had been gained (OED, 1988).

Linkage to civil society was usually vague and fragile, especially in the early projects, although subsequent project preparation (along with considerable institutional commitment in the 1990s such as the appointment of responsible offices in most resident missions), and implementation of rural development initiatives, has emphasized close working arrangements with diverse NGOs. Also, this has come with a sharpened understanding of the need for more decentralized approaches and administrative structures to engage effectively with communities in both design and implementation of rural development efforts.

The following observations recap (Ridley Nelson, World Bank, personal communication) the problems of this era (Donaldson, 1991):

- The starting point of IRDPs was predominantly households with productive land assets, and design was strongly oriented to soil, crops, and livestock. There was a tacit recognition that such projects could do little directly to help the landless.
- IRDPs were supply-driven, central-planning exercises, although often decentralized to the regional or provincial level. They were designed and implemented as blueprints with limited flexibility.
- IRDPs were only holistic in the sense that they were multisectoral, *Christmas tree* projects. There was limited analysis of the cross-sectoral complementarities *ex ante*, and in evaluations these were not obvious *ex post*.
- There was little institutional analysis in IRDPs; typically, institutions were accepted as found, usually government departments and parastatals. There was little involvement of local governments and limited building of capacity either at the national or local levels. Generally decentralization *per se* was not an element.
- IRDPs failed partly because of inadequate policy environments. Where policies were recognized as serious constraints, sometimes attempts were made to resolve them, but largely through conditionality rather than strong analysis; usually the extent of single-project policy leverage was limited. Inadequate policies would, of course, also have affected most types of rural projects.
- There was limited local participation or use of NGOs (not widely available in the 1970s) in the design and implementation of IRDPs, although substantial use was made of sometimes massive farm management surveys. These surveys gave those preparing the projects quite good contact with local households and a valuable quantitative analytical base, something that is often missing from present-day Participatory Rural Appraisal techniques. Furthermore, IRDPs typically took place within a governance environment that was largely inimical to local consultation and feedback.
- Partnerships and donor coordination were limited in the IRDP era. Regions or provinces were parceled out, and donors went about their business largely in isolation, although with some attention to comparative advantage.
- Typically, IRDPs were enclaved from the rest of the sector and economy. IRDPs were typically managed by project management units that lay outside the normal government structure. There was usually a presumption that expatriate technical assistance was essential, which, for complex projects with the limited local capacities at the time, was partly correct.
- IRDPs generally did not consider the importance of privatization and cost recovery, although this direction has been followed in Bank projects for some time.

- Typically IRDPs exhibited weak financial sustainability analysis. There was limited focus in IRDPs on environmental sustainability, apart from some soil conservation components, and limited attention to longer term operation and maintenance.
- Generally there was quite strong official local ownership in IRDPs, although in many of the earlier cases the concept was introduced initially by donors.
- Monitoring and evaluation (M&E) was typically a substantial component in IRDPs, with sometimes massive expatriate-staffed M&E units. However, there were serious questions about efficiency, with large household surveys yielding limited results usable by management. This legacy still influences M&E thinking today.

Needless to say, understanding of these intrinsic weaknesses featured strongly in the evaluation of the Bank's new rural vision and was reflected in the 1996–1997 development strategy (*VtoA*) as well as the Bank's emerging fresh framework (the CDF, defined and discussed later in this chapter).

VISION AND ACTION

In 1995, the opportunity arose for a fresh approach to rural development with the arrival of a new president at the World Bank. In a Bankwide consultative process nurtured by the new director of agriculture, a vision of what was needed was put together by distilling the lessons of past endeavors in and outside Bank operations. When the president said: "That's great, but what are you really going to do on my watch?" a further extensive brainstorming took place in the Bank to devise an action plan for a new rural development strategy (*VtoA*) that was debated and accepted by the Bank's board of executive directors. Thus *VtoA* became one of the planks of a new strategic compact for Bank renewal, with special additional funding for a period of 4 years (terminating in fiscal year 2000).

The new rural strategy *From Vision to Action* had four goals:

- Poverty reduction
- Widely shared growth
- Household, national, and global food security
- Sustainable natural resource management

These goals were guided by five key principles (World Bank, 1997a). First, the policy and institutional framework must be supportive of project success. Second, where possible, the private sector must be mobilized to provide investment capital, production, and most services. Third, the state must shift away from heavy intervention in the economy toward enabling macroeconomic, fiscal, and sector policy environments. Fourth, a plurality of institutions must be involved — community-level groups and lower-level governments as well as central ministries. Fifth, where feasible and advantageous, projects and programs are decentralized, designed, and executed with a high degree of influence and participation by community associations and local governments.

In addition, a Strategic Checklist for Rural Development was developed (World Bank, 1997a):

- Macroeconomic and sectoral policies are stable. The foreign exchange, trade, and taxation regimes do not discriminate against agriculture.
- The growth of private agriculture is encouraged by minimizing distortions in input and output markets and by market development for agricultural products.
- Public expenditure programs for economic and social infrastructure, health, nutrition, education, and family planning services do not discriminate against rural populations.
- Large farms and large agroindustrial firms do not receive special privileges and are not able to reduce competition in output, input, land, or credit markets.
- The agrarian structure is dominated by efficient and technologically sophisticated family operators. The rights of women farmers and laborers are explicitly recognized.

- Security of land and water rights is actively promoted. Restricting land rentals hurts the poor, so their access may need protection. Land reform is needed where land distribution is highly unequal. Decentralized, participatory, and market-assisted approaches to land reform are preferred.
- Private and public sectors complement each other in generating and disseminating knowledge and technologies. Public-sector financing is generally important for areas that are probably of limited interest to the private sector, such as strategic research and smallholder extension.
- Rural development programs mobilize the skills, talents, and labor of the rural population through administrative, fiscal, and management systems that are decentralized and participatory, and through private-sector involvement.
- Rural development programs are designed so that the rural poor and other vulnerable groups are fully involved in the identification, design, and implementation.

This list is not comprehensive, especially with respect to natural resource management and rural resource stewardship.

NATURAL RESOURCE MANAGEMENT ISSUES IN *VISION TO ACTION*

The diagnosis in *VtoA* went from the global to the regional as follows. Future increases in food supplies must come primarily from rising biological yields rather than from area expansion and more irrigation, because land and water are becoming increasingly scarce (Crosson and Anderson, 1992; Mitchell et al., 1997; McCalla, 1998). Many new lands brought under cultivation are marginal and ecologically fragile and cannot make up for the land removed from cultivation each year because of urbanization and land degradation. Sources of water that can be developed cost-effectively for irrigation are nearly exhausted, and irrigation water will increasingly need to be reallocated for municipal and industrial use. Thus, expansion of irrigation or increased intensification through irrigation are not viewed as major opportunities. New irrigation projects are increasingly expensive and subject to much stricter environmental standards.

The analysis identified that production on existing rainfed land will need to nearly double to provide a diversified, storable, and transportable food supply to an expanding urban population. The particular problems of livestock production systems and their often unhealthy links to their surrounding ecosystems must be addressed (de Haan et al., 1997).

REGIONAL PRIORITIES FOR DEVELOPMENT

Thus, the four major challenges of reducing rural poverty and hunger, raising economic growth, increasing global food production, and halting natural resource degradation require action on a broad and complex rural development front. It is not only a matter of raising food output but also of ensuring that growth is widely shared and sustainable.

Africa

The specifics of what must be done vary around the world. The long-recognized (FAO, 1986) overwhelming challenge in Africa is to increase food production and raise incomes in rural areas (Lele, 1991; Crosson and Anderson, 1995). Seventy percent of people in sub-Saharan Africa live in rural areas; agriculture accounts for 30% of GDP, 40% of exports, and 70% of employment. Far more so than in any other region, a prosperous agriculture is the engine without which poverty cannot be reduced, natural resources cannot be managed sustainably, and food security cannot be assured (Cleaver and Schrieber, 1994). New lending must focus on a few selected national programs of high impact (Cleaver, 1997) — in research, extension, animal health, and natural resources management — water, soil fertility (Sanchez, 1994a; Pieri, 1999), forests, pastures, and wildlife. The second major challenge

is to pursue rural growth rather than only agricultural growth. This is being done by designing a common strategy for development of the rural economy, with investment in infrastructure and social services to be undertaken through nonagricultural projects. The third major challenge is to make national programs work. Sector investment lending is rapidly becoming a privileged instrument; although still not yet proven, it has the potential to generate systemic change in the whole public rural expenditure program. This is particularly important in Africa where, with official development assistance recently at around 10% of GNP* and many donors active in rural areas, donor coordination is essential. Agricultural policy reform would continue to be vigorously pursued through adjustment operations.

Eastern Europe and Central Asia

The main challenge in Eastern Europe and Central Asia is to reform agricultural policies that in the past encouraged inefficient and environmentally unfriendly farming and other practices. The strategy is to base rural lending on a graduated response to thresholds of policy reform including price and trade liberalization, change in agribusiness and farmland ownership, demonopolization and deregulation of marketing, and financial sector reforms. Exceptions are made for projects with long lead times, such as research, or for activities such as land registration that will enable a policy change, when made, to take effect promptly. A second major challenge, unique to the region, is the severity of the needed restructuring and rebuilding of agriculture and the agroindustrial complexes. This is a task without precedent. The Bank will continue to devote a large share of its resources to nonlending services, particularly to analyze land and rural property issues, and the impact of privatization on efficiency and equity, and to assist with determining the necessary legal and regulatory framework for agribusiness, environmental, and rural services.

Middle East and North Africa

The most scarce resource in the Middle East and North Africa is water, and the overwhelming challenge is to increase the efficiency of water use in agriculture. Water charges are merely symbolic in nearly all cases, and operations and maintenance are inadequate because of weak user participation. Intersectoral water transfers are inevitable in the future, and urgent action is sought by the Bank through a series of investment operations in the water sector. A second major challenge is to improve the competitiveness of agriculture, while taking account of most governments' preoccupation with maintaining low urban food prices. In the past, this preoccupation has led to the prevalence of state marketing companies that stifle commerce and the implementation of ineffectively targeted food subsidies that result in enormous fiscal drain. While sector adjustment operations have made significant progress in addressing aspects of competitiveness, much more remains to be done in designing targeted food consumption programs that are effective and politically acceptable. A third major challenge in the Middle East and North Africa is the scarcity of arable land, the severity of soil erosion, the indifference of many governments, and the low levels of investment in watershed management. Many of the region's poorest people live in the upper watersheds, eking out livelihoods from forests, rangelands, and steppes, and degrading watersheds in the process. Given the pervasiveness of urban bias in public expenditures, more persuasive analysis is required to focus attention to investment in watershed management.

South Asia

South Asia has the world's largest concentration of rural poor, particularly in rainfed areas, where the resource base is both more limited and more fragile than in the irrigated plains. Landlessness is far more common in this region than elsewhere. Thus, poverty reduction is the main challenge. Another major challenge is water resources management. This has several dimensions: intersectoral

* One contextual note on this is the observation in *WDR99* that in much of the developing world, environmental damage amounts to something of the order of 5% of GNP.

and intercountry disputes over allocation of scarce water, a crisis in irrigation service delivery, a worsening problem of waterlogging and salinization, and the buildup of pollution of ground and surface water that threatens rural domestic water supply. Innovative projects in irrigation and drainage, flood control, and rural water supply are planned.

Latin America and the Caribbean

A striking characteristic of Latin America and the Caribbean region is the large diversity of socioeconomic conditions and agricultural practices. In many cases, there is extreme income inequality in the rural population as a result of a long history of governments providing discriminatory access to land and capital to the wealthy and powerful. Poverty is deep and prevalent in rural areas, and a high proportion of the rural poor have fled to urban peripheries. Of those remaining, rural poverty is closely connected to issues of natural resources management (Lopez, 1996), and many rural poor earn their livelihoods as laborers or subsistence smallholders in environmentally fragile areas or on the frontiers. At the same time, commercial farmers are beginning to better understand concepts of land conservation and sustainable farming and are seeking assistance in developing and implementing these techniques. Poverty reduction, better use of existing productive capacity, and sustainable natural resource management are the main challenges. Meeting these challenges often requires, however, a redefinition of the roles of government, emphasizing community-based approaches to natural resources management, targeting interventions to reduce rural poverty, protecting the rights of indigenous peoples, increasing efforts to speed the pace of land reform and land allocation, and working with governments to remove policy biases against small farmers (Binswanger and Deininger, 1997).

East Asia and the Pacific

The main characteristics of East Asia and the Pacific are (until recently) generally fast growth, including fast agricultural growth (4% per year since 1980), and good provision of social services nationwide in many countries. The result, however, is that environmental problems abound, especially in watershed management. Unless action is taken soon, these may reach catastrophic proportions in the near future. Another major challenging aspect is the sheer heterogeneity of the region, which ranges from some of the largest economies (China and Indonesia) to some of the smallest (Laos, Mongolia, and the Pacific Islands).

PROGRESS IN IMPLEMENTING THE NEW STRATEGY

While *VtoA* did not set targets for rural lending, there was a clear expectation that the recommended actions would result in a resurgence of lending for agriculture in particular and continued growth in other rural lending. The overall trend has been generally positive, although not as pronounced as had been anticipated:

- Rural lending is expected to increase from about 58 to perhaps 75 projects a year, if present intentions come to pass. The uncertainties, however, are considerable.
- In terms of commitments (Figure 34.1), agricultural projects are expected to increase from \$2.6 billion a year in FY98–99 to \$4.3 billion in FY00–01, with rural nonagricultural projects increasing from \$0.8 billion a year to \$1.2 billion. Total rural lending is thus anticipated to increase from \$3.4 billion a year to \$5.5 billion, or approximately 20% of total bank lending.
- Among subsectors, the largest increase in shares of commitments is expected in a category called *Other Agriculture* that includes community-based rural development and natural resources management. This increase will offset the apparent decline in projects formally classified as natural resource management (NRM).

Figure 34.1 Rural approvals: U.S. dollars in billions.

Reviewing Country Assistance Strategies

VtoA is a strategy to ensure that rural development is better reflected in Country Assistance Strategies (CASs) that are the most important investment plans for Bank lending. Now that the country dimension of Bank management has been strengthened through the Bank’s latest reorganization, it follows that the CAS process gained in authority. CASs are the vehicles through which key decisions about resource allocation are made.

A recent review by OED showed that the current approach to rural development was judged to be broader than before, but the extent of this breadth is underestimated; and there is no integrated strategy that trades on the large role rural areas play in the Bank’s work program. There are several reasons for this. The Bank’s knowledge base was judged to serve the cause of rural development poorly. Rural sector work is declining. Poverty assessments rarely contain good estimates of the incidence of rural poverty, even in that majority of countries where most of the poor live in rural areas. Many agree that the off-farm dimension is important, but the dynamics of nonfarm rural enterprise are still poorly understood. There is, unfortunately, no magic bullet for rural development and no consensus about which of the lengthy menu of possible interventions is likely to have the largest payoff in terms of growth and poverty reduction.

Changing Portfolio

Changes by subsector have been significant (Figure 34.2).

Figure 34.2 Subsectoral share of rural portfolio commitments.

- Irrigation and drainage continues to be, by far, the most important rural subsector. While its share in number of rural projects has been close to 20% for some time, its rather larger share in commitments has now slipped from a high of nearly 33% in FY98 to about 28%.
- Adjustment and natural resources management (and in FY99 also rural roads) are the subsectors that have grown most rapidly, particularly in terms of the volume of commitments.
- Forestry, perennial crops, extension, and livestock have all declined, both by number of projects and commitments (although part of the decline in free-standing extension and livestock projects has been offset by the inclusion of these components in agricultural services projects).

Two aspects with particular relevance to a more comprehensive approach to World Bank forest policy have already become clear. First, the frontiers of the forestry issue have broadened vastly over the past 5 years. To reach any considered position on a bank forest policy, it is now essential to bring into focus the potential impacts on forests of economic adjustment policies, energy policies, agriculture policy, land use legislation, public expenditure strategies, biodiversity, etc. Second, it is increasingly appreciated that not only are many of the poor in rural areas but also rural development is central to combatting poverty, but that many of the poor in rural areas rely at least partly on forest resources, and what is done in forests, and by extension to other natural resources, can be central to rural poverty and global goods, such as containment of atmospheric carbon (Lopez 1996). Of course, while national governments can do good for their citizens through better attention to forest management and policy, they may also be contributing to global goods, some of which may be partially marketable. An example is the deal between Costa Rica and Merck in the work of INbio (*WDR99*; World Bank, 1999).

THE COMPREHENSIVE DEVELOPMENT FRAMEWORK

Further improvements in project quality may require more attention to institutional development, a message that is reiterated in the latest and still emerging bank development thrust: the *Comprehensive Development Framework*. The framework, or CDF, includes the following as one of its five principles: “Sustainable poverty reduction requires holistic, long-term country development strategies with equal weight to the social and structural as to the macro and trade agenda.” Some recent analysis of aid effectiveness (World Bank, 1998) reinforces this message. Now that many of the macro and sector policy distortions identified in the 1980s have been sorted out, a good case can be made for paying more attention to institutional capacity, especially resource custody. Fortunately much emphasis is also given to effective partnerships, a concern increasingly mirrored by many potential partners (e.g., Farrington and Bebbington, 1993; FIPA/IFAP, 1996; Thrupp, 1996; Gibbs et al., 1998). Many of the Bank’s partners have their own vision of how better to proceed with future rural development work, and there is an active interplay between their ideas and the Bank’s own emerging thinking as it seeks to work more effectively with its diverse partners. By way of illustration, one of these deserving mention is that crafted by the U.K. Department for International Development, namely, Sustainable Rural Livelihoods (Carney, 1998; Farrington et al., 1999). In this, the central focus on poverty elimination is set around an appreciation of the several different types of capital (human, financial, physical, social, and natural) available to rural households, their vulnerability to change, and instruments to increase their well-being without undermining the natural resource base. Unfortunately, this strategy is still incomplete with respect to rural landscapes. The logical framework increasingly used in this work makes clear distinctions between outputs, project development objectives, and sector-related goals from the CAS; there is some hope that it will help to ensure clarity in stating objectives and systematically describing project design.

CONCLUSION

This chapter describes the current status and the evolving work programs of the World Bank related to ecosystem health. Progress has been made in rural development, especially in learning from past experience; but there is much that is increasingly urgent to do. In the current global picture, there are still too many poor people, too many in poor health, too many living in poor housing, too many poorly fed and subsisting in poorly managed ecosystems. The discussion has concentrated on project-level interventions, but there are also other entry points for the Bank.

On the global environmental agenda, the Bank is mainstreaming the relevant international conventions including the Convention to Combat Desertification and the Conventions on Climate Change and Bio-diversity, and it is working toward capturing the benefits that sustainable land management provides in conserving biodiversity, sequestering carbon, and reducing global warming. Neglected areas of land management and fisheries are also being tackled — the former described in the companion Bank paper in this session, the latter in a proposal to form a worldwide coalition of multilateral agencies, development banks, bilateral and private donors, civil society, national governments, and the private fishing and processing sectors. This Forum for Sustainable Fisheries will be a coordinating mechanism aimed at better husbandry of marine resources and conservation of the ocean's natural resources.

There is clearly much yet to be done in fostering better ecosystem health. Many of the challenges are in the rural sectors of developing countries. The World Bank has a responsibility to assist its client countries to meet the challenges through provision of analysis, advice, and financial resources. But the tasks are great and many players must be involved. The commitment to work closely with all relevant players is at the center of the new bank approaches, both to the rural sector specifically through *VtoA* and more generally through the emerging CDF.

Agricultural Biodiversity: A Key Element of Ecosystem Health and Sustainable Food Security*

Lori Ann Thrupp

INTRODUCTION

There is growing worldwide realization that biodiversity is fundamental to agricultural production and food security as well as a valuable ingredient of ecosystem health and environmental conservation. Yet predominant patterns of agricultural and economic growth have eroded biodiversity in agroecosystems, including plant and animal genetic resources. This erosion has caused economic losses, jeopardizing productivity and food security in some areas and leading to broader social costs. Equally alarming is the loss of biodiversity in natural habitats from the expansion of agricultural production to frontier areas.

The conflicts between agriculture and biodiversity are by no means inevitable. With sustainable farming practices and changes in agricultural policies and institutions, they can be overcome. Historical evidence and current observations show that biodiversity and the maintenance and integration of agricultural systems can have multiple ecological and socioeconomic benefits, including sustaining productivity, ecosystem functions, and food security. Practices that conserve and enhance *agrobiodiversity* are necessary at all levels. The sustainable use of diverse biological resources is critical for food production, nutrition, and for maintaining or improving the health and sustainability of ecosystems.

This chapter summarizes the main conflicts and complementarities between biodiversity and agriculture, discusses the ecosystem services provided by agricultural biodiversity, and highlights principles, policies, and practices that enhance diversity in agroecosystems.

AGROBIODIVERSITY AS A BASIS FOR PRODUCTION AND SURVIVAL

Biodiversity and detailed knowledge about it have allowed farming systems to evolve since agriculture began some 12,000 years ago (Shand, 1997; FAO, 1998; UNDP, 1992). Although sometimes perceived as an enemy of biodiversity, agriculture is actually *based* on richly diverse biological resources. Likewise, agriculture comprises a variety of managed ecosystems — *agroecosystems* — that benefit from resources in natural habitats.

Agrobiodiversity is an important feature of farming systems around the world. It encompasses many types of biological resources tied to agriculture, including:

* This chapter is derived from a longer report published by the World Resources Institute in 1998 titled *Cultivating Diversity: Agrobiodiversity and Food Security*, by Lori Ann Thrupp.

- Genetic resources — the essential living materials of plants and animals
- Edible plants and crops
- Livestock (small and large, lineal breeds, or thoroughbreds) and freshwater fish
- Soil organisms vital to soil fertility, structure, quality, and soil health
- Naturally occurring insects, bacteria, and fungi that control insect pests and diseases of domesticated plants and animals
- Agroecosystem components and types (polycultural/monocultural, small/large scale, rainfed/irrigated, etc.) indispensable for nutrient cycling, stability, and productivity
- *Wild* resources (species and elements) of natural habitats and landscapes that can provide services (for example, pest control and ecosystem stability) to agriculture (Brookfield and Padoch, 1994; Altieri, 1991; FAO, 1998; Shand, 1997; UNDP, 1992)

Agrobiodiversity therefore includes not only a wide variety of species but also the many ways in which farmers can *use* biological diversity to produce and manage crops, land, water, insects, and biota. (Figure 35.1) The concept also includes habitats and species outside of farming systems that benefit agriculture and enhance ecosystem functions, such as host plants that harbor natural enemies and predators of agricultural pests.

As recorded by Egyptian, Mesopotamian, Chinese, and Andean civilizations, ancient agricultural settlements made use of diverse plants, livestock, and agroecosystems. Over many centuries, farmers have employed numerous practices to use, enhance, and conserve this diversity in traditional farming systems. Many such practices continue today: the use of diverse species for pest control and the integration of trees and woody shrubs into farming systems are two examples. Wild plant and animal species in surrounding habitats also provide services and value to the farming system. Such practices are a basis of survival and well-being for millions of people.

Examples of these traditional farming systems that maximize diversity are the polycultural plots, sometimes called home gardens, found in many regions, including Central America, Southeast Asia, sub-Saharan Africa, and even Europe. Others are traditional agroforestry systems, such as the shaded coffee plantations common throughout Central and South America. These traditional agroforestry systems commonly contain well over 100 annual and perennial plant species per field (Altieri, 1991). Farmers often integrate leguminous trees, fruit trees, trees for fuelwood, and types that provide fodder on their coffee farms. The trees also provide habitat for birds and animals that benefit the farms. For example, a shaded coffee plantation in Mexico supports up to 180 species of birds that help control insect pests and disperse seeds (Greenburg, 1994). Ethnobotanical studies show that the Tzeltal Mayans of Mexico can recognize more than 1200 species of plants, while the P'urepechas recognize more than 900 species and Yucatan Mayans some 500 (Altieri, 1991). Such knowledge is used to make production decisions.

Numerous studies show that shifting cultivation systems in traditional forms are agroecologically diverse and contain numerous plant species. These can also be relatively sustainable in certain areas of the world, especially where economic and demographic pressures for growth are low

Figure 35.1 Conceptual view of agrobiodiversity.

(Brookfield and Padoch, 1994; Thrupp, 1996). Another important dimension of traditional agrobiodiversity is the use of so-called folk varieties, also known as *landraces*. Defined as “geographically or ecologically distinctive populations [of plants and animals] which are conspicuously diverse in their genetic composition” (Brown, 1978), landraces are products selected by local farmers over time for their various production benefits (Cleveland et al., 1994). In some areas in the Andean region, for example, farmers have also developed complex techniques to select, store, and propagate the seeds of landraces.

Many practices for using and enhancing agrobiodiversity are tied to the rich cultural diversity and local knowledge that are valuable elements for community livelihood. Rural women are particularly knowledgeable about diverse plants and tree species and about their uses for health care, fuel, and fodder, as well as food (Abramowitz and Nichols, 1993; Thrupp, 1984). Many principles, as well as intuitive knowledge, from traditional systems are applied today in both large- and small-scale production. In fact, “traditional multiple cropping systems still provide as much as 20 percent of the world food supply” (UNDP, 1995).

From ancient times to the present day, plant collecting has also enhanced agrobiodiversity. The earliest record dates back to 1495 B.C., when Egyptians gathered plants for food, medicine, and other purposes from various parts of the world. Throughout the colonial period, the search for and collection of diverse plants and foods was a driving interest of European explorers and played an important role in colonial expansion.

Also significant was the work of N. Vavilov, a renowned Russian botanist who carried out systematic plant collection, pioneering research, and conservation of crop diversity starting in the early 20th century. Vavilov developed a theory of the origin of domesticated crops and launched numerous worldwide expeditions to collect crop germ plasm. He established an immense seed bank in St. Petersburg that still endures, now containing some 380,000 specimens from more than 180 locations in the world (Raeburn, 1995). Vavilov also identified major areas of high concentrations of crop diversity around the world, most of which are in developing countries.

The innovative uses of plant genetic resources has continued to be valuable for scientific advances in plant and livestock breeding and seed improvements up to the present day. These discoveries have been important to all forms of agriculture, from large-scale industrial agribusiness to traditional small-scale farming (Raeburn, 1995). Access to germ plasm is vital for modern agriculture and for the development of medicinal products, fibers, and foods. In the U.S., for example, exotic germ plasm “adds a value of \$3.2 billion to the nation’s \$1 billion annual soybean production and \$7 billion to its \$18 billion annual maize crop” (Shand, 1997).

In sum, it is clear that the many forms of agrobiodiversity yield an array of benefits (Box 35.1). They reduce risk and contribute to resilience, food security, and income generation. Agricultural biodiversity also provides ecosystem services, such as biological control of pests and improving the health of soils, and benefits nutrition and productivity in many cases.

THE DECLINE OF AGROBIODIVERSITY

The links between agriculture and biodiversity have changed over time and should be viewed in the context of global agricultural development trends. Agricultural production and productivity have increased greatly in the last 30 years, and the international trade and exchange of seeds and food products have also expanded. This growth stems from both the expansion of cultivated area (*extensification*) and the increased output per unit of land (*intensification*) through technological inputs, improved varieties, and the management of biological resources such as soil and water. Agricultural development trends have also failed to overcome problems: hunger and malnutrition persist; food security has declined in many developing countries; food and land are distributed highly inequitably; and biological resources have been degraded. Consequently, the ecosystem services provided by agricultural biodiversity have declined, therefore undermining

BOX 35.1 **BENEFITS OF AGROBIODIVERSITY**

Experience and research have shown that agrobiodiversity can:

- Increase productivity, food security, and economic returns
- Reduce the pressure of agriculture on fragile areas, forests, and endangered species
- Make farming systems more stable, robust, and sustainable
- Contribute to sound insect pest and disease management
- Conserve soil and increase natural soil fertility and health
- Contribute to ecosystem services and ecosystem health
- Diversify products and income opportunities
- Reduce or spread risks to individuals and nations
- Reduce dependency on external inputs
- Improve human nutrition and provide sources of medicines and vitamins

Adapted from UNDP, 1985; Altieri, 1987; Brookfield and Padoch, 1994; Thrupp, 1998.

ecosystem health. These problems pose tremendous challenges to meet growing food needs while conserving resources.

These general trends in agriculture and biodiversity have been shaped by demographic pressures, including high population growth rates, the migration of people into frontier areas, and imbalances in population distribution. Additional influential forces are the predominant paradigms of industrial agriculture and the green revolution, beginning in the 1960s. These approaches generally emphasize maximizing yield per unit of land, uniform varieties, reduction of multiple cropping, standardized farming systems (particularly generation and promotion of high-yielding varieties), and the use of agrochemicals. Seed and agrochemical companies have also influenced these trends. High-yielding varieties (HYVs) are now planted on high percentages of agricultural land — estimated as 52% for wheat, 54% for rice, and 51% for maize. Use of HYVs has increased production in many regions and sometimes reduced pressure on habitats by curbing the need to farm new lands.

EROSION OF CROP AND LIVESTOCK DIVERSITY

Although people consume approximately 7000 species of plants, only 150 species are commercially important; and about 103 species account for 90% of the world's food crops. Just three crops — rice, wheat, and maize — account for about 60% of the calories and 56% of the protein people derive from plants. Along with this trend toward uniform monocropping, the dependence on high levels of inputs such as irrigation, fertilizers, and pesticides has increased worldwide. The reduction in diversity often increases vulnerability to climate and other stresses, raises risks for individual farmers, and can undermine the stability of agriculture. In Bangladesh, for example, “promotion of HYV rice monoculture has decreased diversity, including nearly 7000 traditional rice varieties and many fish species. The production of HYV rice per acre in 1986 dropped by 10% from 1972, in spite of a 300% increase in agrochemical use per acre” (Hussein, 1994). In the Philippines, HYVs have displaced more than 300 traditional rice varieties that had been the principal source of food for generations. In India, by 1968, the so-called miracle HYV seed had replaced half of the native varieties, but these seeds were not high-yielding unless cultivated on irrigated land with high rates of fertilizer, which is often unaffordable to poor farmers (Shiva, 1991). Thus, the expected production increases were not realized in many areas.

Table 35.1 Extent of Genetic Uniformity in Selected Crops

Crop	Country	Number of Varieties
Rice	Sri Lanka	From 2000 varieties in 1959 to fewer than 100 today 75% descend from a common stock
Rice	Bangladesh	62% of varieties descend from a common stock
Rice	Indonesia	74% of varieties descend from a common stock
Wheat	U.S.	50% of crop in nine varieties
Potato	U.S.	75% of crop in four varieties
Soybeans	U.S.	50% of crop in six varieties

Data from World Conservation Monitoring Centre, *Global Biodiversity: Status of the Earth's Living Resources*, Groombridge, B., Ed., Chapman & Hall, London, 1992.

In Africa, transfer of the green revolution model has also reduced diversity. In Senegal, for example, a traditional cereal called fonio (*Panicum laetum*) — which is highly nutritious as well as robust in lateritic soils — has been threatened by extinction because of its replacement by modern crop varieties (IFOAM, 1994). In the Sahel, reports also confirm that traditional systems of polyculture are being replaced with monocultures that cause further food instability (Mann, 1994) (Table 35.1).

Homogenization also occurs in high-value export crops. Nearly all the coffee trees in South America, for example, are descended from a single tree in a botanical garden in Holland. *Coffea arabica* was first obtained from forests of southwest Ethiopia that have virtually disappeared (Fowler and Mooney, 1990). Uniform varieties are also common in export crops of bananas, cacao, and cotton, replacing traditional diverse varieties. Such changes have increased productivity, but the risks of narrowing varietal selection have become clear over time. In the north, similar losses in crop diversity are occurring. Many fruit and vegetable varieties listed by the USDA in 1903 are now extinct. Of more than 7000 apple varieties grown in the U.S. between 1804 and 1904, 86% are no longer cultivated, and 88% of 2683 pear varieties are no longer available (Fowler and Mooney, 1990) (Table 35.2). Evidence from Europe shows similar trends — thousands of varieties of flax and wheat vanished after HYVs were introduced (Mooney, 1979). Similarly, varieties of oats and rye are also declining in Europe (Vallve, 1993). In Spain and Portugal, various legumes that had been an important part of the local diet are being replaced by homogeneous crops; and in the Netherlands, four crops are grown on 80% of Dutch farmlands (Vallve, 1993).

Livestock is also suffering genetic erosion; the FAO estimates that somewhere in the world at least one breed of traditional livestock dies out every week. Many traditional breeds have disappeared as farmers focus on new breeds of cattle, pigs, sheep, and chickens (Plunknett and Horne,

Table 35.2 Reduction of Diversity in Fruits and Vegetables, 1903 to 1983 (Varieties in NSSL Collection)

Vegetable	Taxonomic Name	Number in 1903	Number in 1983	Loss (%)
Asparagus	<i>Asparagus officinalis</i>	46	1	97.8
Bean	<i>Phaseolus vulgaris</i>	578	32	94.5
Beet	<i>Beta vulgaris</i>	288	17	94.1
Carrot	<i>Daucus carota</i>	287	21	92.7
Leek	<i>Allium ampeloprasum</i>	39	5	87.2
Lettuce	<i>Lactuca sativa</i>	497	36	92.8
Onion	<i>Allium cepa</i>	357	21	94.1
Parsnip	<i>Pastinaca sativa</i>	75	5	93.3
Pea	<i>Pisum sativum</i>	408	25	93.9
Radish	<i>Raphanus sativus</i>	463	27	94.2
Spinach	<i>Spinacia oleracea</i>	109	7	93.6
Squash	<i>Cucurbita</i> spp.	341	40	88.3
Turnip	<i>Brassica rapa</i>	237	24	89.9

Data from Fowler, C. and Mooney, P., *The Threatened Gene — Food, Politics, and the Loss of Genetic Diversity*, The Lutworth Press, Cambridge, 1990.

1992). Of the 3831 breeds of cattle, water buffalo, goats, pigs, sheep, horses, and donkeys believed to have existed in this century, 16% have become extinct, and a further 15% are rare (Hall and Ruanne, 1993). Some “474 of extant [livestock] breeds can be regarded as rare. A further 617 have become extinct since 1892” (Hall and Ruanne, 1993). Over 80 breeds of cattle are found in Africa, and some are being replaced by exotic breeds (Rege, 1994). These losses weaken breeding programs that could improve hardiness of livestock.

As agricultural biodiversity is eroded, food security is often reduced and economic risks increased. Evidence indicates that such changes can decrease sustainability and productivity in farming systems (Tillman et al., 1996). Loss of diversity also reduces the resources available for future adaptation.

INCREASED VULNERABILITY TO INSECT PESTS AND DISEASES

Homogenization of varieties increases vulnerability to insect pests and diseases that can devastate a uniform crop, especially on large plantations. History has shown serious economic losses and suffering from relying on monocultural uniform varieties (Table 35.3). Among renowned examples are the potato famine of Ireland during the 19th century, a winegrape blight that wiped out valuable vines in both France and the U.S., a virulent disease (*Sigatoka*) that damaged extensive banana plantations in Central America in recent decades, and devastating mold that infested hybrid maize in Zambia.

In addition, a serious decline in soil organisms and soil nutrients has occurred. Beneficial insects and fungi also suffer under agriculture that involves heavy pesticide inputs and uniform stock — practices that make crops more susceptible to pest problems. These losses, along with fewer types of agroecosystems, also increase risks and can reduce productivity. In addition, many insects and fungi commonly seen as enemies of food production are actually valuable. Some insects benefit farming — for pollination, contributions to biomass, natural nutrient production and cycling, and as natural enemies to insect pests and crop diseases. Mycorrhizae, the fungi that live in symbiosis with plant roots, are essential for nutrient and water uptake.

The global proliferation of modern agricultural systems has eroded the range of insects and fungi, a trend that lowers productivity. Dependence on agrochemicals, and particularly the heavy use or misuse of pesticides, is largely responsible. Agrochemicals generally kill natural enemies and beneficial insects as well as the target pest. “Pesticides [especially when overused] destroy a wide array of susceptible species in the ecosystem while also changing the normal structure and function of the ecosystem” (Pimentel, 1992).

This disruption in the agroecosystem balance can lead to perpetual resurgence of pests and outbreaks of new pests — as well as provoke resistance to pesticides. This disturbing cycle often

Table 35.3 Past Crop Failures Due to Genetic Uniformity

Date	Location	Crop	Effects
1846	Ireland	Potato	Potato famine
1800s	Sri Lanka	Coffee	Farms destroyed
1940s	U.S.	U.S. crops	Crop loss to insects doubled
1943	India	Rice	Great famine
1960s	U.S.	Wheat	Rust epidemic
1970	U.S.	Maize	\$1 billion loss
1970	Philippines, Indonesia	Rice	Tungo virus epidemic
1974	Indonesia	Rice	3 million tons destroyed
1984	U.S. (Florida)	Citrus	18 million trees destroyed

Data from World Conservation Monitoring Centre, *Global Biodiversity: Status of the Earth's Living Resources*, Groombridge, B., Ed., Chapman & Hall, London, 1992.

leads farmers to apply increasing amounts of pesticides or to change products — a strategy that is not only ineffective but also further disrupts the ecosystem functions and elevates costs. This *pesticide treadmill* has occurred in numerous locations throughout the world. Reliance on monocultural species and the decline of natural habitat around farms also cuts beneficial insects out of the agricultural ecosystem.

ADDITIONAL LOSSES — HABITATS, NUTRITION, AND KNOWLEDGE

Agricultural expansion has also reduced the diversity of natural habitats, including tropical forests, grasslands, and wetland areas. Projections of food needs in the coming decades indicate probable further expansion of cropland, which could add to this degradation. Modifying natural systems is necessary to fulfill the food needs of growing populations, but many conventional forms of agricultural development, particularly large-scale conversion of forests or other natural habitats to monocultural farming systems, erode the biodiversity of flora and fauna. Intensive use of pesticides and fertilizers can also disrupt and erode biodiversity in natural habitats and ecosystem services that surround agricultural areas, particularly when these inputs are used inappropriately.

Other direct effects of reduced diversity of crops and varieties include:

- Decline in the variety of foods adversely affects nutrition (IIED, 1995).
- High-protein legumes have often been replaced by less nutritious cereals (Shiva, 1991).
- Local knowledge about diversity is lost as uniform industrial agricultural technologies predominate (Altieri, 1991).
- Institutions and companies in the north have unfair advantages in exploiting the diverse biological resources from the tropics (Shand, 1997).

In sum, the loss of agrobiodiversity adds immediate costs to producers, creates social costs to communities and nations, has long-term effects on agricultural productivity, and jeopardizes food security.

CAUSES OF AGROBIODIVERSITY DECLINE

The causes of agrobiodiversity loss are very complex and they vary under different conditions. In general, however, the proximate explanations are often tied to the use of unsustainable farming methods and degrading land use practices. More deeply, the root causes that underlie the erosion of agricultural biodiversity are generally tied to policies, economic, and institutional factors that largely determine field-level practices and behaviors. Other root causes include demographic pressures, disparities in resource distribution, the prevalent influence of industrial monocultural agricultural models or paradigms that contribute to decline of biodiversity, the depreciation and devaluation of diversity and accumulated local knowledge, and market demands for standardized products (Shand, 1997; Raeburn, 1995; Fowler and Mooney, 1990). Changing these patterns requires reforming land use and technology policies, broader socioeconomic changes that give the rural poor more economic and educational opportunities, and changes in the predominant scientific models or paradigms.

CONSERVATION AND SUSTAINABLE USE OF AGROBIODIVERSITY

Humanity faces a major challenge to prevent and mitigate the losses of agricultural biodiversity and to build strategies to integrate biodiversity and agriculture. The conservation and enhancement

of agrobiodiversity have been upheld in major international conventions, particularly the Convention on Biodiversity (CBD, 2001) and the World Food Summit of 1996. These significant global conventions establish a framework for biodiversity conservation for all signatory nations, and they identify specific mandates for implementing agrobiodiversity conservation measures, sustainable use, and benefit sharing of plant genetic resources. The FAO has also recommended strategies and approaches for the conservation and sustainable use of agricultural biodiversity, to implement the Convention on Agrobiodiversity (FAO, 1998, 1999).

DIVERSITY THROUGH SUSTAINABLE AGRICULTURE PRINCIPLES AND PRACTICES

Proven practical experiences provide lessons and opportunities to integrate biodiversity in agriculture. Such experiences and practices must be strongly supported and multiplied. Effective approaches to conserve and enhance agrobiodiversity fit within a general framework of sustainable agriculture. This approach merges the goals of productivity, food security, and social equity with ecological health. A shift to sustainable agriculture requires changes in production methods, models, and policies, as well as the full participation of local people. In this approach, scientific advancements in genetics and improved varieties can have significant roles, but they need to be reoriented toward conserving and using diversity in farming systems.

To achieve such transformations for the conservation and enhancement of agricultural biodiversity, the following strategic principles are critical:

- Application of *agroecological principles* helps conserve, use, and enhance biodiversity on farms and can increase sustainable productivity and intensification that avoids extensification, thereby reducing pressure on off-farm biodiversity.
- *Participation and empowerment of farmers and indigenous peoples*, and protection of their rights, are important means of conserving agrobiodiversity in research and development.
- *Adaptation of methods* to local agroecological and socioeconomic conditions, building upon existing successful methods and local knowledge, is essential to link biodiversity and agriculture and to meet livelihood needs.
- Conservation of plant and animal genetic resources — especially *in situ* efforts — helps protect biodiversity for current livelihood security as well as future needs and ecosystem functions.
- Reforming genetic research and breeding programs to enhance agrobiodiversity is essential and can also benefit production.
- Creating a *supportive policy environment* — including eliminating incentives for uniform varieties and for pesticides and implementing policies for secure tenure and local rights to plant genetic resources — is vital to enhance agricultural biodiversity and food security.

Applying these basic principles can generate considerable public and private benefits. Specific practices that have proven effective for this purpose have been discovered and adapted in many areas of the world; they are listed in Box 35.2. Building on the knowledge of rural people has also proven to be effective in many contexts to make scientific advancements and to help ensure adoption and spread the benefits of agrobiodiversity innovations (Altieri and Merrick, 1988; Brookfield and Padoch, 1994; Michon and de Foresta, 1990). The use of such principles and practices has resulted in production increases in both small- and large-scale farms. Additional advantages include improvement of soil nutrient cycles and soil quality, added economic value, increase in sustainability and stability of systems, and alleviation of pressures on habitats.

Ecologically oriented Integrated Pest Management (IPM) methods illustrate well the use and benefits of biodiversity. IPM approaches usually highlight diversity as a key feature. Examples of best practices that are effective for insect management include:

BOX 35.2**KEY PRINCIPLES AND PRACTICES TO USE AND ENHANCE AGROBIODIVERSITY**

1. Management of diverse productive resources
 - a. Diversification and diversity enhancement
 - Temporal (crop rotation, sequences)
 - Spatial (polycultures, agroforestry, crop/livestock systems, intercropping)
 - Genetic (multiple species/varieties, multilines, interspecies)
 - Regional (i.e., variation in watersheds, zones)
 - b. Recycling and conservation of soil nutrients and organic matter
 - Plant biomass (green manures, crop residues, mulch, for diverse soil nutrients)
 - Animal biomass (manure/dung, urine, etc.)
 - Reuse of nutrients and resources internal and external to the farm (e.g., tree litter)
 - Integrate diverse plants or organisms (vermiculture, cover crops, mainly legumes)
 - c. Integrated Pest Management, stressing agroecological approaches
 - Natural biological control (enhancing natural control agents)
 - Imported biological control methods (e.g., add natural enemies, botanical products)
 - Diverse cropping/soil management methods to enhance natural fauna
 - Enhancing use of habitats and species in habitats
2. Conservation and regeneration of resources (stressing diversity aspects)
 - a. Germ plasm conservation (plant and animal species, landraces, adapted germ plasm)
 - b. Beneficial fauna and flora (multiple use vegetation, pollinators, natural enemies)
 - c. Soil health (erosion control, fertility enhancement, see recycling above)
 - d. Water (harvesting, conservation, management, irrigation)

Adapted from UNDP, 1995; Altieri, 1991.

- Multiple cropping and crop rotations, used to prevent buildup of pests
- Intercropped plants that house predators of insect pests
- Intercropped plants that act as alternative host plants for pests; for example, in Tlaxcala, Mexico, farmers grow lupinus plants in their corn to attract the scarab beetles, and thus protect corn; in California, vineyards and orchards use cover crops for similar purposes
- Use of certain plants as natural pesticides; for example, in Ecuador, castor leaves that contain a paralyzing agent are used to control the tenebrionid beetle
- Weeds that are used to repel insects; for example in Colombia, grassweeds are grown around bean fields to repel leafhoppers; and in Southern Chile, the shrub *Cestrum parqui* is used to repel beetles in potato fields
- Integration of biocontrol agents, including various parasites, animals, and fish that consume insect pests (such as use of ducks and fish in rice paddies in Asia)
- Elimination or reduction of pesticide use to avoid adverse agroecological effects on the insect diversity in agroecosystems

Effective disease management practices using agrobiodiversity include:

- Mixed crop stands that slow the spread of diseases by altering the microenvironment; for example, in Central America, cowpeas grown with maize are less susceptible to the fungus *Ascochyta phaseolorum* and to the cowpea mosaic virus
- Use of nonhost plants as decoy crops to attract fungus (or nematodes) (Altieri, 1987; Thrupp, 1996; UNDP, 1995, 1992; Lee, 1991; NRC, 1989)

Successful IPM programs in Asia illustrate that building agrobiodiversity — particularly using diverse beneficial insects — is a key ingredient of effective pest management in rice production. These initiatives, coordinated by the Food and Agriculture Organization along with governmental and nongovernmental organizations, have resulted in remarkable reductions of pesticide use and increased rice yields. In Bangladesh, for example, thousands of farmers involved in IPM projects

have also integrated fish into rice paddies, have adopted agroecological methods to restore the natural balance between insects and other fauna, and have planted vegetables on the dikes around the edges. This approach has increased rice yields, provided new sources of nutrition, and made hazardous chemical use unnecessary. For example, farmers in the pilot IPM program achieved an 11% increase in rice production while eliminating pesticides (Thrupp, 1996).

Practices for improving soil fertility and soil health also make use of agrobiodiversity. Good examples include:

- Compost from crop residues, tree litter, and other plant and organic residues
- Intercropping and cover crops, particularly legumes, which add nutrients, fix nitrogen, and pump nutrients to the soil surface
- Use of mulch and green manures (through collection and spread of crop residues, litter from surrounding areas, and organic materials and under crop)
- Integration of earthworms (vermiculture) or other beneficial organisms and biota into the soil to enhance fertility, organic matter, and nutrient recycling
- Reduction of agrochemicals — especially toxic nematicides — that destroy beneficial diverse soil organisms and organic material (UNDP, 1992; Altieri, 1991, 1987; Lee, 1991)

These kinds of soil management practices have proven effective and profitable in a variety of farming systems. Agroforestry illustrates *best practice* of using agrobiodiversity that also generates multiple benefits (Michon and Foresta, 1990). In many contexts, the integration of trees into farming systems is highly efficient, and the trees have multiple functions, such as providing fuel, fodder, shade, nutrients, timber for construction, and aiding soil conservation and water retention. (In West Sumatra, agroforestry gardens occupy 50% to 85% of the total agricultural land.) Complex forms of agroforestry exhibit forest-like structures as well as a remarkable degree of plant and animal diversity, combining conservation and natural resource use. (In Indonesia, for example, smallholder “jungle rubber” gardens incorporate numerous tree species.) Agroforestry systems in traditional forms also shelter hundreds of plant species, constituting valuable forms of *in situ* conservation (Michon and Foresta, 1990). Many of the practices noted here serve multiple purposes. For example, intercropping provides pest and soil management as well as enhanced income. For example, an estimated 70% to 90% of beans and 60% of maize in South America are intercropped with other crops. Farmers in many other parts of the world have recognized such diversity as valuable sources of soil nutrients, nutrition, and risk reduction — essential for livelihoods as well as other economic values (UNDP, 1995).

A common misperception is that agrobiodiversity enhancement is feasible only in small-scale farms. In fact, experience shows that large production systems also benefit from incorporating these principles and practices. Crop rotations, intercropping, cover crops, IPM, and green manures are the most common methods used profitably in larger commercial systems, both in the north and in the south (Box 35.3).

These situations illustrate *sustainable approaches to intensification*. Examples are found in tea and coffee plantations in the tropics and in vineyards and orchards in temperate zones (UNDP, 1995). In most large-scale settings, the change from monocultural to diverse systems and practices entails transition costs and sometimes trade-offs or profit losses for the first two or three years. However, after the initial transition, producers have found that agroecological changes are profitable as well as ecologically sound for commercial production and that they present new valuable opportunities.

USING PARTICIPATORY APPROACHES

The incorporation of farmers’ local knowledge, practices, and experimentation is advantageous in such efforts in agrobiodiversity and sustainable agriculture. Evidence shows that full involvement of local farming practices in agricultural research and development — through participation and

BOX 35.3
DIVERSITY IN LARGE-SCALE FARMING: COFFEE, TEA, AND GRAPES

India

The Singampatti Group of Estates is a large tea plantation (312 hectares) located in Tamil Nadu, India. A subdivision of the Bombay Burmah Trading Corporation Ltd., it emphasizes integrated, organic management. Several practices enhance diversity. Shade trees (e.g., *Grevilla robusta*, *Erythrina lithosperma*, and *Gliricidia sepium*) are cultivated along with commercial bush and tree species like cinchona and cardamom. The shade trees fix nitrogen, recycle nutrients, and prevent nutrient leaching. Open areas are planted with leguminous crops to control erosion and weeds. The tea bushes are planted in trenches, which are filled with compost, prunings, and castor or neem cakes to conserve water, increase nutrients, and reduce erosion. Cattle are a source of dairy products and income for the workers, and their dung is also used to produce gas. Labor conditions are also improved in this estate. The plantation houses many species of endangered animals, including tigers, the lion-tailed macaque, and the Malabar squirrel. The yields on this organic estate are 11% higher than in conventional production, but cultivation costs are about twice that of conventional tea production. The market price for organic tea is about 80% higher than conventional tea. The greatest concern of the plantation is the “loss of ... genetic diversity” of seed tea because of the tradition of planting clones. Although the clone has built-in resistance to blister blight, the managers fear that uniformity invites pests and diseases.

Mexico

Started in 1928, Finaca Irlanda, in the state of Chiapas in Mexico, is one of the oldest organic and biodynamic coffee estates in the world. The owner, a naturalist, is committed to maintaining diversity on his farm. The farm area is 320 hectares, and the main crops are Arabica and Robusta varieties of coffee, intercropped with cardamom and cacao. The farm also raises dairy and beef cattle. All waste from the farms' animals and plants are used to improve nutrients. More than 40 varieties of leguminous trees provide both shade and nitrogen. Pest control is practiced by maintaining crop diversity and by using biological agents, such as a wasp introduced in Mexico from Africa to control the fungi *Beauveria bassiana*. Indigenous wild animals that are threatened with extinction, such as puma, wild boar, pheasants, and toucans, are protected on the plantation. Some of the animals, such as the ocelot and gray fox, are used as natural predators to control pests such as rodents. Even though the gross income on this organic farm is much higher than on a conventional farm, the costs of maintenance are higher on an organic farm since it is more labor-intensive, so the profit margin is narrower. However, the coffee estate serves as a center for learning for other farmers and “serves as a tool for local extension.”

Vineyards

Large-scale commercial winegrape plantations, both in the north and the south, are increasingly turning to integrated crop/pest management methods and organic production. Renowned California wine companies (such as Fetzer, Gallo, and Mondavi) are converting from conventional chemical-intensive practices to diverse cover-cropping and other sustainable practices. They generally plant a mixture of cover crops between rows of vines; these include clovers, vetch, native grasses, radishes, and flowering grasses. The cover crops are then mowed and incorporated into the soil several times in a year. The cover crops have multiple purposes:

(Continued)

BOX 35.3 (CONTINUED)
DIVERSITY IN LARGE-SCALE FARMING: COFFEE, TEA, AND GRAPES

- Improving soil structure and water penetration, adding organic matter and roots to increase soil aeration, and decreasing tillage requirements
- Preventing soil erosion, partly by spreading and slowing the movement of water
- Improving soil fertility by adding organic material
- Helping control insect pests by harboring beneficial insect predators and parasites

This management method has proven both economical and sustainable. Grape growers in other countries have also begun to adopt such methods.

Cases adapted from UNDP, 1995.

leadership of local people — has had beneficial outcomes and needs to be done consistently. In other words, a farmer-friendly approach is essential to develop changes. Efforts to integrate agrobiodiversity in farming can be made more relevant by drawing on farmers' own informal knowledge and methods of experimenting with varieties and new practices. At the same time, the involvement of farmers as partners in research and development helps to ensure adoption of agroecological methods and can help to empower local people (Chambers et al., 1987; Rajesekaran, 1993; Thrupp, 1996; Altieri and Merrick, 1988).

In Mexico, for example, researchers worked with the local people to recreate *Chinampas* — multicropped, species-diverse gardens developed from reclaimed lakes — that were native to the Tabasco region and part of Mexico's pre-Hispanic tradition (Morales, 1984; Altieri, 1991). A similar project conducted in Veracruz also incorporated the traditional Asiatic system of mixed farming — mixing *Chinampas* with animal husbandry and aquaculture. These gardens also made more productive use of local resources and integrated materials from plant and animal waste as fertilizers. Yields of such systems equaled or surpassed those of conventional systems.

In Burkina Faso, on the other hand, a soil conservation and integrated cropping project in Yatenga province was based largely on an indigenous technology of Dogon farmers in Mali — building rock bunds for preventing water runoff (UNDP, 1995). The project added innovations — bunds along contour lines — and revived an indigenous technique called *zai*, which is adding compost to holes in which seeds of millet, sorghum, and peanut are planted. These crops are in a multicropping system. Animals are incorporated for their manure. In fields using these techniques, yields were consistently higher than in fields using conventional practices, ranging from 12% higher in 1982 to 91% in 1984. Yields in the *zai* method reached 1000 to 1200 kg/ha, compared to conventional yields of 700 kg/ha. Water management was enhanced and food security of the local people was also improved through this approach. The techniques have been widely adopted, covering 3500 hectares by the end of 1988 (UNDP, 1995).

In these efforts, the active participation of women has significant benefits. As managers of biodiversity in and around farming systems in many areas of the world, women can make important contributions and have a promising role in research, development, and conservation of agrobiodiversity. In Rwanda, for example, in a plant breeding project of the International Center for Tropical Agriculture, scientists worked with women farmers from the early stages of a project on breeding new varieties of beans to suit local peoples' needs (CGIAR, 1994). Together they identified the characteristics desired to improve beans, run experiments, manage and evaluate trials, and make decisions on the trial results. The experiments resulted in stunning outcomes: the varieties selected and tested by women farmers over four seasons “performed better than the scientists' own local mixtures 64% to 89% of the time” (CGIAR, 1994). The women's selections also produced substantially more beans, with average production increases as high as 38%.

The development of participatory approaches requires deliberate measures, training, and time to change the conventional approaches of agricultural R&D (Chambers et al., 1987; Thrupp, 1996). The application of such participatory methods improves the likelihood of adoption and success of agrobiodiversity efforts. Some basic principles of participatory research and development include joint problem-solving among farmers and scientists and responsiveness to local needs, mutual listening and learning between farmers and scientists, flexibility in selecting methods so that they are adjusted to local timing, and interdisciplinary and holistic perspectives (Chambers et al., 1987; Thrupp, 1996; Rajasekaran, 1993).

In sum, the use of these participatory approaches can help planners and communities to identify and develop best practices in sustainable production, meaning practices that are adapted to diverse local conditions, integrating agriculture with biodiversity while meeting socioeconomic needs.

CONFRONTING THE CAUSES OF AGROBIODIVERSITY DECLINE THROUGH POLICY CHANGES

Efforts to conserve and enhance agrobiodiversity must also address the underlying causes that accelerate its loss. Therefore, changes are required in agricultural policies, and commitments are needed by governments and institutions to confront the roots of the problems.

Several policy initiatives and institutions have already been established to address some of these policy issues. For example, several international institutions influence and regulate the use of plant genetic resources. Among the key players are the Consultative Group on International Agricultural Research, the International Plant Genetic Resources Institute, the Food and Agriculture Organization, the Commission on Plant Genetic Resources, and the World Intellectual Properties Organization. Recent important international conventions and agreements, particularly the Convention on Biological Diversity and the General Agreement on Tariffs and Trade, are also influential in setting guidelines that affect agrobiodiversity and use of genetic resources.

Concerns about the control of plant genetic resources have generated intellectual property regulations that govern the activities of public institutions and private companies and affect farmers' legal access to genetic resources. Gene banks conserve a remarkable diversity of plant genetic resources, and increasing numbers of agricultural research institutes have begun *in situ* conservation projects as well. Along with these large formal institutions, many NGOs and local farmer organizations are also increasingly involved in promoting the conservation and equitable distribution of benefits from agrobiodiversity.

Although many institutions are already actively involved, more coordination and work is needed *at all levels* to ensure effective reforms and agrobiodiversity conservation policies that benefit the public. Policy changes that attack the roots of problems and ensure citizens' rights can help achieve these aims. Strategies needing further attention include:

- Ensuring public participation in the development of agricultural and resource use policies
- Reducing or eliminating subsidies and credit policies for HYVs, fertilizers, and pesticides to encourage the use of more diverse seed types and farming methods
- Policy support and incentives for effective agroecological methods that make sustainable intensification possible
- Reform of tenure and property systems that affect the use of biological resources to ensure that local people have rights and access to necessary resources
- Development of markets and business opportunities for diverse organic agricultural products
- Changing marketers' and retailers' demands to favor diversity of food instead of standardized uniform products, and to reflect the actual diversity of preferences in human populations

Integrating biodiversity and agriculture will also require changes in agricultural research and development, land use, and breeding approaches. Such changes are urgently needed to overcome threats from the ongoing erosion of genetic resources and biodiversity. Experience shows that enhancing agrobiodiversity economically can benefit both small- and large-scale farmers, while at the same time serving the broader social interests of ecosystem health and food security.

ACKNOWLEDGMENTS

I am grateful to research assistants Rita Banerji, Dina Matthews, and Nabih Megateli, and to the following WRI colleagues for sharing their expertise and assistance: Walt Reid, Kenton Miller, Thomas Fox, Robert Blake, Arthur Getz, Nels Johnson, Paul Faeth, and Consuelo Holguin. I appreciate the support and comments from the World Bank Environment and Agriculture Departments, particularly to World Bank staff Jitendra Srivastava, Lars Vidaeus, and John Kellenberg (Kellenberg and Vidaeus, 1997). The comments of Calestous Juma, Miguel Altieri, Kristin Schafer, Daniel Debouck, David Williams, and Frances Seymour are also appreciated. I thank the Swedish International Development Cooperation Agency for support for the project on agrobiodiversity.

Evolving Opportunities for Management of Agricultural Landscapes and Ecosystem Health: Sustainability by Opportunity

Julian Dumanski, Steen Joffe, E.R. Terry, and Christian Pieri

INTRODUCTION

The intimate connections between economic growth and ecosystem health are becoming increasingly clear. Pursuing these concomitantly makes good business sense and provides for considerable growth opportunities. The only choices are short-term economic gains vs. long-term prosperity. The debate between “jobs or the environment” is becoming a debate of the past.

Agriculture and related biology-based land uses, including forestry and agroforestry, occupy major areas of the Earth’s land areas. Vitousek (1994) estimates that currently about one third to one half of the Earth’s nonglaciaded land areas are regularly managed, and up to 70% receive some degree of human intervention. How these lands are managed and the nature of management systems have a direct impact on the health of local and even global ecosystems and the services derived therefrom. These sectors have both major opportunities and responsibilities to ensure healthy ecosystems, but their current performance leaves much to be desired. Also, even though there are major trends toward global urbanization, the proper husbandry of rural landscapes has huge consequences to the provision of high-quality environmental services, such as clean water, to urban dwellers.

In the years since the 1992 Rio accords, economic growth of \$2.4 trillion and population growth of about 400 million have placed continuing pressures on the Earth’s natural resources and ecosystems (Brown et al., 1998). Tropical forest cover, wetlands, and other natural habitats have declined by 3.5%, carbon emissions have increased by 4%, while natural carbon sinks in soils and forests have been degraded or lost. As much as 10 million hectares of land are lost annually to severe degradation; we currently consume about half of the available fresh water, and more nitrogen is fixed by humanity than by all natural sources combined. Each year about 1000 new chemicals are released for use without any knowledge of their biological or synergistic effects, but only a few are regularly monitored. About one quarter of the bird species has been driven to extinction, and two thirds of the global fishery is fully exploited or overexploited.

We are transforming the Earth through land clearing, forestry, overgrazing, urbanization, mining, trawling, dredging, and so on. We remove species through overexploitation while adding new variations through biotechnology and other means. In these activities, we alter the major biogeochemical cycles, with impacts on the global climate and, increasingly, on global life-support systems. A statement from the Ecological Society of America (Lubchenko, 1998) asserts that

“environmental problems resulting from human activities have begun to threaten the sustainability of earth’s life-support system. Among the most critical challenges facing humanity are the conservation, restoration, and wise management of the earth’s resources.”

For the first time in history, global populations are of such magnitude that how we manage the land has a direct impact on the ecological services that support life on this planet. These services include purification of air and water, mitigation of floods and droughts, detoxification and decomposition of wastes, generation and renewal of soil and soil fertility, pollination of crops and natural vegetation, control of potential agricultural and forestry pests, dispersal of seeds, translocation of nutrients, maintenance of biodiversity (from which humanity derives major agricultural, medicinal, and industrial benefits), protection from harmful ultraviolet rays, stabilization of climate and moderation of climatic extremes, provision of aesthetic beauty, and support of human cultures. The importance of the global environment and ecosystem health is not an issue just for the resource industries. Increasingly, it is viewed also in the context of human health, world trade, social justice, and even national security (Lubchenko, 1998). As a society, we have never been at this point and we are unsure how to proceed.

Many of the problems arise from our penchant to control rather than live within the bounds of nature. In the process we create wastes and other excesses beyond the capacity of global and local ecosystems to absorb. Examples are soil erosion beyond the capacity to form new soil, CO₂ emissions beyond the capacity for carbon sequestration, pollution beyond the capacity of local ecosystems to filter the wastes, crop yields beyond levels of ecological baseline productivity, groundwater withdrawals beyond recharge capacity, and deforestation beyond sustainable yields. In most cases the problems arise with natural resources that are simultaneously viewed as depletable and renewable.

OPPORTUNITIES THROUGH THE INTERNATIONAL CONVENTIONS

Agriculture has historically been a major contributor to environmental degradation, but under improved systems of land management, it could be a major partner in the environmental solution. Land management decisions by individual farmers have implications for many environmental goods and services,* such as effects on *habitats* for fauna and flora, on a variety of *ecological services*, and on *amenity* or aesthetic values (Joffe et al., 2002). The impacts may arise directly on land managed for agriculture and livestock, or indirectly as a consequence of fragmentation and degradation of natural (less managed) habitats such as forests and wetlands. Many of the environmental benefits associated with sustainable land management will accrue locally and nationally. These include productivity effects such as pollination, biological control, nutrient cycling, and soil conservation, as well as off-site effects such as water regulation and supply, disturbance regulation, waste treatment, and flood control. Others are more clearly global, or at least *supranational* in scope, such as climate regulation, conservation of genetic resources with potential value in plant breeding or pharmaceuticals, international tourism, and transboundary water-mediated effects (Figure 36.1). Sometimes it is essential to promote intensified uses in more favored areas to reduce pressures on marginal, fragile environments.

Although the ecological functions are discrete, in practice the boundaries are far from clear-cut. The global environmental benefits and costs are those for which the global community, through international agreements and nascent trading frameworks, has expressed a willingness to pay. The rationale is on the grounds that:

- They would normally receive suboptimal attention within a national accounting and planning framework
- They are considered highly valuable or irreplaceable
- There is considered to be an unacceptable economic or humanitarian risk associated with further depletion.

* Also referred to in this chapter as *biodiversity goods and services*. The stock of natural resources from which these goods and services flow is also referred to as *natural capital*. An important principle is that sustainably managed land constitutes a form of natural capital from which a variety of key services may be derived in the long term.

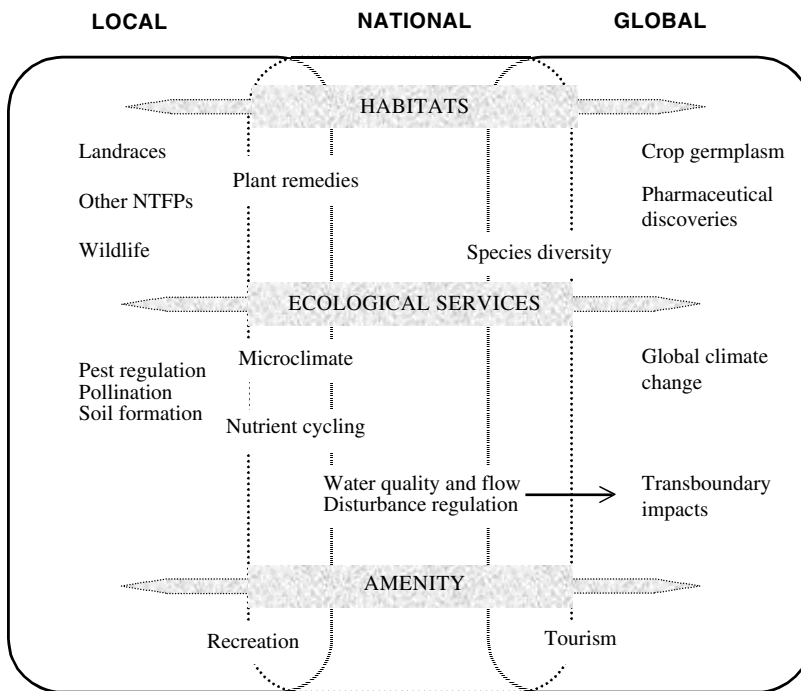

Figure 36.1 Examples of environmental benefits of sustainable land management: local, national, and global layers. (From Joffe, S. et al., *Opportunities to Capture the National and Global Environmental Benefits of Sustainable Land Management*, The World Bank, Geneva, in press.)

The three categories relate to (1) biodiversity (which embraces all goods and services associated with terrestrial ecosystems); (2) climate change (to do with concerns about emissions of greenhouse gases); and (3) international waters (where the negative impacts of depleted water flow or quality have serious transboundary implications). In all cases, there are direct linkages between global environmental change and land management, as well as opportunities under the international agreements to generate funding to achieve these objectives. The main relevant United Nations agreements and financing mechanisms are:

- Convention on Biological Diversity (CBD)
- Framework Convention for Climate Change (UNFCCC)
- Convention to Combat Desertification (CCD)
- Global Environment Facility (GEF)

Biodiversity and Agriculture

Biodiverse* ecosystems have a fundamental role and importance in sustainable development and provide many important benefits. They often contain a variety of economically useful products that can be harvested or serve as inputs for *production* processes. In addition, they provide *habitats* for flora and fauna and many key *ecological services* including those associated with nutrient cycling, disturbance regulation, availability and quality of water for agriculture, industry, or human consumption. Agriculture remains dependent on many biological services, such as provision of

* Biological diversity, often shortened to biodiversity, embraces the whole of *life on Earth*; it encompasses the variability among living organisms from all sources, including terrestrial and aquatic ecosystems and their ecological complexes. This includes diversity within species, among species, and of ecosystems. Decline in biodiversity includes all those changes that have to do with reducing or simplifying biological heterogeneity — from individual members of a species to regional ecosystems.

genes for improved varieties and livestock breeds, but also for crop pollination, soil fertility services provided by microorganisms, and pest control services provided by insects and wildlife. Conversely, sustainably managed agricultural landscapes are important to the conservation and enhancement of biodiversity. The term *agrobiodiversity* has been coined to describe the important subset of biodiversity that contributes to agriculture.

Climate Change and Agriculture

The linkages between agricultural land use and greenhouse gases relate to land use dynamics and management of rural landscapes. During the 19th century, rapid agricultural expansion, primarily in temperate regions, led to widespread clearing of land and losses of organic carbon in vegetation and soils. In recent years, deforestation in temperate regions has been reversed, but land conversions in the tropics has greatly expanded. This has become a major source of CO₂ emissions to the atmosphere, in the order of 1.6 Gt C or about 20% of total anthropogenic CO₂ emissions, the continuing net global loss of C from cultivated soils contributes approximately an additional 5% of anthropogenic CO₂ (Paustian et al., 1998). Also, agriculture contributes around 50% of anthropogenic CH₄ emissions globally, primarily from the rumen of livestock and from flooded rice fields, and about 70% of anthropogenic N₂O, largely as a result of nitrogen inputs (synthetic fertilizers, animal wastes, and biological nitrogen fixation) (IPCC, 1996).

International Waters and Agriculture*

More than 200 river basins are shared by two or more countries, accounting for about 60% of the Earth's land area. For example, at least 54 rivers cross or form international boundaries in sub-Saharan Africa (SSA), and 10 river basins have drainage areas greater than 350,000 km², affecting 33 SSA countries and Egypt.

Many of these shared watercourses are subject to alarming rates of environmental degradation that have strong linkages with land and water management. For example:

- Water withdrawals from lakes and reservoirs, water diversions, upstream dams, and lake reclamation for agriculture and aquaculture significantly deplete the size of the water bodies, destroying habitats for plants and animals and sometimes causing very high levels of salinization.
- Deforestation and land degradation in international watersheds such as the Nile, Niger, or Indus affect rainfall patterns, increase the range of local temperatures, and cause major variations in water flow and quality. Soil erosion leads to siltation and sedimentation of lakes and reservoirs, shortens their lifetimes, destroys aquatic environments, reduces the productivity of their ecosystems, and diminishes their flood control capacity.

LINKAGES BETWEEN SUSTAINABLE LAND MANAGEMENT AND THE INTERNATIONAL CONVENTIONS

Any measure of physical and biological sustainability must combine measures of productivity enhancement, measures of natural resource protection, and measures of social acceptability. Thus, it is essential to integrate concepts of those who focus on resource quality with those who emphasize economic productivity measures. Such an integrated approach is being developed as a *Framework for Evaluation of Sustainable Land Management* (FESLM) (Smyth and Dumanski, 1993).

The FESLM was developed through collaboration among international and national institutions as a practical approach to assessing whether farming systems are trending toward or away

* Although the other conventions clearly identify global environmental benefits, the benefits under the various agreements on international waters are primarily national and transboundary.

from sustainability. In this context sustainable land management (SLM) combines technologies, policies, and activities aimed at integrating socioeconomic principles with environmental concerns so as to simultaneously:

- Maintain or enhance productivity/services
- Reduce the level of production risk
- Protect the potential of natural resources and prevent degradation of soil and water quality
- Be economically viable
- Be socially acceptable

These factors are referred to as the five pillars* of sustainable land management, and they can be applied for sustainable agriculture. Performance indicators for each pillar are used for assessing the contribution of that pillar to the general objectives of sustainable land management. Thus, for any given agricultural development activity, sustainability can be predicted if the objectives of all five pillars are achieved simultaneously. However, as is the likely case in the majority of situations, only degrees of sustainability can be predicted if only some of the pillars are satisfied, and this results in partial or conditional sustainability. The recognition of partial sustainability, however, provides valuable direction for the interventions necessary to enhance sustainability.

The linkages between the pillars of sustainable land management, the agricultural challenges to achieve food security, and the international conventions are shown in Table 36.1. This shows that agricultural objectives, under food security, still emphasize productivity and economic returns, whereas the international conventions encompass environmental goods and services. This dichotomy, developed under the historic paradigm of economically driven national development and nonlimiting natural resources, is being challenged in many parts of the world. The evolving debate creates opportunities to better harmonize the common ground and to capture the synergy between sustainable land management and food production. However, this requires that agricultural systems recognize that sustainable systems must also ensure ecosystem health. Conversely, it requires that conservationists recognize that improved local, national, and global environmental management will not be realized without first securing economically viable rural economies.

Capturing the mutually reinforcing interactions (synergy) between these two aspects — the biophysical and the social — is the major opportunity for achieving the concomitant objectives of improved food security and ecosystem health. An important premise is that farmers normally are keen to manage their land better if they know how, but their management choices are often constrained by outside influences, including financial, marketing, and other constraints.

Table 36.1 Relationships among Sustainable Land Management, Food Security, and the International Conventions

	The Pillars of Sustainable Land Management				
	Productivity	Risk Management	Soil/Water Conservation	Economic Viability	Social Acceptability
Food security	X			X	X
Biodiversity	X	X	X		X
Climate change		X	X		X
International waters		X	X		X

* The pillars are carefully designed so that they can be aggregated into the physical, economic, and social dimensions of sustainability.

SELECTED EXAMPLES OF CONCOMITANT BENEFITS BETWEEN AGRICULTURE AND ECOSYSTEM HEALTH

Examples of natural resource improvements are becoming increasingly available, and much can be learned from the factors and processes that led to their success. In some cases, e.g., Brazil, millions of hectares have become more stable, productive, and sustainable under improved land management systems, whereas in others, e.g., Kenya, profound improvements in land quality have been made in local areas, but the technologies have not yet spread to large areas. In either case, success is triggered by two key components of true sustainability (El-Swaify et al., 1999):

- Resilience reflected in the inherent capacity of living systems, including soils, to regenerate themselves when suitably managed
- Deployment of the latent skills and enthusiasm of rural people when adequately informed, supported, and empowered

Parana, Southern Brazil

A microwatershed, integrated soil and water management program was adopted in 1987 as the basis for comprehensive statewide rural development. The basis of the program was to help local communities address their land management problems while improving the economic viability of their operations. Local decision making, planning, implementation, and monitoring (participatory approach) was ensured from the beginning. Integrated technology adoption (no magic bullet) was employed, based on conservation tillage and crop residue management, cover crops and crop rotations, and fertilizer and lime applications. Agricultural cooperatives provided efficient marketing and a reliable supply of required inputs. There was strong political support over the life of the program, and funding was provided by the state and complemented by additions from the World Bank and others. Within 5 years the program was working with local communities in 2100 small catchments, covering over 5 million ha and 165,000 farm properties. After 10 years of close monitoring, it was shown that the program was successful in controlling soil erosion, while agricultural incomes and rural economies improved. Also, it was shown that reduced sedimentation of waterways and improved water quality alone more than paid for the cost of the program.

Kakamega, Kenya

This is a program to assist self-help groups of small, resource-poor farmers to improve their livelihoods through soil conservation coupled with a strong marketing component in local and export markets to improve cash flow. The basic philosophy is that smallholder farmers can, with enhanced skills and their own enthusiasm, bring themselves out of poverty by making better use of the natural resources to which they have access, notably rainwater, organic materials, and soils. Products are marketed under predetermined *conservation supreme* standards, and under the *Farmers' Own* label, which enables the group to gain and retain market share. Since the start in 1993, 300 farm families in over 150 groups have joined the process, and participation is expanding rapidly. It is promoted by a small nongovernmental organization, the Association for Better Land Husbandry.

Gestion de terroirs, Sahelian West Africa

This approach evolved from the need to mitigate the serious impacts of land degradation and desertification on local livelihoods. The process introduced involves management of common lands by the community, under sets of locally adapted rules. The necessary steps are:

- Participatory diagnosis by local people to identify resource problems
- Election of a village or community committee responsible for resource management decisions
- Establishment of the committee's jurisdiction
- Preparation of a management plan, zonation, and allowable land uses
- Implementation, monitoring, and evaluation

The approach requires commitment to local decision making, local diagnosis of problems, and creation of clear lines of responsibility. Although not universally successful, the approach deals up front with issues of equity, power-sharing, self-reliance, and community environmental management. The approach has become widely endorsed by national governments and many donors.

Changar, Northwest India

The issues centered on severe land degradation, runoff, and erosion, especially on common land and state forestlands, due to inappropriate management of pastures and forests. The consequences were decreases in productivity and severe water scarcity in summer months. The project worked with local communities (570 villages with 140,000 people) on catchment-based development in the highly fragile sediment hills in the western Himalayan foothills. The project used a combination of interdisciplinary measures focused on better land management, effective soil and water conservation, and community-based forestry and animal husbandry. Through strengthening community organizations in land management, the project contributed to the simultaneous economic development and ecological stabilization of the region.

The Catskill Watershed, New York

New York City's water supply comes from a watershed in the Catskill Mountains. In recent times, poor land management in the upper watershed and contamination from sewage, fertilizers, and pesticides deteriorated the water quality to below EPA standards. The options were to build a super filtration plant at a cost of \$6 to 8 billion, plus annual maintenance costs of about \$300 million, or restore the ecosystem integrity of the Catskill watershed. The city chose to purchase the land in and around the watershed so that its use could be restricted (agricultural land uses that contributed to pollution were eliminated), and to upgrade existing treatment plants for a total cost of \$1 to 1.5 billion. Thus an investment of \$1 to 1.5 billion to restore ecosystem functions resulted in a saving of \$6 to 8 billion in physical capital. The project is expected to give a rate of return of 90 to 170% in a payback period of 4 to 7 years (Chichilnisky and Heal, 1998).

Summary

These few examples illustrate the opportunities that can be gained when the objectives of economic development and ecosystem maintenance are combined. In all cases, successes were achieved by building on the knowledge and capacity of rural communities to manage their resources better. New technologies were introduced in most cases, but only under conditions of local decision making. The international conventions provided an enabling policy framework and often incremental funding to cover initiation and transaction costs. These are classical win-win illustrations of sustainable rural development.

THE WAY FORWARD: SUSTAINABILITY AS OPPORTUNITY

The challenges for the future are considerable, but so are the opportunities. However, we need to change our perceptions and develop some new ways of thinking if we are to take advantage of the opportunities available. Sustainability will never be achieved by *overcoming constraints*, which has been the driving paradigm of the past. Overcoming constraints promotes the concepts of human dominance over nature and recognizes neither the limits nor the capacity of natural systems.

A more promising emerging paradigm, which is promoted by the World Bank, is *sustainability as opportunity*. This approach is based on the practical reality that sustainable agricultural systems require economic growth while simultaneously protecting natural resources.

A broadly acceptable definition of sustainable agriculture has been proposed by the Technical Advisory Committee (TAC) of the Consultative Group on International Agricultural Research (CGIAR):

Sustainable agriculture involves the successful management of resources for agriculture to satisfy changing human needs, while maintaining or enhancing the quality of the environment and conserving natural resources.

This is a practical approach to sustainability as it recognizes the legitimate use of natural and anthropogenic resources for satisfaction of human needs, but it cautions against the exploitation of these resources in a manner that would degrade the quality and potential of the resources on which production depends. More important, the definition recognizes that human needs change and, therefore, the systems of production also must change. This definition embodies the concepts of system flexibility and natural resource resilience as primary criteria for achieving sustainability.

A logical outgrowth of this approach to sustainability leads to the concept of sustainability as opportunity.* This can be defined as ensuring that the choices for future production systems are not reduced by decisions made in the present.

That view of sustainability is based on the following:

- Sustainability will not be achieved by overcoming constraints, but rather as a process to concomitantly capture economic and environmental opportunities. For example, investment in new knowledge has allowed many traditional farming systems to become more sustainable in the face of rapid population growth, by shifting from extensification based on expanding land area, to intensified use of existing land area.
- Considerable substitution is possible in agricultural systems (the physical, biological, economic, and social dimensions of sustainability), but the substitution is not perfect. For example, most agricultural production systems allow for a certain amount of input substitution, such as among different sources of crop nutrients, substitution of labor for land, and so forth. Such substitutions may contribute positively to sustainability as long as the impacts of the substitution are reversible and they contribute to more resilient and flexible systems. Substitutions that lock a system into a restricted range of options, e.g., reduced agrobiodiversity, monocropping, etc., will not lead to sustainability.
- Agricultural systems with the capacity to change — that is, the capacity to remain flexible and resilient in response to major influences such as shifts toward a global market, important recent advances in science and technology, and changes in labor availability — will ensure more sustainable systems. Static agricultural systems are not sustainable systems. These continual shifts and adjustments often lead to new opportunities to intensify production, increase productivity, and exploit emerging commodity markets. In other cases, negative market forces and adverse natural conditions beyond the control of producers will lead to transition out of agriculture and a search for off-farm employment.
- Whereas the principles and criteria in sustainable land management systems are universal and transferable, technologies and application must be local. In sustainable agriculture there are no single solutions, shortcuts, or magic bullets. In fact, the magic bullet approach must be consciously avoided.** Blanket recommendations are rarely successful, and innovations found to be successful in one area will likely have to be modified somewhat to be successful in another. For example, zero-till is a successful technology contributing to sustainable land management,

* Sustainability as opportunity was first proposed by Serageldin (1995) as a definition for sustainable development: sustainability is to leave future generations as many, if not more, opportunities as we have had ourselves.

** For the extension agent, this means the requirement to work more actively in a participatory approach with farmers and to develop an enabling atmosphere for local farmer innovation regarding what will work and what is not acceptable. However, providing technological backup to the store of local farmer knowledge is often a critical component.

but some local modifications of the technology are almost always required for it to be successful. However, the basic principles of zero-till — that is, minimal disturbance of the soil surface and maintenance of continual soil cover — are universal and therefore transferable.

- The primary agents of change toward sustainable agricultural systems are the rural communities (farmers, pastoralists) who depend on the land for their livelihoods, and the primary emphasis is on community-based or farmer-centered interventions. Rural families make decisions about production practices and land use in line with their objectives, production possibilities, and constraints; but these decisions are part of a wider process to secure and improve the family's food security and livelihood. They are in turn influenced by government policies and market forces.
- Many of the environmental benefits associated with sustainable land management, such as pollination, biological control, nutrient cycling, soil conservation, water quality, waste treatment, etc., accrue locally and nationally. Others are more clearly global, or at least supranational in scope, such as climate regulation, conservation of genetic resources of potential value in plant breeding or pharmaceuticals, international tourism, and transboundary water-mediated effects. Policies and programs designed to capture economic growth as well as environmental benefits are more likely to ensure sustainability.
- A strong local and national commitment toward sustainable land management is required to bring down transaction costs and to capture national and global environmental benefits. In this respect, functioning rural markets for traditional goods and services, an appropriate system of land tenure and property rights, and a broadly enabling policy framework for natural resources conservation are prerequisites to the capture of global flows.

CONCLUSION

The need for agricultural growth strategies that can achieve the required growth and food security, while reversing the historical conflict with natural resources conservation, is now a front-line issue for global sustainable development. It is widely recognized that agriculture and environmental management are inseparably linked and that tackling problems of natural resource degradation must be seen as part of a wider set of actions to revitalize the rural sector as a whole. Promoting rural development strategies that have win-win outcomes for agricultural livelihoods and the environment is mainstream policy for the World Bank and other major development agencies and is considered vital to provide a sustainable basis for future productivity growth and poverty alleviation.

The Bank's Rural Vision to Action (World Bank, 1997) and related policies establish sustainable land management at the heart of such strategies. It is increasingly recognized that well-designed, farmer-centered, sustainable land management interventions have distinct advantages as vehicles for pursuit of joint agriculture-environment objectives. The pillars of sustainable land management (Smyth and Dumanski, 1993) are the application of agroecological principles to farming; an emphasis on human resource development and knowledge-based management techniques; a participatory and decentralized approach; the value placed on natural and social capital enhancements in addition to economic efficiency gains; and the role of strong and self-reliant rural institutions.

Agriculture that is truly sustainable will not be business as usual. It will be a type of agriculture that will provide environmental, economic, and social opportunities for the benefit of present and future generations, while maintaining and enhancing the quality of the resources that support agricultural production. This will not be the agriculture of today or of the recent past, with its emphasis on *maximizing* yields and economic returns, but rather one with the objectives of *optimizing* productivity and conserving the natural resource base. The objective of optimization implies *trade-offs* in the production systems to ensure maintenance of environmental quality and global life-support systems. Experience indicates that these trade-offs will be defined and implemented voluntarily by farmers and other rural land users, or they will be implemented through policies and legislation. Society is beginning to demand that agriculture

become more than simply putting food on the table; it is beginning to demand that it also becomes the steward of rural landscapes.

The objective is to evolve sustainable systems in which appropriate technological and policy interventions have created resilient production systems that are well suited to local socioeconomic and physical conditions and that are supported by affordable and reliable policies and support services. However, these systems cannot be static systems but must be carefully designed to be flexible and responsive to change — that is, systems in transition. Sustainability of any system cannot be ensured unless the production technologies and associated management practices continuously evolve to accommodate changes in the agroclimatic, economic, and demographic environment in which agricultural intensification is undertaken. The appropriate level of analysis of sustainability is at the level of the cropping or farming system on a relatively homogeneous agroecological resource base, within which similar choices of crop and livestock management decisions can be made.

Agricultural sustainability is a concept that is continuously evolving, and therefore it is difficult to define and measure. Because it reflects our understanding of systems that in themselves are in continual transition, sustainability should be approached as a concept to strive for, such as social well-being, rather than an objective that can be measured with common analytical techniques. In this sense, the ability to track the performance of core indicators toward this goal is more useful than setting specific targets to be achieved (although setting targets is often useful to identify levels of satisfaction). This is not unlike tracking the performance of national economies, where, in most cases, this is done simply to know how we are doing and in what direction the economies are trending.

The Ecological Footprint as Indicator for Sustainable Development — Results of an International Case Study

Detlef P. van Vuuren, E.M.W. Smeets, and Hans A.M. de Kruijf

INTRODUCTION

The topic of the conference session for which this contribution was originally made was formulated as an objective: *securing everybody's quality of life within the means of nature*. This objective, although sometimes worded differently, is also referred to as *sustainable development*. The concept of sustainable development has become (at least officially) a widely accepted goal of national and international policy making, since it was used by the World Commission on Environment and Development (WCED) to advocate a kind of development that would not only aim for economic objectives per se but also include a fuller sense of human and ecological well-being (WCED, 1987). Since 1987, considerable attention has been paid to developing indicators that could support decision making in this context (e.g., Hammond et al., 1995; Meadows, 1998). The ecological footprint (EF) has frequently been mentioned as one of these. The EF is defined as the amount of the world's environmental resources required to support the consumption of a defined population regardless of where this capacity is used (Wackernagel and Rees, 1996).

Most attention to the EF has come from educational and environmental organizations. They have used the results of the EF to convey the message that at the moment: (1) human consumption requires more natural resources than can be provided in a sustainable way; and (2) many industrialized countries use a disproportionately large share of available resources. The strongest use of the EF so far is as a heuristic device, as its results are readily understandable and can be directly related to personal activities.

However, the question is now raised whether EF information can also be used in decision-making processes (for instance, the question was asked explicitly in the Netherlands by the Minister of the Environment; Pronk, 1998). For this purpose, it should comply with strict criteria with respect to measurability, usefulness/policy relevance, and analytical soundness. In this chapter, we will use the results of an application of the EF to Benin, Bhutan, Costa Rica, and the Netherlands to discuss whether the EF could be a useful sustainable development indicator. The methodology of the case studies and its results have been described earlier (Van Vuuren and Smeets, 2000; Van Vuuren et al., 1999). Following a brief introduction to sustainable development and sustainable development indicators, the main results of the case study are discussed. Finally, we draw attention to both strong and weak points of the EF based on this application and the ongoing discussion in the literature. The focus of this discussion is on the environmental aspects of sustainable development.

SUSTAINABLE DEVELOPMENT AND SUSTAINABLE DEVELOPMENT INDICATORS

Although a large body of literature exists on different definitions and interpretations of sustainable development, no definition has attained general approval and support. Most scholars now seem to agree that sustainable development encompasses economic, ecological, and social objectives. This is elegantly shown by the Sustainable Development Indicator Framework proposed by the Balaton Group (Meadows, 1998) (Figure 37.1). In this framework, well-being is seen as the ultimate end of development supported by various types of intermediate means (infrastructure, social relationships) and ultimate means, which are natural resources. Sustainable development can now be defined as the long-term growth potential of all these types of capital (Serageldin, 1996). In many cases, however, development decisions imply value-laden trade-offs between different types of capital. Obviously, it is clear that any useful set of sustainable development indicators would consist not only of the economic indicators mostly used now but also include indicators capturing the ultimate means and ends of development. Such a set should show us whether imbalances develop between the different types of capital or whether critical limits are passed.

The objective of sustainable development can also be characterized by a growing awareness of and responsibility for the impacts of human actions in space and time. For environmental capital, for instance, sustainable development requires an additional focus on long-term effects and management of global environmental resources, in combination with more traditional policies looking at short-term effects and the direct environment. Obviously, this is a difficult task as everybody will automatically spend the most time thinking about here and now. Indicators that are able to bridge the gap between these different levels of abstraction could be very important in motivating people to action.

These notions have also been the basis for the project Multidisciplinary Indicators for Sustainable Development (Van Vuuren and de Kruijf, 1998). Within this project, institutes in Benin, Bhutan, Costa Rica, and the Netherlands have been collaborating to develop indicators for sustainable development. These countries are all relatively small and, thus, potentially very open to influences from outside their national borders. This is certainly the case for the Netherlands, which is densely

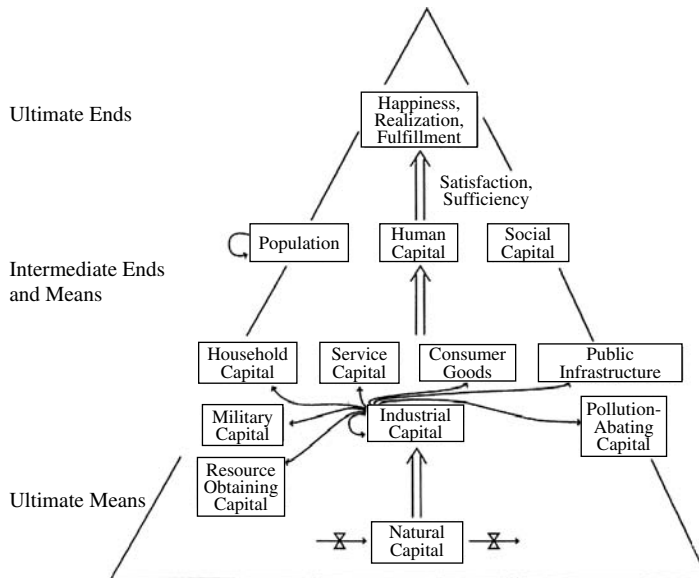

Figure 37.1 Sustainable development indicator framework of the Balaton Group. (From Meadows, D., *Indicators and Information for Sustainable Development: A Report to the Balaton Group*, The Sustainability Institute, Hartland Four Corners, VT, 1998. With permission.)

populated and highly industrialized. In many other respects, the countries are totally different — which makes the project interesting as a potential case study for indicators meant to be universally applicable. The collaborating institutes decided to apply the EF concept in a case study to consider whether this indicator could be used further within the project.

MAIN RESULTS OF THE EF APPLICATION IN BENIN, BHUTAN, COSTA RICA, AND THE NETHERLANDS

The methodology of the calculations shown here is based on Wackernagel and Rees (1996) and Wackernagel et al. (1997). Land use and carbon dioxide emissions are attributed to consumption in each country on the basis of production, trade, and consumption data. However, we have made two important modifications (Figure 37.2):

- We disaggregated the indicator into separate indicators for land and carbon dioxide emissions, thus avoiding the controversial topic of combining real land use and land equivalents for carbon sequestration.
- We calculated land use on the basis of both local yields and global average yields to show the real land use of countries vis à vis a more comparable land-use measure.

The data were collected from FAO and national data sources (Van Vuuren et al., 1999).

Looking at overall land use, the results of our assessments indicate that total land use in the four countries increased between 1980 and 1994 (Figure 37.3). This is obviously a disturbing trend, because globally land is clearly a limited resource. Comparing land use of each country to its surface area, one can see that, for the Netherlands, more land is used than is domestically available (Figure 37.4). This was expected in view of the high population density. For consumption in the other three countries, less land is required than is available within their borders. This results mainly from relatively large areas that are still undomesticated and indicates the trade-off between the size of the EF in land use and protection of biodiversity by large natural areas. In addition, in Benin and Costa Rica, much land is allocated to export of fruit and coffee (thus needs to be attributed to land use of other countries).

Both differences in consumption per capita and productivity determine the size of the total land use. These differences in productivity complicate comparisons among different countries because productivity is influenced (actively) by human management factors and (passively) by natural circumstances (such as soil and climate). Thus, countries with less favorable conditions for agriculture (savannah, alpine areas) necessarily use more land per unit of consumption and thus have higher EFs, if calculated on the basis of real productivity. In most current EF work, the issue is altogether avoided by calculating *virtual land use* for all types of consumption directly based on global average yields. For national governments, however, land use based on local yields might be much more relevant because the calculated area is in that case equal to a real, touchable area.* The results differ enormously; in fact, on the basis of local yields, per capita land use is smallest for the Netherlands (0.7 ha per capita), while per capita land use of Benin, Bhutan, and Costa Rica are, respectively, 0.7, 0.9, and 1.2 ha. If, instead of local yields, global average yields are used, the EF directly reflects consumption levels: it is smallest for Bhutan (0.6 ha), followed by Benin (0.7 ha), Costa Rica (1.7 ha), and the Netherlands (3.0 ha). The reason for this is that agricultural production per hectare is much higher in the Netherlands than the global average yields.

The EF can also be calculated for carbon dioxide emissions. Here, the EF increased for all four countries both in per capita and absolute terms between 1980 and 1994. For the Netherlands, the EF for 1994 was 8.9 tons of carbon dioxide per capita, two times the global average level. The EF for the Netherlands was, however, 20% lower than the domestic emissions of the country (due to net exports of energy-intensive products). Emissions of the other three countries were below the global average: 2.5 ton per capita and less than 0.1 ton per capita for Benin and Bhutan, respectively.

* Local yields are defined as the real yields for each product in the country of production.

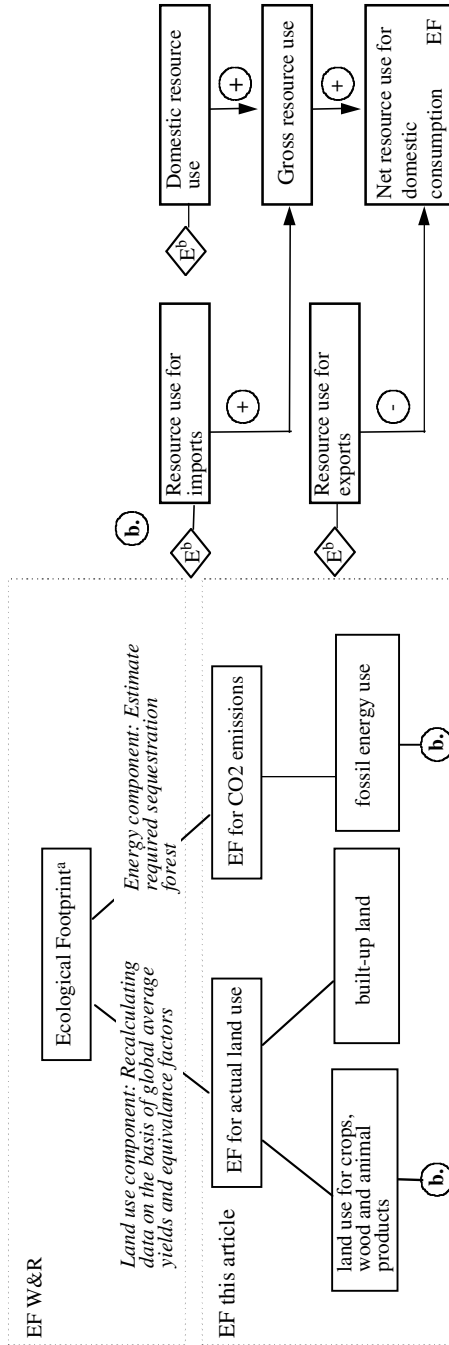

Figure 37.2 Components of the EF indicating differences in focus between Wackernagel and Rees and this chapter. E indicates efficiency of resource use; averages are either local or global. (From Van Vuuren, D.P. and Smeets, E.M.W., Ecological footprints of Benin, Bhutan, Costa Rica and the Netherlands EF, information to stimulate debate or debatable information *Ecol. Econ.*, 34:115–130, 2000. With permission.)

Figure 37.3 Net land use for agricultural products and wood. The horizontal line indicates the actual size of each country; nonfood includes land use for cotton and rubber. (From Van Vuuren, D.P. and Smeets, E.M.W., Ecological footprints of Benin, Bhutan, Costa Rica and the Netherlands EF, information to stimulate debate or debatable information *Ecol. Econ.*, 34:115–130, 2000. With permission.)

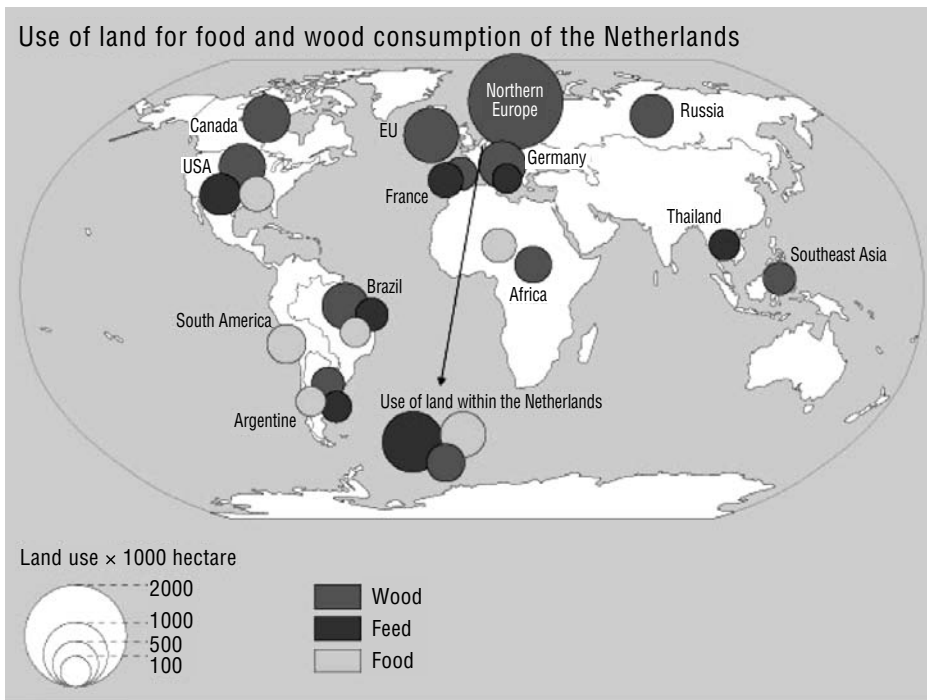

Figure 37.4 Land use for food and wood consumption of the Netherlands. (From RIVM, *Milieubalans 1999 [Environmental Balance]*, National Institute of Public Health and the Environment, Bilthoven, The Netherlands, 1999.)

Figure 37.5 Aggregated EF following definition of Wackernagel and Rees, 1996. Land use is included using real land use and global average yield as a base. The horizontal line indicates the level considered to be sustainable on the global scale by Wackernagel et al. (1997). Be = Benin; Bh = Bhutan; CR = Costa Rica; NL = Netherlands. (From Van Vuuren, D.P. and Smeets, E.M.W., Ecological footprints of Benin, Bhutan, Costa Rica and the Netherlands EF, information to stimulate debate or debatable information *Ecol. Econ.*, 34:115–130, 2000. With permission.)

In addition to these EFs for specific resources, the aggregated EF (according to Wackernagel and Rees, 1996) can now be calculated by translating carbon dioxide emissions into the hectare carbon-sink forest that would be required for sequestering these emissions. The resulting figures can be compared to the globally available capacity — that is, the available ecologically productive land (Wackernagel et al., 1997) (Figure 37.5). The following results arose:

- The Netherlands has the largest EF, independent of the question of whether global average yields are used.
- The EF of the Netherlands is made up largely by carbon dioxide emissions — which are indeed considered by many in the Netherlands to be the most important environmental problem. In the other three countries, land use represents the largest pressure — again according to our expectations.
- The EF per capita of the Netherlands is larger than the per capita globally available capacity.
- The EF of Costa Rica is currently near this level. Trend extrapolation indicates that, if unabated, the EF of Costa Rica will rapidly increase. This suggests that industrializing low-income countries such as Costa Rica approach the high consumption levels of high-income countries. Benin and Bhutan are still far below the global available capacity.

DISCUSSION ON THE POTENTIAL USE OF THE EF

In the previous section we have shown that the EF can be actually applied to different countries on the basis of available data. The numbers give interesting information — but the question still remains whether it might also be useful for policy-making purposes. On the basis of our work and current discussions on the EF, particularly in the Netherlands, the following conclusions could be drawn:

1. The Indicator Should Be Part of a Larger Set

EF-type indicators should be part of a larger set of indicators, as they cover only some of the environmental topics and do not contain any information on how biophysical constraints can be linked effectively to economic and social policy or on social aspects of sustainable development.

2. The Use of the EF Is Value Related

In the Netherlands, the Minister of the Environment recently indicated his interest in the EF and asked an important advisory council to look deeper into the issue. A dynamic debate started, part of which could be followed in the international literature (van den Bergh and Verbruggen, 1999). Several nongovernmental organizations (NGOs) and dedicated scientists promoted greater use of the EF for policy development — while, in particular, some environmental economists vigorously rejected it. How could such a lively debate come about? The debate reflected the fact that indicators are not absolute truth machines but function within a network of values, worldviews, and paradigms (see Rotmans and de Vries, 1997).

In this debate, the economists' position includes the assumptions that resources (e.g., the types of capital in Figure 37.1), in principle, can be substituted, and that sustainable development is the optimal allocation of resources. Necessarily, there is less focus on absolute limits — in contrast to most of the EF literature, which has tended to emphasize limits. The implicit weighting method within the EF was regarded by the involved economists as too rigid because it does not reflect changes in scarcity (Verbruggen, 1999). The economists in the debate indicated that the most important criterion for judging the EF is *scientific soundness* (van den Bergh and Verbruggen, 1999); according to them, the EF fails to meet this criterion. Finally, they argued that the EF implicitly promotes autarchy or is against trade. However, there is nothing on how the EF is calculated that substantiates this argument. If international trade is truly based on ecologically comparative advantages (including the effects of transport), it will result in a lower overall EF. Their argument must, therefore, be directed against some of the EF literature, which has put forward self-sufficiency as a mean of restoring the direct link between environmental pressure and consumption.*

In contrast, the NGOs began their argument from the assumption that limits are a crucial aspect of ecology. Therefore, for sustainable development to occur, all resources need to be protected. Moreover, this position is combined with the view that equity is an important aspect of sustainable development. It is clear that the EF does exactly fit into this position (focus on environmental resources, emphasis on personal and local responsibility). But above all, they will argue that the most important criterion to judge the EF as an indicator is its power to motivate (Juffermans, 1999).

Fortunately, all parties seem to disagree less on policies. All agreed about a need to strengthen policies and research with regard to (1) environmental consequences of consumption patterns, (2) environmental impacts of trade, and (3) current state of natural resources. One could say that despite all discussion, the EF stimulated a debate on certain issues that previously had not had a high priority on the policy-making agenda.

The final conclusion reached in the advisory council (in which both parties mentioned above participated) is that the EF is not a policy indicator. The most important reasons were that the EF is too aggregated and at the same time leaves out several issues considered to be important for sustainable development (VromRaad, 1999). Immediately after this conclusion, however, the council also concludes that the issues raised by the EF are very important and the council in fact welcomes the boost to the discussion on sustainable development in the Netherlands given by EF. The council also acknowledges that the EF can play a role in raising awareness by application at the individual level. Finally, it should be noted that in the state-of-the-environment reports and the environmental statistical compendium of the Netherlands, EF-type indicators are now regularly used.

* That some of the proponents of the EF indeed emphasize production and consumption within each range can be seen in Ferguson (2001) and the response by van Vuuren and Smeets (2001).

3. From a Policy Perspective, the EF Is Able to Generate Some Relevant Information; but There Are Obstacles to the Approach

On the basis of our own work, we conclude that EF-type research could be an assessment framework complementing or adding to production or domestic pollution-oriented approaches. EF-type indicators are attractive because they highlight several interrelated topics of sustainable development:

- *Focus on consumption:* Traditional environmental policies have often aimed at reducing emissions on the production side of the economy (industry, business, agriculture). However, state-of-the-environment reports on the national, continental, and global scale (RIVM, 1998; EEA, 1998; UNEP, 1997) indicate that, for several environmental issues, results of such policies are partly or completely offset by increased consumption (for example, global warming). The EF focuses on consumption and is able to quantify the consequences of reallocation of environmental pressures, squandering of resources, and impacts of the size and composition of consumption patterns.
- *Focus on renewable resources:* An attractive attribute of the EF is its focus on resources that are key to sustainable development (land, carbon dioxide emissions). The UNEP Global Environment Outlook, for instance, concluded that land — suffering from degradation and becoming increasingly scarce — is one of the key resources for sustainable development in most of the world's regions (UNEP, 1997).
- *Distribution of available environmental resources:* The EF addresses the current distribution of resource use by calculating the per capita footprint for individuals, cities, or countries and comparing them to a global averages. In the context of ongoing climate change negotiations, this is already an important issue, with proposals to base burden-sharing initiatives in the next century on an equitable distribution of per capita emissions rights.
- *Communication and proactive aspects:* Results of the EF are relatively easy to visualize. Moreover, since the EF can be calculated on a per capita basis, EFs can be compared among countries, with a global average or a potentially more sustainable level. These features allow for powerful communication of the results; this explains its popularity among advocacy groups.
- *Aggregation:* Different authors have argued for the development of aggregated environmental indicators that are able to give a rough overview of environmental pressure or sustainability (for example, Jesinghaus, 1996). At the same time, aggregation is extremely difficult and controversial for complicated systems (such as the environment) since there are no general scientific rules or theories to evaluate different impacts from an ecological perspective.

There also remain some obstacles to overcome with the method. Issues in particular need of attention are:

- *Possibilities and limitation of aggregation of resources:* van den Bergh and Verbruggen (1999) argue that by using land as an aggregated indicator, the EF implies that we are talking of a specific environmental resource (land); actually it represents (at least partly) a hypothetical amount of land. As we have shown in our work, it is possible to avoid the issue of aggregation by focusing not on the aggregated EF but on its components in their own typical units. We think this improves the policy relevance of the indicator.
- *Differences in agricultural productivity in international comparisons:* This chapter has shown the enormous consequences of using local instead of global average productivities.
- *Accounting for unsustainable use of resources in the context of the EF:* In calculating EFs, no distinction is made between sustainable and unsustainable use of land; this limitation might lead to the paradoxical situation that unsustainable agricultural production methods (contributing to soil degradation) decrease EF because of higher yields.

Table 37.1 summarizes some of the attractive attributes and obstacles found. Overall, we conclude that the EF has been a positive force in evoking a debate on important sustainable development issues. As a communication instrument, the EF can be very useful. For policy purposes, the focus is the underlying information, not the aggregated EF; overcoming the obstacles identified will improve its analytical soundness.

Table 37.1 Overview of Attractive Attributes, Limitations, and Obstacles of the Ecological Footprint

Attractive Attributes	Limitations and Obstacles
Vivid metaphor	Aggregation/false concreteness
Focuses on consumption	Agricultural productivity
Focuses on key resources (implicitly land and carbon dioxide)	Multifunctional land use
Connects environmental problems and distribution of material wealth (built-in references)	Unsustainable land use
Easy to communicate	Does not and will not include all relevant resources
Aggregates	
Consistent accounting scheme

PART II

Issues and Methods

SECTION II.1

Managing for Biodiversity

Overview: Managing for Biodiversity

Jonna A.K. Mazet

In this age of technology and information, humans are better equipped than ever before to assess the impact that our activities have on the Earth and its ecosystems. Our ability to investigate these changes has rapidly increased our awareness of the speed and scale of the current progression of environmental degradation. Fortunately, that awareness has directed us to use our newfound tools, not only to monitor the damaging processes, but also to evaluate strategies to minimize environmental degradation and initiate restorative processes.

In North America, management methods intended to reduce and resolve environmental problems traditionally have followed a resource path; in other words, agencies were created to protect and regulate the use of land, air, and water resources, as well as to manage specific flora and fauna. The effectiveness of these traditional methods has recently come into question because of our failure to protect our ecosystems as a result of focusing on one piece at a time. Major reorganizations of large bureaucratic machines have begun to change the management focus to the larger reticulated systems in which survival of one species requires the vitality of numerous others. This major management shift, driven by evidence of dwindling biodiversity, is definitely encouraging, but requires such an enormous cultural change in existing institutions that its benefits may not be achieved for decades.

In the meantime, scientists continue to use technological innovations to direct management resources in the most beneficial fashion and to decrease the lag time between investigative processes and changes in environmental policy. Unfortunately, humans are, and will continue to be, the source of the majority of our ecosystem problems. No matter how much we want to reduce our impact on the Earth that sustains us, we cannot diminish the innate drive to propagate and strive for a more comfortable lifestyle. Ironically, these innate forces will no doubt result in the loss of the biodiversity on which we are dependent for healthy and aesthetically pleasing lives. Thus, we must continue to seek solutions to environmental problems that protect the reticulated systems of which we are only a part.

The chapters contained in this section focus on balancing solutions and application of technologies to respond to the rapid loss of biodiversity on four continents. Development of progressive solutions like these must continue and should be encouraged by governing bodies responsible for ecosystem management. As individuals, we must also recognize our impacts on the systems in which we thrive and must teach our children to respect the Earth as a whole rather than only the little piece in which they live.

The Greater Addo National Park, South Africa: Biodiversity Conservation as the Basis for a Healthy Ecosystem and Human Development Opportunities

Graham I. H. Kerley, André F. Boshoff, and Michael H. Knight

INTRODUCTION

The recognition that ecosystem health is strongly linked to human welfare, and that many ecosystems have been heavily degraded under human domination — resulting in reduced capacity to support human populations — is a dominant feature of the environmental debate (e.g., Rapport et al., 1998). This has led to a search for ecosystem management strategies to maintain ecosystem health, ranging from water pollution management to disease control and sustainable resource utilization. To some extent this process has been hampered by the inability to look beyond conventional management strategies in order to recognize and develop new opportunities for extracting resources from ecosystems, while maintaining these systems in a healthy and functional state. This deficit is particularly apparent in rangeland ecosystems that traditionally have been used for domestic herbivore production through pastoralism, despite considerable evidence of the threats to ecosystem health that this strategy imposes (e.g., Fleischner, 1994). We present here the background of ecosystem degradation and loss of ecosystem resources due to pastoralism in the Eastern Cape Province (hereafter “Eastern Cape”) in South Africa (Figure 39.1), an area of spectacular biodiversity, and assess the consequences of alternate management strategies. We show how an initiative to address these problems, based on the recognition that biodiversity conservation yields tangible human development opportunities that include the full range of ecosystem services, is developing.

DESERTIFICATION OF THE THICKET BIOME

The Thicket Biome, one of the seven terrestrial biomes in South Africa (Low and Rebelo, 1996), is largely confined to the hot, dry valleys of the Eastern Cape, hence its alternative name of Valley Bushveld (Acocks, 1975). In the pristine state, thicket is characterized by dense, low-growing (3 to 5 m) vegetation that includes small trees, woody and succulent shrubs, grasses, lianas, forbs, and geophytes (Low and Rebelo, 1996). These plants tend to be evergreen; succulence and/or spinescence is common, and they form a virtually impenetrable, spiny thicket (Everard, 1987). The high diversity of growth forms reflects the transitional nature of these thickets, which occur at the interface of four major phytochoria or phytogeographical regions

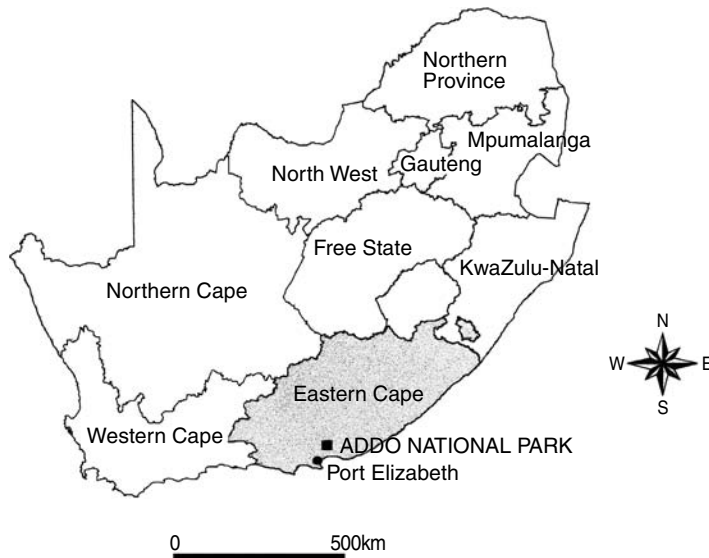

Figure 39.1 The nine provinces of South Africa and the location of the City of Port Elizabeth and the Addo Elephant National Park.

(Cowling, 1984; Lubke et al., 1986). The wealth of growth forms and the transitional nature of the thicket result in very high plant diversity, and these may be the most species-rich formations of woody plants in southern Africa (Hoffman and Everard, 1987). In addition, these thickets form part of the IUCN-recognized Albany center or *hot spot* of biodiversity (Cowling and Hilton-Taylor, 1997). At a regional level these thickets have the highest endemism (30%) within the Eastern Cape (Lubke et al., 1986). This endemism is not symmetrical across the growth forms; it is highest among the succulent forbs and shrubs and geophytes (Hoffman and Cowling, 1991; Moolman and Cowling, 1994).

In addition to the high floristic diversity, the Thicket Biome historically supported a high diversity of vertebrate herbivores, including charismatic species such as the African elephant, *Loxodonta africana*, and black rhinoceros, *Diceros bicornis*, as well as a range of smaller species such as Cape buffalo, *Syncerus caffer*; eland, *Taurotragus oryx*; kudu, *Tragelaphus strepsiceros*; bushbuck, *T. scriptus*; bushpig, *Potamochoerus porcus*; and common *Silvicapra grimmia* and blue duikers, *Philantomba monticola* (Skead, 1987). Associated with these herbivores was the full complement of large predators, including lion, *Panthera leo*; leopard, *P. pardus*; African wild dog, *Lycaon pictus*; brown hyena, *Hyaena brunnea*; and spotted hyena, *Crocuta crocuta*. This high faunal diversity extends also to the birds (more than 300 species), herpetofauna, and probably invertebrates (Kerley and Boshoff, 1997).

Fire plays a minor role in the natural dynamics of the Thicket Biome, and drought, another major form of disturbance, appears to have little impact on the flora. Hence, animal/plant interactions appear to constitute the most important process to generate and maintain the high floristic diversity (Kerley et al., 1995). Animal-driven seed dispersal is a common feature of the reproductive strategies of many of the plants (Cowling, 1984); in addition, the evergreen, nutritious, and spinescent nature of the vegetation supports the hypothesis that herbivory is an important process in structuring the vegetation, with strong co-evolution between the flora and associated herbivores. The megaherbivores (elephant and rhinoceros) are thought to be particularly important in terms of herbivory, patch creation, and seed and nutrient dispersal (Kerley et al., 1995).

Whatever the role of the fauna in structuring the floristic communities, these processes were severely disrupted by the extirpation of many of these species, coincident with the arrival of modern pastoralists of European and African origin (Skead, 1987). Large predators (lion, cheetah, hyenas)

were exterminated in an attempt to protect domestic herbivores, and leopards managed to survive in only the most remote areas. Herbivores were actively hunted for meat, leather, and ivory, and suffered the familiar loss of habitat. Elephants were reduced to a population of 11 individuals in 1931 and did not receive full protection until 1955. The black rhinoceros was extirpated by 1858, remaining so until reintroduced in 1961; buffalo persisted under the umbrella of elephant conservation (Kerley and Boshoff, 1997). The medium-sized herbivores (kudu, bushbuck, duiker) managed to persist in the dense thickets.

The dominant land use in the Thicket Biome is now pastoralism, particularly the husbandry of goats, *Capra hircus*. Pastoralism has led to not only the loss of a large proportion of the indigenous fauna but also to a collapse of ecosystem health. These changes can be expressed at a number of different levels. At the landscape level, pastoralism is associated with a loss of landscape heterogeneity, which reflects a loss of landscape elements critical for hosting a range of habitats and other resources for species of plants and animals (Fabricius, 1997). At the floristic level, pastoralism has led to a loss of plant cover and phytomass, a replacement of dominant species by less palatable species, a decrease in the cover of perennial plants, and an increase in the cover of annuals, as well as invasion by alien plant species and extirpation of plant species (Hoffman and Cowling, 1990, 1991; Kerley et al., 1999; Moolman and Cowling, 1994). These localized plant extinctions are not random among growth forms; succulents and geophytes, many of which are endemics, suffer the most (Moolman and Cowling, 1994). Soils also are affected, with pastoralism leading to large-scale erosion; loss of soil organics, N, Mg, Ca, and moisture; and an increase in soil Al (Kerley et al., 1999; La Cock, 1992; Palmer et al., 1988). These observed indicators of ecosystem degradation also are expressed in terms of productivity: degraded thicket habitats can support fewer herbivores. In addition, forage production is more variable in degraded thickets, virtually collapsing during drought (Stuart-Hill and Aucamp, 1993). Finally, these changes are apparently irreversible within normal management time frames, and therefore this loss of ecosystem resources and productivity can be characterized as desertification (Kerley et al., 1995).

The mechanisms of the degradation, through pastoralism, of a system that evolved with high levels of herbivory appear to occur through the management and specific foraging behavior of domestic herbivores, chiefly goats. Goats are stocked at high densities in response to the economic constraints of farmers (Kerley et al., 1995). In addition, goats are able to overcome the physical plant defenses that protect the plants from the indigenous herbivores with which they have co-evolved (Haschick and Kerley, 1999). Goat feeding behavior also exposes the soil to erosion (Kerley et al., 1999) and prevents vegetative regeneration of some plants (Stuart-Hill, 1992). In addition, goats are poor dispersers of seeds compared to the indigenous herbivores (Sigwela, 1999).

The degradation of the Thicket Biome can be expressed in terms of the three indicators of ecosystem health listed by Rapport et al. (1998): vigor (i.e., loss of productivity, soil resources); organization (loss of biodiversity, keystone species); and resilience (shift in herbivores and the increased response of the system to drought). Ecosystem services, although not well documented, also are strongly affected. Loss of phytomass — ~150,000 kg wet plant mass/ha (Penzhorn et al., 1974) — and soil carbon — ~20,000 kg C/ha in the top 10 cm (Kerley et al., 1999) — indicates a reduced ability of the system to counter global warming through carbon sequestration. Similarly, the reduction in productivity has consequences for human resource extraction and leads to an increase in rural poverty and increased urbanization (Geach, 1997).

LAND USE OPTIONS: ECOLOGICAL AND ECONOMIC SUSTAINABILITY

Although pastoralism is the dominant form of land use in the Thicket Biome at present, it is fraught with problems, as discussed earlier. Game ranching and ecotourism/conservation, based on

the indigenous fauna (primarily herbivores) are the other major land use options. The desirability of these alternative land use options has to be evaluated in terms of ecological and economic sustainability — i.e., in terms of the consequences of pastoralism, game ranching, and ecotourism/conservation to ecosystem health.

Although pastoralism is apparently financially rewarding in the short to medium term, it cannot be considered to be economically sustainable, given the observed erosion of the natural resource capital upon which it is based (Birch, 1991; Kerley et al., 1995). However, government subsidy policies and artificially inflated land prices have contributed to maintaining pastoralism. Associated with ecosystem degradation has been an observed depopulation of rural areas (urbanization) and increased rural poverty. Ecosystem services (soil stabilization, primary productivity, carbon sequestration, biodiversity, and economic opportunities) suffer under pastoralism (Kerley and Boshoff, 1997).

More and more previously pastoral operations are switching to game ranching, relying on the diversity of medium-sized herbivores (particularly kudu) to produce venison and to attract local and foreign hunters. All available evidence indicates that the indigenous, medium-sized herbivores are ecologically sustainable (Stuart-Hill, 1992). There are some indications that areas from which megaherbivores are excluded do tend to lose some patch diversity (Fabricius, 1997; Stuart-Hill, 1992), although the amount of such patch diversity before the extirpation of the megaherbivores is unknown. Game ranching therefore appears to maintain healthy ecosystems.

In financial terms, game ranching is not as lucrative as pastoralism, generating only about 40% of the income that a comparably sized pastoral operation would generate (Kerley et al., 1995). The critical issue here is that, although game ranching generates less income in the short term, it is ecologically sustainable and hence can continue operating long after a pastoral operation has collapsed due to the loss of the natural resources (Kerley et al., 1995). Attention needs to be paid to the problems of appropriate scale and technology, efficient marketing, and adding value to the products through producer-based processing (Kerley et al., 1995) in order to improve the economic opportunities of game ranching if this form of land use, with its associated ecosystem health benefits, is to thrive. Given the benefits accruing to society through the ecological and economic sustainability of game ranching, consideration should be given to developing incentives (e.g., tax rebates, advice) to encourage and assist landowners in making the transition from pastoralism to game ranching.

The third major land-use option in the Thicket Biome is that of ecotourism/conservation. Under this model, tourists pay to experience the indigenous biodiversity, particularly the megaherbivores, within formal conservation areas. The best developed and studied of these is the Addo Elephant National Park (AENP), northeast of Port Elizabeth (Figure 39.1). Although elephants (78% of vertebrate herbivore biomass in the AENP) do have a significant impact on the vegetation, they are ecologically sustainable in the Thicket Biome at densities of much less than two elephants/km (Stuart-Hill, 1992). In the process of protecting elephants, conservation is also conferred upon the full suite of biodiversity (excluding the large predators at present) as well as maintaining ecosystem services (Kerley et al., 1995, 1999).

Ecotourism is also highly desirable in financial and economic terms: for example, in 1994 the AENP generated a profit and employed twice as many staff members at four times the salary of a comparably sized pastoral operation (Kerley et al., 1995). The benefits also extend well beyond the borders of the AENP. For example, a travel cost study estimated a recreational value of approximately \$60 million for the nearly 100,000 tourists who visited the AENP in 1996, which clearly represents significant economic activity (Geach, 1997). Furthermore, it has been estimated (Kerley and Boshoff, 1997) that the visitors to the AENP generate at least 4000 additional employment opportunities in the tourism-related industry. Ecotourism/conservation in the Thicket Biome is therefore a winning option in both ecosystem health and sociopolitical terms.

THE EASTERN CAPE AS A BIODIVERSITY HOT SPOT

Southern African Biodiversity in the World Context

A comparison of the world's 18 biological hot spots (areas with high species richness, a high concentration of endemics, and a high degree of threat) highlights the importance of the temperate Mediterranean climatic areas (Myers, 1990). In particular, southern Africa and its Cape Floristic Region were identified as one of the hottest of all hot spots in terms of plant diversity and threats (Myers, 1990). On a subcontinental scale, southern Africa registers in the upper quarter of the world's 12 megabiodiversity countries (McNeely et al., 1990). Subsequently, an additional hot spot, the Succulent Karoo, has been recognized in South Africa (Mittermeier et al., 1999).

Yet within southern Africa, South Africa is distinct as one of the most biologically diverse countries in the world. Its 23,404 recorded vascular plant species, at an average density of 8.1 species/106 km², exceeds species-rich countries such as Brazil, Ecuador, Madagascar, and other countries in southeast Asia, all of which have rich tropical forests (Cowling et al., 1989; Gibbs Russel, 1985). In addition, South Africa has an exceptionally large proportion of endemic vascular plants (80%), exceeded only marginally by New Zealand with 82% endemic species (Cowling and Hilton-Taylor, 1994).

Among the vertebrate fauna of southern Africa, a similar species-rich picture emerges. The region's amphibian, reptilian, avian, and mammalian faunas account for about 2, 6, 7, and 6%, respectively, of the world's total species for each taxon (Siegfried, 1989). On average, the density of these southern African taxa exceeds the African and world species densities by 6.6 and 5.5 times, respectively (Siegfried, 1989). Faunal endemism in southern Africa shows marginal congruence between taxa with the amphibians and reptiles (44 and 31%, respectively) having relatively high levels of endemic species, while the mammals and birds are relatively less well endowed with 6 and 15%, respectively (Drinkrow and Cherry, 1995; Siegfried, 1989; Skinner and Smithers, 1990).

To a large degree, southern Africa's rich biodiversity and high numbers of endemics can be attributed to contemporary ecological conditions (Lombard, 1995). Southern Africa offers transitional climates between the subtropical summer rainfall and temperate winter rainfall, in combination with complex topography, geology, pedology, biomes, vegetation types, and habitats, all situated at the base of the continent (Branch et al., 1995; Coe and Skinner, 1993; Cowling and Hilton-Taylor, 1994; Gelderblom and Bronner, 1995). The complexity of the region is reflected in the description of five phytochoria (White, 1983), seven biomes (Low and Rebelo, 1996; Rutherford and Westfall, 1986), 68 vegetation types (Low and Rebelo, 1996), and 5.2% of the world's vertebrates, on 0.8% of the land area (Siegfried, 1989).

Yet this rich biodiversity is also under great threat; about 47% of South Africa's natural vegetation already has been transformed (Low and Rebelo, 1996). South Africa has the third highest number of threatened reptile, amphibian, and invertebrate species (IUCN, 1996). Although only 13% of its diverse mammalian fauna is considered threatened, the country is still noted to be among those areas under severe threat of extinctions (IUCN, 1996). Among the vascular plants, southern Africa records the highest number of Red Data Book species (2575 species) per area, exceeding Australia, India, and Mexico (McNeely et al., 1990). Thus, in the global context, South Africa, with its rich biodiversity and increasing levels of threat, is worthy of conservation attention. South Africa contains multiple hot spots, of which the Eastern Cape clearly stands out.

The Eastern Cape Biodiversity Hot Spot

The Eastern Cape of South Africa sits in a transition zone of topographical, geological, pedological, and climatic complexity (Lubke et al., 1986). The wide range of habitats is conducive to supporting a wide diversity of plants and animals. The diversity of abiotic conditions prevalent in the Eastern Cape has made the region the most botanically diverse area of the

country. Of the subcontinent's five major phytochoria, the Eastern Cape forms a major transition or tension zone between four of them: the Cape, Afromontane, Karoo-Namib, and Tongaland-Pondoland (Werger, 1978). That tension zone is characterized by the convergence within the Eastern Cape of all (Nama Karoo, Succulent Karoo, Fynbos, Savanna, Grassland, Forest, and Thicket) of the seven recognized biomes in the country (Low and Rebelo, 1996) (Figure 39.2). Furthermore, within these biomes in the Eastern Cape, a total of 27 different vegetation types are represented, more than any of the other eight provinces of South Africa (Low and Rebelo, 1996). Thus, at the level of the vegetation type and biome, biodiversity in the Eastern Cape is the highest in southern Africa.

The Albany plant diversity hot spot in the Eastern Cape has been identified as one of the subcontinent's eight biodiversity hot spots (Cowling and Hilton-Taylor, 1997). Although the approximately 2000 species and endemism (10%) within the Albany hot spot is not particularly high, the species-to-area relationships compare with the other southern African hot spots, which together should be ranked among the world's most conservation-worthy areas. In addition, the transitional

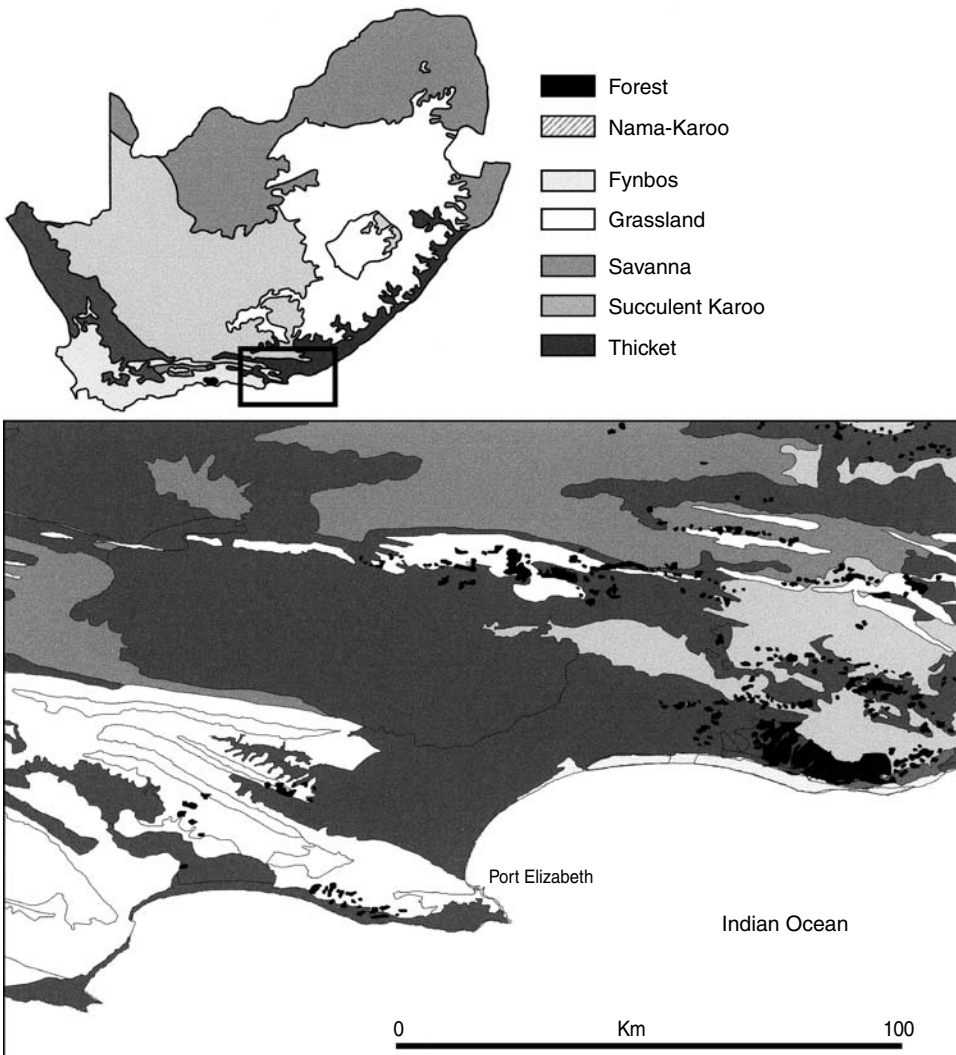

Figure 39.2 The seven South African biomes (bioclimatic regions), with details of the area in the vicinity of the Addo Elephant National Park.

nature of the vegetation types within the Albany area — where many of the species are at their distributional limits — is unique. This phenomenon likely accounts for the relatively low endemism in the Albany hot spot because most of the species tend to be generalists rather than specialists. Endemics within the Albany hot spot typically are succulents from the succulent thicket vegetation types. For example, 30% of southern Africa's succulent *Euphorbia* species are represented in the Eastern Cape, of which 48% are endemic to the region (Court, 1988). In addition to the diverse terrestrial elements, the Eastern Cape also includes the coastal, marine, and estuarine components, further adding to the biodiversity of the area.

Biodiversity at the Biome Level

Table 39.1 shows that the Eastern Cape is particularly important in terms of the representation, and hence conservation, of the biomes and vegetation types of South Africa. All seven biomes are represented in the province.

Biodiversity at the Landscape Level

The Eastern Cape encapsulates a broad ecological and geomorphic diversity within relatively short distances. This diversity ranges from the grass-covered escarpment to the flat semiarid Karoo plains on the African erosion surface with its previously large herds of springbok; to the folded sandstone Zuurberg and Baviaanskloof Mountains, with their accompanying high rainfall vegetation types on the south-facing slopes; to drier rain-shadow north-facing slopes that are home to the endemic Cape mountain zebra, *Equus zebra zebra*. It also encompasses the more nutrient-rich post-African surface south of the mountains, with its dense succulent vegetation and rich mammalian browsing community; the marine and coastal aeolian sediments on the coast; and the marine province with its continental islands (Kerley and Boshoff, 1997). In the aggregate, these terrestrial and marine landscapes comprise the most biologically diverse area in southern Africa.

The Eastern Cape marine component includes a diversity of sandy and rocky shores and two island groups (Bird Island and St. Croix), adding to the biological diversity of the region. This section of the South African coast falls within the South Coast marine biogeographical province — one of three identified (Hockey and Buxton, 1989) — and has been independently identified as

Table 39.1 The Conservation Status of Biomes and Their Vegetation Types in South Africa and Specifically in the Eastern Cape

Biome	Biomes		Number and Percent in Eastern Cape	Vegetation types	
	Percent Conserved Nationally	Percent Conserved in Eastern Cape		Approximate Percent Transformed	Restricted to the Eastern Cape
Thicket	4.50	4.20	5 (100)	45	Xeric succulent thicket, Mesic succulent thicket
Nama Karoo	0.47	0.01	3 (50)	?	None
Succulent Karoo	2.82	17.40	1 (0.25)	?	None
Fynbos	11.84	21.40	3 (30)	47	None
Forest	17.90	15.80	2 (67)	44	Coastal forest
Savanna	9.40	0.33	4 (16)	46	Eastern thorn bushveld, sub-arid thorn bushveld
Grassland	2.23	0.30	9 (60)	58	Coastal grassland, Southeastern mountain grassland

Data adapted from Low, A.B. and Rebelo, A.G., *Vegetation of South Africa, Lesotho and Swaziland*, Department of Environment Affairs and Tourism, Pretoria, South Africa, 1996.

a region in need of protection (Payne and Crawford, 1989). Much like the terrestrial areas in proximity to Algoa Bay, this section of the coast appears to be a transitional area of marine species from the cool temperate west coast and warm tropical elements, and it is particularly important for its diversity of bivalves, limpets, and endemic fish species. East of Algoa Bay, the proportion of endemic fish species rapidly declines (Hockey and Buxton, 1989).

Biodiversity at the Species Level

Invertebrates

Little is known about the invertebrate fauna of the Eastern Cape, although researchers believe that the conservation of the larger mammalian species as flagship species within conservation areas will benefit the invertebrates (Fabricius, 1997). For example, conservation of the larger mammalian herbivores in Addo has been beneficial to the endemic flightless dung beetle, *Circellium bacchus* (Kerley and Boshoff, 1997).

Vertebrates

Comparisons between the distribution of total species richness, endemics, and rarity across six vertebrate taxa (fish, tortoises, frogs, snakes, birds, and mammals) in South Africa revealed little congruence within and between taxa, indicative of the different environmental conditions necessary for each taxon (Lombard, 1995). However, the general trend to emerge is one of species richness in the northeastern subtropical areas of the country, with centers of endemism in the more remote south and southwestern temperate regions, and the rare species split between the two. The Eastern Cape emerges as a species-rich transitional area. Analysis of each of the six taxa revealed the following:

1. *Fish*: The northeastern subtropical low-lying areas of South Africa have the greatest diversity of freshwater fish species, yet the majority of the country's 33 endemic species are restricted to the southern regions, with the Sundays River area identified as one of 10 national endemic species hot spots (Skelton et al., 1995). The Zuurberg Mountains of the Eastern Cape provide protection to two indigenous species of minnows, *Barbus pallidus* and *B. anoplus*, both of which are considered in need of conservation (Skelton, 1987).
2. *Frogs*: Southern Africa has a particularly rich amphibian fauna; and the Eastern Cape, with 10 to 18 amphibian species, of which 5 to 8 are endemic, is considered to be one of the country's amphibian hot spots (Drinkrow and Cherry, 1995).
3. *Reptiles*: The Eastern Cape harbors a high diversity of reptiles, particularly snakes and lizards, 9% of which are endemic to the Eastern Cape. Such reptiles include the Tasman's girdled lizard, *Cordylus tasmani*, the Cape legless burrowing skink, *Scelotes anguina*, and southern dwarf chameleon, *Bradypodion ventrale ventrale* (Branch, 1988a,b). In this regard the Algoa basin is a minor center of endemism (Branch, 1988b). The Eastern Cape also has the most diverse tortoise fauna in the world — five species, three endemics (Branch et al., 1995).
4. *Birds*: More than 500 bird species have been recorded in the Eastern Cape, with more than 300 species breeding in the area (Harrison et al., 1997; Skead, 1967), 13 of which are Red Data Book species (Brooke, 1984). The Eastern Cape also has an endemic hot spot located in the coastal areas west of Algoa Bay (Lombard, 1995). Unique features include the presence of four of southern Africa's five large eagle species: namely, the black eagle *Aquila verreauxii*, crowned eagle *Stephanoaetus coronatus*, martial eagle *Polemaetus bellicosus*, and the fish eagle *Haliaeetus vocifer*. Additionally the region hosts three species of large bustard: the Kori *Ardeotis kori*, Stanley's *Neotis denhami*, and Ludwig's *N. ludwigii* bustards (Kerley and Boshoff, 1997).
5. *Mammals*: Although the Eastern Cape is neither species rich nor an endemic mammalian hot spot, it does register as an important hot spot for endemic insectivore species that are associated with the indigenous forests (Gelderblom and Bronner, 1995; Lombard, 1995). The Eastern Cape is

home to the second-largest population of elephants *Loxodonta africana* in South Africa (Kerley and Boshoff, 1997). In addition, the Eastern Cape, particularly in the Thicket Biome, supports the second-largest population of the threatened black rhinoceros *Diceros bicornis* in South Africa (Hall-Martin and Knight, 1994).

Flora

The juxtaposition of the seven biomes within the Eastern Cape provides for great botanical diversity yet relatively low endemism, led by the grassy fynbos and succulent thicket vegetation types (Cowling, 1983). Within the latter, most of the endemics are geophytes and succulents, and these are predominantly restricted to the understory layer. This makes them particularly prone to grazing pressure mainly from domestic stock, although high densities of elephants also have a deleterious affect (Cowling and Holmes, 1991; Johnson, 1992; Moolman and Cowling, 1994; Stuart-Hill, 1992).

Of the indigenous forest patches, the Alexandria forest is particularly important, given its mix of Cape and Tongaland-Pondoland species. A total of 27 (16%) of its species are found either exclusively in this forest or within a single other forest patch in the area (Phillipson and Russell, 1988). Three species are endemic to this forest — the Cape wing-nut *Atalaya capensis*, the buig-my-nie *Smelophyllum capense*, and the Cape star-chestnut *Sterculia alexandria*. The region harbors seven (25%) of South Africa's 28 species of cycad *Encephalartos* spp. (Giddy, 1974) and the endemic Willowmore cedar *Widdringtonia schwarzii* (Van Wyk et al., 1988). Many of the indigenous trees such as the cycads are now not only under threat by collectors but also through the harvesting of their products for medical purposes (Cunningham, 1988; La Cock and Briers, 1992; Simelane, 1996).

Three main points emerge from the evidence presented in this section. First, the Eastern Cape, and particularly the region encompassing Algoa Bay and its hinterland, possesses an immense diversity of plants, animals, and landscapes. Second, much of this biodiversity is under threat due to desertification and to poorly planned urban and rural development. Third, the region holds great potential for increased conservation action as well as for underpinning a vibrant tourism industry, based on its spectacular natural assets.

THE PROPOSED GREATER ADDO NATIONAL PARK

Emerging from the considerations of the ecological and economic sustainability of land-use options in the Thicket Biome is the recognition that conservation/ecotourism is the best form of land use for ecosystem health and that conservation should be expanded in order to take advantage of the opportunities presented (Kerley et al., 1995). This area boasts spectacular biodiversity from the species to the landscape level, providing further opportunity to combine conservation and tourism. The region is also well placed to exploit the steady growth in the number of tourist arrivals in South Africa since the ground-breaking 1994 democratic elections. In addition, the territory (terrestrial and marine) acquired for national parks in the Eastern Cape has been increased significantly during the last 20 years. This combination of factors led to a proposal to develop a major conservation area that would have explicit human development opportunities (Kerley and Boshoff, 1997).

This vision sees the amalgamation of two large protected areas with one small, existing protected area — the Addo Elephant National Park (60,000 ha), the Woody Cape (24,142 ha), and Tootabie (343 ha) Nature Reserves — to form a core conservation area. The expansion of this core area would create a Greater Addo National Park (GANP) (Figure 39.3), thereby providing an opportunity for a viable regional and national development and conservation initiative. The selection of the footprint of the proposed GANP (Figure 39.3) is based on 11 recognized criteria and on national and international environmental legislation and treaties. These criteria encompass issues related to

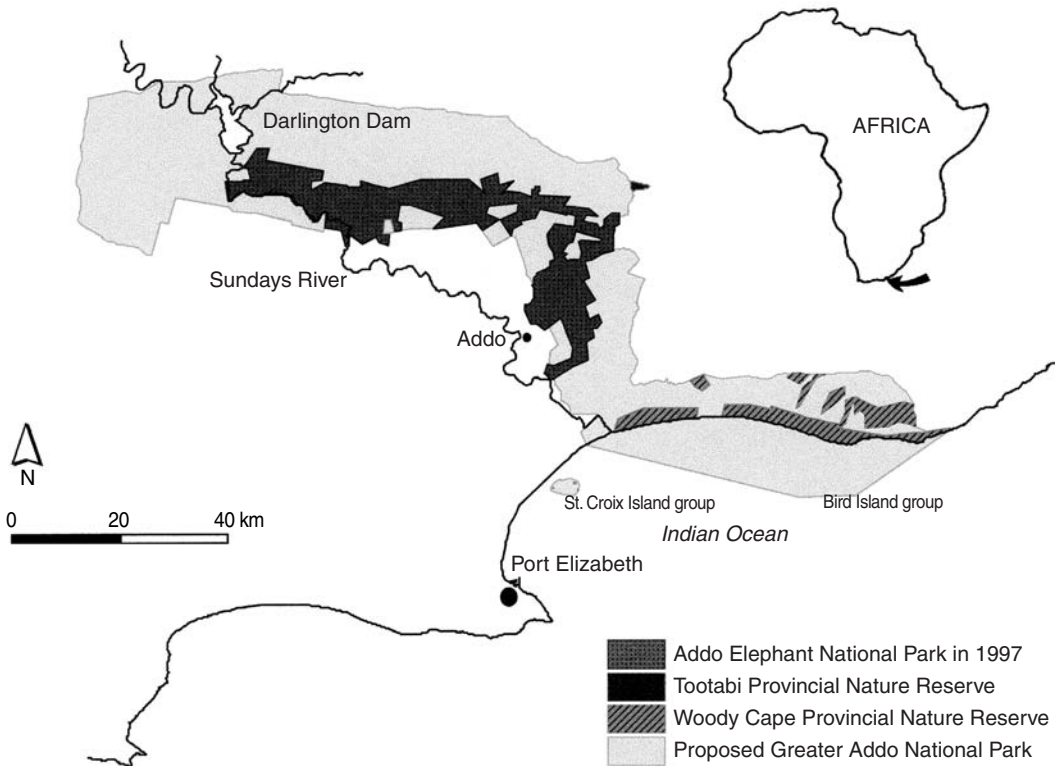

Figure 39.3 The proposed Greater Addo National Park: the core conservation areas in 1997.

biodiversity, spatial complexity and representativeness, ecosystem functioning, naturalness and uniqueness, protection of flagship species, multipurpose (buffer) zones, financial viability, economic potential, ecotourism, and management factors. The vision for the proposed GANP is fully motivated on the basis of sound conservation, ecotourism, and economic principles, perspectives, and information. Space precludes the inclusion of a fully referenced account of the GANP proposal here. However, details are available in Kerley and Boshoff (1997) and at the Web site <http://www.upe.ac.za>. A brief synopsis of the key features and advantages of the proposed GANP follows.

The proposed GANP is some 398,000 ha in size, consisting of a 341,000-ha terrestrial zone and a 57,000-ha marine zone. The former includes the Darlington Dam and almost 90 km of the Sundays River, and the latter includes the Bird and St. Croix island groups in the Indian Ocean (Figure 39.3). The proposed park, which forms a continuous conservation area more than 200 km in length, will be the third largest national park in South Africa. It will be geomorphologically and biotically the most diverse conservation area in South Africa, and probably one of the most diverse in the world. In addition it will create enormous potential for socioeconomic development in the economically depressed Eastern Cape, a province identified by the government as a priority for development.

In terms of its conservation value, the GANP will contribute significantly to South Africa's conservation requirements. It will be unique through the inclusion of examples of six of the seven biomes identified in South Africa (Low and Rebelo, 1996) as well as a diverse marine component. Major landscapes included are the Zuurberg Mountain range, part of the former African land surface, the Alexandria coastal dune field, fossil dune ridges, and karstic landforms. The Alexandria coastal dune field is the largest, most impressive, and least degraded coastal dune field in South Africa, and one of the most spectacular in the world. The GANP also will offer some protection to fragile and threatened river systems, with the Sundays River estuary of particular conservation significance.

The Bird and St. Croix island groups are of immense conservation value; they support, for example, the largest population of the threatened African penguin *Spheniscus demersus* and the largest Cape gannet colony *Sula capensis* in the world, as well as a range of other species of special conservation significance, notably the Cape fur seal *Arctocephalus pusillus*. The marine zone also supports populations of threatened and ecologically and economically important species, e.g., reef and game fish, bottle-nosed *Tursiops truncatus* and humpback *Sousa plumbea* dolphins, southern right *Eubalaena glacialis* and Bryde's *Balaenoptera edeni* whales, and great white sharks *Carcharodon carcharias*, all of which are also important ecotourism resources.

A particular attraction in the proposed GANP will be the megaherbivores (elephant, black rhinoceros) and other charismatic animals, ranging from the large predators such as lion *Panthera leo* and cheetah *Acinonyx jubatus*, to an endemic flightless dung beetle. The GANP will be a true *Big Five* (lion, leopard, elephant, rhinoceros, buffalo) park, a critical feature for tourism success. It will ultimately be able to carry genetically viable populations of most of the large species. With more than 400 species within its boundaries, it will provide habitat for almost half of the bird species recorded in South Africa, and it will play a significant role in conserving the region's reptiles and amphibians.

The proposed GANP also will contribute significantly to the conservation of a range of threatened freshwater and estuarine fish species as well as to the conservation of a number of threatened invertebrates — e.g., rare butterfly species *Aloeides clarki* and *Lepidochrysops bacchus*, an endemic dune grasshopper *Acrotylos hirsutus*, and the flightless dung beetle.

The proposed GANP will conserve an impressive array of plant species, ranging from the desert-adapted succulents in the Karoo to the stately trees of the Alexandria coastal forest. It is characterized by a wide range and high diversity of plant species and by the proximity of several very different and unrelated vegetation types. Part of the Albany hot spot, recognized by the WWF–IUCN as a global center of plant biodiversity, falls within the GANP footprint. The GANP also will provide increased protection for 25% of South Africa's cycad species.

The proposed GANP and its surrounds additionally have an important and interesting paleontological record, consisting of a range of plant and animal fossils; these include dinosaur bones and unique fossil fish deposits. The fact that the GANP includes areas of six biomes ensures that at least some of these bioclimatic regions will persist there in the face of global climate change; in this regard the marked altitudinal variation over a relatively short distance — sea level to 1000 m above sea level over 50 km — within the proposed boundary is noteworthy.

The proposed GANP is located in an area with an extensive and interesting archaeological and historical record. This region includes an important Late Stone Age site; remains of Khoi/San settlements; and sites of conflict between early African and European pastoralists, and between the Boers and the British. The two island groups also have a particularly interesting and valuable history of whaling and shipwrecks.

All the above features and attractions will combine to ensure the success of the proposed GANP as national and international ecotourism destination. Available evidence clearly indicates that ecotourism/conservation is an ecologically sustainable form of land use and that it is successful in terms of wealth generation, economic activity, and job creation. In terms of ecotourism and its economic role, the proposed GANP has enormous potential and would be ideally located to exploit the fast-growing ecotourism market. It will offer a wide and exciting range of attractions, from lions to penguins, from forests to deserts, and from mountains to beaches. The climate of the region is ideally suited to ecotourism, the area has a good tourist safety record, and it is free of malaria. The GANP would be well serviced in terms of tourism infrastructure, such as an airport, transport, surfaced roads, and hospitality facilities. The GANP would provide opportunities for linkages with private conservation areas within the context of the creation of a biosphere reserve, and it is thus obvious that it would be a highly desirable form of land use and development in the region.

The development and operation of a major national park such as the GANP will undoubtedly provide a number of socioeconomic benefits at the local, regional, and national levels. For example, numerous permanent and casual jobs will be created within the GANP and within service and peripheral industries. The potential for the long-term viability of these jobs is considered to be good, and local communities stand to gain most from the economic activity that the GANP will foster. The Mayibuye Ndlovu Crafts Project, involving communities neighboring the present Addo Elephant National Park, has laid a solid foundation for further community relationships with respect to a GANP. A wide range of institutional, social, and management issues were identified and discussed at a GANP Stakeholders Workshop held in February 1999; workshop delegates unanimously endorsed the GANP concept in 1999 (Boshoff and Kerley, 1999).

The potential of the proposed GANP as a national development opportunity has been accepted by the South African government. At a presidential jobs summit organized by the national government in October 1998, one of the three areas in the country singled out was the Algoa Bay region. As a key part of the overall plan for this region, emphasis was laid on “the development of tourism centred on an enlarged Greater Addo [Elephant] National Park” (*Eastern Province Herald*, 3 November 1998). A GANP is now regarded as an integral part of the Fish River Spatial Development Initiative — a development project of the national Department of Trade and Industries, which commissioned an economic viability analysis of the proposal by an independent firm of chartered accountants. The proposed GANP was named as a provincial achievement by Premier of the Eastern Cape Province Government, Mr. M. Stofile, in his speech at the opening of the Provincial Legislature on 12 February 1999; President Thabo Mbeki confirmed the government’s commitment to the concept at the opening of the South African Parliament in February 2001.

In November 1998, the Global Environment Facility (GEF) Operational Focal Point, attached to the Department of Environmental Affairs and Tourism in Pretoria, provided formal country endorsement of the proposal in a letter to the World Bank Biodiversity Program in Washington, D.C. On the strength of this, the World Bank, operating as an agent of GEF, invited the submission of a formal project proposal to World Bank/GEF for the establishment of GANP. This will include all aspects of park planning and development except land purchase. The required process has been initiated, and the first step was the previously mentioned inclusive participatory GANP Stakeholder Workshop in February, 1999. The workshop, which attracted more than 150 delegates representing a wide range of stakeholders (Boshoff and Kerley, 1999), was followed by the submission of a proposal to the World Bank for a Project Development Fund grant. This project development phase was initiated in November 2000, with GEF funding, and was completed in 2002. The full project, supported by GEF, will commence in January 2003.

Since the GANP proposal was launched in September 1997, the expansion of the Addo Elephant National Park (AENP) has proceeded apace. By the end of 2001 the AENP had increased in size by some 36,000 ha, with units of land acquired in the south, in the Zuurberg Mountains in the western part, and in the noorsveld to the northwest of the Zuurberg Mountains. Negotiations are under way or have been completed for the use or purchase of a further 30,000 ha of land. In November 2001, the Woody Cape Provincial Nature Reserve (24,142 ha) was handed over to South African National Parks for inclusion into the GANP. The latter acquisition completed the link between the present AENP and the coast and, with this extension, the AENP had effectively doubled in size since the proposal was developed.

It is noteworthy that a substantial proportion of the funds used for the purchase of additional land is in the form of donations from the private sector, in particular from the International Fund for Animal Welfare and the Leslie Hill Succulent Karoo Trust. The Worldwide Fund for Nature–South Africa also has indicated its willingness to purchase land for the GANP as funds become available. Furthermore, the GANP proposal, with its explicit linkages between conservation and socioeconomic development opportunities, has provided the incentive for the South African government to budget funds for the purchase of land for the expansion of the AENP.

THE PROPOSED GANP AND ECOSYSTEM HEALTH

Environmental degradation, as documented earlier, is not restricted to the Thicket Biome; the other biomes that fall within the GANP footprint also exhibit various levels of degradation. Problems include overgrazing, soil erosion, invasion by alien plants, and poorly planned rural and industrial development (Low and Rebelo, 1996). Although the ecosystem health benefits of the proposed GANP will be confined largely to the GANP footprint, the proposal serves as a model and catalyst for other similar initiatives elsewhere in South Africa.

The benefits of a healthy ecosystem, expressed in terms of the contribution of the proposed GANP, are characterized by the provision of clean water and air, the sequestration of carbon, the maintenance of stable soils, enhanced plant productivity, and enhanced biodiversity conservation (species, ecosystems, and landscapes) (Rapport et al., 1998). In addition, the latitudinal and altitudinal variations within the GANP footprint will promote biodiversity persistence in the face of global climate change. We consider that the proposed GANP will presently more than adequately satisfy all three of the indicators of ecosystem health — vigor, organization, and resilience (Rapport et al., 1998).

CONCLUDING STATEMENTS

We contend that the conservation/ecotourism type of land use espoused in the GANP proposal, and based on the tenets of sustainable utilization of natural resources, holds the greatest potential for the meaningful improvement of human communities, especially in the vicinity of the park. There are ultimately only two choices for the region: one that will enable a healthy ecosystem, providing ecosystem services and concomitant opportunities for socioeconomic development, or desertification followed by loss of these services and exacerbated human poverty. Lackey (1998) contends that ecosystem management is a society-driven process. In this regard, the stakeholder endorsement of the GANP concept, and the tangible support for its implementation, indicates the recognition of the benefits of ecosystem health by society.

Our overriding conclusion is that ecosystem health can generate political and financial support, if couched in both conservation and human terms — *conservation for the people*.

The Role of an Accidentally Introduced Fungus in Degrading the Health of the Stirling Range National Park Ecosystem in Southwestern Australia: Status and Prognosis

David Newsome

INTRODUCTION AND BACKGROUND

The ecological status of national parks and nature reserves is usually considered to be healthy when compared to intensively managed landscapes and land that has been cleared for agriculture. The Stirling Range National Park (Figure 40.1) is a large area (115,600 ha) of original vegetation that was designated national park status in 1913 (Underwood and Burbidge, 1993). It is a zone of exceptional biodiversity and contains 1500 plant species, 87 of which are endemic to the park. Historical records of vertebrate fauna show that the park supported 27 species of terrestrial mammals; however, 12 of these are now extinct. Their decline is largely attributed to predation by introduced carnivores (Friend and Muir, 1993). The avifauna is more diverse with 140 species recorded, 90 of which are known to have bred or breed in the park (Burbidge and Rose, 1993).

The park is now completely surrounded by cleared land comprising agricultural ecosystems, parts of which are showing signs of degradation in the form of land salinization. The impact of this secondary salinity, brought about by clearing natural vegetation and perturbing the water table, is profound and obvious. Because of this, agricultural land is degraded, and conventional forms of agriculture and associated economic activity are rendered useless.

The Stirling Range by contrast appears to comprise a healthy original ecosystem. Significantly, however, it is argued here that the Stirling Range ecosystem is in the process of being degraded. The loss of mammal species could perhaps be perceived as an indicator that ecosystem health has been compromised. A more serious threat to the Stirling Range ecosystem is in the form of an accidentally introduced fungus, *Phytophthora cinnamomi*, which has been shown to kill a wide range of plant species. The disease manifestation is the development of chlorotic tissues, the death of leaves, and eventual plant death. It is referred to as *dieback* and is caused by the fungus preventing water uptake by the roots. Although the Stirling Range is a reserve and has therefore been subject to minimal disturbance, the disease continues to spread throughout the park.

This chapter draws on the work that has been done to identify, assess, and manage the dieback problem in the Stirling Range National Park. The objective of this work is to place the dieback problem within the framework of ecosystem health. The significance of placing dieback within

Figure 40.1 Location map.

such a context is in demonstrating the role of exotic organisms in degrading valued ecosystems and in the need to communicate this problem to the public.

ECOLOGICAL SERVICES PROVIDED BY THE STIRLING RANGE NATIONAL PARK

Like many national parks around the world, the Stirling Range provides for tourism, recreation, and the conservation of biodiversity. The mountainous scenery and rich array of wildflowers in spring makes the Stirling Range an increasingly popular tourism destination, with the number of visitors increasing on an annual basis (Figure 40.2). Almost all visitors walk in the park, with a significant percentage undertaking self-guided touring by car. Roads for tourist access were initiated around 1920, and since that time further road improvements and the development of walking tracks have occurred (CALM, 1996). A number of mountain peaks provide for hiking, wildflower viewing, and the appreciation of scenery. In 1992–1993 the Stirling Range National Park had 209,000 visitors, and the highest peak, Bluff Knoll, received 36,000 walkers (Wills and Robinson, 1994).

The Stirling Range National Park contains some of the only mountainous scenery in southwest Western Australia, and this alone is a significant attraction for many visitors. Western Australia is, however, well known for spectacular displays of wildflowers during the period of September to November. This wildflower resource is valued in the region of Au\$280 million to \$560 million annually (Wills and Robinson, 1994), and wildflower tourism is actively promoted both at national and international levels. The Stirling Range National Park ecosystem is a particularly impressive example of such a wildflower resource. Diverse assemblages of plants, coupled with spectacular flowering (e.g., *Banksia* spp.) and variety of leaf form, constitutes a major part of the tourism experience. A survey in 1992 revealed that 90% of the visitors staying overnight in the nearby Stirling Range Caravan Park had come to view wildflowers (Wills and Robinson, 1994).

The large number of plant species in the Stirling Range provides for a substantial genetic library. Most of these plant species have not been investigated for possible economically significant secondary compounds. In recent years, extracts from a species of *Conospermum* (Proteaceae) were found to contain compounds that could be used in the treatment of human immune deficiency viral infections. Potential royalties from commercial interests were at the time estimated at Au\$100 million per annum (Wills and Robinson, 1994). The genetic resources of the park are also of

Figure 40.2 Bluff Knoll track, Stirling Range National Park.

potential significance for the cut wildflower industry. Various species of *Banksia* in the park are significant in this regard.

The Stirling Range is also a significant refuge for fauna, especially birds, and is therefore an important site in relation to conserving terrestrial biota typical of the wider region. The park also provides suitable habitat for reintroduction programs for those species that have become locally extinct.

An ecosystem service that is often not recognized without education and interpretation of the natural environment is one of aesthetic enjoyment per se. Although this service is appreciated by some, for example, ecotourists, much work must be done in order to achieve widespread acknowledgment by the public that the conservation of nature, and therefore ecosystem health, is essential in promoting and maintaining our quality of life.

MEASURES OF ECOSYSTEM HEALTH IN THE STIRLING RANGE NATIONAL PARK

The health of the Stirling Range ecosystem can potentially be measured against the component biodiversity baseline. In simple terms, it answers two fundamental questions — what species should occur in the Stirling Range, and what should the natural communities look like? From an ecological standpoint, the answer to these questions is often very difficult to resolve, mainly as a result of incomplete knowledge about an ecosystem in undisturbed or pristine condition, and the role that

humans have played in modifying that ecosystem. If we assess the ecosystem according to the services it provides — that is, attach a value to the services — then measuring and assessing the health of an ecosystem becomes much more straightforward. In the case of the Stirling Range, in which the flora controls many of the ecosystem services, the characteristics of the plant communities provide the measures of ecosystem health.

Pignatti et al. (1993) provide a comprehensive analysis of the plant communities based on extensive phytosociological studies. Eight main communities are described, with Kwongan or heathland as the most widespread community, and rich in flora, with an average of 56.3 species occurring per sampling site. Keighery and Beard (1993) provide a simpler description of the vegetation based on structural characteristics.

Five structural types of plant community are seen to occur in the Stirling Range and consist of the following:

1. *Thicker*: Present on the upper levels of all the major peaks; characterized by a diverse array of genera that belong to the family Proteaceae, e.g., *Banksia*, *Dryandra*, *Adenanthos* and *Isopogon*
2. *Mallee heath*: Variable in species composition and a widespread plant community; contains the main populations of species endemic to the Stirling Range; particularly diverse where it grades into the thicket community
3. *Mallee*: Not well represented in the park but characterized by well-spaced, emergent eucalyptus with a heath understorey
4. *Low Woodland*: *Eucalyptus marginata* and *Corymbia calophylla* in low-lying and valley areas; *Banksia attenuata* and *Banksia coccinea* woodland present on deep, sandy soils
5. *Woodlands*: *Eucalyptus marginata* and *Corymbia calophylla* on lateritic soils; *E. wandoo* occurs in association with *C. calophylla*

These five structural types of vegetation contain 90 plant families and 1517 plant species. There is a high degree of endemism (87 species), and the mallee heath (Kwongan) community contains 60 to 120 species/100 m. The Proteaceae, Epacridaceae, Myrtaceae, and Papilionaceae are major plant families. Keighery and Beard (1993) note that the Stirling Range is a zone of species richness for several genera within the Myrtaceae and a center of diversity within the Proteaceae and Epacridaceae.

The diversity of plants, their biology, and variety of vegetation, structure, and habitat, supports 15 species of native mammals and 140 species of birds. The Stirling Range is also an important refuge for reptiles and amphibians due to widespread clearing beyond the park boundaries (Dell and Harold, 1993). The park is also important for invertebrates and provides habitat for a number of relict species (Main, 1993).

The abundance and diversity of plants and animals provides a baseline against which the health of the Stirling Range ecosystem can be measured (Yazvenko and Rapport, 1996). These measures also fit with indicators of ecosystem health identified by Rapport et al. (1998), who use vigor, organization, and resilience to assess ecosystem health. In the Stirling Range any loss of vigor can be measured in terms of declines in species abundance (for example, *Banksia coccinea*). Ecosystem organization can be measured against the baseline level of the morphological and functional diversity of species. Rapport and Whitford (1999) have demonstrated this in three different ecosystems. For example, changes in community structure were used as a measure of ecosystem health in the North American desert grasslands. Because of the ecosystem services provided by vegetation, changes in community structure would be an important measure of health in the Stirling Range.

Resilience is identified by Rapport et al. (1998) as the capacity of an ecosystem to maintain structure and function in the presence of stresses with which it has evolved. In the Stirling Range, the prevailing climate with summer drought and wet winters, combined with nutrient-poor soils, provide for regular stress on the vegetation. Fire causes the largest changes in vegetation structure but is a regular feature in the Australian landscape. The plant communities are well adapted to these prevailing environmental stresses and, although the structure of vegetation may vary

depending on the fire regime, under natural conditions the vegetation maintains its original form. The ability of plant communities to recover from stress and disturbance events is therefore a useful measure of ecosystem health.

FACTORS COMPROMISING ECOSYSTEM HEALTH IN THE STIRLING RANGE NATIONAL PARK

The Stirling Range National Park is managed for conservation, recreation, and tourism (CALM, 1996). Management programs are also in place to deal with the fire risk during summer and to control introduced species that pose a threat to the ecological integrity of the park (Gillen and Watson, 1993; Wills and Kinnear, 1993; CALM, 1996). Active management is necessary to monitor visitor activity, maintain tourism facilities, and prevent degradation, such as path erosion. The fire hazard is managed according to a program of prescribed burning and firebreak corridors (Gillen and Watson, 1993). Management action to control weeds and feral animals is expensive, but considerable progress has been made in controlling the introduced European fox (*Vulpes vulpes*) in recent years.

The task of managing these threats to the integrity of the Stirling Range ecosystem requires further funding and additional human effort because the introduced species problem remains unresolved. Degradation of the park continues in the form of edge effects from surrounding agricultural land. This includes increased fire hazard, weed invasion, and the immigration of feral animals from adjacent farmland. The Stirling Range already has lost 12 species of mammals, and any introduction program is likely to be compromised by the continuing presence of introduced carnivores. Fire management and erosion control constitute ongoing management needs.

The single most serious threat to the health of the Stirling Range ecosystem is an introduced fungus, *Phytophthora cinnamomi* (CALM, 1992; Wills, 1992; Gillen and Watson, 1993; Wills and Kinnear, 1993; CALM, 1996). The fungus is considered to have been introduced in 1960, when a number of roads, footpaths, and fire management tracks were constructed (Gillen and Watson, 1993; CALM, 1996). According to Wills and Kinnear (1993), the fungus had spread throughout the park by 1975, before the biology of the disease was properly understood. The disease is originally thought to have come from Southeast Asia and was probably introduced to Western Australia around 1900 (Wills and Kinnear, 1993).

ACTIVITY, SPREAD, AND ECOLOGICAL IMPACT OF *PHYTOPHTHORA CINNAMOMI* (DIEBACK DISEASE) IN THE STIRLING RANGE NATIONAL PARK

Phytophthora cinnamomi is a soil-borne fungus that enters the roots of plants that are susceptible to attack. Vegetative reproduction produces sporangia (Figure 40.3), which release mobile zoospores that infect the roots of host plants. It then spreads by root-to-root contact, through the movement of soil, and is readily transported in water (Shearer, 1994). Widely dispersed infection is the result of soil movement on the wheels of vehicles (Figure 40.4) or on footwear. Activities such as road building and maintenance and the construction of firebreaks would have been the initial mechanism through which the disease spread through the park (Gillen and Watson, 1993; CALM, 1996). The fungus also has spread along recreational hiking tracks as a result of infected soil carried on the boots of walkers. Wills and Kinnear (1993) report that nearly all of the walking tracks in the park are, in part, infected and that some of the infection is of recent occurrence. A significant correlation exists between the distribution of the fungal infection and the more accessible and popular tourist peaks (CALM, 1996). The presence of the disease in upland areas is of particular significance because of the potential for downhill spread of infectious zoospores through surface and subsurface runoff (Gillen and Watson, 1993; CALM, 1996).

Figure 40.3 *Phytophthora cinnamomi* sporangium containing zoospores.

Figure 40.4 Mud on the wheel of a vehicle.

Figure 40.5 Mass death of native vegetation caused by *P. cinnamomi* infection.

Infected host plants are killed as a result of impaired root function. The disease is characterized by the death of photosynthetic tissues and is known as dieback (Figure 40.5). Research into host susceptibility has found that a wide range of species can become infected. Susceptible species are contained mostly in the plant families Proteaceae, Myrtaceae, Papilionaceae, and Epacridaceae (CALM, 1992; Wills, 1992; Shearer, 1994). These plant families comprise a very high proportion of the plants that make up the biotic communities in the Stirling Range.

Wills and Kinnear (1993) estimate that up to 85% of species in the Proteaceae are at risk. In the Stirling Range the entire population of the rare *Banksia brownii* is infected with *Phytophthora cinnamomi* (CALM, 1992). Bridgewater and Edgar (1994) identify the local and uncommon *B. coccinea* as highly susceptible, and Shearer (1994) points out that two species of *Dryandra*, *B. brownii* and *Lambertia orbifolia*, are threatened with extinction as a result of *P. cinnamomi* infection.

More important than individual species, however, the health of the Stirling range ecosystem is under threat from the total effect of *P. cinnamomi* on plant communities. The disease is known to have a major impact on the species-rich understory that is an essential component of mallee heath in Western Australia. Wilson et al. (1994) report that as many as 60% of the component species present can be destroyed following infection by *P. cinnamomi*. Studies carried out in the Stirling Range National Park by Wills (1992) have shown an abundance of susceptible species to be present and that the disease is widespread (Figure 40.6). Moreover, because the Proteaceae contribute the bulk of floristic structure to many plant communities in the park, their loss due to *P. cinnamomi* infection causes a decline in species richness, changes in community structure, and a reduction in plant biomass.

Building on the work of Rapport et al. (1998) in assessing ecosystem health, these changes can be represented diagrammatically (Figure 40.7). The loss of a large number of species from the Proteaceae is a critical factor in ecosystem degradation. The death of species of *Banksia* and *Dryandra* and other members of the Proteaceae cause marked changes in community structure and a decline in species richness (Wills, 1992). The observed and predicted changes to vegetation are illustrated in Figure 40.8. The overall effect on an infected site can be summarized by:

- Change in community structure
- Loss of plant biomass and productivity
- Reduced capacity of a site to support dependent biota (Wills, 1992)

The resultant change in community structure and function degrades the vegetation and its capacity to provide suitable habitats and resources for fauna. Wilson et al. (1994) provide an overview of the likely effects on wildlife. They point out the potential consequences for arboreal mammals and birds that rely on the canopy of dominant species, such as *Banksia* spp., for food and shelter.

Resilience is viewed by Rapport et al. (1998) as an important indicator of ecosystem health. The ecosystem changes described in this chapter are predicted to be long-lasting and even permanent, as has been demonstrated at *P. cinnamomi*-infected sites in eastern Australia (Kennedy and Weste, 1986; Weste and Ashton, 1994). These changes reflect the low resistance of many species to fungal infection. Moreover, recovery following fungus-induced death of vegetation appears to be low, as evidenced by the complete loss of key species (such as *B. coccinea*), reduced seedling regeneration, increased invasion of annual weeds, and colonization by resistant native species such as *Lepidosperma* spp. (Wilson et al., 1994; Wills and Keighery, 1994). Furthermore, as long as the fungus is present, the plant community will not return to its original condition.

Such changes reveal a lack of plant community resilience to *P. cinnamomi* infection. Although at present only pockets of infection causing ecosystem distress syndrome have materialized, up to 70% of the Stirling Range National Park is to some degree infected with *P. cinnamomi*. The implications of this widespread but localized pattern of infection (Figure 40.6) for ecosystem health

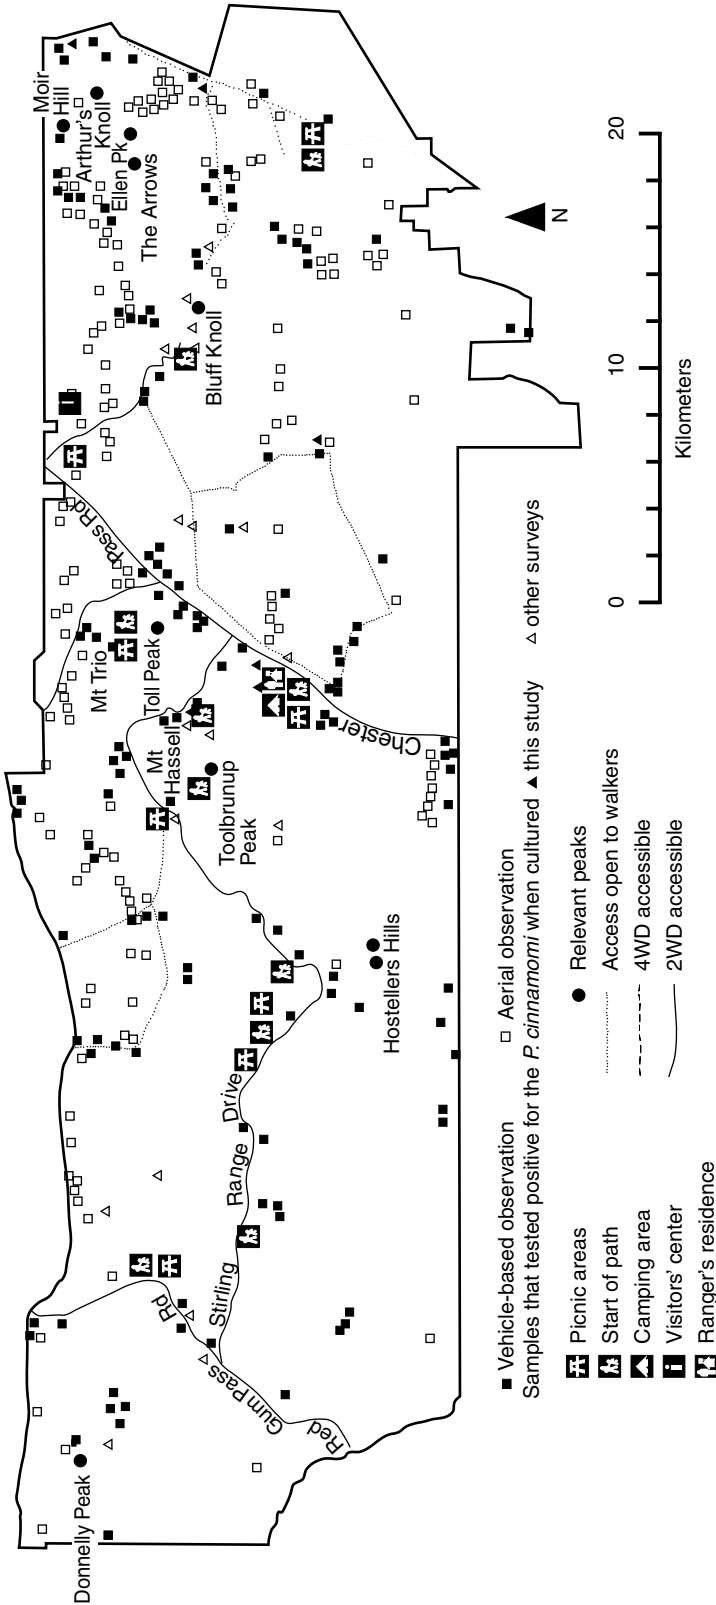

Figure 40.6 Distribution of *Phytophthora cinnamomi* infection in the Stirling Range National Park. (Adapted from Willis, R., Ecological impact of *Phytophthora cinnamomi* in the Stirling Range National Park, *Aust. J. Ecol.*, 17:145–159, 1992, and CALM, Stirling Range and Porongorup National Parks, Draft Management Plan, Department of Conservation and Land Management, Perth, Western Australia, 1996.)

are profound, and without some measure of control, the prognosis is for a gradual degradation of vegetation communities and progressive loss of ecosystem services.

THE IMPORTANCE OF APPLYING THE CONCEPT OF ECOSYSTEM HEALTH TO THE *PHYTOPHTHORA CINNAMOMI* PROBLEM IN WESTERN AUSTRALIAN NATIONAL PARKS AND NATURE RESERVES

Widespread infection by *Phytophthora cinnamomi* has the capacity to degrade the conservation and tourism value of the Stirling Range National Park. Although much research and effort is exerted toward controlling the disease, it continues to spread. The Stirling Range National Park presents managers with a significant problem in controlling the spread of the disease because of the need to maintain access for fire management, scenic driving, hiking, picnicking, and wildflower viewing.

Attempts to control the spread of *P. cinnamomi* infection consist of:

- Minimizing spread through quarantine and hygiene practices
- Monitoring its distribution and assessing the risk of spread
- Educating the public and researching methods of control
- The use of a chemical treatment, phosphonate, either as a foliar application or directly injected into woody plants, is showing some promise as a means of controlling the disease (Hardy et al., 1994).

Because controlling spread is critical in managing the disease in the Stirling Range National Park, managers have implemented a number of strategies to reduce spread of the fungus. These consist of designating special conservation zones that are closed to vehicles and walkers, track management to avoid erosion, the closure of uninfected peaks, and public education (CALM, 1996).

Gillen and Watson (1993) emphasize the problems associated with controlling the spread of *P. cinnamomi* from a tourism perspective. More importantly, they point out the lack of appreciation by the public about the significance of the disease and how it can be spread by activities commonly perceived as low impact. For example, many international tourists are accustomed to restriction of access. However, Australians have an attitude and tradition of belief that they can go where they please, and consequently visitors can perceive control of access as a restriction on their recreational experience. Walkers are still seen along the uninfected Mount Monderup track despite its closure and the presence of a public information sign.

Many visitors see the Stirling Range and other national parks as safe from environmental degradation because they are protected areas, because only low-impact activities are permitted, and because a management authority is in attendance. The public is largely unaware that *P. cinnamomi* poses a serious threat to the ecological integrity of the park. Although education and public information programs are in place about the *P. cinnamomi* problem, for a large part the public still does not appreciate natural landscapes for the services they provide. Furthermore, although many people do recognize the salt-damaged land in Western Australia, they cannot see the impact of *P. cinnamomi* infection until mass deaths occur, such as is the case in the eucalyptus forests that lie north and west of the Stirling Range.

This chapter proposes that a recognition and promotion of ecosystem health will make a significant contribution to educating the general community about the importance of natural ecosystems to society. The task needs to be done initially as a scientific dialogue that must be communicated to the public. The intelligent layperson will understand the scientific arguments presented in relation to assessing ecosystem health. For others, however, a more human-centered approach will be required, such as the cancer analogy to describe *P. cinnamomi* as a malignant tumor that is gradually spreading and compromising the health of plant communities that are central to the health of the Stirling Range ecosystem. Recognition of ecosystem health thus becomes

another much-needed approach in attempting to reverse the gradual and continuous degradation of many ecosystems in Australia and elsewhere in the world.

ACKNOWLEDGMENTS

I thank G. Hardy and P. Ladd for providing photographs and useful discussion about the *Phytophthora cinnamomi* problem in Western Australia. M. Roeger and C. Ferguson helped with cartographic work.

Mangrove Conservation and Restoration for Enhanced Resilience

Nguyen Hoang Tri, Phan Nguyen Hong, W. Neil Adger, and P. Mick Kelly

TRENDS IN MANGROVE ECOSYSTEM CONVERSION

Mangrove forests encompass those areas that include some species of mangrove trees and are intertidal tropical and subtropical coastal wetlands. Despite being among the most productive ecosystems in the world, the area of mangrove forests has been globally declining to less than half the former area from the beginning of the 20th century (Field et al., 1998). These trends are due to conversion for agriculture, forestry, and urban uses, and to extraction of timber for fuel and other uses (Farnsworth and Ellison, 1997).

In Vietnam, large areas of mangroves have been converted to agriculture and, in particular, to shrimp aquaculture, causing ecological disturbance and enhancing instability in the coastal physical environment (Hong and San, 1993). The total mangrove area of Vietnam has been in decline through the second half of the 20th century, according to contemporary historical estimates of this total area (see Figure 41.1). Before the two Indochina wars, mangrove areas were distributed extensively in coastal and estuarine areas and were estimated to have an area of around 400,000 ha in 1943 (Maurand, 1943), with over 250,000 ha in the southern parts of the country concentrated in the Ca Mau peninsula (150,000 ha) (Hong, 1994). Conversion occurred throughout the past half century, and an estimate by Rollett (1963) puts the area at less than 300,000 ha in the early 1960s.

From 1962 to 1971 nearly 40% of the mangrove area in southern and central Vietnam, or almost 159,200 ha, was destroyed as a result of chemical warfare, including over half of the mangrove in the Ca Mau peninsula (Hong, 1994). Estimates of the impact on productive areas suggest that more than 4 million m³ of timber was destroyed during this period, with severe impact on the fauna and flora in these areas.

The legacy of Agent Orange and other dioxins remains until the present day not only in the higher fauna but also in human populations in these areas. But as shown in the estimates of total mangrove area in Figure 41.1, a significant proportion of the area degraded by herbicides was subsequently replanted, such that a mid-1980s estimate of total areas suggests around 250,000 ha remaining (Hong, 1994). Despite this restoration effort, areas all along the coast of Vietnam, including those rehabilitated areas, have now been converted again for use in agriculture, aquaculture, and human settlement. Where agricultural land has been reclaimed, it is often necessary to build significant sea dikes to protect the land from storm surges, where once the land would

From Hong et al., 1997.

have been buffered by the mangrove forests. The best estimate of the remaining area of mangroves is shown by province in Table 41.2, which also shows that nearly one quarter of the coastline of Vietnam is now protected by sea dikes.

Mangrove conversion is an important ecological issue as well as an economic issue. The functions and services provided by mangrove areas are diverse and have been well documented and appraised (Lugo and Snedaker, 1974; Mitsch and Gosselink, 1993; Field et al., 1998). Mangrove ecosystems are diverse in both their species and in terms of their functional diversity, yet little is really known about the role of biodiversity per se in maintaining the services they provide. The environmental determinants of the successful restoration of mangrove habitats may be related to two observations:

- Substrate and physical factors only loosely explain the natural zonation of mangrove trees (Ewel et al., 1998a). In other words, there is some flexibility in the conditions in which mangroves can be planted.
- Disturbed mangrove ecosystems lead to rapid vegetation reestablishment and substrate stabilization (Field et al., 1998).

These two factors suggest that the physical niches in which mangroves can enhance landscape resilience are widespread. This is particularly so given the circumstances in Vietnam, where much planting is simply restoring former mangrove areas.

Economic analysis has recognized that the functions and services provided by mangroves, and wetlands in general, have economic value and that these are often ignored in the ongoing process of mangrove conversion (Barbier, 1993; Ruitenbeek, 1994; Barbier and Strand, 1998). Mangrove wetlands display the features of public goods in that their use is nonexclusive, and they are converted because these functions are undervalued. Often mangrove conversion takes place through overriding traditional common management of the resources (Adger and Luttrell, 1998; Bailey and Pomeroy, 1996). Identification of the functions and services, the incorporation of these into the land allocation process, and the encouragement of appropriate property rights — whether communal or private — are, therefore, necessary first steps in promoting sustainable utilization of such resources.

The economic rationale behind mangrove restoration in the case of three coastal districts of Nam Dinh Province in northern Vietnam is reported. In these areas, mangrove rehabilitation is often subsidized by international development agencies such as the World Food Programme, Oxfam, and Save the Children Fund as part of rural income-generating projects, based largely on an assumed benefit to local communities. This chapter provides some quantification of the economic and environmental parameters of restoration in the context of resilience and adaptability at different scales.

MANGROVE RESTORATION IN NAM DINH PROVINCE

Nam Dinh's Remaining Mangroves

This section describes conditions in Nam Dinh Province, located in the southwest portion of the Red River delta in northern Vietnam. The province includes three coastal administrative units: Xuan Thuy, Hai Hau, and Nghia Hung districts. The region has a sea dike system to protect people, houses, and crops. Freshwater reserves help mitigate against damage from saline intrusion, flood, storm, and seawater incursion. The total area of the three coastal districts is approximately 72,052 ha (Table 41.3).

Within Nam Dinh Province, the impacts of severe storms are generally concentrated in the coastal districts. The total population of the three coastal districts of Xuan Thuy, Hai Hau, and Nghia Hung is almost 0.5 million, with a population density of 1076 per km², which is typical of the densely populated areas of the Red River delta plain. The economy of these districts is primarily dependent on agriculture. Paddy cultivation, aquaculture, and salt making are the major agricultural activities. Each of these activities is susceptible to, and differentially affected by, typhoons.

Given the prevailing circumstances in the coastal districts of Nam Dinh Province and similar regions elsewhere, it is clear that mangrove restoration can have a variety of benefits where the topography of the coastal shelf and other social, physical, and ecological factors are appropriate. In such situations, mangrove restoration can provide income where households are often severely constrained in cash income sources, and restoration can yield environmental benefits through productive assets and reduction of potential damage from coastal storm surges.

Table 41.3 Mangrove Area in Nam Dinh Province

District	Present Mangrove Areas (ha)	Land Estimated to be Available for Planting (ha)
Xuan Thuy	3000	7640

Nghia Hung	5200	9826
Total	8400	18107

From Nam Dinh Province data.

Mangrove Restoration: Economic Analysis

Some economic values of the goods and services can be assessed by observation of existing markets, but many functions and services associated with replanting mangroves result in indirect or functional benefits. The crucial aspects of value for local decision making and for the differential impacts of environmental change are determined by whether these benefits stem from direct or indirect use. The major goods and services that accrue from mangroves in this area are outlined in Table 41.4. Some economic benefits of the mangrove resource will increase in value over time, while others will remain constant or decline. For example, as agricultural development intensifies, the potential economic losses from storm surges increase; thus, the value of the coastal protection function of the mangroves will rise accordingly. Exogenous environmental change associated with global climate change may increase the frequency and intensity of storm surges, and hence the value of this function of the mangroves is likely to rise over time.

The first step in this appraisal framework is therefore to delineate the resource issue and potential environmental change to be examined. In this case, the analysis allows examination of the resource efficiency of using land, labor, and capital resources to rehabilitate or restore mangroves in the coastal areas of Vietnam. Table 41.4 highlights an important distinction between the direct benefits of using mangroves, almost always extractive in nature and located within the mangrove areas, and those which are largely off site and indirect. It is often more difficult to quantify these indirect benefits because of the dynamic nature and ecological complexity of the relationship between the productive output

Table 41.4 Location and Nature of the Economic Benefits of Mangrove Restoration and Conservation

Type of Service	Location of Goods and Services	
	On Site	Off Site
Marketed goods and services	<i>Timber, tannin</i>	<i>Honey from beekeeping</i> , fishing
Nonmarketed benefits	Fish nursery function, <i>medicinal plants</i> , *crisis foodstuff, fodder, wildlife habitat	Storm protection function: Avoidance of cost of maintaining sea defenses and dikes Avoidance of impact on agriculture and infrastructure

Note: Goods and services in italics are quantified in this study.

* Medicinal plants utilized are surveyed and classified, but no economic value is estimated (see text).

Adapted from Dixon, J.A. and Lal, P.N., The management of coastal wetlands: economic analysis of combined ecologic-economic systems, in Dasgupta, P. and Mäler, K.G., Eds., *The Environment and Emerging Development Issues*, Clarendon, Oxford, 1997.

and the mangrove forest. The fish nursery function of mangroves, for example, is well established (Primavera, 1998), yet it is difficult to attribute the value of final commercial or subsistence fish catch to this single function among many of the whole system (see Barbier and Strand, 1998).

The second step in this appraisal is the identification among these services of a set of costs and benefits. The allocation of effects into costs and benefits involves determining the current situation, and focusing in partial analysis on the values of the marginal changes. The economic cost-benefit analysis of mangrove rehabilitation schemes in this case is of the form:

$$NPV = \sum_{i=1}^{\gamma} \frac{B_t^T + B_t^{NT} + B_t^P - C_t}{(1+r)^t}$$

where

NPV = net present value (VND per ha)

B_t^T = net value of the timber products in year t (VND per ha)

B_t^{NT} = net value of the nontimber products in year t (VND per ha)

B_t^P = value of the protection of the sea defenses in year t (VND per ha)

C_t = costs of planting, maintenance, and thinning of mangrove stand in year t (VND per ha)

r = rate of discount

t = time horizon (20-year rotation).

Estimates of the data sources and methods for carrying out the quantification and valuation of costs and benefits in establishing the rehabilitated mangrove stands are summarized in Table 41.5.

Direct Costs and Benefits of Restoration

The costs of establishing the rehabilitated mangrove stands are estimated primarily based on the cost of labor for the activities described. The survey research was carried out in 1994, when the cost for a workday was typically 2.5 kg of rice or VND 5500. Planting of 1 ha of mangroves required 95 workdays or VND 522,000, as shown in Table 41.5. The estimates are averaged across the three districts, with variations in costs dependent on where the seedlings were obtained. The planting and handling fees for seedlings obtained from forests in the area under rehabilitation are not significant compared to costs for collecting, handling, and transportation for other areas that

Table 41.5 Benefits, Costs, and Valuation of Mangrove Rehabilitation in Vietnam

Impact or Asset Valued	Method and Assumptions for Valuation	Timing of Costs and Benefits
Benefits		
Timber benefits	Market data: thinning (VND 180 per tree); extraction mature trees (VND 5000)	Thinning and extraction from year 6 with 3-year rotation
Fish	Market data: mean price of VND 12,500 per kg; yield 50 kg per ha	Fishing benefits from year 2 after planting
Honey	Market data: potential yield estimated at 0.21 kg per ha	Honey collected from year 5 after planting
Sea dike maintenance costs avoided	Morphological model: costs avoided three-dimensional (stand width, age, mean wavelength)	Benefits rising from year 1
Costs		
Planting, capital, and recurrent costs	Market and labor allocation data: costs of seedlings and capital (VND 440,000 per ha); workdays valued at local wage in rice equivalent (VND 5500 per day)	Planting costs at year 1; thinning from year 6 on 3-year rotation

US\$1 = VND 11,000.

increase depending on the distance from the seedling source site to the planting site. The seed mortality rate between time of collection and time of planting adds an additional cost factor.

For some mangrove species, such as *Sonneratia* sp., *Avicennia* sp., *Aegiceras* sp., and others, planting directly onto mud flats is unsuccessful due to the exposure to strong wind and wave forces that wash away the seedlings. The cost of raising such species in a nursery and transplanting them at 8 months old is relatively high, with fees for maintaining the nursery, care, protection, and transportation adding to overall expenditure. The costs of establishing a stand, including planting, gapping, and protection, occur mainly in the first year. Maintenance, beginning with the second year, incurs an estimated annual expenditure of VND 82,500 per hectare. The cost of thinning occurs in years 6, 9, 12, 15, 20, and 25.

The benefits from wood and fuelwood sources from the processes of periodic thinning and extraction are derived from observations in local markets and are shown in Table 41.5. The timber benefits represent wood for poles and fuelwood. The benefits from direct fishing sources were estimated on site. Fishing activities in the three districts are undertaken through the use of simple fishing nets, simple tools, or even by hand. Aquatic products include fish, crab, shrimp, and shellfish. The yield is estimated at approximately 50 kg per hectare within mature mangrove stands annually for all types of aquatic products. The average unit price in 1994 was around VND 12,650 per kg averaged across the products. Some evidence exists indicating that present exploitation of mangrove aquatic products in the Red River delta may lead to declines in fish stocks, although they are considered conservative for the districts surveyed.

Honey from beekeeping is derived from the flowers of a number of mangrove species, though the season spans a limited number of months. The honey from mangroves is obtained during the first flowering season of *Kandelia candel*, from January to March, and from July to September for other mangrove species and the second flowering season of *K. candel*. The potential yield from this bee honey source was estimated to be an annual minimum of 0.21 kg per hectare. Honey production is possible from 5 years after planting, though some species of mangrove can flower after 3 to 4 years, and even after 1.5 years from planting.

In addition to these direct uses, mangroves produce other subsistence and indirect services as shown in Table 41.4. In particular the diverse species within a mangrove forest are used extensively for medicinal purposes. For the established mangrove area of Xuan Thuy, the major utilized flora are shown in Table 41.6 along with other subsistence uses. This information is based on extensive

Table 41.6 Useful Species within the Mangrove Area of Xuan Thuy Protected Ramsar Site

Species	Timber, Fuelwood, and Charcoal		Tannin	Green Manure		Food	Fodder	Beekeeping	Medicinal Plant	Medicinal Use
<i>Acanthius ebracteatus</i>									+	Boiled bark and roots used for cold symptoms, skin allergies; bark in malaria treatment and back pain
<i>Acanthius illicifolius</i>									+	Leaves for relief of swelling, rheumatic pain, neuralgia
<i>Achyranthes aspera</i>									+	Leaves as poison antidote and applied to boils

Based on Tri, N.H. et al., Economic Valuation Studies of Mangrove Conservation and Rehabilitation in Nam Ha Province, Red River Delta, Progress report for SARCS/WOTRO/LOICZ, Mangrove Ecosystem Research Centre and CERED, Hanoi, Vietnam, 1997; and Hong, P.N. and San, H.T., *Mangroves of Vietnam*, IUCN, Bangkok, 1993.

surveys in Xuan Thuy District and on the identification of these uses more generally by Hong and San (1993). Leaves, bark, or roots from more than 30 species of plants are commonly used in medicines in the district, with other parts of the plants used for tannin, manure, and directly as food in times of food shortage. These direct consumptive uses are not included in the cost–benefit analysis presented here. Medicinal uses of plants and their associated cultural significance constitute primary reasons for conservation of forest areas, to an extent more significant than can be captured in any economic analysis (Crook and Clapp, 1998; Brown, 1995). The utilization of these areas, particularly for subsistence and nonmarket uses, adds weight to the argument for restoration and conservation.

MANGROVES AS COASTAL PROTECTION

The planting of mangroves on the seaward side of the extensive sea dike system helps reduce costs that would otherwise be expended in maintenance of these defenses. Such maintenance takes place on an annual basis in most of the coastal districts of Vietnam — previously through the obligatory labor of district inhabitants organized by the district committees, and now primarily financed through local land taxes. These commitments draw a heavy burden on labor-scarce households and constitute a source of conflict over the interdistrict allocation of labor contracts (Adger, 1998).

The impact of typhoons on coastal Vietnam is significant. One typhoon in October 1985 was responsible for the loss of almost 900 lives. In addition, 3300 boats were sunk and over half a million people were rendered homeless. While this was a particularly extreme single disaster, over 400,000 hectares of crops were lost in the coastal provinces of Vietnam as a result of tropical cyclone impacts over the 10-year period 1977 to 1986 (Thu, 1991). Protecting vulnerable coastal areas from typhoon impacts is, therefore, of high social and economic importance. Yet in a nation where resources are limited, affording adequate protection can prove difficult even in the present day (Wickramanayake, 1994). Estimates of the magnitude of impacts in Nam Dinh Province from floods and typhoons for the 20 years between 1973 and 1992 show that more than 990 people were injured or killed, and damage totaling VND 470 billion (1993 constant prices) occurred as a result of severe storms.

The evaluation of the role of mangroves in protecting sea dikes is estimated from expenditure on their maintenance and repair in comparison with a case in which no mangroves exist, using a control situation assumed to have similar morphological characteristics. In general terms, the greater the area of mangrove, the greater the benefit in terms of avoided maintenance costs. Establishing a precise set of relationships in order to estimate the benefits is not, however, a straightforward matter because the mechanisms by which mangroves protect the adjacent dike are complex. Mangrove stands provide a physical barrier, resulting in drag effects and dissipation of wave energy. They also help stabilize the seafloor, trapping sediment, and can affect the angle of slope of the sea bottom, resulting in dissipation of wave energy.

Studies in southern China have demonstrated an empirical relationship through which the benefit, in terms of avoided cost (B_i^p), can be expressed as a function of the width of the mangrove stand as a proportion of the average wavelength of the ocean waves to which the stand is exposed, as well as various parameters related to the age of the stand (mangrove size and density) expressed as a buffer factor. The key parameters are illustrated in Figure 41.2. The relationship was developed and tested in mangrove stands in southern China and has been calibrated in Vietnam through simulation (Vinh, 1995). We have used a simplified version of this relationship in estimating indirect use value in this study. Here, the buffer factor, α , is given by:

$$\alpha = \frac{2\pi R^2}{1.73b^2}$$

Figure 41.2 Profile of rehabilitated mangrove stands showing parameters of estimation of avoided maintenance cost.

where R is the mean radius of the canopy of an individual tree (m), which increases with age, and b is the typical distance between trees (m), which generally increases with time. As the stand matures, α increases from a minimum of around 0.1 to close to 1.0 as the stand presents a more and more effective obstacle.

Observations indicate that a mature stand will avert 25 to 30% of the costs of dike maintenance, assuming a stand width at least comparable to the characteristic wavelength of the incident waves. Tri et al. (1998) extended this analysis and showed that beyond a certain point, increasing stand width results in decreasing gains in protection. Typical wavelengths would be between 25 and 75 m, suggesting that the stand width should be on the order of 50 to 100 m.

For the Nam Dinh example, the model is calibrated using survey data on the annual costs of maintenance of sea dikes in each of the three coastal districts and data on mangrove productivity (growth in terms of mean annual increment, height, canopy density) for *Rhizophora apiculata* (Aksornkoae, 1993). The model was tested for its sensitivity to various parameters including the costs of maintenance in the districts and the design of the protection schemes in terms of the width of the stand in front of the sea dikes.

The model used here must be regarded as a provisional attempt to estimate the benefits associated with reduced maintenance costs. In particular, we consider the model may be overestimating the benefits when the stand is not fully developed or the width of the stand is much less than the incident wavelength. Nevertheless, uncertainties in this area may not be critical for two reasons. First, as will be seen, the direct benefits from use of the resources are considerably more significant than this indirect use value; and second, the value estimated here is only part of the true storm protection value, which must also include broader damage avoidance benefits and is, therefore, a lower bound figure.

The model of maintenance costs avoided was used for the three coastal districts to derive the indirect benefit of mangrove rehabilitation. The baseline costs of maintenance are incurred by the district committees, which keep detailed records of workdays and expenditure on annual maintenance. Recent estimates of the number of person–days a year spent on dike maintenance were used in the calculations. Because the results represent the average situation, the impact of the most severe storm surges on both the cost of maintenance and repair of dikes is not tabulated. In addition, this model does not account for other damage costs associated with storm occurrence, such as agricultural losses.

COMPARING THE COSTS AND BENEFITS OF RESTORATION

The full results of the cost–benefit analysis are presented in Table 41.7. This cost–benefit analysis is of a partial nature, comparing establishment and extraction costs with the direct benefits from extracted marketable products and with the indirect benefits of avoided maintenance of the sea dike system. We assumed that present-day conditions continue to prevail with respect to storm

Table 41.7 Costs and Benefits Comparison of Direct and Indirect Use Values of Mangrove Restoration

Discount Rate	Direct Benefits (PV million VND per ha)	Indirect Benefits (PV million VND per ha)	Costs (PV million VND per ha)	Overall B/C Ratio
3	18.26	1.40	3.45	5.69
6	12.08	1.04	2.51	5.22
10	7.72	0.75	1.82	4.65

Notes: Stand width = 100 m; incident wavelength = 75 m. US\$1 = VND 11,000. B/C ratio = NPV Total Benefits/NPV Costs.

Data from Tri, N.H., Adger, W.N., and Kelly, P.M., Natural resource management in mitigating climate impacts: mangrove restoration in Vietnam, *Global Environ. Change*, 8:49–61, 1998.

frequency. The results show a benefit–cost ratio in the range of four to five for a range of discount rates. The low relative changes in benefit–cost ratios illustrates that most of the costs, as well as the benefits of rehabilitation, occur within a relatively short time frame, with even the reduced maintenance cost beginning to accrue within a few years of initial planting.

Choosing the rate of discount is considered by many economists to be somewhat arbitrary and dependent on whether the project to be appraised is undertaken in the public or private domains. A range of real discount rates from 1 to 20 have been used in many circumstances, but rates at the lower end of this range tend to reflect the time preferences implicitly applied by governments in investments on behalf of society (see Markandya and Pearce, 1991). The results presented in Figure 41.3 appear to be robust in comparison to the discount rates adopted as a sensitivity test.

Figure 41.3 illustrates that the direct benefits from mangrove rehabilitation are more significant in economic terms than the indirect benefits associated with sea dike protection over a range of realistic parameter values. As might be expected, the greater the stand width, the more important the direct benefits in comparison to the avoidance of maintenance costs (Figure 41.3a). Yet even at the lower end of the range of realistic stand widths, offering the greatest return per hectare given suitable conditions, the direct benefits dominate (Figure 41.3b).

As shown in Table 41.4, the sea dike protection estimates do not include the benefits of reduced repair after serious storm damage or the potential losses of agricultural produce when flooding occurs. Flooding associated with severe tropical storms can lead to large economic losses, as well as to loss of life, and a reduced probability of flooding associated with the protection afforded by the mangrove would be an additional indirect benefit. This benefit has not been estimated to date, though the impact of historic storms can be discerned by examining aggregate agricultural production from district archival records. Figure 41.4 shows total rice production in one of the case study districts, Xuan Thuy, from 1981 to 1995.

The radical increase in agricultural production over the period coincides with the liberalization of agricultural production practices and distribution of leaseholds to individual households, beginning with the *output contract* system in the early 1980s. But the major storms crossing the coast close to this district over the period can be seen to have some effect on agricultural production, at least in 1986 and in 1994. However, despite little evidence of the impact of the 1992 storms on agricultural output, we know that the timing of extreme events as well as institutional and other factors directly affect vulnerability in both physical and social senses. The impact of the presence or absence of mangroves in its role as protecting agriculture in coastal areas cannot be directly deduced from these data. Again, the complexity of the relationship between mangroves and economic and social systems is the limiting factor in such analysis.

In any event, it is clear from the results of the economic analysis summarized in Figure 41.3 that the direct benefits from mangrove rehabilitation mean that this activity is economically desirable, as evidenced by the positive net present values at all discount rates considered. The increase in net present value associated with mangrove planting resulting from the inclusion of dike main-

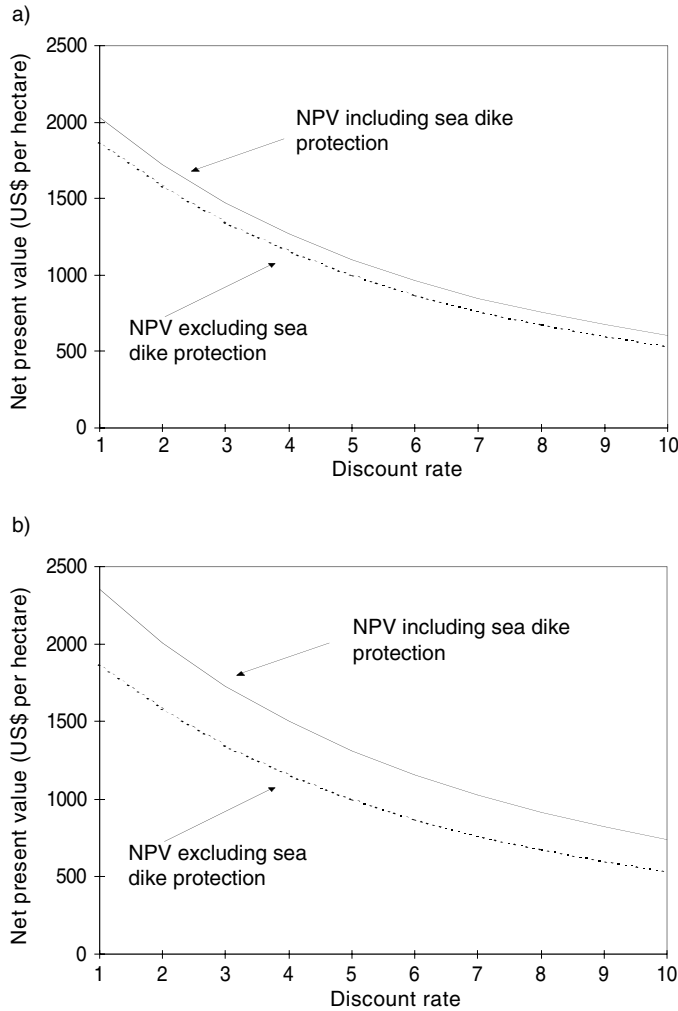

Figure 41.3 Net present value of mangrove rehabilitation, including value of sea dike protection, for two cases: (a) stand width = 100 m; incident wavelength = 75 m, and (b) stand width = 33.3 m; incident wavelength = 25 m.

tenance savings supports the desirability of planting. The results presented in Table 41.4 show that this indirect joint product benefit of mangrove rehabilitation is significant in further strengthening the economic case for such action in these locations.

CONCLUSION

This chapter argues that mangrove restoration has the potential, under suitable social and physical conditions, to provide *win-win* situations, whereby the dichotomy between short- and long-term concerns in adaptation to environmental change is avoided. It can be contrasted with one alternative course of action — building higher sea dikes — which, while possibly necessary if the threat of increased storm impacts materializes, provides limited benefits in the short term.

A broader lesson can be drawn from this analysis regarding approaches to the problematic issue of adaptive responses to long-term environmental change. Decision makers face difficult choices in assigning priorities when faced with an uncertain future in a resource-limited present.

Figure 41.4 Total rice production and production per capita for Xuan Thuy District and timing of major storms, 1981–1985. (Data from Xuan Thuy District archives.)

We would argue that this difficulty can be minimized by adopting a precautionary approach that focuses attention on present-day or near-future benefits that will accrue regardless of the nature and magnitude of the impact of environmental change. In the example presented in this chapter, mangrove restoration — a practice that is widespread and is based on available and appropriate technology — provides immediate economic benefits to residents of the adjacent settlements that are most vulnerable to storm impacts, while reducing the potential for storm damage over the near and long term.

A Comparison of Landscape Change Detection Methods

Curtis M. Edmonds, Anne C. Neale, Daniel T. Heggem, James D. Wickham,
and K. Bruce Jones

INTRODUCTION

This chapter compares change detection analysis using Normalized Difference Vegetation Index (NDVI) data derived from satellite images, with the analysis of change based on the same images classified into land cover. The NDVI index has provided the researcher with a reliable method to measure vegetative biomass through the use of satellite imagery (Tucker, 1979) for nearly 20 years. NDVI can be used as a fast and convenient method for measuring temporal changes associated with vegetation (Lyon et al., 1998). This chapter will show that the NDVI change detection process can provide a cost-effective method of accurately targeting areas within a region that have undergone extensive human land use change.

STUDY AREA LOCATION

The data for this evaluation were made available through a study conducted in the Tensas River Basin, located in northeast Louisiana and documented in *An Ecological Assessment of the Louisiana Tensas River Basin* (Heggem et al., 1999b). The study area encompasses approximately 930,000 acres of historical Mississippi River alluvial floodplain (Figure 42.1). The Tensas River is now hydrologically connected to the Atchafalaya River, which is a major tributary of the Mississippi River (Gosselink et al., 1990). Historically, most of the Tensas River Basin was covered with bottomland hardwood forested wetlands. The bottomland hardwoods of the Tensas River Basin have been described as some of the richest ecosystems in the country in diversity and productivity of plant and animal species (Rainer et al., 1994). At the same time, these lands are recognized as among the nation's most productive regions for grain and fiber farming (Townsend, 1996). The result is a conflict between advocates of land use for traditional row crop agriculture and defenders of a healthy, diverse, and stable ecosystem. In years past, the stakeholders of freshwater marshes, stream bank areas, and bottomland swamps of the basin were under strong development pressure to increase agriculture production. As a result, large portions of forest near streams and in backwater swamp areas were converted to agriculture (Heggem et al., 1999a). This loss of forested areas allowed increasing levels of pollution to enter streams, lakes, and estuaries. Loss of wetland forests

Tensas River Basin

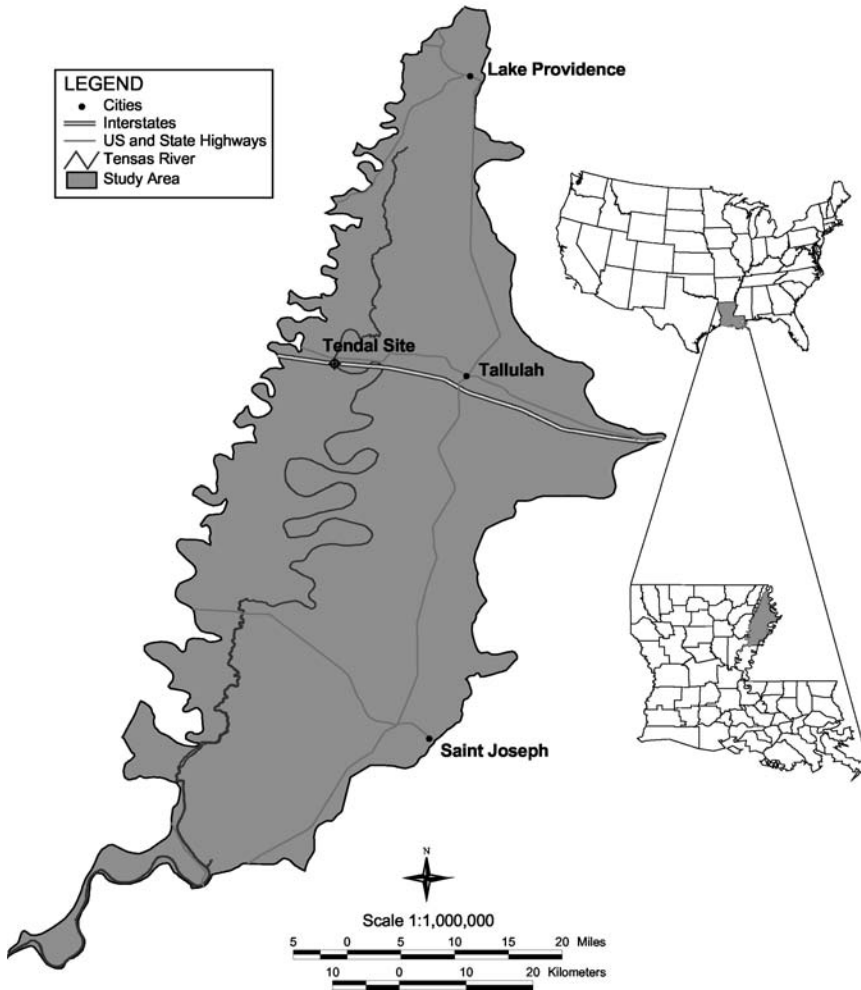

Figure 42.1 Tensas location map.

also impeded flood control efforts because wetlands absorb peak flows during floods, reducing damage to downstream farms and cities. These economic and environmental benefits, coupled with their recreational value, make preserving and restoring the wetland forests an important concern for the people living within the Tensas River Basin.

MATERIALS AND METHODS

Our study area roughly corresponds to the U.S. Geological Survey (USGS) Hydrologic Unit 08050003, which includes the area around the main channel of the Tensas River. During the course of our study, we divided the watershed into topographically relevant subwatersheds, or zones, and examined landscape indicators based on these subwatersheds. These subwatersheds, known as 11-digit hydrological accounting zones, were defined by combining the 8-digit hydrologic unit boundary with the Natural Resources Conservation Service (NRCS) 11-digit boundaries (Figure 42.2). Note that zones 2, 7, and 9 were not defined as 11-digit hydrologic accounting units by NRCS,

Figure 42.2 The 11- and 8-digit HUCs from Tensas River.

but they do fall within the boundary of the 8-digit USGS hydrologic unit code (HUC) boundary. Subwatersheds 2 and 7 may be parts of other subwatersheds or contain, most likely, bayous in which water could flow in many directions.

The North American Landscape Characterization (NALC) (Lunetta et al., 1993; 1998) data set contains triplicate images from the early 1970s through the early 1990s and covers the lower 48 states and Mexico. These data were derived from multispectral scanner imagery and processed to a resolution of 60 m. Images were selected from this data set to cover the Tensas River Basin. The Tensas River Basin study area is not contained within one path/row scene. Therefore, it was necessary to mosaic (combine) two NALC images to cover the study area for the 1970s (Figure 42.3a) and again for the 1990s (Figure 42.3b). The images that were available for the 1970s were created on the same date in 1972; however, the two images for the 1990s were from different years, 1991 and 1992. The 1970s and 1990s mosaicked images were then adjusted using a multiple-date empirical radiometric normalization process (Jensen, 1996) in order to produce a statistical comparison between the two time periods.

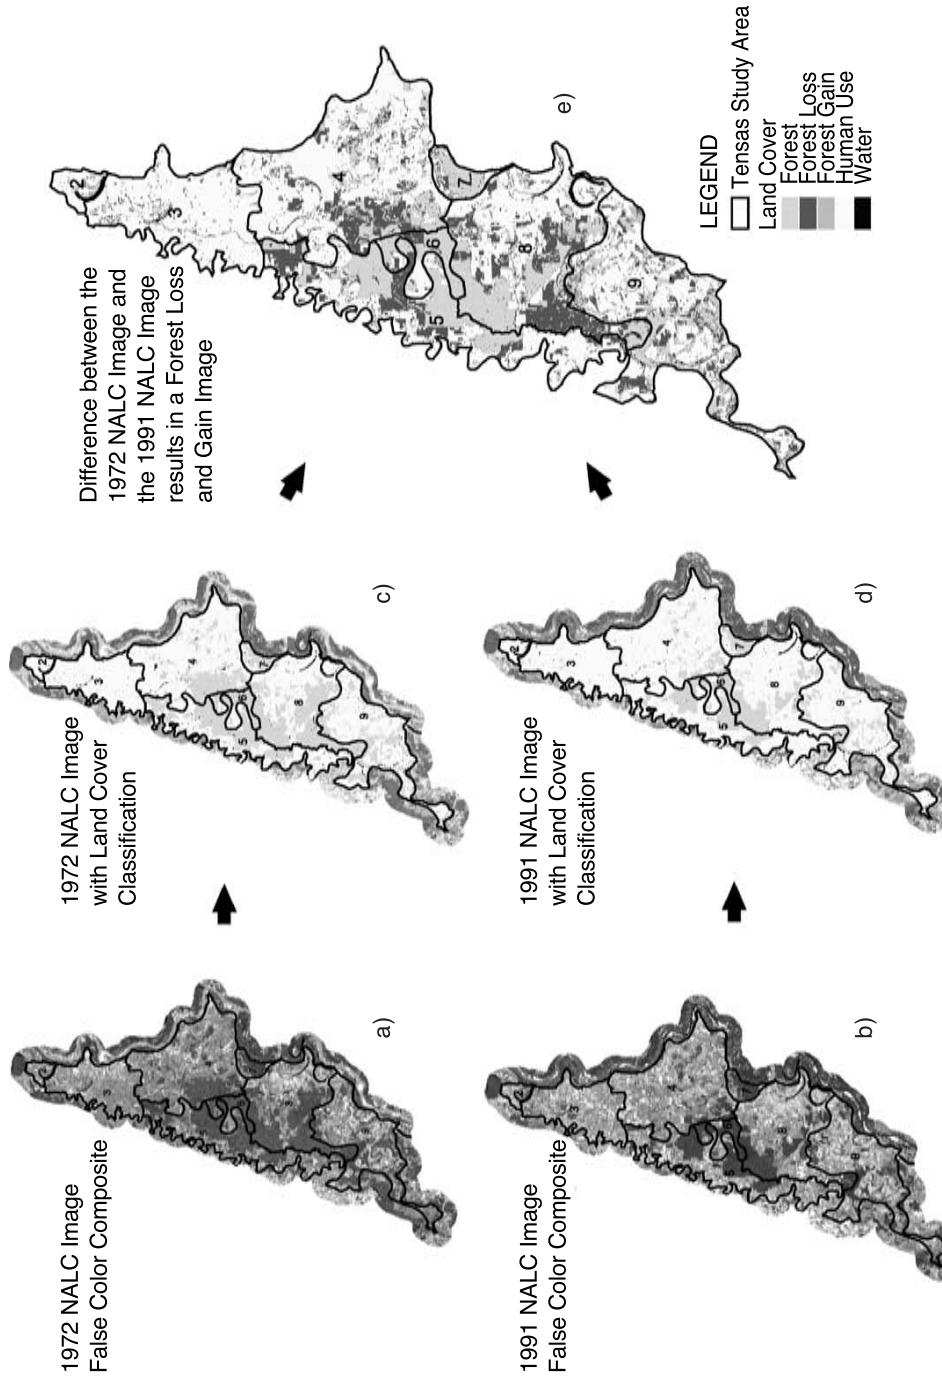

Figure 42.3 a, 1972 mosaic of Tensas River Basin (cut out to show only the study area), b, 1991 and 1992 mosaic of Tensas River Basin (cut out same as a), c, Land cover derived from the 1972 mosaic image, d, Land cover derived from the 1990s mosaic images, e, Difference between the 1972 and 1990s mosaic images, showing gains and losses.

Classification Method

The images were classified into a three-class system of forest, human use (urban and agriculture), and water. Classification of images was conducted using a combination of alternating supervised and unsupervised classifications (Lillesand and Kiefer, 1994) until a high percentage of features on both images (i.e., 1970s and 1990s) were classified. In areas difficult to classify, digital raster graphic maps were used to locate and identify features. In addition, air photos (1:24,000) were used to identify forests and wet agricultural fields. Analyses were performed by zone for each image, and then the number of picture elements (pixels) within each land cover type was calculated. The 1970s image and the 1990s images were compared, and the resultant change image is shown in Figure 42.3e.

Normalized Difference Vegetation Index (NDVI) Method

The same images that were used in the land cover classification method, previously described, also were used to calculate NDVI. Images were then created from the NDVI values. NDVI is calculated from the following equation:

$$\text{NDVI} = \frac{(\text{NIR} - \text{red})}{(\text{NIR} + \text{red})}$$

where NIR represents the band in the near infrared, and red represents the band in the visible red. Band seven (800 to 1100 nm) from the NALC data was used for the NIR band, and band five (600 to 700 nm) was used for the visible red band. Values derived using NDVI range from -1.0 to +1.0, where negative index values represent clouds, water, and snow; index values near zero represent barren soil and rocks; and positive index values are indicators of the vegetation biomass (Lillesand and Kiefer, 1994). A difference image was then generated by subtracting the 1970s NDVI image from the 1990s NDVI image. Positive values represent gains in vegetation, while negative values depict losses in vegetation. The standard deviation was calculated from the difference image across the entire basin. In Figure 42.4, pixels that exceeded 1.5 standard deviations of loss were set to red, and pixels that exceeded 1.5 standard deviations of gain were set to green. This method of differentiating change is described in the appendix of *An Ecological Assessment of the United States Mid-Atlantic Region* (Jones et al., 1997). The large patches of forest loss shown in Figure 42.3e and in Figure 42.4a clearly bear a strong resemblance to the large patches of NDVI loss shown in Figure 42.4b.

RESULTS

The majority of changes in the Tensas River Basin result from the conversion of forested areas to agricultural use. The classification method showed a net loss of 46,234 hectares, or 12.3% of the study area. The NDVI method showed a net loss of 42,807 hectares, or 11.4% of the study area. Loss and gain data are represented in hectares and percentages of area by subwatershed in Table 42.1 for the land cover classification method and in Table 42.2 for the NDVI method. The data from both of these processes are then ranked (greatest to least loss) by subwatershed and are presented in Table 42.3.

The data presented in Table 42.3 reveal that the results ranked from the NDVI change detection are quite similar to those resulting from the land cover change detection method.

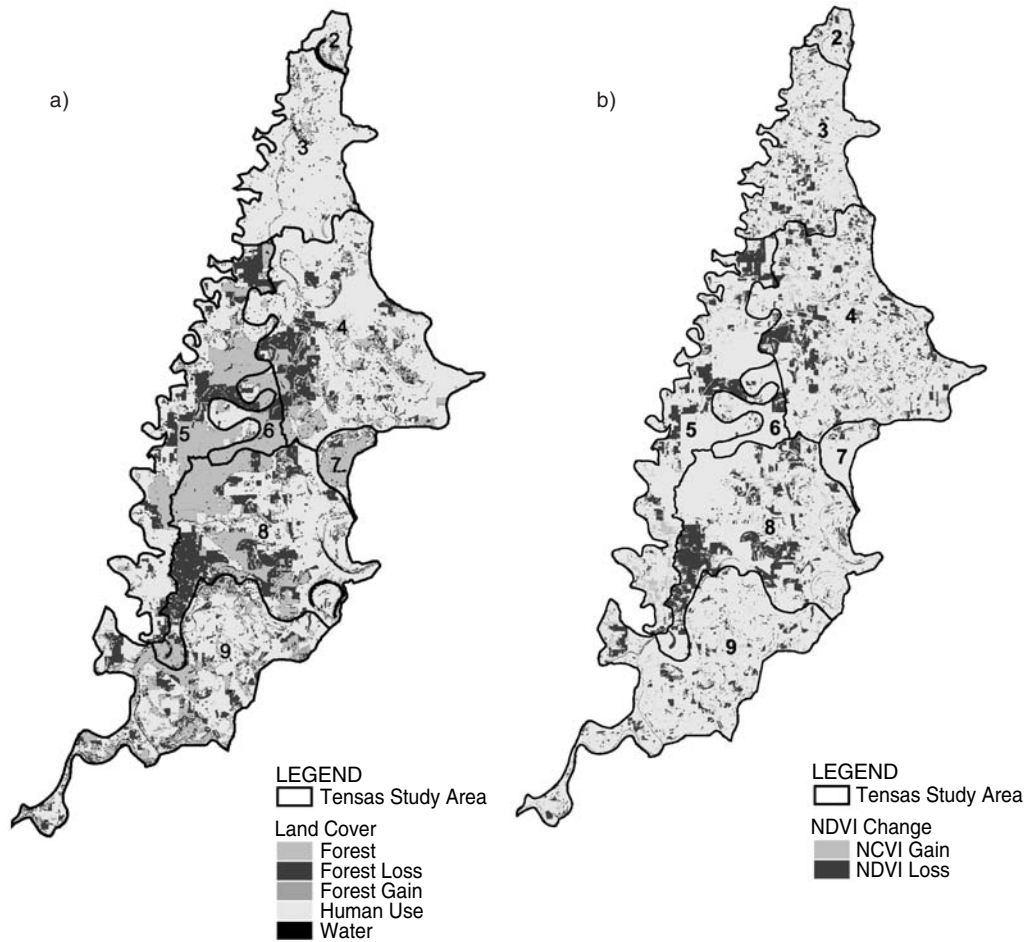

Figure 42.4 NDVI change image with loss set to black and gain set to gray (1.5 standard deviation).

DISCUSSION AND CONCLUSIONS

In this study, the two methods produced very similar results. This is an encouraging finding because the NDVI method is far less time-consuming than the land cover classification method. However, several issues should be analyzed and reconciled before this method of analysis could be applied confidently to a study area.

One issue concerns NDVI changes occurring as a result of agricultural practices. For example, subwatershed 3 had very little forested area in the 1970s image (less than 2%) and, thus, any loss in vegetation as calculated by NDVI change may be the result of agricultural practices, such as crop rotation, or growing season and harvesting differences. Another issue concerns climate differences. Images that are derived, for example, during particularly wet or dry time periods could conceivably cause misleading results when performing change detection. The causes of changes in NDVI may not be as easily identifiable as changes found by the land cover classification method. Losses in NDVI, for example, could be caused by road improvements, new residential developments, urbanization projects, and construction of reservoirs, as well as by increases in agriculture. Gains in NDVI may be caused by additions of golf courses and municipal parks or by increases in forested areas. Obviously, interpretation of NDVI values for actual land cover change requires additional work beyond simply calculating the difference over time; it requires a knowledge of the area studied.

Land Cover Forest		NDVI Vegetation	
Zone	Net Change	Zone	Net Change
8	-21.3	8	-18.7
5	-15.9	5	-11.7
4	-12.0	4	-11.4
9	-9.1	9	-6.9
6	-8.9	3	-8.1
3	-1.4	6	-5.5

The availability of a temporal data set like NALC, coupled with NDVI change detection methods presented in this chapter, gives researchers a fast and consistent method of targeting ecosystems at varied scales. For example, with the need to study the hypoxia problem in the Gulf of Mexico, this method could be used to target high-nutrient runoff areas within the Mississippi Basin requiring further study. This may be a more cost-effective method than analyzing millions of individual farm fields in the basin, as other investigators have suggested (Warrick, 1999).

ACKNOWLEDGMENTS

The authors would like to thank Lee Bice and Karen Lee of Lockheed Martin Corporation for their support during the preparation of this document. Their contribution has been funded by the U.S. Environmental Protection Agency's Region 6 under Contract 68-C5-0065 to Lockheed Martin Corporation. This chapter has been subjected to the agency's review, and no official endorsement should be inferred.

Relationships among Environmental Stressors and Fish Community Composition and Health: Case Study of Chesapeake Bay

Susanna T.Y. Tong

INTRODUCTION

Located within the states of Maryland and Virginia, the Chesapeake Bay is the largest estuary in the U.S. Biologically, it is one of the most productive systems in the world. The primary production exceeds $400 \text{ g/Cm}^2/\text{year}$ (Sellner, 1987). Stretching from the mouth of the Susquehanna River at Havre de Grace in Maryland seaward to Cape Charles and Cape Henry, it is about 322 km long and varies in width from 5 to 48 km. The bay's drainage basin is 166,000 km² in extent, and it includes more than 150 rivers, creeks, and branches. About 94% of Maryland's land area drains into the Chesapeake Bay. The Susquehanna, Potomac, and James Rivers are the largest rivers in terms of drainage areas and freshwater input to the bay system.

Chesapeake Bay is a very young estuary, less than 10,000 years old. It was formed during the most recent rise in sea level in the postglacial period. More than 12.7 million people live in the region. Virtually every type of economic activity and land use is found in its watershed. Agriculture, residential, and forest are the predominant land use types. Although it is situated so closely to human residential and industrial activities, the estuary encompasses a variety of aquatic environments that support a rich and diverse assemblage of freshwater and marine resources of flora and fauna. Besides the emergent tidal wetlands, the estuary hosts more than 20 species of submerged vascular plants in seven families (Hershner and Wetzel, 1987) and well over 900 different species of benthic invertebrates (Diaz, 1987). The bay produces over one half of the nation's blue crabs and soft-shelled clams and one fourth of its oyster harvests. Striped bass, menhaden, shellfish, finfish, and rockfish are also commercially harvested (Sellner, 1987).

Since the time of the industrial revolution, sound ecological management practices were neglected in the Chesapeake Bay and water quality has been deteriorating. This decline has accelerated throughout the past three decades. During this period, the bay region has undergone serious losses of farm and forest and has been subject to an increased threat from atmospheric deposition of nitrogen. Most important, the region is faced with the prospect of 1 million additional people moving into the watershed by the next decade. The rapid urbanization process in the watershed, widespread use of fertilizer and pesticides in the farms, and physical modification of the shoreline, combined with overharvesting, have caused substantial degradation of the estuarine habitat, reduction of the reproductive capabilities of many species, and depletion of the renewable

natural resources. Numerous chemical and physical pollutants are found in the Chesapeake Bay and its tributaries. Sediments, fertilizers, pesticides, herbicides, heavy metals, sewage, and petroleum products arrive in the bay from both point and nonpoint sources.

In the 1970s, the bay was so deteriorated that the distribution of the submerged and emergent aquatic vegetation, as well as that of the macro-invertebrates and game fish, had dramatically declined. More than 10 species of submerged aquatic vegetation have experienced significant decreases in abundance in Susquehanna Flats, in the lower reaches of the Patuxent, Potomac, Rappahannock, and York Rivers, and in innumerable other places throughout the bay (Price et al., 1985). Fishes collected from the Elizabeth River and Baltimore Harbor have a variety of maladies: lesions of the skin, liver, and gill, fin erosion, and cataracts. Today, probably no pristine, uncontaminated sites remain in the Chesapeake Bay.

In 1976, the USEPA established the multiyear, \$27 million Chesapeake Bay Program. The bay was the first ecosystem in the U.S. to be targeted for restoration. In 1983, a comprehensive study of the bay was concluded and the Chesapeake Bay Study Report was released. It has identified four areas of greatest concern: nutrient enrichment and associated algal growth; erosional inputs of sediments; the presence of toxic chemicals (such as agricultural herbicides, atrazine, and linuron); and the loss of submerged aquatic vegetation (DeFur, 1997). Among these, nutrient enrichment — regarded as the most important — is a problem in all watersheds, especially on the eastern shore (Kemp et al., 1983).

In the Chesapeake Bay, the primary production and the carbon dynamics and flux are dominated by the photosynthetic activity of algae rather than vascular plants. The distribution of phytoplankton reflects the concentrations of nutrients and turbidity. Excessive nutrient loading, coupled with a high temperature, often provides a favorable condition for the growth of blue-green algae, even to the detriment of higher aquatic organisms. Massive blooms of harmful blue-green algae and dinoflagellates, such as *Pfiesteria piscidida*, have been observed frequently in recent years. In aquatic ecosystems, nitrogen concentrations of 0.5 to 1.0 mg/L are commonly used as threshold values for eutrophication. However, in estuarine environments, where salinity levels are greater and more sensitive to eutrophication, the threshold level drops to <0.6 mg/L (USDA, 1991). In addition to eutrophication, nitrate pollution poses a direct health threat to humans and other mammals. In cattle, nitrates can cause anemia as well as abortions. Nitrate levels of 40 to 100 mg/L in livestock drinking water are considered risky. High concentrations of nitrate also have been linked to methemoglobinemia in infants. The USEPA has established a maximum contaminant level for nitrate nitrogen in drinking water of 10 mg/L to protect the safety of U.S. drinking water supplies (USEPA, 1985). In many areas of the Delmarva peninsula, groundwater nitrate levels often exceed the 10 mg/L drinking water standard (Hamilton and Shedlock, 1992).

Agriculture is a major nonpoint source of nutrients in the Chesapeake Bay drainage basin (USEPA, 1983). Maryland agricultural statistics document approximately 18,000 farms in the state, totaling 2,650,000 acres. In the Chesapeake Bay watershed alone, approximately 17.9% of the land is cropland with more than 540 farms. Pastures comprise another estimated 16.5% of the land (Macknis et al., 1983). Fertilizers applied to farms contain nitrogen and phosphorus. Agricultural runoff from cropland and pasture is often enriched with nutrients. Consequently, runoff from these fields after rainfall constitutes one of the leading causes for nutrient loading in rural rivers. The USEPA and USGS estimated that annual total nitrogen loading to the bay ranged from 84.0 to 179.5×10^6 kg per year, depending on the dryness or wetness of individual years (USEPA, 1983; Lang, 1982). During the past 30 years, nutrients and chlorophyll *a*, an indicator of phytoplankton biomass, have increased in many areas of the bay. For example, in the upper bay, north of the Patapsco River, annual average concentrations of total nitrogen, phosphorus, and chlorophyll *a* have approximately doubled during this period. On the eastern shore, agriculture was estimated to contribute approximately 87% of the phosphorus and 70% of the nitrogen deposited into the bay. A study of the Upper Potomac River basin found that 28% of the nitrogen load to the watershed came from atmospheric deposition, 12% from biotic fixation and adsorption on surfaces of leaves,

16% from fertilizer, and 44% from animal waste (Jaworski et al., 1992). Another estimate suggested that 40% of the nitrogen load to the Chesapeake Bay watershed came from atmospheric deposition, 33% from livestock waste, and 27% from fertilizer (Fisher and Oppenheimer, 1991).

If we are to restore the ecological integrity of the Chesapeake Bay area and protect its fish resources, the trend of increasing nutrient loading must be reversed. Therefore, it is critical to understand the environmental factors that are controlling the nitrate levels and the health and composition of the fish communities in the bay area. By using a quantitative exploratory approach involving spatial and multivariate analyses, this chapter examines these intrinsic relationships.

METHODS

The data used included the water chemistry, habitat, and fish information from the 1995–1997 Maryland Biological Stream Survey, MBSS (Maryland Department of Natural Resources, 1997a,b). The MBSS is a statistical survey designed to characterize the biological and habitat conditions of the first-, second-, and third-order nontidal streams. Land use data were derived from the 1991–1993 leaves-on summer Landsat TM data. They were then calculated as percentage of land use for each 11-digit hydrological unit code (HUC) using a geographical information system (GIS). A list of the environmental attributes, together with their abbreviations used in this chapter, is shown in Table 43.1.

Table 43.1 Environmental Attributes Used in the Analyses

Environmental Attribute	Abbreviation
Stream Habitat Variables	
Aesthetic rating	AESTH
Bank stability	BNKST

Industrial	INDUS

Fish, a valuable biological resource of food for humans, is important to conserve because of its commercial and sport recreation values. Fish communities are at the top of the food chain. They are highly visible. As one of the most sensitive components of aquatic ecosystems, they respond predictably to changes in both abiotic and biotic factors. Hence, they are useful indicators of biological integrity and ecosystem health. When used in bioassessment, they can indicate the long-term conditions of the aquatic habitat. For these reasons, this research focuses on the composition and health of the fish communities.

Fish IBI is an *Index of Biological Integrity* for biological assessment of stream conditions. It is a synthetic index that combines several metrics, including tolerance, trophic status, native and introduced species, and lithophillic spawners (see Maryland Department of Natural Resources, 1997a,b). The MBSS IBI values range from 1 to 5. A score of 3 or higher represents a stream condition that is comparable to the minimally affected reference sites. Scores of 3 or lower represent conditions that are influenced by human activities and therefore are significantly different from the reference sites. Hence, in certain respects, IBI denotes the general structure, ecology, and health of the fish communities. The percentage anomalies (expressed as the number of anomalies for game and nongame fish divided by the total number of fish examined $\times 100\%$) is also used as an indicator of the general health of stream fish. Anomalies refer to hooking injuries, cuts, presence of visible parasites, and pathological abnormalities (such as ocular abnormalities, skin lesions, and skeletal deformities).

The approach to the analyses entailed, first of all, the examination of the relationships of in-stream nitrate levels, fish IBI, and percent of fish anomalies with environmental attributes in a few selected watersheds for which a complete set of environmental and fish data is available. The Maryland Biological Stream Survey sampled 18 subwatersheds. However, a complete set of environmental data is available for only nine of these subwatersheds (see Table 43.2 and Figure 43.1). Moreover, data documenting fish anomalies were lacking in most subwatersheds. Consequently, analyses of fish anomalies were confined to only three river basins.

To identify the watersheds with the highest concentrations of nitrate, the mean nitrate levels in each HUC of each subwatershed were calculated and plotted in a map. Correlation analysis was then conducted to examine the associations of in-stream nitrate levels and environmental attributes. For those watersheds that have elevated levels of nitrate, further regression analyses were conducted to quantify the relationships.

Fish IBI and percentage of anomalies were selected to indicate the general structure and health of the fish communities. They were used in correlation and stepwise multiple regression analyses

with environmental factors. However, these analyses cannot provide much information about the species composition and distribution. To ascertain the relationships among environmental factors and fish assemblages, an ordination technique was adopted.

Multivariate ordination techniques are useful exploratory tools to help elucidate latent environmental relationships and to define specific biocriteria. In this chapter, a nonmetric multidimensional scaling ordination technique was employed. This is a multivariate indirect ordination analytical method. The choice of nonmetric multidimensional scaling in this research is based on the fact that the model uses nonparametric mathematical algorithm and theoretical assumption; as such, it does not require metric, ratio, and normally distributed data, nor any linear and metric relationships among the variables. In addition, since it is an indirect ordination technique, a prior knowledge or assumption about the dependent and independent variables is not needed. The environment is holistic. Many factors are interrelated or interdependent to each other. The causal relationships among these factors are often very complex and may not be apparent to investigators. The indirect technique is therefore advantageous. Furthermore, nonmetric multidimensional scaling is proven to be a powerful and robust technique, capable of revealing the latent and meaningful environmental structure (Gauch, 1982; Davidson, 1983; Tong, 1989). Hence, it is a more flexible, unbiased, objective, yet reliable diagnostic approach to exploratory analyses in ecological studies (Minchin, 1987).

Based on the presence and absence values of fish species in each sampled site, the nonmetric multidimensional scaling was used to arrange the sites. According to the species distribution and composition, the pairwise similarities between the sites were calculated and a distance matrix constructed. The sampling sites were arranged in a special manner, the order of which is in accordance with the species distribution, thereby imparting the latent environmental gradients that are controlling the intrinsic structure of the fish species composition. The output of the ordination analyses were in the forms of site coordinates. To characterize the environmental gradient, the site coordinates were correlated and regressed with the environmental attributes, such as land use types and nitrate levels. However, since the ordination axes may not parallel the actual environmental gradients, the ordination axes were rotated in 10° steps through 180° . This generated 18 coordinate sets for each dimension. For each rotation, correlation and stepwise multiple regression analyses were performed using the habitat, land use, and water chemistry variables as the independent variables. The use of stepwise multiple regression was chosen to reduce the multicollinearity between the independent variables. Rotation of 1° is not feasible in this case, because doing so would generate 180 coordinate sets and 180 regression equations for each dimension. Environmental variables/factors that were highly related to the site coordinates were graphed against the angle of rotation (x -axis), with the y -axis depicting the level of correlation. Based on the graph, a rotational angle is selected for each dimension that resulted in the maximal level of correlation between the most important variable and the rotated site coordinate. The stepwise regression equation at that rotational angle was then selected for detailed interpretation. The environmental variables/factors that are featured in the graph and the stepwise regression equation were regarded as the latent controls for that environmental gradient.

Using the nitrate map generated earlier, the most contaminated sites with the highest nutrient loading and the worst fish performance (such as IBI) were depicted through GIS overlays. These *hot spots* represented the most deteriorated sites with adverse ecological effects. They are the sites that warrant our immediate attention. Such information would be useful to land use planners, resource managers, and personnel at regulatory agencies for assessing the current conditions and prioritizing restoration efforts.

RESULTS

Table 43.2 and Figure 43.2 show the nitrate content in each watershed. Out of the nine watersheds examined, six have mean in-stream nitrate nitrogen levels above 1.0 mg/L, which is the threshold level for eutrophication. Among these watersheds, Nanticoke has the highest nitrate level. Other streams that

are enriched by nitrates are the Choptank and Middle Potomac. Stepwise multiple regression of land use variables (independent variables) on in-stream nitrate nitrogen (dependent variable) demonstrates that land use is an important factor in affecting the nitrate levels. For example, in Nanticoke, mixed forest and agricultural land use accounts for 77% of the variation of nitrates. In the Middle Potomac, deciduous forest and pasture account for 46% of the variation in nitrates (Tables 43.3 and 43.4).

The relationships of percent fish anomalies with environmental attributes were performed in only three watersheds: Nanticoke, Middle Potomac, and Choptank (Tables 43.5 and 43.6). In Nanticoke, only DOC is significantly related to fish anomalies. Land use variables (MIXED, DECID, AGR, and PAST) together explain about 40% of the variations of fish anomalies. In the Middle Potomac, VDPTH, EMBED, and RQUAL are apparently important in affecting the percentage of fish anomalies. SHADE, EMBED, and PAST are the variables that are significantly related to the percentage of fish anomalies in the Choptank.

The results of the IBI analyses for each subwatershed are shown in Tables 43.7 to 43.9 and Figures 43.3 and 43.4. The river basins that have high mean IBI values are the Choptank, Chester, and Lower Potomac — meaning that they are the “better” basins, comparable to the reference sites. Based on the IBI values, the state of Maryland (Chesapeake Bay and Watershed Programs 1997, 1998a,d) reported that 52% of the stream miles in the Choptank were in good condition. In Chester, however, the portion in good condition was 17%, and in the Lower Potomac it was 28%. River basins like North Branch Potomac and Upper Potomac have low IBI scores and are more degraded. The relationships of nitrates and fish IBI are unclear because not all of the basins that have high nitrate levels also have low IBI scores, or vice versa. The Nanticoke, Choptank, and Middle Potomac are the river basins that have the

highest levels of nitrate, yet their IBI scores are all acceptable with a score of 3 and above. Out of the nine basins analyzed, only two — the Lower Potomac and the Youghiogheny — have low mean nitrate levels and high IBI scores (see Tables 43.2 and 43.7 and Figure 43.3). In the Chester and Patapsco, the correlation coefficients of nitrates and IBI are significant; yet they are positively related. It means that as the levels of nitrates increase, the fish IBI values will increase and the stream conditions will be better. Hence, contrary to common belief, in-stream nitrate levels may not be a good diagnostic indicator of fish IBI in these river basins. Instead, other environmental factors are more prominent in

influencing IBI. For example, in the Choptank, correlation and regression results show that land use variables are more important. Industrial land use (INDUS) alone explains 66% of the variation of fish IBI in this river basin. Similarly, in North Branch Potomac, many land use variables are significantly related to IBI. LRES, DECID, AGR, MIXED together explain 63% of the IBI variation in the stepwise multiple regression. Once again, the harmful effects of land use are prevalent only in these watersheds. Consequently, land use cannot be regarded as a universal stressor for the region. Figure 43.4 offers an example of the relationships of land use with IBI. The GIS overlay shows that the North Branch Potomac is the only area with low AGR and high IBI values. In the Chester, Lower Potomac, Middle Potomac, Upper Potomac, and Youghiogheny, stream habitat variables like VDPTH, INSTH, EPSUB, and RQUAL are more important in affecting fish IBI. The *r* values for most of these variables with IBIs are above 0.41. Water chemistry, such as DOC, is more influential in the Patapsco and perhaps also in the Chester.

Ordination analyses implicate that different environmental factors are in control of the fish composition in different subwatersheds. However, a few environmental factors are more prominent. They are in-stream nitrate levels, land use, and velocity-depth/remote/riffle quality/shading (Table 43.10). In Nanticoke, Patapsco, and Upper Potomac, NO₃ is more important. The simple correlation coefficients of NO₃ with the rotated site coordinates for these river basins are all significant at a level above 0.45. COND is significant in the Youghiogheny, where the maximum *r* value is 0.74. It is the only variable that is featured prominently in the site coordinates rotation. Land use (DECID, HRES, and MIXED) is a significant environmental factor in the North Branch Potomac and Lower Potomac. Although the ordination results reveal two significant variables (DECID and DOC) in the North Branch Potomac, land use variables (in terms of DECID, AGR) are found in both stepwise regression equations. In the Lower Potomac, land use variables (HRES and MIXED) are featured in both rotated axes. Hence, it seems that land use has an important role to play in influencing the species composition and distribution in these two river basins. In the Middle Potomac, Choptank, and Chester, in-stream habitat characteristics, such as VDPTH, SHADE, RQUAL, and RMOTE, are the major environmental gradients. The maximum *r* value for VDPTH in the Middle Potomac is –0.68. It is the only variable isolated in the rotation. In the Choptank, both regression equations are predominated by in-stream habitat variables (SHADE, RQUAL, and EMBED). The *R*² values for both equations are above 0.75.

DISCUSSION AND CONCLUSION

In the Chesapeake Bay, the Nanticoke, Choptank, and Middle Potomac Rivers are enriched with nitrates. According to the Chesapeake Bay and Watershed Programs (1998a-c), elevated nitrate nitrogen above 1 mg/L occurred at 92% of the stream miles in the Nanticoke, 82% in the Choptank, and 83% in Middle Potomac. Reduction of the nitrate levels in the Chesapeake Bay will require concentration of efforts in these subwatersheds. Results from stepwise multiple regression and correlation analyses implicate that land use variables (percent of cropland and pasture) are important in affecting the levels of nitrate nitrogen in these streams. These results are in agreement with the suggestions of the Chesapeake Bay and Watershed Programs (1998a-c).

Similar results were reported by Lowrance (1983). He found that the movement of nitrate nitrogen from row crops was significantly higher than in pastures and upland pine forest. Likewise, Hall et al. (1996) concluded that nutrients were influenced by agricultural activities. The mean nitrate value and IBI scores for streams in agriculture areas were significantly higher than in forested areas. Correll (1987) has also noted that cropland/riparian forest watersheds discharged five times as much nitrogen and seven times as much phosphorus in runoff as forested watersheds, while pasturelands had intermediate discharges. The nitrate concentrations decreased as the proportion of forested land in the watershed increased. In drainage basins that are more than 85% forested, the nitrate concentrations were below 0.7 mg/L.

In terms of fish IBI values, the North Branch Potomac and Upper Potomac have the lowest scores. The conditions of these river basins are far from pristine, and they warrant our restoration effort if the ecology and structure of the fish communities are our major concerns.

The factors that control the health, ecology, structure, and composition of fish communities are revealed by synthesizing the results from nonmetric multidimensional scaling ordination and statistical analyses. A few environmental factors, including $\text{NO}_3/\text{DOC}/\text{ANC}/\text{COND}$ (water chemistry), $\text{DECID}/\text{HRES}/\text{MIXED}$ (land use), and $\text{VDPTH}/\text{SHADE}/\text{RQUAL}/\text{RMOTE}$ (stream habitat), appear to be important controls. But the effect of each environmental variable is different in individual watersheds. For example, the predominant environmental controls for the health and distribution of fish assemblages in the Nanticoke appear to be DOC , NO_3 , and perhaps land use. The Patapsco is dominated by $\text{ANC}/\text{COND}/\text{NO}_3$, and possibly land use. Likewise, land use is a major environmental gradient in the North Branch Potomac. SHADE and land use are the key factors in the Choptank. In the Middle Potomac, VDPTH , and perhaps EMBED and RQUAL , seems to be important. Hence, evidence indicates that nitrates, land use, and — in the case of the Middle Potomac — velocity–depth ratio are the latent environmental structures in these river basins.

The research methodology used in this project involved an exploratory approach integrating statistical, ordination, and GIS analyses. The results of the analyses show that this approach is vigorous and reliable. This chapter has identified the watersheds that are enriched with nitrates as well as with low IBI scores. These may be the areas that warrant our restoration efforts. Moreover, this chapter quantified the relationships of nitrates and land use. Most importantly, it examined not only the health, structure, and ecology but also the composition and distribution of fish assemblages, identifying the environmental factors that are significant in controlling the fish communities.

ACKNOWLEDGMENTS

This project was performed when the author was a summer research faculty fellow with the National Exposure Research Laboratory at the USEPA in Cincinnati, OH. The author is thankful to many contractors, especially Sherry Hu, Rona Fan, Jian Liang, and Jill McAfee of SoBran Inc.; Amy Liu of PAI, Inc.; and Keith Adams of OAO, Inc., for their valuable statistical, GIS, graphics, and data management support. Their help has greatly expedited the progress of the project, and their contributions are gratefully acknowledged.

Special thanks are also due to Paul Kazyak and Scott Stranko of the Maryland Department of Natural Resources for the use of their survey data (MBSS data). In addition, Susan Cormier and Brian Hill of the National Exposure Research Laboratory, USEPA, and Gabriel Senay of SoBran, Inc., have provided helpful discussion about the project.

The author is indebted to Kluwer Academic Publishers for their kind permission to use their copyrighted materials, including Tables 43.2 to 43.10 and Figures 43.1 to 43.4, that appear in the journal article: Susanna T.Y. Tong, “An integrated exploratory approach to examining the relationships of environmental stressors and fish responses,” *Journal of Aquatic Ecosystem Stress and Recovery*, Vol. 9(1), 1–19, 2001.

SECTION II.2

Assessing and Monitoring Biodiversity

Overview: Assessing and Monitoring Biodiversity

Santiago Carrizosa

Since the late 1980s, when the concept of biodiversity was brought to the public domain, scientists, conservationists, and policy makers have increased research activities in order to understand and manage the complexities of our natural world. Since then, biodiversity management objectives have not changed much; they still seek to protect biodiversity, to restore it, and to use it in a sustainable way. In contrast, new biodiversity management strategies and approaches have been undertaken during the past 10 years, as our understanding of biodiversity threats and ecosystem dynamics have increased. These new approaches include *in situ* strategies (e.g., conservation corridors); restoration and rehabilitation strategies (e.g., reintroduction of native species and repair of ecosystem services); major land use strategies (e.g., bioprospecting initiatives and sustainable use practices included in forestry, fisheries, agriculture, wildlife management, and tourism); and policy and institutional strategies (e.g., methods such as access laws, subsidies, and taxes to regulate access to and use of land resources).

In addition, several government and nongovernment organizations have designed national biodiversity action plans and bioregional management programs in order to carry out specific biodiversity management strategies. These strategies have been enacted with different levels of success all over the world. In general, ecologists thus far have not found sound strategies to reconcile the threats to biodiversity with the complex nature of tropical and some temperate ecosystems. The tropics contain the world's least understood ecosystems, which are being depleted at a faster rate than any other habitat. If that damage continues unchecked, we are destined to lose at least 50% of all species found on Earth (Myers, 1988). Discovery of new biodiversity management approaches is imperative. Fortunately, the concept of ecosystem health may have paved the way for a relatively new understanding and management of tropical ecosystems.

In 1992, Haskell et al. defined ecosystem health as a “characteristic of complex ecosystems” and concluded: “An ecological system is healthy and free from ‘distress syndrome’ if it is stable and sustainable — that is, if it is active and maintains its organization and autonomy over time and is resilient to stress.”

Sustainability is certainly a key word in this definition. The ecosystem has to be sustainable from the biological, social, cultural, and economic point of view. It has to maintain its structure, diversity, and biological relationships, and at the same time be able to produce services to society and to recover from external threats. This definition also suggests that the ecosystem health paradigm may be used to assess and understand the ecosystem's overall performance and to restore health to ecological processes at all levels.

Health as a concept has been traditionally associated with humans, but while physicians focus on the health of a single patient, biodiversity managers have to concentrate on the multiple social, economic, and natural levels and scales of the ecosystem (Haskell et al., 1992). The human health paradigm can also be used to develop the following parallel between the approaches followed by physicians and those of biodiversity managers to assess and monitor the health of humans and biodiversity, respectively.

Human Health	Ecosystem Health
Identify symptoms	<i>Identify "Pressure" indicators; they measure the factors that have an effect on ecosystem health (e.g., concentration of pollutants such as heavy metals)</i>
Identify and measure vital signs	<i>Identify "State" indicators to measure the present condition of biodiversity (e.g., species diversity/richness)</i>
Make a diagnosis and prognosis	<i>Develop a comprehensive assessment study; based on the above indicators and additional primary and secondary information, this assessment would describe the many causes of ecosystem stress</i>
Prescribe a treatment	<i>Design and enact a management plan</i>
Conduct tests to verify the effectiveness of the treatment	<i>Develop and implement a monitoring and evaluation plan (this includes collecting information over time for the State, Pressure, and Response indicators^a in order to monitor biodiversity); Response indicators are used to measure the activities enacted to obtain a desired biodiversity condition (e.g., national parks declared)</i>

^a The *State*, *Pressure*, and *Response* indicators framework has been proposed by organizations such as the OECD (1994), United Nations (1996), and SBSTA (1997) to monitor sustainable development and biodiversity conditions. This system can be adapted to respond to the needs of field scientists and policy makers alike.

The ecosystem health problems described in the chapters in this section indicate the need to bridge the gap between science and action; the State, Pressure, and Response indicators presented above constitute a framework that can be used by both scientists and policy makers for monitoring and evaluation goals. In Chapter 45, Gandara and Kageyama, for example, document scientific evidence about tropical rain forest density patterns, pollination, and seed dispersal patterns that can contribute to development of State, Pressure, and Response indicators for management and monitoring purposes. The authors provide a good description of the methods used to analyze tree demographics, genetic, and ecological relationships, and they establish sound connections between their findings and recommendations for a proper management and conservation plan for rare tree species in Brazilian rain forests. For example, the authors found that rare tree species with low population densities (i.e., 1 tree/ha to 1 tree/50 ha) have a low natural regeneration rate and long-distance pollinators and seed dispersals. Therefore, these species are not recommended for sustainable management programs. In this case, regeneration rate and pollination distance can be used as a State indicator of tropical forest health, and it can be used to guide biodiversity managers and politicians.

Chapter 46 by Grigione and Johnson presents an interesting case study about the effects of roads on mountain lions in California. Although the general influences of roads on wildlife have been documented by numerous authors, the specific consequences of roads (e.g., car collisions and habitat alteration) on mountain lions are not well understood. Roads apparently exert greater influence on populations inhabiting the Coastal Range Mountains than those of the Sierra Nevada. The authors also found differences in mountain lion habitat between the Sierra Nevada and Coastal ranges. They conclude that in the Sierra Nevada factors such as tracking deer may be more important than the presence of roads to the survival of the mountain lion. Furthermore, despite lion mortality on highways, they do not appear to be selecting areas with lower road densities. These types of

case studies are particularly useful and pertinent for scientists and policy makers to develop State and Pressure indicators that can be used for monitoring and management purposes.

Recent and rapid developments in remote sensing imagery and geographical information systems also have supported efforts to assess, monitor, and manage biodiversity. Chapter 47 by Kappelle et al. presents an overview of ecosystem mapping methods developed in Costa Rica during the past 30 years and proposes a new method in rapid ecosystem mapping. This method uses techniques of stereoscopic interpretation to identify nine physiognomic classes from major Costa Rican habitats. The proposed physiognomic classes were developed based on the tree, shrub, and herb cover that the researchers were able to distinguish from semi-detailed aerial photographs. This is also a rapid, efficient, effective, and relatively inexpensive method that will allow researchers to repeat their efforts in order to monitor vegetation changes over time. This information will be valuable for Costa Rican ecosystem and wildlife managers who are currently developing a strategic plan to monitor biodiversity based upon the presence of State indicators such as ecosystem area, species richness, and species population viability.

Since 1992, when the Convention on Biological Diversity (CBD) was signed by 157 nations, the term *biodiversity* became part of the lexicon of law and policy makers all over the world. The countries that signed and ratified the CBD committed to develop plans and to enact legislation to help achieve the main objectives and initiate activities proposed by the CBD. Several years ago the Global Environment Facility (GEF) became the financial mechanism of the CBD, and since then it has been supporting countries willing to develop biodiversity national strategies and plans. Uruguay is among these countries. In Chapter 48 Victor Canton, a Uruguayan government official, presents an overview of the participatory process that led to the identification of assessment and monitoring recommendations in the context of the national biodiversity strategy. His chapter offers valuable lessons for countries engaged in the development of national biodiversity strategies and action plans. The chapters presented in this section also demonstrate that current biodiversity assessment and monitoring efforts must be strongly supported in biodiversity-rich countries in which current development trends and lack of local capacity are threatening the survival of many species.

Management and Conservation of Tropical Forests with Emphasis on Rare Tree Species in Brazil

Flávio Bertin Gandara and Paulo Y. Kageyama

INTRODUCTION

Conservation of tropical forests is one of the most urgent and challenging tasks of foresters, biologists, social scientists, environmental managers, nonprofit organizations, and public administrators in relevant departments. The species richness of tropical forests has been greatly emphasized, and the serious consequences of deforestation and consequent loss of biodiversity have been highlighted. However, of all tropical forests, those considered as lowland tropical rain forests contain the greatest number of species, and their destruction would have the worst and most extensive global effects (UNEP, 1995; Whitmore and Sayer, 1992; Alvarez-Buylla et al., 1997).

The conservation of tropical forests poses a number of biological and practical constraints. The number of species that require attention in a single region is large, running into the thousands. Thus, the resources needed for research and conservation have to be prioritized. An overwhelming majority of plant species in tropical forests is involved in mutualistic interactions for growth and reproduction. Pollination and reproduction of forest species involves a wide variety of insects and animals, both as pollen and seed dispersal agents. The prevalence of mutualistic interactions further justifies the conservation of these resources in their natural habitats.

Many tropical forest trees, particularly in lowland rain forests, occur in extremely low densities. For large trees, more than 50% of the species in any one community may have densities as low as one adult or less per hectare. Because the majority of these species is outcrossed, their interbreeding populations can cover areas hundreds of square kilometers in size. Deforestation leading to smaller areas is likely to cause inbreeding, with possible loss of genetic diversity. Because of their long lives, trees can survive as adults without regeneration. Thus, in many areas, populations can occur as *living dead* (Janzen 1988), conveying the illusion of persistence when, actually, the population is on its way to extinction.

Our ignorance about the basic biology of most tropical forest plants is overwhelming. A large number of species that are found in rapidly disappearing habitats require conservation measures. Therefore, to be effective, conservation of tropical forests needs to be integrated into the overall framework of sustainable forest management. In the past, efforts in conserving protected areas, national parks, and reserves have not given sufficient consideration to the distribution of species and their intraspecific variation, an understanding of both of which is central to ensuring the maintenance of adaptive capacity and production potential to meet present and future needs (FAO, 1993; McNeely, 1993).

The Atlantic Tropical Forest in Brazil, specifically, is considered a hot spot, i.e., an area of high species diversity and a high rate of endemism (McNeely, 1990), and therefore an absolute priority for conservation actions. On the other hand, the rate at which these ecosystems have been destroyed from the beginning of Brazil's colonization to date has resulted in elimination of all but 5% of the original vegetation covering (Consortio Mata Atlântica, 1992). This destruction clearly illustrates the importance of the remaining fragments as models for identifying alternatives for resource conservation and utilization, as well as for restoration of the existing degraded areas.

Genetic diversity has a fundamental role in evolutionary theory, because natural selection chooses among the variants that occur within populations based on their adaptations to the immediate environment. Therefore, information on the level and distribution of genetic variation is crucial for the conception of scientifically sound strategies and implementation of cost-effective and efficient plans of *in situ* and *ex situ* genetic conservation.

Advances in genetic diversity quantification techniques — initially with quantitative genetic techniques and establishment of progeny and provenance trials (Kageyama, 1990), and later with isozymes and DNA polymorphisms — have resulted in several studies on Atlantic Forest tree species. Empirical results, which have been obtained for genetic variation within species of well-characterized groups, show that model species may represent part of the community of tropical tree species, and studies with samples of these different groups may permit an advance in the genetic understanding of natural populations of such species (Gandara et al., 1997).

TREE SPECIES DIVERSITY OF TROPICAL FORESTS

A conspicuous characteristic of tropical forests is the diversity of types of tree species. High population density trees (common species), such as those with 100 or more adult individuals per hectare, can be found with those that are very rare, such as 1 tree per 50 hectares. Between the two extreme densities, a wide range of species may be found, most of which are rare tree species. This is why so many species per unit of area are found in these tropical forest ecosystems (Kageyama and Gandara, 1994). From 100 to 300 different tree species per hectare have frequently been reported; moreover, the maximum described to date exceeded 400 tree species per hectare in the Atlantic Forest.

On the other hand, sampling rare species is more difficult than sampling common ones in small plots. Foster and Hubbell (1990) showed that of 409 known species of trees and shrubs in BCI-Panama (1500 ha), only 306 were found in the 50-ha plot studied. Do special characteristics keep 103 species from occurring in the plot? It is important to emphasize that 61% (63) of the species not found in the plot are listed in the forest flora as very rare. Also, it is noteworthy that 1-ha plots in this area contained an average of 180 tree species, constituting only 44% of the total number of species in the 1500 ha area.

Kageyama et al. (1991), cited by Kageyama and Gandara (2000), quantified the participation of the most rare and common species in seven phytosociological surveys conducted in the Atlantic Forest of the state of São Paulo. These authors pointed out that 30% of the species proved to be rare or had sparse distribution, with only one individual per plot of slightly less than 1 ha; in the same samples, 28% of the individuals belonged to only three of the most common tree species. From these data we can clearly see that, by withdrawing rare species from the survey, we exclude many species but few individuals.

How did such rare tree species evolve to this low population density in the forest? Gandara (1996), studying *Cedrela fissilis* in the Atlantic Forest, and Lepsch-Cunha (1996), studying *Couratari multiflora* in the Amazon, with eight and ten adults per hectare, respectively, found that the high cross-pollination rates ($t = 0.92$ and 0.95 , respectively) associated with pollen flight distances (950 and 1000 m, respectively) show that the species under study had essential reproduction characteristics to attain rarity and may have evolved adaptations to deal with their low densities.

Besides population density, other ecological and demographic traits can distinguish different species. Several papers have hypothesized the existence of groups of species with common characteristics and functions, also called *guilds*, which might also have similar populational and genetic structures (Gandara et al., 1997). We putatively suggest division of species into five groups, based on ecological (successional status) and demographic (commonness or rarity) features and responses to anthropic disturbances. These ecological groups are:

Group 1 species are rare in primary forests and become abundant in secondary forests after human disturbance. They are generally emergent or canopy, and secondary tree species.

Group 2 species are rare in primary forests and absent in secondary forests. They require the primary forest environment and are generally shade-tolerant and understory or canopy tree species.

Group 3 species are specialized in forest environments with restrictive edaphic characteristics, such as the tops of hills, seashores, and shallow soils. They may become very common in secondary forests.

Group 4 includes pioneer species limited to large gaps. They are considered rare in primary forests, and occur in high density in the early stage of succession.

Group 5 are shade-tolerant or climax species that are common under the canopy of primary forests and have variable responses in secondary forests.

The task involves monitoring of demographic parameters of model species (abundance, age distribution, mortality, and growth rates) and genetic (expected heterozygosity, outcrossing rate, and spatial autocorrelation). Because these parameters are highly dependent on interactions with other species (through pollination, seed dispersal, predation, competition, and other means), the stability of demographic and genetic parameters would indicate maintenance of the interactions of a considerable part of the community. Data obtained from these few model species can then be extrapolated to the community.

Genetic Structure and Fragmentation

During the last decade many studies have been conducted on population genetics of tropical tree species with increasing sampling efforts and technology. The amount of data generated during this time has shown some important directions to minimize the environmental impacts in these ecosystems. Ecological and genetic studies on tree species in primary and secondary forests show the effects of anthropic disturbances, which helps to define most adequate genetic parameters to monitor actions in these ecosystems.

Gene Flow in Fragments

Gene flow through pollen has rarely been measured in tropical tree species. Estimations of gene flow through pollen have been made directly or by observing the behavior of different pollinators. Measurements show that gene flow encompasses large areas, proving that many pollinators fly long distances. On the other hand, we lack data that quantify the effects of the absence of pollinators in fragmented landscapes.

Estimations of effective gene flow distance in rare and common tropical tree species can be evaluated and compared through the data of Gandara (1996) and Lepsch-Cunha (1996) — evaluating two rare tree species (*Cedrela fissilis* and *Couratari multiflora*, respectively) — and Reis (1996), studying a common species (*Euterpe edulis*). Data show that *Cedrela fissilis* (one adult tree per 8 ha) in Atlantic Forest and *Couratari multiflora* (one adult tree per 10 ha) in Amazon Forest have long-distance pollen flow, quantified through genetic markers (isozymes) in mapped population of 950 and 1000 m, respectively. *Euterpe edulis* (122 adult trees per ha) in Atlantic Forest registered a distance of 56 m.

These data show that rare tree species probably will have bigger reproduction problems after fragmentation as their demes occupy larger areas. Although gene flow through pollen can reach

long distances in natural forests, in a fragmented landscape these distances would be much shorter due to difficulties for dispersers' movement. Besides that, forest fragments generally are further apart than the distance found for pollen flow in natural forests (Viana and Pinheiro, 1998; Kageyama et al., 1998).

Genetic Effects of Fragmentation

Forest fragmentation decreases the number of individuals in a population, leading to loss of genetic variation. These small populations may suffer genetic drift in a short term and/or an increase of inbreeding due to the higher probability of selfing and biparental crosses. Few studies exist showing these aspects in tropical trees. A reduction of genetic variation was observed in *Eucalyptus albens* (Young et al., 1996). Hall et al. (1996) showed lower levels of genetic variation in smaller populations of *Pithecelobium elegans*.

The Escola Superior de Agricultura "Luis de Queiroz"/Universidade de São Paulo (ESALQ/USP), through the Laboratory of Reproduction and Genetics of Tree Species, conducted two studies about fragmentation and anthropic disturbance in populations of two tropical tree species. Results show that the genetic structure of *Cedrela fissilis* Vell. (Meliaceae) exhibited significant changes comparing primary and secondary forests (Gandara et al., 1997). In the same way, the effects of fragmentation on *Chorisia speciosa* St. Hil. (Bombacaceae) show some adequate genetic parameters to quantify genetic drift in fragmented populations (Souza, 1997).

The population density of *Cedrela fissilis* may increase in secondary forests in comparison to primary ones, but that case holds the possibility of spatial genetic structuring, i.e., neighboring trees that are genetically related. This genetic structure may result, in the future, in an increase of inbreeding due to the preferential crossing among neighbors. The spatial genetic structure was quantified through spatial autocorrelation with Moran's I (Table 45.1). Primary forest population (with a population density of one adult tree per 8 ha) has a Moran's I not significantly different from zero, indicating lack of spatial structure. In secondary forest population, Moran's I reached a medium value of 0.43, revealing the existence of spatial structure.

Souza (1997) detected that the heterozygosity was not adequate to quantify the genetic changes after fragmentation. On the other hand, by analyzing the allelic frequencies, she discovered loss of alleles and fixation of loci as well as oscillation of allelic frequencies. Comparing a big reserve (around 200 ha) and three small fragments (25, 23, and 50 ha), the loss of alleles varied from 5 to 16%; and the F_{st} was 0.183, indicating high genetic divergence among these close populations (Table 45.2).

Table 45.1 Spatial Autocorrelation (Moran's I) of Alleles among Near Neighbors, Mean Distance among Compared Individuals, and Number of Comparisons in a Primary Forest Population — Intervalas State Park (Sete Barras — São Paulo State) — and in a Secondary Forest Population — Matão Reserve (Arapoti — Parana State) of *Cedrela fissilis*

FINAL CONSIDERATIONS

Clearly, the huge original area of the Atlantic Forest permitted the occurrence of an explosion of different tree species whose populations are, at present, isolated in large or small fragments of this biome. The study and interpretation of genetic variation between and within populations, based on adequate sampling criteria, undoubtedly represent a major advance in the understanding of such ecosystems and consequently help focus their utilization, conservation, and restoration.

Conservation of tropical tree species in a fragmented landscape can be enhanced through genetic enrichment of secondary forests with the replanting of extinct or genetic eroded species; exchange of seeds or saplings among neighbor fragments; increase of fragment size with the restoration of surrounding areas promoting population growth; and implementation of forest corridors, facilitating gene flow among small populations.

Genetic and reproduction studies of Atlantic Forest tree species, based on the small, directed samples studied to date, disclosed three key findings: the outcrossing rate of tree species in general has been higher than 90%, or they are preferentially cross-pollinated; genetic diversity within populations is invariably much higher than that between populations; and populations of rare tree species are more difficult to handle using management practices and require more efforts to sustain.

The results obtained to date indicate that any action in the Atlantic Forest should be taken only when heeding three considerations: seed collection of tree species may, in principle, be regarded as outcrossed, based on the concept of effective size, to define adequate populations; economic common tree species permit better control of initial and post-exploited populations and are more favorable for sustainable management; and rare species present difficulties in population handling and management, which makes their sustainability difficult.

The Effects of Roads on Carnivores: A Case Study of Mountain Lions (*Puma concolor*) in California

Melissa M. Grigione and Mike B. Johnson

INTRODUCTION

Vehicular traffic in environmentally sensitive areas poses a serious conservation threat to individuals, most wild animal populations, even entire species, and their respective ecosystems and landscapes. This chapter reviews the general ways in which access to their habitat may affect carnivores and their prey, using specific studies to quantify impacts associated with roads. We will then present results from our research on the effects of roads on mountain lions (*Puma concolor*) in three regions of California.

The specific effects of roads on wildlife are manifold and still not entirely understood. However, some of the most prominent threats include habitat fragmentation, direct mortality, direct habitat loss, displacement and avoidance, and associated development (Forman, 2000; Trombulak and Frissell, 2000; Ruediger, 1998). Habitat fragmentation isolates populations and limits successful dispersal opportunities for individuals, subjecting them to demographic, genetic, and stochastic factors that reduce their persistence. Direct mortality involves animals killed by automobiles as well as the amount of poaching that occurs when people can access wild areas readily. Studies that document direct mortality are abundant (Gunter et al., 1998; Tewes and Blanton, 1998; Calvo et al., 1996; Gilbert, 1996; Lehnert et al., 1996; Ruediger, 1996). In addition to direct mortality, roads can displace species or prevent species from accessing important habitats (Forman and Deblinger, 1998; Van Riper and Ockenfels, 1998; Paquet and Callaghan, 1996). In certain circumstances animals are attracted to roads, to their own detriment (Gibeau and Herrero, 1998).

CARNIVORE VULNERABILITY

Carnivores are particularly vulnerable to roads because of their inherently low population densities, their long lives, their late onset of first reproduction (for example, 8 years or older for grizzly bears), and their low reproductive rates (Ruediger, 1996). Carnivores often roam in very large home areas, and dispersal from these areas can include excursions of several hundred miles. Carnivores require large, interconnected areas for long-term persistence and viability.

CASE STUDY: THE EFFECTS OF ROADS ON MOUNTAIN LIONS IN CALIFORNIA

Our research involves the study of changes in home range patterns of mountain lions as road densities increase from relatively undisturbed areas to more urban environments. The overall goal of our study is to compare the spatial ecology of mountain lions in three study areas of California (Figure 46.1).

Study Areas

Mountain lions in the California coastal ranges, consisting of the Diablo Range and the Santa Ana Mountains, inhabit low-elevation and chaparral–oak woodlands. Differentiation between seasons is subtle, and snowfall is uncommon in these areas. The main prey for mountain lions in these ranges is black-tailed deer (*Odocoileus hemionus*) that are nonmigratory. However, mountain lions in California's central Sierra Nevada inhabit a high-elevation, mixed-conifer ecosystem with two distinct seasons. Snowfall is common, and the main prey for Sierra Nevada mountain lions is black-tailed deer that are migratory. Road densities are highest in the Santa Ana Mountains (0.00196 m/m²), lowest in the Sierra Nevada (0.00084 m/m²), and the Diablo Range densities (0.00119 m/m²) are somewhere in between.

Study Objectives

The specific objectives of this study are to answer two questions. How does mountain lion home range size and home range overlap vary for males and females, during winter and summer

Figure 46.1 Map of three study sites in California.

seasons, within each study area, and among all study areas? How do densities of roads, rivers, and the number of vegetation types differ between exclusive and nonexclusive portions of mountain lion home ranges? For the purposes of this chapter, we focused solely on the effects of roads on mountain lions.

A home range is an area that an animal uses to complete most of its daily tasks. It is in this area that an animal obtains food and shelter in addition to reproducing and raising young. Exclusive home ranges are areas that are normally defended in order to keep other mountain lions from obtaining any of the resources found within the home range. In this study, we are assuming that exclusive home ranges (i.e., home ranges that are not shared with other mountain lions) have limited and valuable resources within them that are worth defending. When high levels of home range overlap occur, we assume that these overlap areas either have a bountiful resource providing enough for all mountain lions, or it may be of so little value that an animal expends little to no energy keeping conspecifics out.

We used theories associated with food distribution for carnivores (which involve the distribution and predictability of a food resource, i.e., black-tailed deer for our study) and carnivore social structure (which for our study involves a polygynous mating system, with no typical breeding season or reproductive peak) to develop hypotheses and generate predictions about home range size, home range overlap, and the effect of roads, rivers, and the number of vegetation types on mountain lion space use. This provided us with a means for determining the relative importance of social structure vs. food resources for mountain lion space use.

We divided home range hypotheses into three groups: hypotheses of home range size within and among study areas; home range overlap within and among study areas; and the effects of roads, rivers, and number of vegetation types in exclusive vs. nonexclusive portions of home range for each mountain lion. We reviewed several studies that investigated the effects of anthropomorphic elements, such as logging activities and roads, on mountain lions. Based on these studies, we predicted that exclusive home ranges should have a lower density of roads than nonexclusive areas (Belden and Hagedorn, 1993; Spreadbury et al., 1996; Smallwood, 1994; Van Dyke et al., 1986).

Examples of the Effects of Roads on Mountain Lions

In British Columbia, over a 2-year period, Spreadbury et al. (1996) studied a population of mountain lions that lived near a coal mine. Four of the 34 known mountain lions were killed by automobiles. The authors believed that mountain lions were changing their peak activity hours to coincide with the absence of people at the coal mine.

In Arizona and Utah, Van Dyke et al. (1986) found that mountain lions did not use timber sale areas in proportion to their occurrence. Rarely were lions found in or near active or inactive timber sale areas until 6 or more years after the logging had ceased. Mountain lions in the immediate vicinity of disturbance shifted their activity peaks from daylight hours to after sunset, concentrated other activities during evening hours, and were inactive rather than active at sunrise. The authors believe that habitat alteration itself was the most important factor behind mountain lion avoidance of timber areas.

In a California study, Smallwood (1994) surveyed roads for mountain lion tracks in 1992 and found a 61% decrease in track sets in areas from which timber was removed since 1986 (the year of his previous survey). Deer densities on these transects remained the same.

In a study in the Santa Ana Mountains, California, Beier (1993) documented that 32% (ten animals) of all known animal mortalities in his study population were due to car collisions. Of these ten animals, four were young males trying to disperse.

Literature is also available for the Florida panther (*Puma concolor coryi*), an endangered subspecies of the mountain lion. In urban southern Florida, 47% of mountain lions were killed on highways (Maehr et al., 1991). In northern Florida, 2 of 19 mountain lions were killed on highways, and 2 of 19 were illegally shot (Belden and McCown, 1995). In the same area, mountain lions

established home ranges in areas containing half the density of roads found in the entire study area (Belden and Hagedorn, 1993). For these reasons, we hypothesized that roads were in fact undesirable for mountain lions and not worthy of home range defense. Hence, we predicted that exclusive home ranges in all of our study areas would have a lower density of roads than nonexclusive portions of the home range.

Study Methods

We used Universal Transverse Mercator grid coordinates (UTMs) collected by the primary investigators to construct 95% Minimum Convex Polygons (MCPs). We exported these home ranges into arcinfo that intersected river-, road-, and vegetation-type data. The road data used in our Geographic Information Systems (GIS) analysis were created at 1:100,000 scale. We used one-way analysis of variance (ANOVAS) with the GIS data to understand differences in road density between exclusive and nonexclusive portions of the home range.

Results

In the Sierra Nevada (i.e., the area with the lowest road densities), we found significant differences with respect to road density and home ranges for 2 of 11 seasons (Table 46.1). During the winter of 1985, for male mountain lions, road densities in areas shared with female mountain lions were significantly greater than those in their exclusive home areas, as well as in areas shared with other males. In addition, exclusive home areas for males had significantly greater road densities than those areas shared with other males ($p = 0.001$; adjusted alpha = 0.01). During the summer of 1985, the density of roads was significantly greater in areas females shared with males than in those areas shared with other females; however, these areas were not significantly different from road densities in exclusive portions of the home range ($p = 0.009$; adjusted alpha = 0.01).

We found significant differences with respect to road density and home range in the coastal ranges as well (i.e., the areas having medium and high road densities). When these differences occur, we see a greater density of roads in exclusive portions of the home range than in nonexclusive portions. In the Santa Ana Mountains, significant differences in road densities occurred between exclusive and nonexclusive portions of the home range for 3 of 18 seasons (Table 46.1). For females during the winter and summer of 1986, exclusive home areas contained a greater density of roads than areas shared with males. Areas that females shared with other females had a greater density of roads than areas shared with males ($p = 0.004, 0.0001$; adjusted alpha = 0.0083). However, during the winter of 1991, a greater density of roads existed in areas females shared with males than existed in exclusive areas or in areas shared with females ($p = 0.0001$; adjusted alpha = 0.0083). In the Diablo Range, significant differences occurred in road densities between exclusive and nonexclusive portions of the home range for 5 of 19 seasons (Table 46.1). During four of these seasons, a greater density of roads was shown in exclusive portions of the home range than in nonexclusive areas ($p = 0.001, 0.001, 0.003, 0.006$; adjusted alpha = 0.0083). In contrast, during the summer of 1985, a greater density of roads existed in areas females shared with males than in exclusive female areas or in areas shared with other females ($p = 0.007$; adjusted alpha = 0.0083).

During the study period, no car-related deaths occurred in the Sierra Nevada or the Diablo Range study areas. However, in the Santa Ana Mountains, 10 of 31 mountain lions died car-related deaths (Beier, 1993).

Discussion

Home range overlap is a potentially confounding variable because, while overlapping ranges are easy to detect, it is more difficult to prove that home ranges are exclusive and not shared. Also, two individual animals may have a large area of overlap used little by each or a small area of

overlap used intensively by each. An animal's home range, however, is where it spends most of its life and the area in which most of its interactions with other organisms and its environment occur.

The importance of road densities varied between our two systems, with Coastal Range studies having higher road densities in exclusive portions of the home range than in nonexclusive portions. In the Santa Ana Mountains, a large proportion of the radio-collared population was killed by cars, in comparison to the Diablo Range and Sierra Nevada, where none of the study animals was killed by cars. It is beyond the scope of this analysis, however, to assess whether mountain lions, in any of the study locations, were actively avoiding roads.

The Diablo Range, with its intermediate road densities, is where we see the greatest difference in road densities between exclusive and nonexclusive portions of the home range, with exclusive areas having greater road densities. This is contrary to our original predictions. Could it be that mountain lions in this area are temporally avoiding roads by adjusting their activity patterns (Van Dyke, 1986)? It appears that mountain lions in this area and in the Santa Ana Mountains have activity peaks before sunrise and after sunset (Beier and Barret, 1993; Padley, 1990; Hopkins, 1989). This activity cycle resembles that of mountain lions in undisturbed areas (Hansen, 1992). In the Diablo Range these activity peaks match those of black-tailed deer. Are the deer (and, hence, mountain lions) drawn to roads because of favorable changes in the adjacent vegetative community? Although our information about deer distribution is limited, this could be a possibility since areas adjacent to roads in the Diablo Range are relatively intact as compared to many Southern California locations.

The GIS road density data for this analysis were created at the 1:100,000 scale. This scale simplifies landscape features and as a result does not represent the true sinuosity of roads, hence decreasing the *true* density of roads within an animal's home range. In addition, our analysis did not differentiate between the road types. By treating all roads equally, the analysis could be missing key avoidance areas. Although comparing differences between exclusive and nonexclusive portions of home ranges is revealing, depending on the research question, the scale of GIS-related data (e.g., roads, rivers) may have to be reduced in order to detect important relationships at the level of the mountain lion home range. Despite the large scale at which our data were created, we were able to detect differences in mountain lion habitat use between our two regions (Sierra Nevada and Coastal Ranges).

In the Sierra Nevada, where deer are migratory, few differences occurred between exclusive and nonexclusive portions of mountain lion home ranges for any of our study variables (e.g., road densities, river densities, vegetation type). For mountain lions in this ecosystem, tracking deer both temporally and spatially is crucial to their survival. Tracking deer may not involve intimate familiarity with one home area as much as an ability to move through home areas efficiently and effectively (Grigione et al., in preparation).

In the Coastal Ranges, where ecological variables differed more between exclusive and nonexclusive portions of mountain lion home ranges, deer are nonmigratory (Grigione et al., in preparation; Beier et al., 1995; Neal, 1990; Padley, 1990; Hopkins, 1989). In this system, mountain lions access deer by positioning themselves in a home area that will provide the most deer over time. This "positioning" allows mountain lions to use their immediate home areas in more subtle ways (Grigione et al., in preparation). This could in turn accentuate the importance of ecological variables between exclusive and nonexclusive portions of the home range and possibly negate the effect of roads on mountain lion home ranges.

In conclusion, it is important to examine several variables when exploring questions at the ecological scale. In the Sierra Nevada, we cannot say that roads are unimportant to mountain lions — only that other factors, such as tracking deer, may be more important to their survival. For all of our study areas, all direct mortalities occurred in the Santa Ana Mountains, the area with the highest road densities. However, mountain lions in this system do not appear to be selecting areas of low road density — perhaps they cannot in such a road-dense place. We see a similar pattern

in the Sierra Nevada — mountain lions do not appear to be selecting areas with lower road density, albeit for different reasons (e.g., roads are in low density to begin with and deer are migratory).

It is in the Diablo Range, where road densities are intermediate in comparison to our other areas, that we are seeing the most significant differences in road densities between exclusive and nonexclusive portions of the home range. While these differences do not support our original hypothesis, their occurrence is frequent enough (approximately 25%) to warrant additional analysis. We are going to investigate this relationship further by performing a “nearest neighbor analysis” to determine if single point locations (UTMs) of individual home ranges are significantly different in distance to roads than randomly generated points within the same study area.

ACKNOWLEDGMENTS

This project would not have been possible without the collaboration and generous support associated with the mountain lion research of Paul Beier, Rick Hopkins, Don Neal, and Doug Padley, and the GIS data and analyses of Joshua Viers and Jim Quinn of the University of California, Davis, Division of Environmental Science and Policy.

A Rapid Method in Ecosystem Mapping and Monitoring as a Tool for Managing Costa Rican Ecosystem Health

Maarten Kappelle, Marco Castro, Heiner Acevedo, Pedro Cordero, Luis González, Edgar Méndez, and Huberth Monge

BRIEF HISTORY OF ECOLOGICAL MAPPING IN COSTA RICA

Since the late 1940s Costa Rica has suffered from a severe change in its dense tropical forest vegetation cover and agroecosystem distribution (Sader and Joyce, 1988; Sánchez-Azofeifa, 1997; Van Omme et al., 1998). Over the past decades the original area covered by tropical premontane rain forest, or lower montane moist forest, has been reduced significantly due to forest conversion for agricultural land. Since the late 1960s and particularly throughout the 1980s, degraded or unproductive agricultural lands such as lowland and montane pastures have been abandoned and have given way to successional processes leading to a large area at present covered by secondary forests (Holl and Kappelle, 1999). Simultaneously, the area covered by traditional crops, such as banana, in some regions was reduced due to economic recessions by the mid 1980s. Other areas have lost coffee plantations as a result of the increased extension of urban areas such as Costa Rica's central valley. In order to understand the processes related to these intense land cover changes and the consequences for biodiversity conservation, we recognize a need to map the current vegetation types present in the country.

Citing Dirzo (in press) "the most synthetic and revealing way of describing Central American ecosystems is through the description of the vegetation. A premise for this is that the vegetation constitutes the most obvious descriptor of the ecosystem, constitutes the basis of the food chain, and provides the structural matrix which most communities and populations of animals live or indirectly depend upon." This statement justifies the use of vegetation mapping as an indirect way of ecosystem mapping. Therefore, we have focused on vegetation mapping as a tool in understanding ecosystem makeup and distribution and managing ecosystem health.

In Costa Rica, vegetation mapping has received major attention since the establishment of the Holdridge World Life Zone Classification System (Holdridge, 1967), which describes and predicts the distribution of tropical ecosystems. The Life Zone System formed the basis for Tosi's (1969) ecological map of Costa Rica, which shows potential distribution of the 12 Life Zones (climate-based ecological zones defined by specific temperature, humidity, and evapotranspiration regimes). However, growing empirical evidence has called into question the

predictive power of the Holdridge model (Cornell, 1996). Indeed, throughout the world, criticism has been raised about the Holdridge Life Zone Classification System, which does not take into account parameters related to, for instance, vegetation physiognomy (e.g., evergreen, broad-leaved forest vs. deciduous, thorny scrub). Although environmental aspects such as rainfall distribution (length of the dry season) or edaphic characteristics (e.g., alluvial, inundated vegetation on sandy soils vs. peaty paramo bogs) are included at a second level of organization (associations) within the Holdridge System (Bolaños and Watson, 1993), very few sites in the tropics are classified at this level. The third level of organization, which concerns successional phases and land use types (Bolaños and Watson, 1993), has received even less attention from scientists. Indeed, the Holdridge Life Zone System in Costa Rica is supported by fewer than 50 sample points throughout the country (Holdridge et al., 1971). These limitations contribute to the fact that the Life Zone approach has rarely been applied outside Costa Rica and Puerto Rico — countries in which Holdridge and his collaborators have conducted the majority of their studies (Cornell, 1996).

As a reply to the Holdridge classification system, Gómez (1986) proposed his Vegetation Macrotypes System, which is based on climatic and physiognomic, floristic, and edaphic characteristics rather than primarily on climatic aspects on which the Holdridge system is based. This approach coincides with vegetation classification systems as proposed by the Anglo-American School with scholars such as Beard (1944), Grubb et al. (1963), Whitmore (1990), and, more recently, Ross et al. (1992). Recently, the Gómez Vegetation Macrotypes System has proved its usefulness in a gap analysis directed at defining threatened biodiverse areas (local hot spots) located in critical zones outside Costa Rican protected wildlife areas in need of major conservation efforts (The GRUAS Project; García, 1997). Even more recently, Herrera and Gómez (1993) presented their Biotic Units Map integrating both Holdridge's climatic classification concepts (Holdridge, 1967). It was adapted on the basis of more detailed and recent meteorological data and analysis (Herrera, 1986) and the vegetational and edaphic concepts published in Gómez (1986). However, these three ecological maps show Costa Rica's potential vegetation at scales of 1:750,000 to 1:200,000. The maps indicate the presence of vegetation types void of any human influence in Costa Rica, therefore limiting their usefulness for decision making in actual biodiversity conservation and day-to-day protected area management on the ground.

At a subnational scale, several efforts have been made to map vegetation in Costa Rican protected areas (e.g., Kappelle, 1991; Vargas, 1992). Most of these studies use plant sociological approaches as proposed by the French-Swiss School of Phytosociology (Braun-Blanquet, 1965). These detailed scale maps have been useful in answering specific plant ecological research questions related to floristic composition and plant association distribution but have not been consulted for planning in conservation and development due to limited dissemination or popularization outside the academic scene.

A few years ago, Savitsky and Tarbox (1995) mapped (scale 1:500,000) the current distribution of Costa Rica's vegetation, superimposing deforestation patterns on the distribution of Holdridge's Life Zones. Besides Holdridge's Life Zones (e.g., the deforested area covering more than 60% of the country's territory), areas included eight land cover types: paramos, mangrove forests, pastures, croplands, urban areas, bodies of water, barren land, and unknown cover types that are not in accordance with the Holdridge Life Zone System as represented by the polygons corresponding to remaining primary forest fragments.

Next to these ecological maps, a series of maps shows Costa Rica's dense forest cover at present and over the past few decades (Hartshorn, 1982; Fundación Neotrópica–Conservation International, 1988). The authors of these maps, however, do not clearly indicate what is meant by use of the term *dense forest*. Does *dense forest* refer only to undisturbed primary forest? To what extent are these forests really undisturbed, if we know that the presence of indigenous groups in Costa Rica dates back to more than 10,000 B.C.? And are those forests that have been selectively logged over the years included? How *dense* are all these so-called *dense forests*?

POLITICAL AND SCIENTIFIC NEEDS FOR ECOSYSTEM AND LAND COVER MAPS

Urgent political and scientific needs exist today for development of a series of ecological vegetation and land cover maps (Castro, 1998) to (1) show Costa Rica's present (actual) — not potential — ecosystem and vegetation distribution; (2) display natural as well as seminatural and (agri-)cultural vegetation types; (3) show at a semidetailed scale of 1:50,000, which corresponds to the scale of the country's intensively used topographic sheets; (4) help in defining sites for conducting intensive biodiversity inventories including different taxonomic groups (one of the main activities of Costa Rica's National Biodiversity Institute, INBio; Gámez, 1996); (5) serve as a reference for future monitoring of land use and land cover changes over time; (6) include both digital and printed formats; and, most important, (7) serve as a decision-support tool for local individuals in charge of managing ecosystem health.

These needs are emphasized at the decision-making units of the regional offices of Costa Rica's Sistema Nacional de Areas de Conservación (SINAC). This system is part of the Ministry of Environment and Energy in charge of the administration of the country's approximately 150 protected wildlife areas, which cover some 24% of the nation's territory and are distributed throughout 11 environmental administrative regions. Over the last decade, SINAC and its precursor, the National Park Service, have been considered a model for international conservation (Gámez and Ugalde, 1988).

In order to respond to these needs, INBio and SINAC recently set up the Netherlands-funded ECOMAPAS Project (<http://www.inbio.ac.cr/en/mi/ecomapas.html>), whose goal is to map land cover (principally vegetation) within five conservation areas (Osa, Amistad–Pacific Region, Amistad–Caribbean Region, Arenal, and Tempisque) over a 4-year period (1998–2001). In accordance with INBio and SINAC's mission of saving, knowing, and sustainably using tropical biodiversity (Gámez 1991, 1996), and as a follow-up of the 1998-approved national Biodiversity Law, the ECOMAPAS Project contributes in an advanced and innovative manner to the development of knowledge and wise use of Costa Rica's ecosystems.

A NEW METHOD IN RAPID ECOLOGICAL VEGETATION MAPPING

We have developed a new methodology in rapid ecological vegetation mapping that emphasizes analysis of spatiotemporal dynamics in land cover and vegetation distribution as a decision-support tool in biodiversity conservation planning and ecosystem health management. This innovative methodology, now widely implemented by the ECOMAPAS Project, is based upon principles formulated by Eiten (1968), the UNESCO (1973), Van Gils and Van Wijngaarden (1984), and approaches implemented by the U.S. Geological Service and U.S. National Park Service. This methodology departs from the characteristics that can be distinguished from semidetailed aerial photographs (1:40,000) through techniques of stereoscopic interpretation (Zonneveld, 1995). These photo characteristics include form, size, structure, texture, color, and shade of polygons that can be identified during aerial photo interpretation (API) procedures (Van Gils and van Wijngaarden, 1984).

Based on these characteristics, a classification system was developed using the proportion of tree, shrub, and herb cover in a polygon as a vegetation structure parameter (Figure 47.1). The following nine physiognomic classes could be distinguished as follows: (1) dense shrubland (Spanish: *matorral denso*), (2) shrubby herbland (*herbazal arbustivo*), (3) sparse shrubland (*matorral ralo*), (4) dense, woody shrubland (*matorral denso arbolado*), (5) dense herbland (*herbazal denso*), (6) sparse herbland (*herbazal ralo*), (7) woody herbland (*herbazal arbolado*), (8) sparse forest (*bosque ralo*), and (9) dense forest (*bosque denso*). The spatial distribution of trees, shrubs, and herbs for each of these physiognomic classes is illustrated in Figure 47.2. In addition to these nine classes, five additional cover classes were added in order to map entire areas that also harbor

Figure 47.1 Structural physiognomic vegetation typification for aerial photo-interpretation of areas in which different horizontal layers (strata) can be observed. Nine physiognomic vegetation classes have been distinguished, as occurring along two axes representing proportions of trees and shrubs as observed in mapped polygons.

Figure 47.2 Example of an area mapped on the basis of aerial photo-interpretation, showing different physiognomic vegetation classes. The structure and texture of the nine physiognomic classes as defined in Figure 47.1 and seen from the birds-eye perspective are presented. The minimum mappable area is about 3 ha.

nonvegetated and unidentifiable land cover types: (1) bare soil and rock outcrops, (2) water bodies, (3) infrastructures, (4) shades, and (5) clouds.

IMPLEMENTING THE RAPID ECOLOGICAL VEGETATION MAPPING METHOD

In an attempt to put this methodology into practice, the vegetation of the Osa Conservation Area in Southern Pacific Costa Rica was mapped at a scale of 1:50,000 using 1:40,000 color aerial photographs taken in 1995 and 1996 by the German Hansa–Luftbild Company within the scope of the INBio-GEF Project. In late 1998 and early 1999, approximately 325 aerial photos were stereoscopically interpreted, using the aforementioned land cover classification and vegetation typification system. Preliminary map data were scanned and digitized into a geographical information system (GIS) using the Arc/View and Arc/Info software programs. Subsequently,

ground-truthing was conducted by comparing preliminarily mapped (1995–1996) and current (1999) land cover (both vegetated and nonvegetated patches).

More than 150 sample points were established at which cartographic, geographic, and ecological data were collected. The sample points were selected on the basis of representativeness, in a stratified manner, covering all physiognomic land cover classes. Sample points were well distributed over the full geographic extension of the Osa Conservation Area. More sample points were established in those physiognomic units that covered a greater extension in order to maintain equal sample point densities. Sample points were selected in areas with high to medium levels of accessibility (e.g., near roads, trails, and rivers). In several cases, week-long expeditions (hiking, horseback riding) were organized. Replicates were included in order to generate reliable information on each land cover class.

Measured parameters included Global Positioning System–based altitude, latitude, and longitude, information on physiognomic vegetation class (the nine aforementioned types), vegetation height (in m), leaf phenology (evergreen vs. [semi]-deciduous, or annual vs. perennial in the case of herbaceous vegetation), dominant leaf type (broad-leaved vs. coniferous vs. graminoid), hydrological regime (palustrine, lacustrine, riverine, marine, according to Cowardin et al., 1979), flooding and tidal influences (e.g., in the case of a mangrove forest), current land use (forestry, cropping, grazing), state (natural and seminatural vs. cultural), and grade of human intervention. Additionally, at each sample point the observed presence of vascular plant species was recorded as an indicator of the present floristic composition. Data on species abundance were not collected due to time and budget constraints. However, the establishment of permanent plots in each vegetation type is planned for a second phase dedicated to the monitoring of land cover and vegetation changes — a step particularly important in developing ecosystem health management plans.

Subsequently, different thematic layers will be added to the land cover and vegetation map, including air temperature and humidity regimes, length of the dry season, soil orders, and geomorphological types (landforms). Climatic layers will be based upon cartographic information provided by Herrera and Gómez (1993), who modified the Holdridge System on the basis of much more detailed meteorological information available today (Herrera, 1986). In this way, the up-to-date biotic land cover and vegetation layer generated by ECOMAPAS will be integrated with nonbiotic environmental layers into a flexible decision-support GIS.

As a next step, preliminary map data were digitally adjusted on the basis of ground-truthed field information. The quality of the GIS-based data was controlled to guarantee information reliability and fidelity. Finally, the process of preparing digital maps was initiated and directed to different kinds of users, such as the protected area managers based at SINAC's central and regional offices.

BRIEF DESCRIPTION OF FLORISTIC COMPOSITION OF PHYSIOGNOMIC CLASSES

As a result of the botanical fieldwork at the sample points, the nine physiognomic land cover classes can be typified at the floristic level. More than 700 vascular plant species were recorded. A large number of plant specimens were collected for identification and storage in the herbarium at INBio. The most important plant species, in terms of dominance and exclusiveness, are listed in Table 47.1 for each of the nine physiognomic land cover classes.

EFFECTIVENESS AND APPLICATION

The currently developed methodology has proven to be most useful and effective in the area of project resource limitations and operational capacity restrictions (budget, time, staff, field area accessibility). During the course of about 6 to 8 months, the land cover of an entire conservation

area (Osa, in southern Pacific Costa Rica, covering 422,008 ha) was mapped at the semidetached scale of 1:50,000, including an extensive ground-truthing effort. Further repeated field research at permanent plots in selected vegetation/ecosystem patches belonging to different physiognomic classes will help understand land cover and vegetation changes over time. Their monitoring effort should include the inventory of other taxonomic groups than the mere group of vascular plant species. Currently, INBio and SINAC are developing a strategic plan to monitor biodiversity at the ecosystem level over time. Such a monitoring plan will be based on the presence and abundance of key indicator species (e.g., selected plants) that are diagnostic for different levels of ecosystem health. Specific indicators such as ecosystem area, species richness, and species population viability may also be included in the monitoring system (Carrizosa, S., personal communication).

One of the specific uses for this type of map is ecosystem health management, including restoration. Patches representing seminatural vegetation types such as dense, woody shrublands or

sparse shrublands are experiencing processes of vegetation recovery following clearing of tropical rain forest, subsequent cattle-ranching, and final abandonment. Restoration efforts to recover biodiversity and manage ecosystem health (to be stimulated by the Costa Rican Government through SINAC), depend heavily on technically processed information on the monitored presence and distribution of different stages of secondary vegetation as expressed in different kinds of shrublands (Castro et al., 1999). This is of particular interest in those areas in which the establishment of biological corridors is at stake.

The ECOMAPAS Project will contribute significantly to the knowledge base developed on biodiversity at the ecosystem level for governmental and nongovernmental decision-making organizations such as SINAC and INBio, which direct their efforts toward the integration of biodiversity conservation and the sustainable use of natural resources *in situ* for the benefit of Costa Rica's society and the world community at large (Lovejoy and Gámez, 1995).

ACKNOWLEDGMENTS

We thank the staff at SINAC, particularly Luis Rojas, Vera Violeta Montero, Luis Barquero, Sara Araya, Jairo Mora, Celso Alvarado, and Jose Miguel Valverde, for technical cooperation and facilitation of field operations. We are very grateful to Rodrigo Gámez, Alfio Piva, Erick Mata, Jesús Ugalde, Randall García, Nelson Zamora, and Gabriela Córdoba of INBio. We thank Reynaldo Aguilar and José González for their botanical assistance. This study was financed by the Netherlands Ministry for Development Cooperation, represented by the Netherlands Embassy in San José.

Identification and Monitoring in the Context of the National Biodiversity Strategy in Uruguay

Victor Canton

INTRODUCTION

The Convention on Biological Diversity (CBD) was one of the most important results from the United Nations Conference on Environment and Development (UNCED), also called the Earth Summit, that was held in Rio de Janeiro, Brazil, in 1992. The CBD is a legally binding international instrument with three main objectives: the conservation of biological diversity, the sustainable use of its components, and the fair and equitable sharing of benefits arising from the use of the genetic resources.

Today almost 170 countries worldwide have ratified the CBD, and most of them are working to the full implementation of the CBD commitments — actually, a very hard task, if we take into account the complexity of the issue and the different kinds of problems that must be resolved to achieve the three CBD objectives.

The CBD refers to different levels and scales about the biodiversity problems: species, ecosystems, and genes. During the last negotiations of the conference of the parties of the CBD, the Subsidiary Body of Scientific, Technical and Technological Advice (SBSTTA) recommended the use of the ecosystem approach to effectively deal with the issues related to the management of biological resources. Article 6 of the CBD asks to develop national strategies and action plans for conservation and sustainable use of biodiversity in areas within the limits of its national jurisdiction, and integrate this concept into relevant sectoral or cross-sectoral plans, programs, and policies.

Uruguay, as a party of the CBD, started in early 1998 a multisectorial and participative process to develop its national biodiversity strategy and action plan with the financial support of the GEF (Global Environment Facility), the participation of UNDP (United Nations Development Program) as implementing agency, and the National Environmental Division (DINAMA) of the Ministry of Housing, Land Planning and Environment (MVOTMA) as the coordinating agency.

STATUS AND TRENDS OF URUGUAYAN BIODIVERSITY

Uruguay, located in the southern cone of South America between Brazil and Argentina, has a temperate climate and is a transition zone from the subtropical ecosystems of southern Brazil and

the flat pampas of Argentina. The country is included within the broader biological entity called the biogeographical Pampas Province, characterized by the dominance of grasslands.

Uruguay is located downstream of the Parana River Watershed and the Uruguay River Watershed, both included in the major Cuenca del Plata Watershed; thus, terrestrial, aquatic, and marine biodiversity are influenced by this factor.

With grasslands as a predominant natural ecosystem, Uruguay has important areas of wetlands, gallery forest, ridge forest, palm groves, and coastal and lagoon ecosystems. Uruguay shares important areas of estuarine and marine ecosystems with Argentina (Rio de la Plata and the Atlantic continental shelf) that have a rich marine biological diversity.

The existing animal species correspond to the available habitats, comprising some 1226 species of vertebrates that have been identified in Uruguay. These species include 600 fish, 111 mammals, 62 reptiles, 41 amphibians, and 412 birds. The modifications suffered by the natural ecosystems with the development of livestock and later agriculture (early main economic activities) generated a loss of habitats for native biodiversity. In the case of animals, various species have disappeared, particularly the large carnivores (puma and jaguar), the peccary, and the swamp deer.

Today, other activities are arising as a potential menace to biodiversity (mining, tourism, exotic forestation planting), but DINAMA, in combination with the public and private sectors, is working to develop strategies and actions to achieve conservation and sustenance of Uruguayan biodiversity.

THE STRATEGY PROCESS: FIRST STEPS

One of the first steps in the Uruguayan biodiversity strategy process was gathering existing information about Uruguayan biodiversity and, as far as possible, identifying the activities that threaten the species and ecosystems.

It was necessary to determine where information was available, and who produced any information; in other words, the situation was to locate information that could be useful to develop a strategy and identify gaps of knowledge. A small team of biologists, a marine biologist, an agronomist, a veterinarian, and a geographer spent several months on research. Article 7 of the CBD requires identification of components that are critical to conservation of national biodiversity. Parties are to identify activities or processes that have adverse impacts on biodiversity and organize that data to support future activities to implement the national strategy and action plan. Influenced by DINAMA, we started the task with an orientation to the policy-making and management contexts in order to work with the best knowledge available and to take actions as soon as possible. One of the constraints in this process in developing countries is the lack of baseline information (several times dispersed) and a short time frame to take advantage of protective measures from the government.

CONTINUING THE PROCESS: PUBLIC INVOLVEMENT AND MULTISECTORIAL APPROACH

DINAMA started to organize workshops with broad participation from representatives of the public sector (ministries, agencies, local governments, etc.) and the private sectors (universities, educational institutions, and NGOs. About 125 people from the 58 different institutions attended the workshops and contributed their points of view in strategy discussions.

The main goal in each workshop was to reach a consensus about the main guidelines to implement the CBD objectives in Uruguay. This part of the process took about 1 year. The issues of the workshops concentrated on how to implement the articles of the CBD at the national level. The workshops addressed Article 7 (identification and monitoring), Article 8 (*in situ* conservation), Article 9 (*ex situ* conservation), Article 10 (sustainable use of the biodiversity components), Article

11 (incentive measures), Article 12 (research and training), Article 13 (public education and awareness), Article 14 (impact assessment and minimizing adverse impacts), and Article 15 (access to genetic resources). In every workshop the concern about the topic of identification and monitoring arose among the participants and was included as a priority issue.

This participative way to resolve the biodiversity issues is strongly recommended from the well-respected organizations involved (UNEP, UICN, WRI) and is believed to be the best way to move forward and take advantage of concrete actions; gain a minimum consensus between the various sectors necessary to make progress; and include the general populace, which must be part of the process of construction of the national strategy on biodiversity.

Biodiversity is a part of the environment; it is not possible to separate biodiversity as an isolated topic. The strategy to protect Uruguay's biodiversity must be part of the more comprehensive strategy to protect the whole environment (ecosystems health).

In December 1998, Uruguay sent to the CBD Secretariat its Advanced Draft of the National Biodiversity Strategy. The document was published by MVOTMA in late 1999.

RECOMMENDATIONS TO IDENTIFICATION AND MONITORING

The experience of the Uruguayan biodiversity effort leads to some comments and recommendations about identification and monitoring on the conservation process.

1. The monitoring system must be in accordance with the policy-making schedule to take action (e.g., ecological rapid assessments). In developing countries there is a lack of experience in long-term planning processes. In most cases, the problem is that politicians need concrete deadlines to take biodiversity conservation measures.
2. The spatial perspective (Maps/GIS/Remote Sensing) is an important tool for the monitoring system; species and ecosystems have a place in the territory, and it is necessary to be familiar with them to appropriately manage; otherwise, developing a set of regulations to protect biodiversity can lose effectiveness if the decision makers do not know where the problems are located in the territory.
3. Indicators of biological diversity must be developed at the national and local levels. These indicators must draw from the experience of the developed countries but should be adapted to the biogeographical conditions of each country.
4. It is very important to identify those activities that can threaten the biological diversity, such as mining, deforestation, large-scale forestation with exotic species, unsustainable agriculture, spread of invasive species, major infrastructure constructions, and so on.
5. It is equally important to identify other components such as sectorial policies, international agreements, market changes, and other factors that can influence biodiversity.
6. Environmental Impact Assessments and Environmental Strategy Assessments could be excellent tools to prevent or minimize the loss of biodiversity and also should be considered sources of information about status and trends.
7. More research is needed about native species, ecosystems, and genetic resources as well as investments in capacity building and transfer of technology.
8. More education and awareness about the significance of biological diversity is necessary, not only in the educational system but also for civil society and policy makers. At times the public confuses the concept of biodiversity with the megabiodiversity that is often found in tropical countries. However, flora and fauna of each country result from the climate, the soils, and other conditions such as altitude, latitude, water resources, etc. This point is a constraint in a temperate country such as Uruguay; it is important to explain the need for protecting the native biological diversity to the civil society.
9. It is also necessary to give an economic value to biodiversity; biological resources are a raw material for food, medicine, etc., as a direct value and provide us with indirect values such as ecological services, leisure, aesthetics, etc. It is a priority to determine how to transmit this concept to policy makers and economists to get their support to take actions for conservation.

10. Public participation in identification and monitoring is very important. The people who are living close to the biodiversity problems can understand better and support actions for conservation and sustainable use. They can also constitute an early warning system against activities that lead to the loss of biodiversity.
11. Conservation efforts are hampered by *lack of financial resources*, *lack of coordination* among the involved institutions (public, private, academia, etc.), and *gaps in trained people* to perform biological inventories. Additional *requirements of cooperation* must be undertaken soon to attain success in the conservation and sustainable use of Uruguayan biodiversity. Greater cooperation among participating organizations is necessary before real progress is made.

SECTION II.3

Climate Change and Ecosystem Health

Overview: Climate Change and Ecosystem Health

Ruth A. Reck

Given that an ecosystem is defined by a dynamic arrangement of competing and evolving populations controlled by common nutrient cycles and energy pathways, consideration of how climate change can alter the stability of these cycles and pathways may be useful. Change in climatic variables — either in terms of the mean, the seasonal cycle, or day-to-day variability — can affect all constituents of ecosystems, flora, and fauna, including mammals and birds as well as herbivorous insects, parasitic plants, and fungi. A change in any constituent's essential role can change the details of the ecosystem's structure and function. Depending upon the scale of a disturbance, climate change can alter the sustainability of the ecosystem and can upset the hierarchy and the composition of biotic species.

RELATIONSHIP OF ECOSYSTEM HEALTH TO CLIMATE CHANGE

Many persons have some idea about what is important or unimportant if ecosystem health is affected by climate change, but in general the concept appears to be difficult to define. Ecological variables may be chosen to relate to climate change, but for these to be useful they must be measurable, affordable, and reliable. And for any database to be useful for detecting changes in ecosystem health, it must be capable of describing both structural and functional characteristics. Some researchers have suggested that an ecosystem's condition can be characterized by key elements: rate of plant growth and primary productivity; the physical conditions necessary for support of life; available nutrients, particularly nitrogen and phosphorus; abundance of chemical contaminants and how they are altered by climate change; the biological community condition; condition of native species and whether the group might be imperiled by climate change; and the effects of biological invasions, outbreaks, and diseases (see *The State of the Nation's Ecosystems*, 2000). A significant change in each variable must be identified as either having values within normal behavior or as having values outside the normal range, which then could be termed pathological. Developing these concepts is a tall order when the climate is expected to change over decades to centuries. Alas, following the impacts of climate change on ecosystems will be a very challenging but important area for study in the future.

The certain common physical factors that can help to define the role of climate impact include changes in water availability leading to drought or flooding, changes in the effects of insects and pathogens, changes in nutrient cycles, and shifts in climate zones. Both succession and competition can interact, but in different ways, depending upon whether changes are the least or greatest benefit to

a given member of the population. Alteration in the availability of solar radiation from changes in the amount or type of cloudiness, or in the abundance and optical characteristics of aerosols (Ramanathan et al., 1987), can immediately alter plant growth and primary productivity. Shifts in seasonality — either the length of the season or changes in weather variables such as temperature and wind convection, or in nighttime minimum temperature and related humidity — can greatly alter the physiology of one species compared with another and can lead to changes in the biological community condition.

EFFECTS OF ECOSYSTEMS ON CLIMATE

Scientists accept the fact that ecosystems affect the weather on regional and continental scales. Large tracts of forest, for example, tend to help regulate rainfall. Researchers have estimated that 50 to 80% of the moisture in the Amazonia region is held by the forest system. The water is constantly recycled between the growing plants and the atmosphere, released to the atmosphere to again condense and form storm systems and precipitation.

Almost three quarters of the Earth's surface is water covered, and most of the remainder (26.34%) contains the terrestrial biosphere. The sun is the only source of energy to fuel the Earth-atmosphere system. Incident solar radiation interacts with the Earth's surface and, depending upon the optical properties of the surface — i.e., the color of the surface, meaning its albedo (or reflectivity) — greater or lesser amounts of sunlight are reflected back outward to space. Hence, the color of the surface features in a given region greatly influences the climate every bit as much as the abundance of greenhouse gases.

Figure 49.1 shows the effects of seasonality in a section of Wisconsin. The figure shows that large shifts in surface albedo result from snowfall, which changes the local albedo from around 12 to 15% to as high as 70%. Drought can change the color of the surface characteristics in much the same way as snow, from dark green (which can absorb as much as 80% or more of the incoming radiation) to sand-colored (which can be much more reflecting, changing the absorption from 80% to 20 to 30%). So the ecological well-being not only influences the water cycle but also has a most profound effect on the amount of solar energy available to run the Earth-atmosphere weather system. Changes in the ecosystem's optical characteristics and moisture possibly could alter where and how storm patterns can form, and in a most intimate way can influence the weather it experiences. Table 49.1 shows the surface albedos for different types of ecosystem surface cover, and Figure 49.2 shows how it is distributed across the globe on an annual basis. From the values in Table 49.1 and the distribution in Figure 49.2, the reader can perform mental experiments to identify some of the most critical areas of

Figure 49.1 Measured values of the surface albedo for each month of a typical year in a small area of Wisconsin. (From Bauer, K.G., and Dutton, J.A., Albedo variation from an airplane over several types of surfaces, *J. Geophys. Res.*, 67, 2367–2376, 1962. With permission.)

Table 49.1 Ecological Surface Area Types across the Globe, Percentage of Surface Area Covered, and the Seasonal Values of the Surface Albedo (in the Northern Hemisphere)

Surface Category	Surface Area (km ²)	Percent of Total Surface Area	Albedo (%)			
			January-March	April-June	July-September	October-December
Arable land with intensive farming						
Snow in the winter	5.237 × 10 ⁶	1.026	50.0	16.0	15.0	27.0
No winter snow	1.598 × 10 ⁷	3.129	14.0	16.0	15.0	14.0
Grazing and marginal farming lands						
Snow in the winter	5.488 × 10 ⁶	1.075	50.0	18.0	16.0	20.0
Heavy snow in winter	3.804 × 10 ⁵	0.074	50.0	38.6	16.0	20.0
No winter snow	2.520 × 10 ⁷	4.935	20.0	16.0	18.0	20.0
Rice lands or regions where paddies dominate	2.633 × 10 ⁶	0.516	12.0	12.0	12.0	12.0
Other irrigated land in dry areas where paddies do not dominate						
Snow in winter and fall	1.687 × 10 ⁵	0.033	50.0	39.0	17.0	32.0
Snow in winter	2.008 × 10 ⁵	0.039	50.0	17.0	17.0	26.0
No winter snow	1.246 × 10 ⁶	0.244	20.0	20.0	20.0	20.0
Coniferous forests						
Heavy snow areas	1.019 × 10 ⁷	1.995	47.0	47.0	14.0	47.0
Snow in winter	2.625 × 10 ⁶	0.514	36.0	16.0	14.0	11.0
No winter snow	4.197 × 10 ⁵	0.082	16.0	16.0	14.0	11.0
Deciduous forest						
Snow in winter	3.508 × 10 ⁵	0.069	33.0	14.0	14.0	19.0
No winter snow	4.654 × 10 ⁶	0.911	19.0	14.0	14.0	19.0
Mixed coniferous and deciduous forests						
Snow in winter	2.025 × 10 ⁶	0.397	34.5	15.0	15.0	19.0
No winter snow	2.117 × 10 ⁶	0.415	15.0	15.0	15.0	15.0
Tropical woodlands and grasslands	6.641 × 10 ⁶	1.300	16.0	16.0	16.0	16.0
Equatorial (rain) forests	1.513 × 10 ⁷	2.962	7.0	7.0	7.0	7.0
Deserts

Shrubland with no winter snow	1.447 × 10 ⁷	2.833	22.0	22.0	22.0	22.0
Sand	4.769 × 10 ⁶	0.934	42.0	42.0	42.0	42.0
Marshes						
Snow in winter	8.494 × 10 ⁵	0.166	55.0	34.5	14.0	55.0
No winter snow	1.951 × 10 ⁶	0.382	10.0	10.0	10.0	10.0
Tundra	1.172 × 10 ⁷	2.295	82.0	82.0	17.0	82.0
Total	1.345 × 10⁸	26.34				

From Hummel, J.R. and Reck, R.A., A global surface albedo model, *J. Appl. Meteorol.*, 18:239–253, 1979. With permission.

the globe that could influence the surface albedo in the future. To compare with the well-recognized surface heating effect from carbon dioxide, a 5% change in the rain forest area from a surface albedo of 7% to a value of 42% (an extreme case) — an albedo value characteristic of sand — would be equivalent to decreasing the atmospheric concentration of carbon dioxide by ~70%. The previous estimate assumes the sensitivity of a 1% change in global surface albedo and is equivalent to a 50%

Figure 49.2 Annual values of the surface albedo at each square degree area across the globe (the plot is a modified Gall projection). (From Hummel, J.R and Reck, R.A., *A global surface albedo model*, *J. Appl. Meteorol.*, 18:239–253, 1979. With permission.)

change in atmospheric CO₂ — surface sensitivity values obtained many years ago with a one-dimensional radiative-convective model (Reck, 1985).

INDIRECT CLIMATE REGULATION BY ECOSYSTEMS

It is well accepted by this time that ecosystems are important regulators of the greenhouse gas, carbon dioxide. Plants, forests, and agriculture take up huge amounts of carbon as carbon dioxide. Ecosystems serve as “sinks” for a portion of the carbon dioxide emitted from burning fossil fuels. Likewise, deforestation and slash-and-burn farming release the carbon previously sequestered. Today’s estimates indicate that about one half of the forest carbon is located in boreal forests, and one third in tropical forests (Matthews and Hammond, 1999). If the deforestation numbers are approximately correct, tropical forests possibly could be releasing as much as 1.6 billion tons of carbon per year, equivalent to 20% of the annual rate of human emissions. In contrast, researchers have estimated that forest expansion in the temperate regions sequesters on the order of 0.7 billion

tons of carbon per year, making the net effects of forests a carbon source, a factor *contributing* to global climate change (Matthews and Hammond, 1999). That result is surprising to many people who think of forests as beneficial in the global balance. The Intergovernmental Panel on Climate Change has suggested that changes in the management of forests through conservation and replanting could help to offset the emissions of carbon dioxide by as much as 12 to 15% up to the year 2050.

FUTURE RESEARCH NEEDS — A SUMMARY OF THE DISCUSSIONS BY CONFERENCE PARTICIPANTS

Climate models were identified as having higher credibility for larger scales but lacked credibility for smaller scales. Understanding the kinds of mechanisms that would be operative under climate change conditions would require identification of a present-day base case with typical responses, and combination of information with an understanding of how nature would respond under future stresses. Participants noted the difficulty in understanding larger scale ecosystems using an experimental approach (see “Relationship of Ecosystem to Climate Change” section above). The need for a common language among related disciplines — for example, a set of glossaries for related fields — was also clearly identified.

Participants described the need for identifying threshold values of ecosystems. Some suggested that stakeholders should specify which combination of variables matter to a given ecosystem. With the identification of these ecosystem threshold values in place, ecologists could then ask climate modelers to focus on the threshold values of ecosystems. For the concept to be useful, of course, the variability of the constituents would need to be identified for current-day conditions. For example, one suggestion urged ecologists to look for critical community properties.

Other participants advocated encouraging interdisciplinary scientists to approach the future with no preconceptions, to start their studies anew. In particular, participants noted that studies of carbon dioxide exchange and balance were difficult to scale up from a local level, and they discussed the concept of strategic cyclical scaling.

More questions than answers developed in the course of the session. Discussions regarding management strategies did not clearly identify what the management efforts should target. Does it in fact make any sense to try to revert a changed ecosystem back to its past state? Should not the future have the priority? How should a generation make decisions for the future? And, more specifically, what determines the regional vulnerability for a region of the globe that is of concern? Should ecosystems be managed with public opinion in mind, and should cost–benefit analysis play a role? Ideas included a suggestion that perhaps the solution should involve ecosystem flexibility so those ecosystems can fill multiple niches. In that regard, scientists can use conventional tools for helping policy makers while they, in turn, allow for imperfect foresight.

Conference participants agreed that lands should be managed rather than holding vegetation fixed in its place. Perhaps a compensation program could be enacted for those whose interests are not served by management practices. One participant suggested that local people could play a supporting role by means of incentives to shape the future of ecosystem management and to ultimately connect this regional-scale idea to broader, global-scale thinking for all land management.

With regard to forests, when should action be taken? Should we not by policy preserve habitats as diverse as possible, recognizing the importance of primary forests? Participants recognized that, for the purpose of taking action and giving credit to owners, *a forest baseline value must be established throughout the globe*. Once an adequate baseline is calculated, determination of how quickly forest areas are cut can be made, and considerations can be given, comparing local vs. global extinction.

One issue that arose in the course of the discussion was the role of the scientist. Should scientists serve as informing voices, or should they advocate a particular policy? At the very least, the scientist should be able to predict what could possibly happen as well as the odds of potential occurrences.

Advocacy promotion could then be left to the value judgments of other individuals. For the sake of good decision making, however, the advocacy should be kept separate from the facts. And in that regard, one participant was asked, "How would it be possible to introduce the best information on global climate change and the potential effects on ecosystems throughout our education system?"

As a final topic of the discussion, scientists at the conference recognized that management would have to continue in the face of uncertainty. Explanation of the levels of uncertainty and integration of those concepts into policy decisions would be necessary to diminish difficulties in identifying proper management approaches. Scientists need to specify ecosystem values in terms of ranges and to identify the precision of their measurements or models. They need to explain their methods with due care and to identify the likelihood of structural possibilities. Scientists need to consider what happens when ecosystems aggregate with consideration for equity and fairness. And when disaggregation is mandated by policy, it should be necessary to give a traceable account of just how the dis-aggregation is to be accomplished.

Climate Change, Birds, and Ecosystems — Why Should We Care?

Jeff Price

INTRODUCTION

A functioning ecosystem is made up of animals and plants, in a matrix of soil and surrounding abiotic conditions, interacting in myriad different ways. However, much of the published work on the potential impacts of climate change on ecosystems has dealt primarily with vegetative responses. While the amount of work on climate change and birds has recently increased, it is still relatively scant. Much of this research has focused on potential impacts on single organisms, or, at most, suites of organisms taken together. Little work has been done on how changes to organisms will, in turn, affect the ecosystems of which they are a part. A given ecosystem might continue to function if species were removed (or added). However, how well it would function would depend on the role of the lost species. While there may be redundancies in the roles of many species in maintaining ecosystem health, as more species are removed the probability increases that the system will break down.

Much of the climate change impacts research has focused on factors known to feed back on climate, such as albedo and vegetation. The strength of the feedbacks caused by birds, from even potentially large changes, has been assumed to be relatively low. Consequently, very little research has been conducted investigating ways in which climatic changes may affect birds. Yet birds are necessary or valued for a number of reasons, including economic benefits and, especially, the ecosystem services (and subsequent influences on climate) they exert.

One important concern of researchers examining the potential impacts of climate change on ecosystems is whether ecosystems will become decoupled. That is, will the species within an ecosystem respond differentially to a changing climate? The ecosystem services birds perform contribute significantly to a healthy ecosystem. Indeed, some ecosystems might break down if a number of birds and their accompanying services disappear.

OVERVIEW OF METHODS

In order to determine how climate change might affect bird distributions, investigators should first verify whether bird distributions are associated with climate at all. If they are (and most are), then models based on current climate can be projected into the future to see how the climatic distributions — that area having a climate suitable for the occurrence of a species — might change

under various climate scenarios. To date, models depicting how the suitable summer climatic distributions of more than 150 species of North American birds might change with a changing climate have been developed using the techniques outlined by Price (1995). Logistic regression was used to develop models of the association between bird distributions based on Breeding Bird Survey (BBS) data and 18 climate variables. The time period used for developing these models was 1985 to 1989. The short time period was chosen in order to minimize changes from anthropogenic influences or random noise. The models were then statistically validated against a separate data set. Maps of the model distribution were created following the techniques of Price et al. (1995). The maps were used to determine whether the model of the distribution was similar to the distribution developed from the BBS data (Price et al., 1995).

Output from the $2\times\text{CO}_2$ equilibrium run of the Canadian Climate Centre's General Circulation Model 2 (GCM2) was used to project how the climate of each of the BBS routes might change. These projected climate data were then processed through the logistic regression equations to determine the probability of a species occurrence on each BBS route. Maps were then generated from these data, and the maps were compared with the current distribution of the species. In short, these maps depict the area where the climate may be suitable for the species in the future based on information about their current distributions.

DISCUSSION

Birds and other wildlife perform a number of valuable services for the ecosystems of which they are a part. These services include seed dispersal, pollination, decomposition of organic matter, primary productivity, and predation on insect pests. This investigation examined how avian predation of insect pests benefits boreal forest, grassland, and agriculture ecosystems, and how these systems might break down as the climate changes.

Case Study 1: Birds, Spruce Budworms, and the Southern Boreal Forest

The eastern spruce budworm (*Choristoneura fumiferana*) is a common, native phytophagous (plant-eating) insect of boreal forests in eastern North America (Fleming and Volney, 1995). Its preferred foods include balsam fir (*Abies balsamea*) and several spruce species (*Picea* spp.). Budworms are estimated to annually defoliate approximately 2.3 million hectares in the U.S. (Haack and Byler, 1993) and affect 51 million m^3 of forests in Canada (Fleming and Volney, 1995). Losses in Canada attributed to budworms can be 1.5 times that due to wildfire and can constitute a notable proportion of the annual harvest volume. Spruce budworms are usually present at low densities ($<100,000$ larvae/ha), but periodic outbreaks occur throughout the species range with densities reaching 22 million larvae/ha (Crawford and Jennings, 1989). These outbreaks can extend over more than 70 million hectares and last for up to 15 years, causing an annual loss totaling greater than 80% of foliage on fir and spruce trees. This foliage loss kills almost all of the trees in mature stands of balsam fir (Crawford and Jennings, 1989; Fleming and Volney, 1995). Trees not killed by defoliation are often at risk from other phytophagous insects and pathogenic diseases, and standing dead trees increase the risk of fire.

While the exact mechanisms behind the beginning and end of outbreaks are unknown, weather is thought to play a role in at least a portion of the budworm's range. Outbreaks in some areas frequently follow droughts (Mattson and Haack, 1987), and outbreaks in central Canada tend to start in stands with high concentrations of mature firs flowering after hot, dry summers (Fleming and Volney, 1995). Drought stresses host trees, leading to increases in concentrations of sugar and sugar alcohols but to decreases in complex carbohydrates. This frequently leads to a reduction in plant defense mechanisms. Drought also changes the microhabitat around affected plants. Drought-stressed plants average 2 to 4°C warmer (maximum 15°C warmer) than abundantly watered plants

(Mattson and Haack, 1987). Average temperature also plays a role in regulating the number of eggs laid by spruce budworms. The number of eggs laid at 25°C is 50% greater than the number laid at 15°C (Jardine, 1994). Drought and higher temperatures may also shift the timing of reproduction in budworms sufficiently that they may no longer be affected by some of their natural parasitoid predators (Mattson and Haack, 1987). Weather may also play a role in stopping outbreaks. Many outbreaks in central Canada are thought to have been halted by late spring frosts that killed new growth on trees, depriving budworms of their food source.

The control of some endemic populations of eastern spruce budworm may be aided by avian predators, especially some of the wood warblers (Crawford and Jennings, 1989). Several warbler species, including Cape May warbler (*Dendroica tigrina*), bay-breasted warbler (*D. castanea*), Blackburnian warbler (*D. fusca*), Tennessee warbler (*Vermivora peregrina*), and Nashville warbler (*V. ruficapilla*) are important predators of spruce budworms. Many of these species, but especially bay-breasted warbler, show functional responses to increases in budworms — individuals moving into the area and increasing their reproductive output in response to increases in the insect's population (Crawford and Jennings, 1989). Birds consume up to 84% of budworm larvae and pupae when budworm populations are low (approximately 100,000/ha) and up to 22% when populations reach approximately 500,000/ha. However, bird predation cannot effectively neutralize budworm populations in concentrations exceeding 1 million larvae/ha (Crawford and Jennings, 1989). These warblers, in concert with other budworm predators (mostly predatory insects), are thought to be able to control some populations of budworms under normal conditions.

Climate change may influence almost every component of this system, both individually and in species interactions. For example, the spruce budworm's northern range may increase with rising temperatures. Currently, this species' distribution is thought to be tied to the completion of larval development before autumn freezes begin (Jardine, 1994). Increasing temperatures and a greater frequency of drought could lead to more frequent and possibly more severe outbreaks. This change would occur because of the effects of both drought and temperature on host plants and insects (Mattson and Haack, 1987; Fleming and Volney, 1995). Increasing temperatures may also reduce the frequency of late spring frosts in southern boreal forests, possibly increasing the duration of budworm outbreaks in those areas.

A changing climate might also decouple budworm population cycles from those of some of its parasitoid and avian predators (Mattson and Haack, 1987). Distributions of most of the warblers that feed on spruce budworms could shift significantly farther north. One set of models projects that three of the most significant predators — Tennessee, Cape May, and bay-breasted warblers — may all be extirpated from below 50°N latitude with a doubling of CO₂ (Price, 2001). Indeed, the average latitude of occurrence of both Cape May and bay-breasted warblers has already shifted significantly farther north in the last 24 years.

This decoupling of predator and prey may exert the greatest change on southern boreal forests. Replacing biological control mechanisms with chemical control mechanisms (e.g., pesticides) could ultimately yield a different set of problems. Besides the economic and social issues relating to large-scale pesticide application, some pesticides may not work as well as expected. Some insects are known to have reduced susceptibility to pyrethrins, DDT, and some carbamate pesticides with increased temperatures (Mattson and Haack, 1987).

While there may be decoupling of some budworm populations from their control mechanisms, the range and timing of reproduction of the species would probably stay synchronized with their host species. A large outbreak area could contain as many as 7.2×10^{15} insects. Even assuming a budworm genetic mutation rate on the order of 1×10^{-5} per generation, billions of rare genotypes would still be present in the population (Fleming and Volney, 1995). These genotypes could help budworms adapt to remain in synchrony with their host species.

One result of these changes may be an increase in the rate of conversion from boreal forests to other habitat types (especially in southern boreal forests). Rising temperatures, drought conditions, and insect damage may increase the likelihood of major fires, particularly in combination.

Indeed, fire frequency in Canada, the western U.S., Alaska, and Russia has increased during the last several decades (Jardine, 1994), although several likely causes may be involved. Scientists need to confront two key questions: how quickly might southern boreal forests be converted to a different habitat type, and what might that habitat be? As fire frequency increases, the successional pathway changes from fir/spruce to aspen/birch to grasslands (Jardine, 1994). If the climate changes quickly, more southerly species may not have the time to migrate into areas as fast as boreal species are lost. That could mean a shift to grassland or grass/shrubland in areas currently dominated by southern boreal forest. That, in turn, may affect regional economies and distributions of species using southern boreal forests.

Case Study 2: Birds, Grasshoppers, and Grasslands

In pastureland and grassland ecosystems, birds are important predators of grasshoppers. Bioenergetic models estimate that a single pair of Savannah sparrows (*Passerculus sandwichensis*) raising their young consumes approximately 149,000 grasshoppers over a breeding season. Considering typical bird densities in these same areas, this implies that approximately 218,000 grasshoppers/ha are consumed each season (Kirk et al., 1996). In many areas, the economic threshold for spraying insecticides occurs when densities reach approximately 50,000 grasshoppers/ha (McEwen, 1987). Thus, birds may help keep grasshopper populations at lower levels, avoiding pesticide spraying. However, models project that the distribution of Savannah sparrows could shift north with climate change (Price, 1995). This shift may then decouple this predator from its prey in much of the U.S. Many other grassland birds are also projected to undergo similar shifts in their distributions (Price, 1995). Unless all components (grasslands, grasshoppers, and birds) of this ecosystem were to change at the same rate — an unlikely prospect — the decoupling of the predators from their prey could lead to an increase in grasshopper outbreaks in the future.

Case Study 3: Birds in Agricultural Ecosystems

Birds may also be effective predators of insect pests in agricultural settings. Numerous studies have documented the efficiency of bird predation on overwintering codling moth (*Cydia pomonella*) larvae in orchards in different parts of the world, with predation levels reaching 90% or more (Neff, 1942; MacLellan, 1959; Hagley, 1970; Solomon et al., 1976; Solomon and Glen, 1979; Stairs, 1985). In southeastern U.S. pecan orchards, a single tufted titmouse (*Parus bicolor*) feeding on pecan nut casebearers (*Acrobasis nuxvorella*) is estimated to save nut growers 52,000 pecans annually (Whitcomb, 1971). While models have yet to be developed for those birds preying on codling moths, the models for tufted titmouse project that the range of that species does not shift out of the southeastern U.S. (J.T. Price, personal communication, 1999).

CONCLUSION

While changes in bird distributions due to incipient modifications to climate may not exert strong feedbacks on climate (except possibly in the southern boreal forest), they could be significant because of disruptions to ecosystem services. Species within ecosystems have evolved together over time and depend on each other to various degrees for services such as food, protection, or reproduction. Rapidly separating, or decoupling, these species may cause detrimental changes. The examples presented here are just a few of the myriad interactions taking place in ecosystems on a daily basis. Furthermore, climate change is just one of the stressors that species in these systems face.

Humans may be able to intervene to help prevent disruption of many ecosystem services, but the costs of such intervention could be large. For example, loss of predators may lead to the need to apply more pesticides. This will not only have direct monetary costs but also indirect costs such

as other ecosystem damages or possible human health problems. Over time, new predators might migrate into the ecosystem, or the prey might become pesticide resistant. Problems may be caused not necessarily by the change itself, but rather by the rate of change. Unless all components of the ecosystem change at the same rate, the systems will decouple, and the new systems may bear little resemblance to the ecosystems to which managers are accustomed. More research is needed to determine not only how more of the pieces of the ecosystem work together but also how they might move and at what rates relative to each other.

A Checklist for Historical Studies of Species' Responses to Climate Change

Raphael D. Sagarin

INTRODUCTION

Biologists have been widely involved in our understanding of global climate change since the early 1980s. The vast majority of work includes studies that attempt to predict future biological changes in response to future climatic change. These studies range from speculation of range shifts and changes in species interactions based on assumptions that species' distributions and behaviors are broadly controlled by temperature, to highly detailed bioclimatic mapping models that identify the climatic variables most important in determining species' ranges and then map future species' distributions based on expected changes in these variables. Such studies cover a broad spectrum of biological systems, including terrestrial plants (Woodward, 1992; Beerling, 1993), infectious disease (Patz et al., 1996), insects (Rubenstein, 1992), other invertebrates (Bhaud et al., 1995), birds (Root, 1993), freshwater fishes (Scott and Poynter, 1991), algae (Breeman, 1990), marine fishes (Frank et al., 1990), coastal marine communities (Fields et al., 1993; Lubchenco et al., 1993), and native human populations (Langdon, 1995). The vast majority of these studies consider climate change solely in terms of its future signal as predicted by large-scale global circulation models. The significant warming trend seen during the 20th century (Intergovernmental Panel on Climate Change, 2001) and its effects on natural populations is largely ignored by these treatments.

Recently, however, a growing number of studies have shown long-term biological changes during this century that are argued to be correlated with warming trends over the same time period. These studies, like their more speculative antecedents, cover a wide range of taxa including butterflies (Parmesan, 1996; Parmesan et al., 1999), birds (Thomas and Lennon, 1999), reptiles and amphibians (Pounds et al., 1999), fish (Holbrook et al., 1997), and marine invertebrates (Barry et al., 1995; Sagarin et al., 1999). These studies are largely examples of "historical science" (Francis and Hare, 1994) rather than strict experimental procedures. While experimental studies of species' responses to climate change have an essential role in determining important mechanisms that will drive species' responses (Chapin et al., 1995) or reveal unexpected indirect effects (Davis et al., 1998; Sanford, 1999), they are largely inadequate or impractical for tracking species' responses to climate change in the present (Sagarin, 2001).

HISTORICAL SCIENCE DEFINED

In Francis and Hare's (1994) definition, historical-descriptive science begins with observations of a system. At this stage, the observations may be anecdotal (e.g., fishermen noticing unusual species in their catches during warm-weather periods) or tangential to a main line of research (e.g., an investigator noticing changes in species composition over many years at a study site). Whatever the source, these observations are intriguing enough that an investigator uses them as a launching point for a more in-depth study of the system.

Simple models, or narratives, are then developed that suggest hypotheses of how the various observations fit together. The many studies that have posited predictions of population or community changes under expected warming climate are examples of these narratives. For example, a large number of these studies suggest that species' ranges should shift poleward or toward higher altitudes with warming climate.

In the final step, historical observations from a variety of sources are examined for patterns that support or do not support the model. The physical data used typically include long-term time-series data for one or more climatic variables, such as daily temperature records or annual tallies of frost-free days. Historical data on biotic systems might include presence or absence data, population counts, or measures of community composition and diversity through time. These data may take the form of snapshot data taken at the same location at separate points in time, or preferably, as time-series data collected for many years, such as catch records for fisheries or Christmas bird counts. The analysis of these data may be as simple as noting a gradual increase in temperature alongside gradual changes in species' abundances (Southward et al., 1995), or more rigorous attempts to correlate physical and biological variables using time-series analysis (Francis and Hare, 1994; McGowan et al., 1996).

The aim of historical science is not to prove a single hypothesis, or to decide in favor of one of two competing hypotheses, but to reject multiple alternative hypotheses, leaving a single hypothesis as the best remaining explanation of the data. Whereas experimental studies are carefully controlled and, in the ideal situation, all components of the system are accounted for, a historical study may be plagued by a number of uncontrolled variables and methodological uncertainties. For these reasons, it is imperative that the investigator thoroughly research all available historical information.

EXAMPLES OF HISTORICAL SCIENCE IN CLIMATE CHANGE STUDIES

Research that I have conducted with Sarah Gilman (University of California, Davis), James Barry (Monterey Bay Aquarium Research Institute), and Charles Baxter (Stanford University, retired) (Sagarin et al., 1999) fits the historical science model well. Our efforts were initiated by anecdotal observations by Charles Baxter that changes were occurring to the intertidal flora and fauna of Stanford University's Hopkins Marine Station (HMS) in Monterey, CA. In order to quantify these changes, we replicated an extensive survey of intertidal invertebrates conducted by W.G. Hewatt at HMS in the early 1930s (Hewatt, 1937). We recorded abundance of more than 100 invertebrate species in 57 0.84-m² plots placed in the precise location of Hewatt's original plots. A quantitative comparison of 62 species for which reliable records could be compared confirm the initial observations (Figure 51.1); 46 species showed a significant change in abundance (paired *t*-test, $P < 0.05$), but no overall direction of change occurred, with 24 species increasing and 22 decreasing. In fact, no pattern could be discerned from the data until species' changes were separated by their geographic ranges relative to HMS. In this case it becomes clear that southern species primarily declined, northern species increased, and cosmopolitan (wide-ranging) species were split between those that increased and those that decreased (Figure 52.2). We argued that these range-related changes are related to long-term warming trends of nearly 1°C on average since 1930 in nearshore sea temperatures taken daily at HMS.

Figure 51.1 Plot of density in 1995 vs. density in Hewatt's study in 57 paired plots for 62 species. Solid symbols are species that showed a significant change in abundance between the two studies (paired *t*-test, $P < 0.05$).

Figure 51.2 Plot of density in 1995 vs. density in Hewatt's study in 57 paired plots for 62 species. Solid symbols are species that showed a significant change in abundance between the two studies (paired *t*-test, $p < 0.05$). Open symbols are non-significant changes. Southern species: circles. Northern species: squares. Cosmopolitan species: triangles. Abbreviations are as follows: *Acanthina punctulata* (Ap), *Alpheus clamator* (Ac), *Anthopleura elegantissima* (Ae), *Anthopleura elegantissima* (clonal form) (Aec), *Anthopleura xanthogrammica* (Ax), *Calliostoma ligatum* (Cl), *Corynactis californica* (Cc), *Crepidula adunca* (Ca), *Lepidochitona (Cyanoplax) hartwegii* (Ch), *Erato vitellina* (Ev), *Fissurella volcans* (Fv), *Leptasterias hexactis* (Lh), *Ocenebra circumtexta* (Oc), *Petrolisthes cinctipes* (Pc), *Pseudomelatomia torosa* (Pt), *Serpulorbis squamigerus* (Ss), *Tectura scutum* (Ts), *Tetraclita rubescens* (Tr). (From Sagarin, R.D. et al., *Ecol. Monogr.*, 69, 465–490, 1999. With permission.)

Because of the large uncertainty in comparing communities in two widely disparate points in time, we considered many alternative hypotheses to explain the range-related pattern of change we observed. These alternatives included anthropogenic effects, habitat changes, seismic effects, the return of sea otters and oyster catchers, shifts in tidal heights by species, sea level changes, upwelling effects, and El Niño effects. Through analysis of our data as well as many relevant contributions from other scientists and historians, we were able to weigh the importance of these alternatives to

varying degrees. In all cases we found that even when the alternative hypotheses could explain some of the changes, they could not account for the overall range-related pattern of change we observed (Sagarin et al., 1999).

A CHECKLIST FOR HISTORICAL STUDIES

Through analysis of this historical research, as well as several other historical studies of species' responses to climate change, I have compiled a checklist of the eight most important features of such study programs. No study to date has covered all these features and I am doubtful that any one study will do so in the future. In fact, many convincing studies have a weakness or are altogether lacking in some of the checklist areas. The purpose of the checklist, then, is not to reject outright studies that don't measure up to its standards, but to highlight potential weaknesses of studies. This checklist also can be used to prescreen existing historical data sets to determine if they are fit for retrospective study. Finally, the list can be used as a prescriptive of important areas to consider when initiating new long-term study programs. Each feature on the list is discussed in the context of studies of species' responses to climate change, and positive and negative examples of its use are given from the literature.

1. Well-marked study site — In most biological systems spatial location and spatial heterogeneity play an important role in species' distribution and abundance. In the rocky intertidal, for instance, rock type, slope, tidal height, exposure to waves, aspect relative to the sun, and biological cover all influence the distribution and abundance of a given organism, which in turn affect the populations of the species that interact with that organism. Thus, any attempt to compare populations or locations of intertidal species from separate time periods is potentially confounded by differences in any of these factors. While experimental studies attempt to overcome this spatial heterogeneity by using fully randomized designs (Underwood, 1997), the many uncontrolled variables in historical studies, the limited sample size of the available data, and the simple fact that many older sampling programs were not designed with statistical considerations in mind, often make this impossible or impractical. Therefore, the best way to rule out the effects of spatial heterogeneity is to resample in the precise location of the original sample size.

Alterations of the physical habitat also contribute to the importance of well-marked study sites. For example, seismic activity can lead to massive habitat changes in the intertidal (Castilla, 1988). In our study, we were able to rule out seismic effects because we were able to compare the tidal height of the study transect relative to sea level and confirm that this height was the same as reported in the original study. As another example, erosion of rock surfaces would be expected to have effects on intertidal populations. We were able to reject this explanation of changes in our system because we had maps drawn by the original investigator that showed details and contours of rock surfaces that are still clearly visible today.

Many investigators have been thwarted in their attempts to assess long-term changes in their systems simply because they could not adequately relocate baseline studies. Even cases in which the original investigators are still alive and able to provide information about the initial study, it is not always possible to relocate the exact study site (Zavaleta, E., personal communication).

2. Protected study area — Historically based research programs have suffered from lack of protected study sites. In a major study of changes to European butterflies, Camille Parmesan et al. (1999) had to eliminate the entire central portion of most species' ranges from consideration because habitat transformation would have confounded interpretations of climate-related species' shifts.

If sites have been protected by law, it is important to recognize that many anthropogenic effects are not mitigated by politically designated boundaries. Airborne or waterborne pollutants originating outside the site, as well as the heat-island effect of cities are examples of such uncontrollable effects. Furthermore, in most cases, humans have already significantly altered study systems, and we may never know the true baseline conditions of a system (Dayton et al., 1998). Nonetheless, conducting

historical studies in areas protected from human tampering in the years between surveys allows us to rule out the role of direct influence of some anthropogenic effects on the study system. In the case of our research, a village at the current site of HMS collected large numbers of intertidal invertebrates for human consumption until at least 1907 (Lydon, S., personal communication), making it highly probable that the site was not pristine when the first investigations were conducted there. However, the subtidal and intertidal area at HMS has been formally protected from collecting and disturbance as part of the state-designated Hopkins Marine Life Refuge since 1931, almost the same time that the original surveys were conducted. Thus, we know that human collections have not played a significant role in the abundance changes we observed.

3. Knowledge of data — One of the most important issues in any historical research is the reliability of historical sources of information. In historical scientific research, this takes on added weight because the data are to be compared with recently collected data that are (presumably) held to a high standard of scientific merit. Obviously, this problem is eliminated if the same investigator has performed both the earlier as well as the later research. Even if the methodology has changed, the investigator would be aware of this and could account for it in the data analysis. The second best option is to have direct contact with the original investigator. This is especially important for filling in gaps in materials and methods. In many cases, however, the original investigators have long departed, and the retrospective analysis must rely completely on written records. In this case, the modern investigators must be very clear on whether data collection was conducted exactly as specified by the original author, inferred from the author's writing, or with no knowledge of the original author's methods.

Ultimately, the determining factor in judging a historical study that must rely on methodological uncertainty is whether or not a bias is introduced into the study by assuming that the modern methods approximate the historical methods. For example, an observed trend toward earlier budding in plants is biased if earlier investigators recorded first budding as plants with 25% of their stems containing buds while later investigators recorded the very first bud on a plant. Likewise, observed range shifts can be biased if earlier records ignored solitary sightings of accidentals in their range maps and later records included accidentals in their maps.

4. Quantitative data — Many ecological surveys record species as present or absent, or categorically as rare, common, or abundant. Except in the most extreme cases, or with a tremendous amount of data, such data will be inadequate to determine species' responses to climate change. Most predictive papers focus on species' range shifts as responses to climate change, yet responses at sites may first be seen in abundance changes that will not be picked up in comparisons of presence or absence data, and cannot be quantified with categorical data. This is clearly the case in our investigations. When we observe our data as if only presence or absence of species was recorded, no range-related trend is apparent (Figure 51.3). While we did find some local arrivals of southern

Figure 51.3 Changes in presence or absence of all species recorded by either Hewatt (1937) or Sagarin et al. (1999) in the 57 resurveyed plots. "Additions" (unfilled areas) are species recorded by Sagarin et al., but not Hewatt. "Deletions" (hatched areas) are species recorded by Hewatt, but not Sagarin et al. "Both studies" (filled areas) are species recorded by both Hewatt and Sagarin et al.

species and local extinctions of northern species, and these may be related to actual range shifts, the strong range-related pattern of change is primarily driven by abundance changes.

In fact, in some cases, abundance data are not enough to reveal long-term trends. For example, Kullman's (1998) long-term studies in Sweden show shifts in altitudinal tree limits that are associated with the condition of trees, rather than tree abundance. Likewise, the many phenological studies that have been published recently (Beebee, 1995; Sparks and Yates, 1997; McCleery and Perrins, 1998; Brown et al., 1999; Menzel and Fabian, 1999) show a strong response to warming trends in timing of biological events, rather than in population numbers.

5. Relevant physical data—When a pattern of biological change is discovered that is consistent with predicted responses to climate change, it is tempting for researchers to attribute the biological signal to the climatic warming seen in average temperatures during this century. It is important to remember, however, that even the coarsest global circulation models do not predict uniform warming throughout the globe (Intergovernmental Panel on Climate Change, 2001), and many areas have experienced both warm and cool periods during this century. In addition to the spatial variability of climate, the temporal component is also important to biological systems. For example, Welch (1998) found that sharp limits in salmon distributions appeared when comparing distributions with monthly temperature data, but these distinctive limits disappear when seasonally or annually averaged temperatures were used. Likewise, Pounds et al. (1999) argued that daily records of mist frequency must be used in order to see an apparent correlation between species' declines and cloud canopy height in the Monteverde Cloud Forest Preserve in Costa Rica.

Thus, climatic information that is relevant to the biological study system should be incorporated into any historical study program. Individual investigators should first determine if the data available are appropriate for their site. For our studies of the intertidal, it was important for us to have long-term records of sea temperatures taken at the shores of HMS, because large local variations occur in sea surface temperature along the California coast (MacCall, 1996) that would make interpreting the role of temperature changes recorded elsewhere on the coast problematic. Nevertheless, it is unlikely that the most relevant physical factor data will be available and researchers will have to use proxies. In our studies, for instance, local sea surface temperature is used as an approximation of the incredibly complex and poorly understood microhabitat temperatures (Helmuth, 1998) that are expected to have a more direct effect on species.

6. Taxonomic resolution—Climate changes would not be expected to target individual species or groups in the same manner as disease vectors, harvesting, or predation. Thus, gathering data from many different species, with a wide variety of life-history strategies, and from multiple trophic levels is an excellent strategy for eliminating alternate hypotheses to the climate change hypothesis. In our study, we compared 62 species quantitatively. This included a group representing several phyla, predators and prey; herbivores and filter feeders; solitary and colonial; mobile and sessile; cryptic and noncryptic; high to low intertidal; and animals with dispersive larvae and those with brooded larvae. Thus, we were able to test the hypothesis that stronger El Niño events, which are characterized by increased northward water transport along the California coast, led to greater abundance changes in species with long-lived larvae. We found no difference in the patterns of abundance changes between species with non-existent, 1 to 10 day, or longer larval periods. In fact, after analyzing species changes along any of the life-history axes described above we found no significant patterns. Only when we divided species by their geographic ranges was a strong pattern apparent.

As another example, Pounds et al. (1999) found dramatic declines in several species of amphibians in the Monteverde Cloud Forest Preserve in Costa Rica, mirroring worldwide declines in amphibians. Because they saw similar declines in reptiles and birds, however, they were able to discount the effects of fungal diseases known only to infect amphibians in favor of their hypothesis that loss of habitat due to a gradually rising cloud level is ultimately responsible for the declines.

7. Spatial resolution—Biological responses to supposedly global or regional climate changes should be somewhat consistent over a wide spatial area. Unfortunately, few of the historical studies

of species' responses to climate change thus far have presented results from more than a single site or limited part of the species' ranges. A notable exception is Parmesan's (1996) study of range shift in Edith's checkerspot butterflies in western North America. Parmesan examined extinction patterns at multiple sites throughout the entire western range of this species and concluded that extinctions were much more likely in the southern part of the range during this century. Interpretations of studies with poor spatial coverage can be bolstered with supporting data from similar studies conducted in other locations. For example, Brown et al.'s (1999) finding of earlier breeding trends in a North American bird corroborates similar findings in spatially limited European phenological records (McCleery and Perrins, 1998). Nevertheless, expected biological responses to climate change, such as geographic range shifts, cannot be determined from data obtained from a single site. Thus, in our study of changes to the intertidal at HMS, we could not confirm range shifts for most species due to lack of spatial coverage.

8. Temporal resolution — By far the most serious and common weakness in historical studies is the lack of high-frequency time-series data tracking the biological changes. Many studies rely on comparisons of two snapshots in time. While this does provide in some cases a dramatic illustration of changes to a system, it tells us little about how a system changed through time. Important questions such as, "Were the changes abrupt and related to an episodic event, or did they occur gradually through time?" must be left unanswered. Denny and Paine (1998) revealed the weakness of our snapshot picture of change in the intertidal in their discussion of an 18.6-year oscillation in the moon's orbital inclination that may be correlated with tidal emersion periods and nearshore sea temperatures. Because we lack regular time-series data on the biological changes at HMS, it is difficult to determine if the species changes we observed are more strongly related to the gradual rise in nearshore sea temperatures over 60 years, the shorter-term sea temperature changes associated with the lunar oscillation, or other changes that have occurred in the last 60 years. Even with the addition of short-term sampling that showed only minor changes over the past 3 years relative to the large changes seen over 60 years (Sagarin et al., 1999), we cannot be certain that interannual changes were always of such a small magnitude. By contrast, scientists with access to long-term time-series data have been able to analyze the signal of change at a range of biologically relevant temporal scales (McGowan et al., 1998) and establish strong correlations between physical and biological variables (Sparks and Yates, 1997).

CONCLUSION

Studies correlating biological changes to climatic changes are a small but rapidly growing area of climate change science. Because global climate change is essentially an uncontrolled experiment in progress, studies of its effects on biological communities will necessarily be observational and historical in nature. As more researchers turn up historical data sets in an attempt to track climate-related changes, they will undoubtedly run into shortfalls in one or several of the areas described above. Likewise, new biological monitoring schemes, which should be a top research priority in climate change science, will always be limited by available funding and effort, and thus will be somewhat incomplete. Nevertheless, particular strengths in one area, such as taxonomic or spatial resolution, have allowed several of the studies cited above to overcome weaknesses in other areas and convincingly show that biotic communities are responding to climate change in the present era.

Weaknesses in individual studies may also be overcome by compiling results of other studies completed on different taxa, in other areas of the world. This is already occurring as evidenced by several meetings sponsored by government and nongovernment agencies in which scientists studying a wide range of biological systems and geographic locales presented their findings (Bird Life International and World Wildlife Fund, 1997; Royal Society for the Protection of Birds et al., 1999). The Southern Hemisphere and Asia are far less represented in these compilations than Europe and North America, but this will change in the future as scientists in those sparsely studied areas are

beginning to investigate historical data sets (Broitman, B., personal communication). Essential to this effort is the continued support of existing monitoring programs and the creation of new monitoring programs with the expressed goal of tracking species' responses to climatic changes.

ACKNOWLEDGMENTS

I thank Stephen Schneider and Francisca Saavedra for their invitation to speak at the International Congress on Ecosystem Health. Charles Baxter, Sarah Gilman, and James Barry coauthored the research that is discussed in this chapter. Financial support for this research came from NASA Earth Systems Science Fellowship (Grant NGT 30339); an NSF graduate student fellowship (RTG Grant BIR94-13141 and GRT Grant GER 93-54870); the National Wildlife Federation's Climate Change Fellowship Program; and grants from the Lerner-Gray Fund for Marine Research, Sigma Xi Grants in Aid of Research, the University of California at Santa Barbara Affiliates, and the Myers' Oceanographic and Marine Biology Trust.

Use of Long-Term Field Trial Datasets in Forestry to Model Ecosystem Responses to Environmental Change

Csaba Mátyás

INTRODUCTION: RESPONSE LEVELS OF FOREST ECOSYSTEMS TO ENVIRONMENTAL CHANGE

Domestication of forest trees is still in its beginnings. In the majority of cases, forest tree populations still maintain their unimproved, wild condition; this provides a comparatively wide adaptability to the diverse site conditions encountered in forestry. With the widespread use of commercial tree species outside their natural range, however, forest stands became more susceptible to environmental extremes and changing ecological conditions. Mass mortality experienced (e.g., in artificially established Norway spruce forests of Central Europe following a prolonged drought period in the 1990s) directed the interest of ecologists and foresters alike in the ability of forest tree populations to adjust to changing conditions, that is, to their adaptation potential.

The issue of adaptedness appears as a crucial problem for forestry in view of the expected climate instability. The longevity of trees makes a fast adjustment to changed conditions more difficult than in agriculture. Long-term adaptedness and stability should be therefore of higher concern than possible gains in timber or fiber yield. Due to the life span of trees, climate fluctuations, secular changes, and rare events must have shaped the natural adaptive strategy both on the individual and population level. Trees are therefore interesting objects for studying long-term adaptation to the environment.

Adaptation in a genetic sense means the change of the gene pool of a population in response to changes in external conditions. However, genetic consequences of climate or environmental changes in a population cannot be separated from processes in the ecosystem. At least three organizational levels of adjustment that must be considered are studied by different disciplines (ecology, coenology, plant geography, genetics, and physiology):

1. On the ecosystem level, prolonged environmental stress or changing conditions will lead first to the loss of sensitive species of secondary importance, later to the substitution of dominant species. At the same time, other better adapted species will immigrate into the ecosystem. The tolerance limits of the species, and the stability of the species community, will decide to which extent and how fast these changes occur. This phenomenon is described by ecologists as succession or degradation (depending on the direction and quality of species composition changes).
2. On the level of the population (or species), environmental stress triggers a selection process that manifests itself through increased mortality. This process will change the gene frequency of the

population; less adapted individuals will leave less progeny or disappear altogether. The rate of adjustment will be largely influenced by the availability of individuals with suitable traits (i.e., by the genetic variability contained in the population). This is the process of natural selection in the sense of Darwin, and is termed genetic adaptation by geneticists. Genetic adaptation is understood as a change in gene frequency, directed toward a theoretical optimum in a given ecological situation. The genetic transformation is expected to increase the average fitness of the population.

3. Finally, on the individual level the question of survival or death is decided by the resistance or tolerance of the organism to cope with changing conditions. Plasticity (stability or homeostasis) is a physiological trait that is, of course, also determined by heredity. Phenotypic plasticity describes the ability of the organism to change its expressed phenotype as a response to changing environmental conditions. Phenotypic changes are transitory (mostly morphological) and do not involve genetic change of the organism itself.

Therefore, the ability to withstand changes on all three levels depends on the adaptive potential and adaptedness, the determination of which is, however, certainly a question of interpretation. This study examines first of all the genetic adaptation on the level of populations.

Without disregarding conflicting opinions for assessing adaptedness, the suggestion of Ayala (1969) is used: "Adaptedness of a population may be judged on the relative ability (as compared to responses under other conditions) to transform available nutrients and energy into its own living matter." This corresponds to dry-matter production, and in forestry to growth and volume (timber) yield. Adaptational difficulties manifest themselves in deterioration of growth rate, hardiness, and resistance, which affect volume production directly and are therefore of critical importance in forestry. Out of the components of yield of a forest stand, height growth is under strong genetic control. Only this growth trait will be discussed.

Throughout this chapter the term adaptive variation is used to indicate climate-related genetic variation between populations, although it is clear that other forms of variation support adaptation (and fitness) as well. However, climate-related variation is the most prudent interpretation of adaptive genetic variation. This chapter addresses phenomena observed on widespread, outbreeding tree species, mostly conifers. Taxa with divergent reproduction systems or fragmented distribution areas may exhibit different patterns, depending on their evolutionary past.

DISCOVERING LONG-TERM EFFECTS OF CLIMATIC FACTORS ON HEREDITARY TRAITS: A RETROSPECTIVE

The awareness that plant development is affected by climate can be traced back into antiquity. The understanding, however, that species distributed across climatically different regions adapt to local ecological (climatic) conditions through adjusting their genetic variation is relatively recent.

Interestingly, forest trees first attracted attention. In the 18th century, operators of naval shipyards were seriously concerned about the declining supply of good-quality oak and pine timber, and became interested in the question whether seed provenance might influence growth and form of trees in forest plantations. *Provenance* means simply the source of a population sample representing a defined area. The provenances originate from seed collected from identified stands or regions. The inspector general of the French navy, the prominent botanist Duhamel du Monceau, established the first comparative trials in France with Scotch pine seed of Baltic origin between 1745 and 1755. However, no records of his pioneering work survived. Seventy years later, André de Vilmorin endeavored in the 1820s to repeat Duhamel's effort. His results were published after 36 years of observation in 1862, stating differences between provenances and proposing the existence of climate-related genetic variation within the species (Wright and Bull, 1963).

Failures with plantations established from imported seed prompted numerous further experiments in the second half of the 19th century. Outstanding with respect to their extent and design were the provenance experiments in Russia. Similar experiments were established throughout

Central and Northern Europe, Germany, Austria, and Sweden (for details see Langlet, 1971). The interest in provenance trials with forest trees was so great that when the International Union of Forest Research Institutions (IUFRO) was founded in 1892, its first tasks included initiating international provenance experiments. The scope of some of these tests is impressive. For example, the international provenance test with Norway spruce initiated in 1962 includes 1100 provenances from Siberia to Iberia; a total of 20 parallel experiments in 14 countries have been established (Weisgerber et al., 1976).

The importance of ecological factors, especially of climate, in shaping within-species (intraspecific) variability became widely recognized, however, only after experiments with herbaceous plants yielded similar results. The work carried out in California with various perennial species is presumably the best-known investigation of plant populations collected along latitudinal transects. The common garden experiments proved the existence of climate-related genetic differences within the species. The results published in four volumes (Clausen et al., 1940, and following publications) became a citation classic in ecological literature.

AIMS AND SIGNIFICANCE OF PROVENANCE RESEARCH

Provenance research is the expression used in forestry for the analysis of common garden plantations of tree populations originating from geographically different locations.

Provenance tests of trees are time-consuming, require large areas, and are very costly. Nevertheless, provenance testing became a standard procedure because of the economic interest in maintaining vitality and growth vigor of forest stands until maturity. Provenance testing has been applied to practically all major forest tree species of the Northern Hemisphere and also to numerous tropical species of economic interest. Many tests originate from international cooperation coordinated by IUFRO, Food and Agricultural Organization of the United Nations, or other agencies.

The principal goal of provenance tests is to identify stands, populations, or areas that provide the most desired traits and commercially best results at the test location. Beyond strongly practice-oriented intentions serving silviculture, the tests offer an excellent opportunity to analyze intraspecific diversity in areas other than growth traits (molecular genetic, biochemical, physiological, morphological variation) that were also exploited for taxonomic purposes.

The tracing of between-provenance variation probably represents the most powerful available tool for testing hypotheses of climatic adaptation in trees. Instead of analyzing genetic changes in subsequent generation — an unthinkable task in forestry — the observed geographic variation can be interpreted as an adaptive response to changes in climate conditions. The transfer of populations to provenance test sites may be regarded as a simulation of environmental change over time, and the response may be modeled (Mátyás and Yeatman, 1987, 1992; Mátyás, 1994). This approach offers direct applications in forecasting climate change effects on trees and forests.

Compared to common garden experiments with short-lived plants, the long duration of the tests is of great advantage. Effects of annual weather fluctuations and rare anomalies are integrated in the result. Longevity provides for a more reliable response to the given environment than in the case of ephemeral plants. This does not imply a much closer adaptation of trees to local conditions; a perfect adaptation would result in narrowing genetic variation, reducing adaptability, and, in the long run, in the extinction of the species. On the contrary, adaptive strategies must provide for the maintenance of a sufficient level of variability to adjust to continuous and unpredictable fluctuation of conditions during the tree's life span and into an obscure future.

These distinct evolutionary and ecological implications make provenance tests important and interesting objects to study beyond direct silvicultural applications. Although provenance research might be among the most important contributions of forestry to biological sciences, up to now its results have failed to capture much attention outside the forestry community. Even the fact that much of the climatic adaptation research has been initiated and studied on forest trees first is not generally known.

GENETIC VARIATION AND CLIMATE FACTORS

To demonstrate the effects of climate on intraspecific genetic variation, plotting provenance data against an important climate (or geographic) factor of the locations of origin is sufficient (Table 52.1). The various traits show independent patterns depending on the effect the climate has on that specific trait. Correlation between trait variation and climate parameters suggest the selective pressure exerted on the trait, in a sense demonstrating its adaptive significance. Comparing different types of traits, the variation of growth- and phenology-related traits seems to be in closest agreement with climatic factors. Essentially neutral traits, such as morphological and molecular genetic variation, generally do not correlate well with climate factors.

From a forestry point of view, growth and survival traits are the most important. In temperate and boreal forests, the adaptive variation pattern of growth-related traits (including height increment, bud break and formation, and hardiness) are primarily shaped by the thermoperiod. Growth and phenology data of provenances correlate best with thermal parameters, whereas heat sum, temperature average, maxima, and minima yield roughly the same results. These findings are also in agreement with experiments in controlled environments (Mátyás, 1997).

The effect of photoperiod on trees has already been demonstrated by early studies, especially because latitude data of the origins are far easier to obtain than thermal parameters (a classical study is that by Vaartaja, 1959). In most cases, however, a strong confounding effect exists between photoperiod (latitude) and thermal conditions for obvious reasons. Surprisingly, moisture-related intraspecific differentiation is difficult to demonstrate (Table 52.1). Its effect is probably included in the thermal component.

Table 52.1 Correlation of Growth and Morphology Traits of 35 East European Scotch Pine Populations with Climate Factors at the Location of Origin

	Number of Frost-Free Days	Geographic Latitude (photoperiod)	Average July Temperature	Annual Precipitation
11-year height	0.81	-0.69	0.62	-0.14
Height increase, 11th year	0.86	-0.74	0.69	-0.17
Branch number, top whorl	0.44	-0.56	0.41	-0.18
Branch angle	0.70	-0.54	0.35	-0.08
Needle-cast resistance	0.46	-0.15	0.06	0.29
Bud break	-0.84	0.72	-0.62	0.11
Bud set	-0.82	0.75	-0.58	0.17
Winter color of needles	0.80	-0.72	0.75	-0.29

Correlation coefficients indicate the varying selection pressure on the respective trait (measured in Kámon, Hungary.)

The most striking feature of provenance tests is the generally low sensitivity of populations to changing environments, even with regard to highly adaptive traits such as height growth. Tree populations transferred over large distances into very different environments are able to grow and compete with the native, local populations, even if survival data indicate that only a certain fraction of the population exhibits the necessary plasticity (Table 52.2). Numerous studies verified a high level of individual and population homeostasis (for Norway spruce and Scotch pine: Eriksson, 1982; Southern pines: Wells, 1969; white ash: Kung and Clausen, 1984). As a consequence, between-population genetic differences are not well differentiated within considerably large geographic areas in the absence of steep gradients (e.g., mountain slopes). On contiguous plains the distance between populations with measurable growth differences may exceed 50 to 100 km along ecological gradients.

Table 52.2 Ten-Year Height and Survival of Some Transferred Scotch Pine Provenances in an Experiment near Moscow

Provenance	In the Moscow Test		At the Location of Origin	
	Average Height (cm)	Survival (%)	Annual Mean Temperature	Geographic Latitude
Moscow (local)	400	87	3.4	56
Minsk	409	88	5.0	54
Brest	435	92	7.0	52
Volynsk	397	65	7.0	50
Donetsk	418	68	8.0	48

Note the comparable growth of populations from substantially warmer environments; maladaptation is indicated by the decline of survival.

PREDICTING EFFECTS OF CLIMATE CHANGE

Numerous approaches can be used to estimate the transfer effect along an ecological gradient (Westfall, 1992) that might be used for modeling the effects of environmental change. The assessment of effects of climate change with the help of multiple regression analysis has been proposed by the author (Mátyás, 1994, 1996). The use of existing provenance tests to predict such effects is based upon the aforementioned concept that spatial (geographic) variation may be interpreted as a simulation of responses to environmental change over time. Accordingly, response regressions of growth of transferred populations on thermal parameters may be interpreted as a model of response to temperature change scenarios.

The investigation of some conifers indicates that a relative growth increase until a certain limit of transfer into cooler environments is a phenomenon regularly encountered in provenance tests, at least into environments not too close to the upper distribution limits (physiological tolerance limits) of the species. (Relative growth means that data are related to the performance of the local populations. In absolute terms, growth decreases naturally under conditions in which the temperature sum is lower.) It is the result of complex hereditary and other biotic effects that demonstrate the repressive character of biological regulation (Mátyás, 1996). On the other hand, raising temperature affects growth negatively through increasing drought stress. As an example, Table 52.3 shows the interpretation of the general response of populations calculated from the dataset of 45 families of ponderosa pine (*Pinus ponderosa*) from the Sierra Nevada in California at four sites. The data were obtained from three-dimensional response regression functions, in which the transfer effect (the ecological distance) was one of the variables, and the ecological conditions at the test site the other (Mátyás, 1997; Morgenstern, 1996; Westfall, 1992).

The growth rate visibly decreases with increasing pace as average annual temperature increases. An increase of only 1°C (or 1.8°F) already leads to a growth loss of roughly 5%, and 3°C (or 5.4°F) corresponds to a loss of 13% of the original height at mid-elevation. The sensitivity difference between high-elevation and mid-elevation conditions, exhibiting a stronger response at higher altitudes, has to be treated with caution and needs further confirmation.

The calculated decline in height growth is only an indication for actual productivity loss, because a similar decline in diameter and basal area has a quadratic effect on stem volume. In addition to growth loss, other consequences of maladaptation increase as a function of growing temperature (or ecological) distances. These include susceptibility to snow break or the loss of resistance to diseases and pests that are otherwise often harmless or of minor importance (e.g., saprophytic fungi may turn into real parasites). A direct link between ecological distance and mortality could be proven for *Pinus banksiana* (Mátyás and Yeatman, 1992).

Temperature increase triggers an upward shift of species distribution bands and, in consequence, of elevational vegetation zones. Within the elevational band of distribution, plant species are clearly

Table 52.3 Estimated Change of Height Growth of California Ponderosa Pine Families at Age 12 as a Result of Different Annual Average Temperature Change Scenarios

Test Site		Annual Mean Temperature Change (°C)					
		4.5	4	3	2	1	0
High elevation	cm	406.9	422.4	449.1	474.8	506.9	537.8
	%	75.6	78.5	83.5	88.3	94.3	100
Mid-elevation	cm			475.1	496.7	520.0	544.0
	%			87.3	91.3	95.6	100
Low elevation	cm					504.6	524.1
	%					96.3	100

Responses are calculated for three elevational positions; no reliable estimates are available for the empty cells.

structured into altitudinal races or clines, as already proven by the classical study of annuals by Clausen. The same is true for tree populations. Because of the altitudinal genetic differences, 300 m of elevation is generally proposed as the critical limit of safe transfer by ecological genetic studies on some western conifers. The temperature lapse rate for the Sierras was established as 0.54°C/100 m or 2.98°F/1000 ft. Elevation of 300 m therefore equals a temperature increase of 1.62°C of yet relatively safe adaptation (Mátyás, 1997). A further increase of temperature will inevitably lead to significant losses in productivity, as shown in Table 52.3.

Considering the long regeneration cycle of trees, the pace of the forecasted climate changes will be too fast to provide enough time for proper genetic adaptation of populations. A temperature shift will in any case pose a threat to most of the populations. At low elevations close to the lower limit of the species, temperature increase certainly will lead to the thinning out and disappearance of the species as it loses its competitive ability against other species. At the upper limits, temperature increase will bring an improvement of site conditions. This offers the possibility of a migration advance for the species in the long run, as often modeled in climate scenarios. However, apart from the fact that natural migration speed of forest trees is relatively low, even in the long run the utilization of climatically improved zones off the present distribution range will be limited by soil conditions. The development of soil profiles takes millennia and the usually shallow, less developed soils of high altitudes and high latitudes will not change for a long time. Thus, contrary to general belief, the site potential will not follow the improvement in climate.

CONCLUDING REMARKS

Common garden tests are carried out in forestry with easy-to-propagate, widely distributed species. The majority of species in large-scale test networks up to now have been conifers that predominantly occupy the initial phases of succession in temperate forest communities. It is therefore not certain that the observed phenomena apply to all widely distributed tree species. The described modeling method has its limitations as well, as the effect of climate variables at a given test location cannot be evaluated in its full complexity. In the described approach the effects of latitudinal (north–south) transfer have been neglected, although changes in the photoperiod might have some effect on light-sensitive species. An additional constraint for the interpretation is the undoubtedly changed environment of a test plantation as compared to a naturally regenerating forest; this cannot be overcome easily.

With the above limitations, the described effects of temperature change on growth and productivity of tree populations seem to have a rather general validity, even though the magnitude and type of response is determined by the actual genetic structure and tolerance of the species. Contrary to the general perception of physiological reaction to environmental change, the response of adapted,

local populations may be assumed to be asymmetric due to the manifold constraints of biologic regulation. As a result, temperature increase leads to relatively fast growth and productivity loss and selective mortality. Apart from economic consequences, growth decline also affects the functioning of the forest ecosystem as a carbon sink in a twofold manner. With increasing temperature, the quantity of sequestered carbon decreases and simultaneously the decomposition rate of dead organic matter accelerates, causing additional carbon release into the atmosphere.

An important feature of the modeling of climate change effects, as presented in the example, is the fact that it is based on directly measured data and therefore the conclusions are fairly realistic. Such information is available in provenance tests for many commercially important tree species in many parts of the world. Their evaluation may contribute to a better understanding of natural processes triggered by environmental changes, and may help in formulating protective strategies.

The results indicate that because of the conservative nature of the genetic adaptation process, and of the relative speed of expected changes, even agricultural crops will demand a strategy to facilitate adaptation. Long-lived, immobile organisms such as trees will especially need human interference in order to enhance gene flow and adaptation to altered conditions, in spite of an impressive hereditary capacity. National forest policies have to incorporate this task into the agenda of the next decades (Eriksson et al., 1993). To counteract genetic erosion and extinction, populations along the southern (or low-elevation) limits of species distribution areas will need special attention.

The Possible Impacts of Climate Change on Pacific Island State Ecosystems

William C.G. Burns

As we are all aware, mini-ecosystems are amongst the most fragile. Such fragility today places small island states in the frontline of nature's reaction to humanity's overuse and abuse of the environment.

— *Maumoon Abdul Gayoom*
President of the Republic of Maldives

INTRODUCTION

While most nations likely will ultimately suffer adverse consequences from climate change,¹ small island states may face the most dire and immediate consequences. A previous piece by this author focused on the socioeconomic and cultural ramifications of climate change on Pacific Island Developing Countries (PIDCs).² This chapter examines the possible impacts of climate change on the ecosystems of PIDCs.

PACIFIC ISLAND DEVELOPING COUNTRIES: AN OVERVIEW

PIDCs consist of 22 political entities, of which 15 are politically independent.³ The region encompasses well over 1100 islands and islets, of which approximately 500 are inhabited.⁴ With the exception of Papua New Guinea and Fiji, all PIDCs fall within the United Nations' definition of "small island states," which are islands with less than 10,000 km² in land mass and with less than 500,000 inhabitants.⁵ The majority of countries in the region fall well below these thresholds, with populations of less than 200,000 and land areas well below 1000 km².

The physical geography of PIDCs can be divided into two broad categories — high and low islands — with a further division into continental and volcanic islands on one hand, and atolls and limestone islands on the other. Most PIDCs, however, do not fall into discrete categories, but rather are a combination of island types.⁶

GLOBAL AND REGIONAL PROJECTIONS OF CLIMATE CHANGE

Incorporating the Intergovernmental Panel on Climate Change's (IPCC) "business as usual" projections for greenhouse gas emissions over the next century into a general circulation model, the Hadley Centre for Climate Prediction and Research recently predicted an increase in global mean surface temperatures of 3°C by 2100,⁷ while Wigley's most recent assessment, incorporating the IPCC's latest "marker" scenarios, yields a range of 1.3 to 4.0°C over the next century.⁸ Based on varying assumptions of future population and economic growth, land-use patterns, and energy policies, the IPCC projects an increase in sea levels of between 15 and 95 cm by the year 2100, with a best estimate of 49 cm.⁹ This is a rate two to four times greater than that experienced in the previous century.¹⁰ Moreover, levels could continue to rise for several centuries after greenhouse gas emissions are stabilized.¹¹

In projecting climate trends in the PIDCs over the next century, it must be emphasized at the outset that regional assessments of climate change remain fraught with uncertainty:

[General circulation models] have difficulty in reproducing regional climate patterns, and large discrepancies are found among models. In many regions of the world, the distribution of significant surface variables, such as temperature and rainfall, are often influenced by the local effects of topography and other thermal contrasts, and the coarse spatial resolution of the GCMs can not resolve these effects.¹²

Indeed, given the massive expanse of the Pacific island region and substantial topographical variations, it is likely that climate change will result in markedly different manifestations across the region.¹³

Climate researchers have developed several strategies to conduct regional assessments. Nested models seek to simulate regional climates by the application of limited area models nested in a general circulation model.¹⁴ In recent years, some of these models have yielded high correlations between regional climate predictions and observed climatic phenomena, including precipitation, thermal inertia of water bodies, and temperature.¹⁵ Downscaling by statistical means, deriving statistical relationships between observed local climatic variables and large-scale variables, also have proved successful, *inter alia*, in linking large-scale spatial averages of precipitation and surface temperature to local precipitation and temperature–time series.¹⁶

However, most efforts to project changes in the region are still conducted with atmosphere-ocean GCMs with insufficient horizontal resolution to simulate island climates.¹⁷ Moreover, future climate projections will most likely continue to be dominated by uncertainties in radiative feedbacks associated with responses of water vapor, cloud cover, and sea ice to warming.¹⁸ At the regional level, these feedbacks may be substantially influenced by systemic nonlinearities that may prove extremely difficult to forecast.¹⁹

With these caveats in mind, recent research by New Zealand's National Institute of Water and Atmospheric Research (NIWA) in collaboration with France's meteorological service, Météo France, concludes that a significant change has occurred in the Pacific climate during the past 20 years, including an eastward movement of the South Pacific Convergence Zone (SPCZ), consistent with model predictions. The study reveals that central and western Kiribati, Tokelau, and north-eastern French Polynesia became 0.3°C warmer between 1977 and 1994, with a 30% increase in rainfall compared with pre-1977 averages. New Caledonia, Vanuatu, Fiji, Tonga, Samoa, and the southern Cook Islands experienced a strong warming of 0.4 to 0.6°C from 1900 to 1977, which has since slowed to 0.1°C, with average rainfall declining by 15% after 1977.²⁰ Based on data from 34 stations in the Pacific, New Zealand's Meteorological Services concluded that surface area temperatures have increased by 0.3 to 0.8°C this century, with the greatest increase in the zone southwest of the SPCZ.²¹

The most recent IPCC assessment predicts that PIDCs will experience "moderate warming."²² Over the next century, however, a recent experiment with a global coupled ocean-atmosphere GCM

projected increases of sea surface temperatures in the Pacific region (under conditions of CO₂ doubling) of 3.49°C in the eastern Pacific and 2.21°C in the western Pacific.²³ These results “resemble not only the climate anomalies associated with present-day El Niño-related events in many areas, but also the decadal timescale climate anomalies observed during the 1980s.”²⁴

In terms of projected sea level rise in the region, most sea level monitoring sites in the South Pacific are recording accelerated rises of up to 25 mm per year, more than 10 times the trend this century — findings that have been validated by satellite data showing 20 to 30 mm rises from Papua New Guinea southeast to Fiji.²⁵ While these dramatic increases may be attributable to El Niño/Southern Oscillation (ENSO),²⁶ recent research indicating that regional climate change in the future may closely track the effects of El Niño²⁷ leads to the inference that sea levels may increase substantially over the next century in the Pacific. The IPCC projects that thermal expansion alone will raise sea levels in the southwest Pacific by 28 to 32 cm at the time of CO₂ doubling,²⁸ although regional projections in this context remain highly speculative because dynamic ocean effects have yet to be effectively modeled.²⁹

Projected buildups in greenhouse gas emissions will likely raise ocean temperatures and ocean surface water temperatures to above 26°C in the next century.³⁰ This could result in a greater exchange of energy and add momentum to the vertical exchange processes critical to the development of tropical typhoons and cyclones.³¹ Therefore, some researchers estimate that the occurrence of tropical typhoons and cyclones could increase by as much as 50 to 60%,³² and their intensity by 10 to 20%.³³

However, by no means do scientists universally agree that climate change will cause an increase in violent weather events on PIDCs. Some researchers believe that the purported linkage between increased ocean temperatures and violent weather events is overly simplistic, citing other factors that influence storm development, including atmospheric buoyancy, instabilities in the wind flow, and vertical wind shear.³⁴ Moreover, some climate scientists argue that ocean circulation changes associated with climate change may counter the effects of added warmth.³⁵ In its most recent regional assessment, the IPCC concluded that “model projections suggest no clear trend, so it is not possible to state whether the frequency, intensity, or distribution of tropical storms and cyclones will change.”³⁶

POSSIBLE ECOSYSTEM IMPACTS OF CLIMATE CHANGE ON PIDCS

Coral Reefs

Temperature Impacts

Coral reefs are rocklike ridges, composed of calcium carbonate in the form of aragonite, formed from the harder outer skeletons, or polyps, of coral animals.³⁷ Most polyps subdivide as they grow and their skeletons fuse together, creating complex coral colonies.³⁸ Reefs have been termed the “tropical rainforests of the ocean.” While covering less than 0.2% of the ocean’s area, they serve as the home for up to one quarter of all marine species.³⁹ Additionally, reefs protect coastal areas from erosion and storms,⁴⁰ and serve as a “sink” or absorber of carbon dioxide, helping to reduce the level of this potent greenhouse gas in the atmosphere.⁴¹

In the context of small island nations, coral reefs constitute “an extensive and vital”⁴² component of the ecosystem. Coral reefs serve as a buffer against coastline erosion,⁴³ a function that will become even more critical in the future if climate change intensifies storm surges⁴⁴ and sea-level rise threatens coastal regions of PIDCs.⁴⁵ Reefs provide habitat for fish species that meet 90% of the protein needs of PIDC inhabitants,⁴⁶ as well as support the livelihood of small-scale fishers in the region.⁴⁷ Moreover, coral reefs are the primary source of carbonate sand that constitutes the majority of beach deposits on PIDCs.⁴⁸

The projected temperature rise over the next century associated with climate change may pose the greatest long-term threat to coral reef ecosystems in PIDs. Coral reefs have extremely narrow temperature tolerances of 25 to 29°C with some species in PIDs currently living near their threshold of thermal tolerance.⁴⁹ Water temperature increases of 1 to 2°C over an extended period can result in coral “bleaching,” whereby dinoflagellates, endosymbiotic algae species that live in coral fish, are expelled or reduced.⁵⁰ Because coral derive most of their food from dinoflagellates,⁵¹ they can quickly die in their absence.⁵²

In 1998, with global mean surface temperature reaching its highest level in recorded history, and sea surface temperatures increasing 2 to 3°C in many tropical areas where reefs are found, and as much as 4 to 6°C in some areas,⁵³ the world’s reefs “appear to have suffered the most extensive and severe bleaching and subsequent mortality in modern record.”⁵⁴ Approximately 95% of shallow water corals in the Maldives died, as well as 75% of corals in the Seychelles Marine Park System.⁵⁵ Massive bleaching also occurred on the coasts and islands of India, Kenya, Tanzania, and in Australia’s Great Barrier Reef.⁵⁶

It is difficult to definitively link reef bleaching and mortality to temperature increases because other stressors also can contribute to the phenomenon, including pollution, sediment loading, a reduction in marine salinity, intense solar radiation, and exposure to the air.⁵⁷ However, a U.S. Department of State report on the 1998 events concluded that only warming could have caused such extensive bleaching throughout virtually all of the disparate reef regions of the world, including remote areas.⁵⁸ Moreover, the authors of a multifactorial analysis of coral bleaching events in the 1980s recently concluded that “of all stresses which could potentially cause widespread mass bleaching, only excessively high temperature was present in all cases.”⁵⁹

Reefs can recover from bleaching if conditions improve, with coral larvae settling on the reef structure to renew the building process. However, if elevated sea surface temperatures and bleaching persists, new building will not occur and the reef frame can gradually erode, resulting in habitat destruction and mortality.⁶⁰ For example, 1 year after the 1998 mass-bleaching incident, 80 to 90% of the bleached corals in the more severely affected areas of the Indian Ocean had died, including previously resistant species.⁶¹ Moreover, the synergism between rising sea levels and anthropogenic damage to reefs, such as destructive fishing practices⁶² and pollution,⁶³ may impede reef recovery.⁶⁴

Sea-Level Rise Impacts

Most researchers believe that reefs’ maximum sustained vertical accretion rate of 10 mm per year will be adequate to keep up with sea-level rise of 1 m or less,⁶⁵ and that even slowly accreting reef flats should be able to cope with projected sea-level rise over the next century.⁶⁶ Historical evidence supports this conclusion, with most reefs keeping up with sea level rises of 20 cm per decade between 14,000 and 6000 years ago.⁶⁷

Indeed, some researchers argue that rising sea levels may be beneficial for coral reef ecosystems by inducing vertical growth.⁶⁸ However, under the stress of rising sea levels, reefs are likely to develop at deeper average depths in the future, exposing coastlines to greater wave and current effects.⁶⁹

Other Climate Impacts on Reefs

Should climate change in the region result in an increase in violent storm activities,⁷⁰ surges could further degrade already weakened coral reef ecosystems.⁷¹ In addition, heightened CO₂ levels in the atmosphere may increase the acidity of surface ocean water, reducing the concentration of calcium carbonate ions, thus inhibiting the ability of coral-forming organisms to create their skeletons.⁷² It has been recently projected that a doubling of CO₂ could reduce reef calcification rates by approximately 17% in 2065 and 35% by 2100.⁷³

Mangroves

Sea-Level Rise

Mangroves, also known as mangals, constitute a group of 34 tree species that grow in sheltered conditions in shallow tropical and subtropical waters.⁷⁴ More than 343,000 hectares of mangroves exist in the Pacific, with the largest stands occurring in Papua New Guinea, the Solomon Islands, Fiji, and New Caledonia.⁷⁵

In addition to providing a range of products for humans, including construction material, firewood, tannin, and herbal medicines,⁷⁶ mangroves comprise a critical ecosystem in many PIDCs. Mangroves serve as important nursery and feeding sites for nekton, including many fishery species, with surveys of fish and crustacean assemblages around mangroves recording high levels of diversity and abundance.⁷⁷ Also, mangrove trees serve as filters for sediment that threaten coral reefs,⁷⁸ and island pests and exotic insects,⁷⁹ and help to detoxify contaminants in PIDC waters.⁸⁰

Mangrove communities often can cope with sea-level rise where sedimentation rates are commensurate with or exceed local sea-level rise.⁸¹ However, most small island states are characterized by microtidal, sediment-poor environments. Stratigraphy from low-island mangrove systems in the Pacific, including Tongatapu, Tonga, the Marshall Islands, Kiribati, and Tuvalu, reveal sediment accumulation rates of only 12 cm per 100 years.⁸² Thus, low-island mangroves are expected to suffer reductions in geographical distribution from projected sea-level rise over the next century.⁸³ Should the IPCC middle-range estimates of sea-level rise come to fruition over the next century, high-island mangroves with sediment accumulation rates of 45 cm per century could also be threatened.⁸⁴ Increased salinity caused by sea-level rises may also result in decreased net productivity and stunted growth in certain species. Changes in competition between mangrove species also can be anticipated.⁸⁵

Temperature Impacts

Warming in the future should prove beneficial to PIDC mangrove ecosystems. Increased temperatures will increase the diversity of higher latitude marginal mangroves, facilitating expansion into mangrove margins occupied currently only by *Avicennia* species, as well as expansion of mangroves into salt marsh environments. Warming also can be expected to increase mangrove productivity, characterized by increased growth and litter production.⁸⁶

Other Climate Impacts on Mangroves

Mangroves operate in the C₃ pathway of carbon fixation for photosynthesis.⁸⁷ Research indicates that increases in atmospheric CO₂ increase the productivity and efficiency of water use by C₃ plants.⁸⁸ Thus, the projected increases in CO₂ likely will enhance mangrove tree growth and litter production.⁸⁹

Climate models predicts that islands north of 17°S may experience increases in annual rainfall, while islands south of 17°S may see rainfall decline.⁹⁰ Snedaker postulates that increased rainfall may benefit mangroves by reducing salinity and exposure to sulfate, while increasing delivery of terrigenous nutrients.⁹¹ Conversely, he contends that decreased rainfall in some regions, with an attendant increase in evaporation, will reduce the extent of mangrove areas, particularly with the projected loss of the landward zone to unvegetated hypersaline flats.⁹²

Seagrasses

Temperature Impacts

Seagrass ecosystems are valuable resources in coastal waters worldwide, including in the shallow, intertidal environments of many island states. Seagrass communities provide habitats for

a wide variety of marine organisms, including meiofauna and flora, benthic flora and fauna, epiphytic organisms, plankton, and fish.⁹³ Additionally seagrass plants provide food for waterfowl, bind and stabilize bottom sediments, and improve water quality by filtering suspended matter.⁹⁴

Seagrass species living near the upper limit of thermal tolerance, as is true in many coastal regions of PIDCs, may experience declines in productivity and distribution as sea surface temperatures rise in the future.⁹⁵ Increased temperatures also could alter seagrass distribution and abundance by affecting seed germination.⁹⁶

Sea-Level Rise and Seagrasses

Elevated sea levels will reduce available light, which may limit plant photosynthesis and result in reduced distribution and decreased productivity.⁹⁷ The projected 50-cm increase in water depth due to projected sea-level rise over the next century may result in a 30 to 40% reduction in seagrass growth.⁹⁸

Higher sea levels also may increase tidal currents, especially in areas of restricted tidal flow. Increased tidal currents can restrict the depth in which plants grow by exacerbating the stress that accompanies light limitation. This may result in a withdrawal of the deep edge of seagrass beds, which could result in a diminution of total seagrass area.⁹⁹

Rising sea levels will result in increased inland and upstream penetration of salt water in tidal systems. Under high levels of salinity, some seagrass species experience declines in seedling growth, limiting both reproduction and distribution. Seagrasses also may suffer from salinity stress resulting from high external osmotic potentials, ion toxicity from excessive salt intake, and nutrient imbalances resulting from inadequate carrier selectivity during ion uptake.¹⁰⁰

IMPACTS ON FLORA AND FAUNA SPECIES

Beyond the potential adverse consequences for marine species resulting from damage to coral reef and mangrove ecosystems, other climate change-related ramifications for PIDC flora and fauna species may manifest themselves.

Endemic species on islands are exceptionally vulnerable to extinction or extirpation for several reasons, including the fact that island populations are usually small, isolated, and often endemic to a single island, and typically have evolved with minimal competition, predators, or disease.¹⁰¹ Moreover, on most islands such species face severe threats from pollution, overexploitation, and poor management.¹⁰² Thus, PIDCs may have the world's greatest rate of endangered species (per capita or per unit of land area),¹⁰³ encompassing one of every three threatened plant species,¹⁰⁴ as well as a very high number of avian species.¹⁰⁵

Climate change could exacerbate threats to island endangered species in several ways. Increased temperatures may result in a diminution of some species, as well as alter species distribution and composition in unpredictable ways.¹⁰⁶ Moreover, clam and sea turtles in coastal areas of PIDCs may be particularly susceptible to temperature change.¹⁰⁷ Warmer waters in bays and lagoons also might stimulate the growth of toxic algae, threatening predator avian species, such as cormorants and pelicans.¹⁰⁸ Inundation of low-lying wetlands also could reduce the abundance and diversity of freshwater species, as well as deltaic species such as turtles and crocodiles.¹⁰⁹

While nontropical forests probably will be most adversely affected by climate change,¹¹⁰ PIDC forests also may face threats in the future. In addition to possible forest losses from rising sea levels,¹¹¹ PIDC forests may be subject to potentially damaging temperature rises and changes in soil water availability.¹¹² Moreover, increased temperatures may result in more frequent outbreaks of pathogens and pests deleterious to forests, and may elevate the frequency and intensity of fires.¹¹³ However, increased amounts of carbon dioxide may enable some forest species to use water and nutrients more efficiently, thereby ameliorating or wholly offsetting some of the threatening aspects of climate change.¹¹⁴

THE UNITED NATIONS FRAMEWORK CONVENTION ON CLIMATE CHANGE AND SMALL ISLAND STATES

The primary legal instrument to confront the possible ramifications of climate change is the United Nations Framework Convention on Climate Change (UNFCCC),¹¹⁵ which entered into force in 1994. (The UNFCCC had been ratified by 179 nations as of June 1999.¹¹⁶) However, while the parties pledged to “achieve ... stabilization of greenhouse gas concentrations in the atmosphere at a level that would prevent dangerous anthropogenic interference with the climate system,”¹¹⁷ their record to this point has been disheartening.

Initially, the major greenhouse gas-emitting states agreed to “aim” to reduce their greenhouse gas emissions to 1990 levels by 2000. Yet, all industrialized nations flouted this pledge, leading the Organization for Economic Cooperation and Development to conclude that emissions from industrialized nations would actually rise by 11 to 24% over the next 15 years.¹¹⁸

At the Third Conference of the Parties of the UNFCCC, the parties adopted the Kyoto Protocol,¹¹⁹ under which industrialized nations agree to reduce their collective emissions of six greenhouse gases by at least 5% below 1990 levels by 2008–2012.¹²⁰ However, hostility to the protocol by powerful sectors in the U.S., including organized labor, fossil fuel producers, and influential members of the Senate,¹²¹ may thwart its adoption.¹²² This would severely undercut the treaty’s effectiveness, because the U.S. is responsible for approximately one quarter of greenhouse gas emissions.¹²³ Moreover, U.S. refusal to adopt the protocol might prompt European nations and Japan to balk.¹²⁴ This could doom the agreement, because it requires ratification by Annex I nations producing at least 55% of greenhouse gas emissions before it will come into effect.¹²⁵

Additionally, even full implementation of the Kyoto Protocol would have very little effect over the next century. Because many greenhouse gases persist in the atmosphere for decades, “their radiative forcing — their tendency to warm Earth — persists for periods that are long compared with human life spans.”¹²⁶ Thus, the legacy of greenhouse gas emissions from the past few decades will persist for many decades to come no matter what policies we adopt.

Additionally, the UNFCCC currently binds only developed countries and economies that are in transition to the reduction of greenhouse gas emissions.¹²⁷ However, given the tremendous projected increases in greenhouse gas emissions in developing countries over the next century,¹²⁸ the future effectiveness of the UNFCCC is contingent on engaging these nations in the regime’s mission.¹²⁹ Yet, great trepidation exists among developing countries about possible economic impacts associated with reducing emissions, as well as a sense of unfairness given the tremendous disparity between per capita emissions of industrialized and those of developing nations.¹³⁰ Developing countries repulsed an effort at the Third Conference of the Parties in Kyoto to establish emission limitation objectives for wealthier developing states.¹³¹ At the Fourth Conference of the Parties in Buenos Aires, Kazakhstan announced its intention to join Annex I and thus assume commitments under the protocol. However, Argentina’s effort to place the issue of voluntary commitments on the agenda was rejected by the G77, most of which declined even to join in informal talks on the topic, and the Argentine proposal was formally excluded from the Fourth Conference agenda.¹³²

As a consequence of the factors discussed above, Martin Parry recently projected that full implementation of the Kyoto Protocol will reduce projected warming by a mere 1/20 of 1°C, and will have a minimal effect on elevation of sea levels.¹³³

Ultimately, the major greenhouse gas-producing nations may find it cost-beneficial to enact more stringent measures to reduce emissions.¹³⁴ As Cline suggests, under a “moderate-central” assumption of the damages caused by climate change, benefits ultimately will begin to exceed abatement costs on a global scale in 2050, with the benefits of damage avoidance rising to about 1% of world gross domestic product (GDP) by 2050, and 5% of GDP by 2275.¹³⁵

Unfortunately, by that time, most small island states may have paid a terrible price, and some may even have ceased to exist. If the UNFCCC mandate to “prevent dangerous anthropogenic

interference with the climate system” is to be complied with equitably (i.e., in a manner that seeks to protect all nations from the most serious ramifications of climate change), then major greenhouse-emitting nations should not wait to act until they deem it expedient. However, given the record of industrialized states in confronting climate change over the past few decades, it is difficult to be sanguine about the future. In a world governed more by realpolitik than international law, small island states likely will remain hostages to forces far beyond their control.

134. For analysis of how nations’ cost–benefit analyses have hindered development of an effective emissions reduction regime, see Fox, S., Responding to climate change: the case for unilateral trade measures to protect the global atmosphere, *Georgetown Law J.*, 84, 2499, 1996; LaLonde, M.J., The role of risk analysis in the 1992 framework convention on climate change, *Mich. J. Int. Law*, 15, 215, 1993.

135. Cline, W.R., Socially efficient abatement of carbon emissions, in *Climate Change and the Agenda for Research*, Hanisch, T., Ed., Westview Press, Boulder, CO, 1994, p. 102. However, even if the major emitters of greenhouse gases ultimately decide to make a serious commitment to emissions reductions, the task of stabilizing emissions will be extremely imposing. As Hoffert et al. recently concluded: "Stabilizing atmospheric CO₂ at twice pre-industrial levels while meeting the economic assumptions of 'business as usual' implies a massive transition to carbon-free power, particular [sic] in developing nations. There are no energy systems technologically ready at present to produce the required amounts of carbon-free power." Stabilizing atmospheric CO₂ at double pre-industrial levels will require about 15 terawatts of carbon-free power by 2050, and even more thereafter. By comparison, total world energy consumption is currently only 13.5 terawatts. Hoffert, M.I. et al., Energy implications of future stabilization of atmospheric CO₂ content, *Nature*, 395, 884, 1998. *But see*, Victor, D.G., Strategies for cutting carbon, *Nature*, 395, 837, 1998 ("if policies to improve energy efficiency could accelerate the 1% annual decline in energy use per unit of economic output to 1.5%, then the carbon-free energy required would be cut in half").

Modeling Assessment of the Biological and Economic Impact of Increased UV Radiation on Loblolly Pine in the Middle Atlantic States

John J. Streicher and Keith Endres

INTRODUCTION

Consideration of the economic impact of environmental degradation provides additional justification for stewardship that imposes regulation and operational costs to aid remediation measures. The assessment of the economic impact of an ecological stressor within a geographic region requires knowledge of the distribution of vulnerable receptors within the region, determination of appropriate spatial and temporal resolution of the stressor, and information about the exposure and effect relationship. The increases in the surface flux of solar ultraviolet (UV) radiation due to decreasing stratospheric ozone are a stressor for numerous plant species, including the commercially important loblolly pine (*Pinus taeda*). The extent of species range and biomass of loblolly pine can be estimated for the Middle Atlantic area from U.S. Forest Service Forest Inventory and Analysis (FIA) data. An empirical exposure and effect function may then be applied to approximate biomass reduction and economic impact in a single-stressor perturbation scenario.

Problem Statement

Terrestrial flux of solar ultraviolet-B radiation (UV-B) is a naturally occurring plant stressor. Internal repair and protection mechanisms at the cellular level have evolved to cope with preindustrial levels of UV-B. The intensity of UV-B radiation reaching the earth's surface is mediated by atmospheric gases and aerosols, with ozone being the predominant mediator. With anthropogenic releases of ozone-depleting substances, increases in surface fluxes of UV have been predicted and observed. Loblolly pine is perhaps the most vulnerable of all conifers found near sea level. Typically, the loblolly pine receives relatively less UV-B than high-elevation conifers and adapts less effectively to increased UV-B than conifers indigenous to higher elevations.

Historical Perspective

The Montreal Protocol (1987) and subsequent amendments and adjustments have restricted the atmospheric release of ozone-depleting substances. The abundances of several chlorofluorocarbons (CFCs) have been monitored since 1978. Recent data suggest that tropospheric concentrations of

some CFCs are now decreasing. However, a 3- to 5-year lag in transport to the stratosphere implies that stratospheric ozone will continue to decline, with total column ozone decreasing to a minimum near 2010. Biological stress responses to increasing UV-B may be expected during this time (Caldwell et al., 1994). Nearly one half of species evaluated have exhibited physiological or morphological sensitivity to UV-B (Sullivan, 1997).

Definitions

Incident solar radiation is measured as a spectral flux with units of watts-per-square-meter-per-nanometer wavelength, or $W/m^2/nm$. Biologically effective exposure, or explicitly, area-normalized biologically effective exposure, is measured as biologically weighted flux, or W/m_{be}^2 . Biologically effective dose, or explicitly area-normalized biologically effective dose, is the time-accumulated biologically effective exposure, and is measured as biologically weighted energy density, with units of biologically weighted joules per square meter, or J/m_{be}^2 .

Risk Assessment

Surface fluxes of UV-B at specific locations are determined by geodesic as well as atmospheric variables. Latitude and elevation, in addition to aerosol loading, total column ozone, and cloud cover, all affect the exposure and cumulative dose received by plants. The radiation microclimate of a specific plant is further determined by slope and aspect of the local terrain, and by shading from adjacent plants and geologic structures. The actual UV-B dose received by individual conifer needles will vary greatly within an individual tree. The risk assessment approach taken here is at a spatial resolution of four-digit hydrologic unit code (HUC) watershed, and at a temporal resolution of 3 years. In meteorological terminology, this assessment falls between mesoscale and synoptic scale. This assessment approach makes no statements with respect to effects on finer than a spatial mesoscale, or a 3-year temporal scale.

This study examines the possible effect of increases in UV-B on the loblolly pine within the Middle Atlantic states area. As an economically valuable species, potential economic loss was examined as well. Current atmospheric total column ozone for the latitude and longitude of the watershed centroid were estimated using a regional regression model based on satellite and ground-based ozone measurements. Backcast and forecast estimates of changes in total column ozone derived from the NASA Goddard Institute for Space Studies (GISS) Global Circulation Model (GCM) were used to calculate average daily biologically effective doses for the months of April and July, in the years 1979 and 2010. Average daily biologically effective doses were calculated by month for each watershed in the Middle Atlantic having measurable biomass of loblolly pine. Dose–response relationships developed by Sullivan et al. (1992) were applied to loblolly growth rates for two cases of ozone loss: reasonable worst-case ozone loss and effect-threshold ozone loss.

MODELING METHODS

Overview

The assessment of risk to loblolly pine due to anthropogenically driven increases in surface fluxes of solar UV-B radiation must consider the temporal and spatial profile of the stressor, the spatial distribution of the receptor, the spectral specificity of effects, and the time-dependence of the cause-effect relationship (i.e., the dose metric). Dose–response function then relates a hypothetical exposure scenario to a biological quantity, such as annual growth rate deficit. The economic aspect of the analysis must assign a dollar value to the growth rate deficit, and scale the calculation from a normalized per unit cost, up to a regional economy scale (e.g., the Middle Atlantic states region).

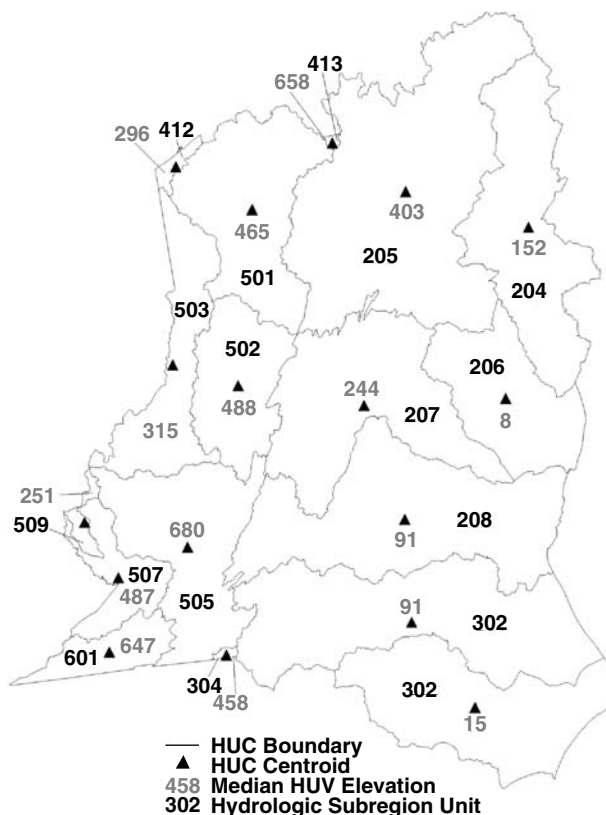

Figure 54.1 Middle Atlantic Integrated Assessment (MAIA) region, showing HUC centroid location and HUC median elevation in meters.

This assessment was completed with spatial subdivision by watershed at the four-digit HUC resolution. This resolution of the Middle Atlantic states region resulted in approximately 20 subregions (watersheds). The UV-B dose profile varies continuously in space across the region. Assignment of a single-dose profile to a subregion required choosing a representative point within the subregion for model calculations. Calculations estimating dose profile were determined for the latitude and longitude of the watershed centroid at the median watershed elevation, as shown in Figure 54.1.

The temporal resolution used in the development of the dose profile varied considerably with model component. A broadband radiative transfer model used to determine solar zenith angle iterated in 1-min time steps. The ozone model iterated in 1-day time steps. A linear dose metric computed a daily biologically effective dose. Daily average biologically effective doses are reported by month, however. Projections of future midlatitude ozone depletion were with 1-year precision. The temporal resolution of the dose–response function, however, was 3 years, and was clearly the limiting factor in the temporal resolution of the assessment. Consequently, dose profiles at 1-month resolution were considered adequate. July is presented as the month of peak biologically effective dose. April is presented as an early growing season month during which emergent growth structures are initially exposed to sunlight.

Model Suite: Description and Usage

No single model existed to perform the entire assessment. Consequently, a series of models and modeling approaches were used in succession to calculate ozone, UV-B surface flux, exposure, dose, growth rate reduction, and cost. A brief description of models/approaches follows.

A regional total column ozone regression model was developed from composite satellite and ground-based ozone measurements. This model was used to calculate current (1999) ozone as a function of Julian day, latitude, and longitude within the Middle Atlantic states region.

A discrete-ordinate spectral radiative transfer model (LibRadtran, version 0.13) was used to calculate the spectral flux $W/m^2/nm$ for selected solar zenith angles, total column ozone levels, and elevations above sea level. Spectral flux was calculated at a resolution of 0.05 nm. Global (beam plus diffuse) radiation was used for subsequent exposure calculation.

The biologically effective exposure W/m_{be}^2 was then calculated by convolution of the Caldwell generalized plant spectral weighting function with the spectral flux (Caldwell et al., 1986). Spectral weighting functions, or action spectra, quantify the relative effectiveness by wavelength of incident light. The Caldwell function was normalized at 300 nm in this analysis, following the convention established in previous photobiological work.

Calculation of the biologically effective exposure for several solar zenith angles, ozone levels, and elevations enabled the development of a simple regression model of biologically effective exposure as a function of these input variables. This simple regression model was then incorporated into a sun-tracking model with a 1-min time resolution to calculate a daily biologically effective dose J/m_{be}^2 using an assumed linear dose metric.

Ultraviolet radiation dose and response data for loblolly pine (Sullivan et al., 1992) were used to estimate growth rate reductions. Laboratory and field experiments approximated diurnal and seasonal variation of UV with supplemental UV corresponding to various hypothetical ozone depletion scenarios (Sullivan et al., 1988; 1989). A dose–response regression function was developed from the data and used to investigate possible growth rate reductions corresponding to two ozone depletion scenarios.

Data from the FIA were queried by four-digit HUC watershed. Total loblolly biomass by HUC was reported for three size classes, as well as annual loblolly biomass growth rate. Annual growth rate by HUC was determined, and future growth rate was estimated by applying the regressed dose–response function for projected ozone reductions.

The economic assessment of growth rate reduction considered fixed stumpage price by tree size. (The stumpage price refers to unprocessed raw wood; value-added wood products would command a substantial price premium.) While lumber prices fluctuate with market demand and supply, and regional pricing variations can and do exist, the prices used in this assessment were recent fixed quotes for Virginia stumpage, published in *Timber Mart-South*. Tree size categories were saw timber (diameter > 8.9 in.); pole timber (8.9 in. > diameter > 5 in.); and sapling/seedling (5 in. > diameter). The dollar values associated with each size category were as follows: saw timber at \$24.16, pole timber at \$19.12, sapling and seedling at \$8.06. Annual biomass production was similarly assigned a dollar value within each watershed, and projected annual growth deficit due to UV-B stress was then evaluated in dollars.

RESULTS

Dose calculations were completed only for watersheds having recorded loblolly pine biomass. Figure 54.2 presents the total aboveground biomass by hydrologic subregion. Loblolly pine trees are found throughout most of the Middle Atlantic states region, but predominantly in the southernmost areas, and nearer the low elevation coastline than the interior highlands. The Chowan–Roanoke (HUC 0301), Neuse–Pamlico (HUC 0302), Lower Chesapeake (HUC 0208), and Upper Chesapeake (HUC 0206) watersheds account for more than 95% of loblolly biomass within the Middle Atlantic states region.

The 1999 estimated UV-B dose profile by watershed for April and July is shown in Figure 54.3. The April biologically effective doses ranged from 3.2 KJ/m^2 in the Delaware watershed (HUC 0204), to 4.0 KJ/m^2 in the Monongahela (HUC 0502), Chowan–Roanoke, and the Neuse–Pamlico

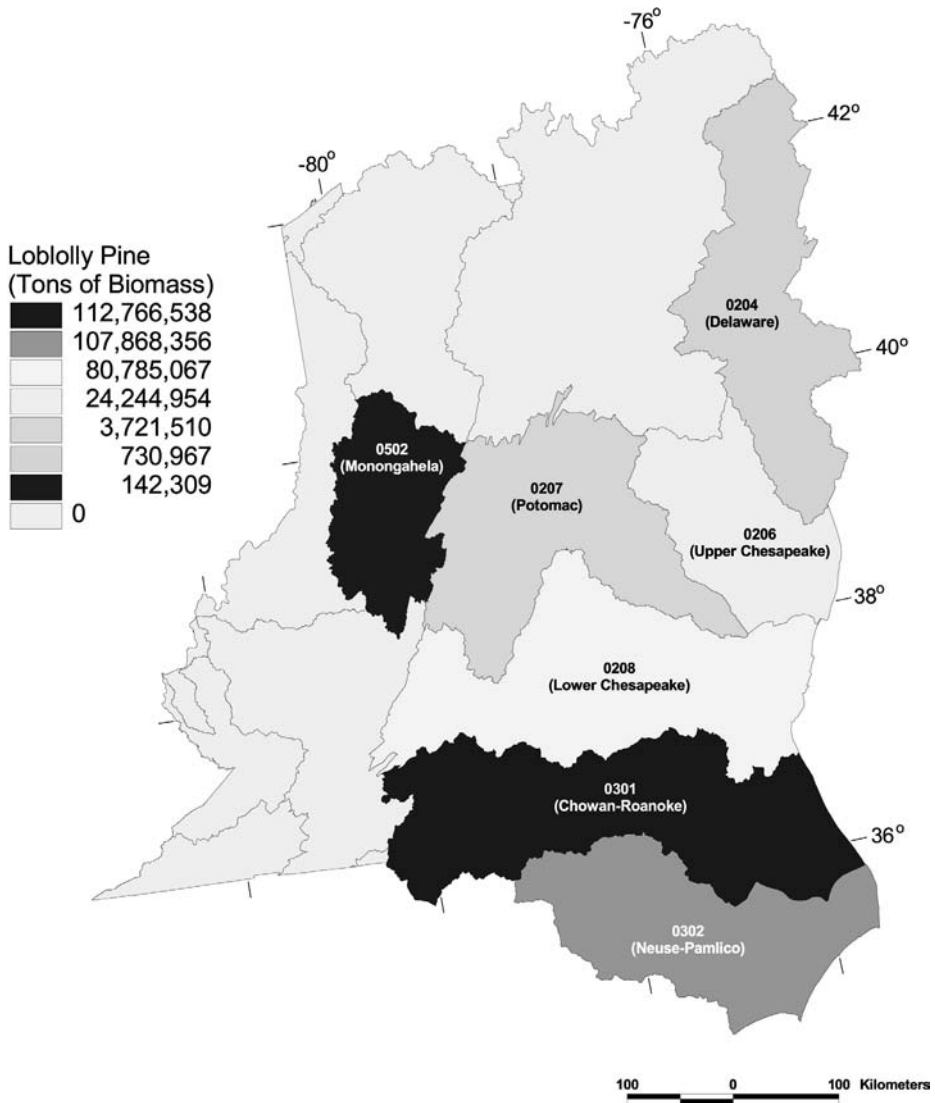

Figure 54.2 Loblolly pine total aboveground biomass (tons) by watershed.

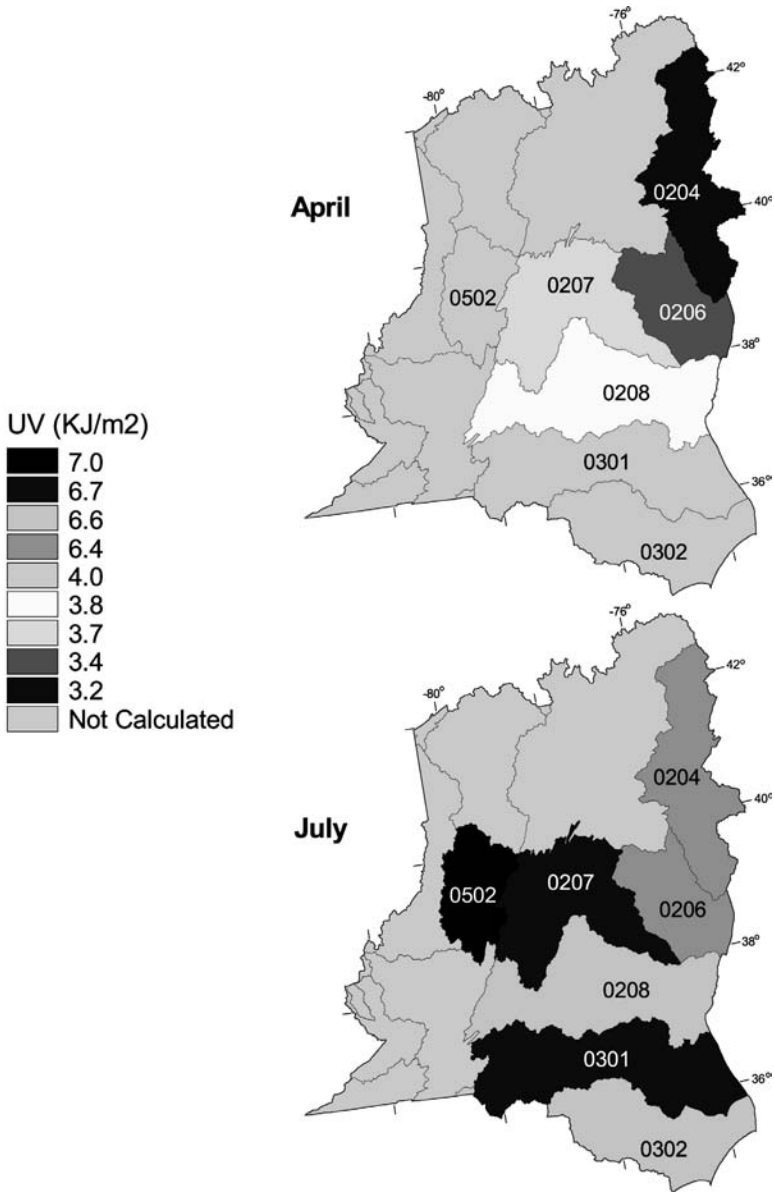

Figure 54.3 Estimated biologically effective UV-B dose profile by watershed for the months of April and July 1990.

watersheds. The July doses ranged from 6.4 KJ/m² in the Delaware and Upper Chesapeake watersheds, to 7.0 KJ/m² in the Monongahela watershed.

For comparison, a 1979 backcast dose profile is shown in Figure 54.4. Total column ozone has decreased by approximately 5% since 1979, and therefore biologically effective dose would have been less in 1979. Figure 54.3 presents 1979 doses relative to base year 1999, expressed as a percentage of base year doses. April UV-B doses have increased significantly more than July doses in the last 20 years. April 1979 doses were 14 to 17% less than those of April 1999, with the Delaware watershed having experienced the greatest increase in the last 20 years. The April relative increases follow a latitudinal ordination, with the more northerly latitudes showing the greatest increase relative to the lower absolute dose that is expected in the north. The July dose changes ranged from 10 to 11%, with latitude being a less significant factor.

Two hypothetical future cases of midlatitude ozone depletion were examined. A reasonable worst-case scenario of 10% total column ozone decrease from current levels by 2010 is shown in Figure 54.5. April and July dose changes are shown relative to current (1999) doses. Note that the April dose is forecast to increase very significantly relative to 1999. As was seen in the backcast, the greatest relative changes are expected to occur in the northernmost watersheds of the region. The Delaware watershed would experience an April increase of 34% relative to April 1999. Overall, April biologically effective dose would increase by 29 to 34% under an additional 10% total column ozone decrease. The July increases would range from 20 to 22%.

A second hypothetical scenario was examined: an effect threshold scenario with 15% ozone depletion from current levels. This is not a forecast of midlatitude ozone depletion; rather, it is an economic exercise to estimate the magnitude of the cost of lost productivity if UV-B radiation were to exceed the threshold known to cause diminished biomass productivity. Figure 54.6 shows the loblolly average annual growth as biomass accumulation. The ordination of growth rate mirrors the biomass tonnage shown in Figure 54.2, with the ranking from greatest to least being: Chowan–Roanoke, Neuse–Pamlico, Lower Chesapeake, Upper Chesapeake, and Potomac (HUC 0207) watersheds. The FIA database recorded insignificant biomass growth in the Delaware and Monongahela watersheds. Figure 54.7 displays loblolly growth rate reduction for the 15% ozone depletion scenario. Percentage reduction biomass accumulation for a 3-year period is indicated in the legend. The Monongahela and Potomac watersheds would experience a 2% reduction in biomass accumulation; the Neuse–Pamlico, Chowan–Roanoke, Lower Chesapeake, and Delaware watersheds would experience a 1% reduction in biomass accumulation; and the Upper Chesapeake would be unaffected. The growth reduction gradients follow physiography more than latitude, with higher elevation experiencing the greatest potential loss of productivity.

A query of the FIA database by tree size class, and by watershed, is presented as a bar chart in Figure 54.8. The Monongahela and Delaware watersheds (HUC 0502 and 0204, respectively) have virtually no loblolly. The Chowan–Roanoke and Lower Chesapeake watersheds (HUC 0301 and 0208, respectively) have substantial loblolly stands, with the sapling and seedling class predominating. The value of loblolly is a function of size. Figure 54.9 presents a bar chart of the dollar value of loblolly stands by tree size class and by watershed. Since larger trees have greater economic value, this economic weighting scheme gives the pole timber class the greatest value in six of seven watersheds.

Figure 54.10 shows the estimated stumpage dollar value for loblolly stands by watershed. The ordination of these watersheds exactly mirrors their ranking by biomass. Figure 54.11 presents the estimated 3-year economic loss due to growth rate reduction under a 15% additional ozone depletion scenario. The losses are concentrated in the southernmost watersheds, with Chowan–Roanoke experiencing the greatest economic loss. The 3-year loss for the entire Middle Atlantic states region is estimated to be approximately \$7.3 million in raw loblolly timber.

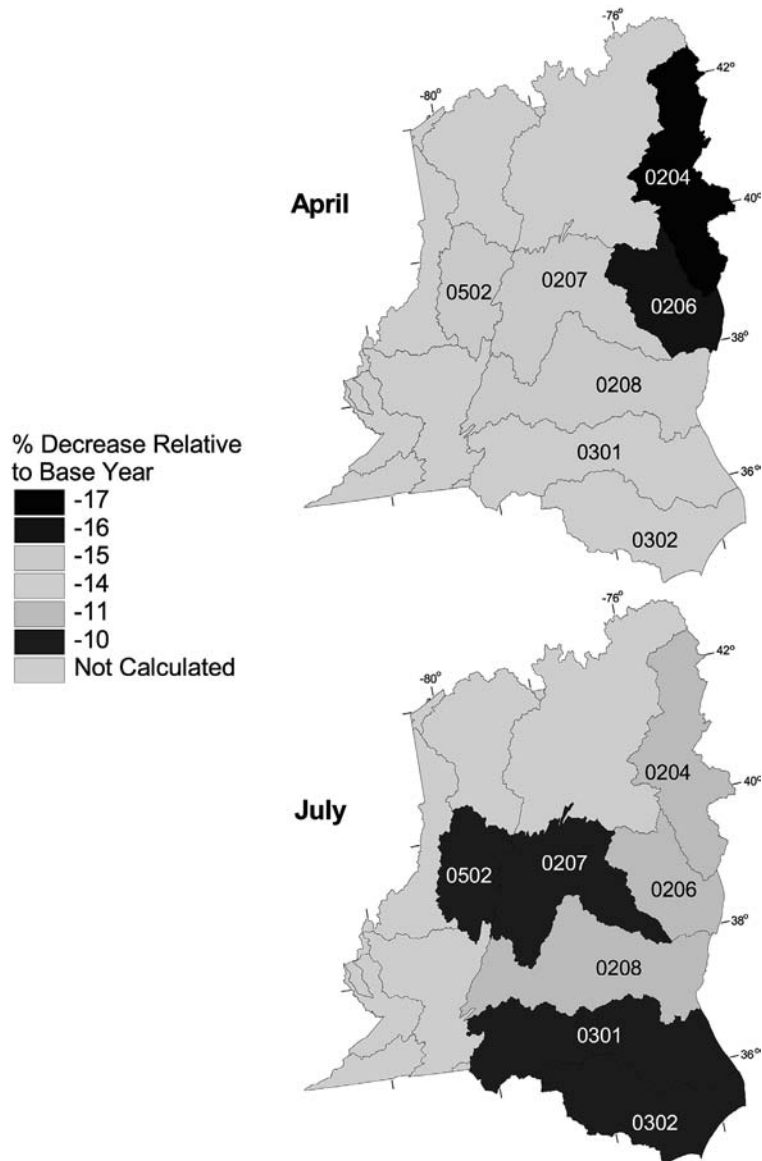

Figure 54.4 Backcast (year 1979) estimated biologically effective UV-B dose profile by watershed for the months of April and July. April 1979 doses are estimated to be 14 to 17% less than April 1999; July 1979 doses are estimated to be 10 to 11% less than July 1999.

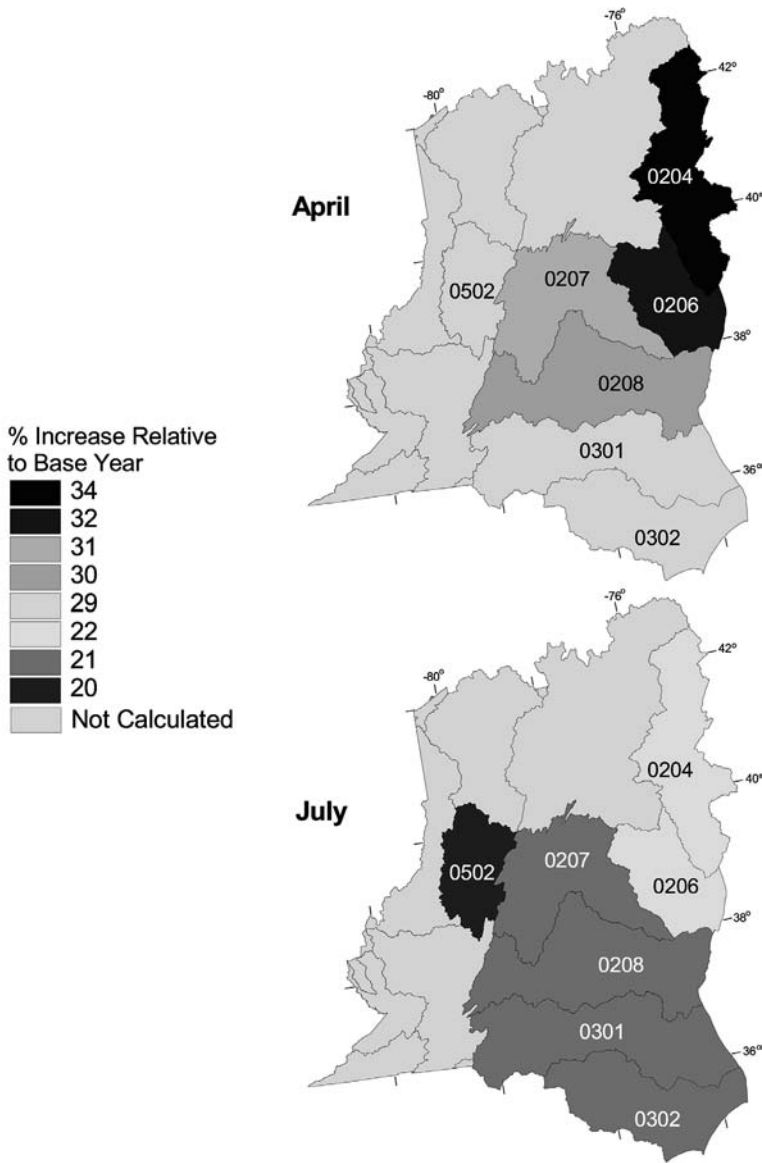

Figure 54.5 Forecast (year 2010) estimated biologically effective UV-B dose profile by watershed for the months of April and July.

DISCUSSION

The sensitivity of the biologically effective dose with ozone, aerosols, and elevation is integral to any consideration of remedial action. The “biological amplification factor,” defined here as the biologically effective dose sensitivity to total column ozone, is approximately -2 for ozone (near 300 Dobson units) (i.e., a 1% decrease in total column ozone results in a 2% increase in the biologically effective dose). Background-level aerosols (summer months) decrease the biologically effective dose by approximately 10% (vs. aerosol-free atmosphere). Finally, increasing elevation from sea level to 1000 m will increase the biologically effective dose by approximately 17%.

In field studies conducted on loblolly pine seedlings, ambient light was supplemented with UV-B radiation from lamps (Sullivan et al., 1988, 1989, 1992). The total UV-B radiation applied was intended to replicate clear skies at Beltsville, MD (39°N latitude), as calculated using Green’s model. The referenced biologically effective dose for current ozone levels was 8.4 MJ/day_{be} on the summer solstice. This dose was comparable to modeling calculations here only when aerosols were neglected. Monthly average biologically effective doses reported here include background level aerosols that diminish surface doses by about 10%.

The mechanism of UV-B effect on loblolly pine growth reduction is uncertain (Teramura, 1996). Leaf surface reflectance in the UV-B region is generally less than 10%. Absorption of UV-B by chromophores in the cell may disrupt physiological and developmental processes in the needles (Naidu et al., 1993; Staxen et al., 1993). Reduced photosynthetic and evapotranspiration capacity were observed in young needles. Developmentally, a thickening of the epidermis was observed, and needle elongation was reduced (Sullivan et al., 1996). The physiological and developmental deficiencies of young needles maturing under elevated UV-B may begin to explain the overall reduced growth rate of the tree. Production of protective, UV-B-absorbing flavonoid compounds within the cell was not observed in loblolly pine to the extent observed in other conifers (Laakso et al., 1998). A protracted growth deficiency, even after elevated levels of UV-B are removed, may be explained by reduced function of damaged needles for the lifetime of the needles on the tree (Sullivan, 1994; Caldwell et al., 1998).

The threshold of UV-B-induced biomass growth rate reduction appears to be greater than a reasonable worst-case scenario of ozone depletion at midlatitudes. While increases in UV-B are anticipated, the dose-response model used here does not predict loss of biomass production. The relative perturbation in ambient UV-B is expected to be greater in spring than in summer. For the reasonable worst-case scenario, April effective doses will increase by 29 to 34%; July effective doses will increase by 20 to 22%. This substantial increase in spring radiation, coupled with existing increases on the order of 15% relative to 1979, imply a cumulative spring dose increase on the order of 50%, worst case, by 2010. This may have implications for bud structures that emerge in spring.

Economic losses in loblolly pine productivity due to a hypothetical 15% ozone depletion (from 1999 base) would affect the southernmost watersheds of the Middle Atlantic states region. The initial 3-year loss is estimated to be \$7.3 million in raw timber; a substantially greater cost would be estimated if losses in value-added processing and finished products were included. Indications of a prolonged, or cumulative, growth rate deficit due to retention of UV-B-damaged needles have appeared; however, extrapolation beyond an initial 3-year period is not possible due to lack of experimental data.

SECTION II.4

Exotic Species: Eradication Revisited

Overview: Exotic Species: Eradication Revisited

James R. Carey

Invasions of nonindigenous species threaten native biodiversity, ecosystem functioning, animal and plant health, and human economies. The best solution is to prevent the introduction of exotic organisms; once introduced, however, eradication might be feasible. Even though the potential ecological and social ramifications of eradication projects make them controversial, these programs provide unique opportunities for experimental ecological studies. Chapters by three leading experts in invasion biology note that deciding whether to attempt eradication is not simple, and alternative approaches might be preferable in some situations.

Judith Myers (University of British Columbia) believes that decisions regarding whether or not to eradicate ultimately must be weighed in terms of costs and benefits, including the possibility of failure. She reviews three eradication programs undertaken in British Columbia, Canada, including programs designed to eliminate the gypsy moth, the codling moth, and the Norway rat. She concludes that such programs should be undertaken only following realistic economic evaluation, and should be carried out only when the benefits are sufficiently large to warrant what may be an extended, expensive effort.

Daniel Simberloff (University of Tennessee) begins his chapter by acknowledging that eradication of nonindigenous species has a bad name among ecologists, largely because many of the highly publicized eradication programs have been unsuccessful. However, he observes that many eradications have been complete successes, identifying in particular three complete eradications: the African malaria vector (*Anopheles gambiae*) from northeastern Brazil, the screwworm fly in the southeastern U.S., and the melon fly and oriental fruit fly in the Ryukyu Archipelago in Japan. After reviewing these and other successes, he outlines five points that appear to demand consideration in successful eradication: sufficient resources, cooperation among parties, biological feasibility (e.g., detectability), prevention of reinvasion, and subsequent problems such as restoration of community. Simberloff's conclusion is similar to that of Dr. Myers: while a useful technique, eradication should be attempted only in certain circumstances.

The chapter by Armand Kuris (University of California, Santa Barbara) focuses on eradication of introduced marine pests. He notes that although prevention is the best strategy under all circumstances, it is particularly important in marine systems because detection is particularly difficult in this environment. Thus, in the past detected marine pests were almost always considered established pests; the detection of introduced marine species was met with defeatism. However, he reviews two propitious eradication programs: a successful one in Cayucos, CA,

where several million South African sabellid worms had infested mollusk shells, and another just undertaken in Darwin Harbor, Northwest Territory, Australia, where early results look promising. He concludes that eradication may be a viable alternative to simply accepting the notion of learning to live with the exotics in marine systems.

Eradication: Is It Ecologically, Financially, Environmentally, and Realistically Possible?

Judith H. Myers

INTRODUCTION

Eradication is the removal of every potentially reproducing individual of a species from an area that will not be reinvaded by other members of the species. The undertaking of an eradication program implies that the program organizers have the right, jurisdiction, and technological ability to eliminate the species, and that cost–benefit analyses support the decision. Exotic species are the most frequent targets of eradication programs, and their potential removal from the ecosystem is likely to be acceptable to most people, particularly those who are not directly involved. However, the financial, environmental, and potential health costs resulting from exposure to poisons or insecticides that accompany large-scale eradication programs are usually unacceptable to a portion of society. In addition, individuals often are required to give up certain rights for the sake of the area-wide program; consequently, obtaining the necessary cooperation for eradication programs is sometimes difficult (Collins et al., 1999; Kazmierczak and Smith, 1996).

Complete eradication, which is really the only kind, is likely to be successful only under certain circumstances. Six requirements for successful eradication outlined by Myers et al. (2001) are (1) sufficient funds, (2) clear authority of a lead agency, (3) a target species that is biologically susceptible to eradication procedures, (4) feasible prevention of reinvasion, (5) methods for continued surveillance, and (6) restoration if necessary. Eradication is most likely to succeed when the target population is very small and restricted. For introduced species, by the time the presence of the species is discovered, the number of individuals can be quite large and possibly past the threshold for feasible eradication. Populations in well-defined island habitats to which dispersal does not occur, are the most vulnerable to eradication. For example, it may be possible to eradicate wasps from a building, or plants or animals from small islands or lakes, or a disease organism from a human body. But on a larger scale, eradication is unlikely to succeed except in cases of homogeneous habitats, and in programs in which financial support is plentiful and environmental side effects are of no consideration.

An eradication program may be undertaken when an exotic species is first identified in a new geographic area or it may involve a pest species that is well established. Almost always, programs are initiated by a government agency that has the necessary jurisdiction, but may require further regulations that compromise private property rights. To engender support for an eradication program, the agency involved must inform and convince the public that the program should be

undertaken. Public relations are particularly difficult because initially there could be little interest in the project. Furthermore, the agency may already have decided to proceed with the project, and a skeptical public may interpret the agency's promise of success as unrealistic, or doubt the potential damage that the target species can cause. A danger is that the program proponents assume the attitude of the experts: "Just trust us, because we know best." Critical review of proposals may be avoided to reduce controversy, but in the long run doing so is probably not wise.

Justification of eradication programs usually begins with a cost-benefit analysis. The biases involved in cost-benefit analyses have been reviewed in Myers et al. (1998). Estimation of the benefits of eradication is influenced by the length of time over which the costs will be amortized. If a pest species is eliminated, its destructive actions will be removed forever. Therefore, the estimated benefits can be enormous. However, projecting the benefits into the future can be misleading. If, for example, successful eradication increases the supply of a commodity, this could reduce its value and the profit made by the grower. Accurately predicting the influences of a newly established exotic organism can be difficult, thereby biasing the cost-effectiveness estimates. Will it become established? Will it create economic damage? A strong commitment by the lead agency may cause the estimates of benefits to be inflated and those of costs to be conservative. Estimated costs do not always cover all of the contingencies. Unanticipated costs are almost always going to occur. Some factors that may not be adequately estimated include costs for long-term monitoring of:

- Success or failure
- Public relations
- Preventing reintroductions
- Lawsuits
- Human health problems
- Human error
- Compensation for lost crops
- Initial population reduction that may require removal of host trees and extensive spray programs
- Continuing the project until the last individual is eliminated.

Three eradication programs that have been undertaken in British Columbia, Canada, and serve to illustrate prospects for success in estimating cost-effectiveness and in eradicating the target species.

GYPSY MOTH

The gypsy moth (*Lymantria dispar*) is native to Europe and Asia. The European form of gypsy moth was first introduced to North America in Massachusetts in 1869 (Elkinton and Liebhold, 1990). The preferred hosts of the gypsy moth are deciduous trees, particularly oaks, although larvae will feed on conifer foliage. The species has now spread north through Quebec, Ontario, New Brunswick, and Nova Scotia, in eastern Canada, south into Virginia and North Carolina, and west into Michigan. After an efficient pheromone trapping system was developed in the mid-1970s, monitoring for new introductions of the moths was undertaken in western states and provinces. The first captures of male gypsy moths in British Columbia occurred in 1978 (Pacific Forest Centre Web site, August 1999). Since that time, captures have been made at approximately 120 sites (Figure 56.1). Eradication programs have been carried out at 20 of these sites to "prevent" establishment. A microbial spray with the active ingredient *Bacillus thuringiensis* kurstaki (Btk) has been used in these programs. The advantage of this spray is that it is specific to lepidopterans, but the belief of some people that spraying of bacteria threatens human health is disadvantageous. Therefore, proposed aerial spray programs in British Columbia all have been associated with public outcry.

Figure 56.1 Number of sites with captures of male gypsy moths in the pheromone trap monitoring program in British Columbia. (Data from the Canadian Forest Service, Pacific Forestry Centre Web site.)

The largest gypsy moth eradication program in British Columbia was undertaken in 1992. The city of Vancouver (20,000 ha) was sprayed from the air three times at the cost of approximately \$6 million. This followed the capture of 23 males of the Asian form of gypsy moth in a relatively restricted area near the grain port in Vancouver in 1991. The Asian gypsy moths are more likely to feed on conifers, particularly larches, and unlike the European gypsy moth, female Asian gypsy moths fly and are attracted to lights. During population outbreaks in the early 1980s and 1990s in eastern Russia, female moths were attracted to the well-lit grain terminals, and many hatching egg masses were found aboard Russian grain ships arriving in Vancouver during spring of those years. Small caterpillars are assumed to have been carried from the ships to trees near the port by the wind.

The proposed eradication program initially aroused very little public interest, but as awareness grew, discussion eventually became heated. Of particular controversy was the use of the microbial spray, its possible effects to human health, and the patent protection that prevented disclosure of all of the ingredients in the spray, Foray B. Experts were imported from the U.S. to describe the potentially devastating result they anticipated if this species should become established. Local officials declared that once the spray program was undertaken, the Asian gypsy moth would be eradicated. That claim was optimistic, and in 1993, 1994, and 1995 several male Asian gypsy moths were captured in the vicinity of Vancouver, although no further spraying was undertaken and no moths have been captured subsequently. The Asian gypsy moth seems to have not become established.

Since 1987, various numbers of male European gypsy moths have been captured at sites in southern Vancouver Island almost yearly. Eradication programs were begun in 1988. Between 1995 and 1998, the number of males collected in traps that were placed to delimit the distribution of the gypsy moth in this vicinity rose from 5 to 280, and egg masses were found (Pacific Forest Centre Web site, 1999). In 1999, Southern Vancouver Island was declared to be a regulated area requiring inspection of Christmas trees, nursery stock, and outdoor household articles before they may be transported from that area into unregulated areas (those without established gypsy moth populations) of the U.S. In 1998, a spray program was proposed, but permits were denied following court action involving health concerns of some citizens. However, in the summer of 1999, a \$3 million aerial spray program was undertaken.

Is the gypsy moth a threat to British Columbia? The gypsy moth primarily defoliates deciduous trees and therefore its potential influence is largely as a nuisance in recreational and urban areas. However, Canada regulates gypsy moths to protect export trade with the U.S. Regulated areas are

established based on survey results, and certification programs ensure that material shipped from infested areas are inspected for freedom from gypsy moths (Stubbings, G., personal communication). Although expensive, the cost of aerial spray programs is less than that for certification of materials, including lumber, which would result if the whole province were to become a regulated area. Jurisdiction in this case falls to the U.S., which requires eradication of the gypsy moth in British Columbia to prevent trade restrictions.

Gypsy moth introductions to British Columbia from eastern North America will continue, and each aerial spray program is likely to be met with an outcry from concerned citizens. While eradication programs with Btk have reduced gypsy moth populations, moths frequently are caught in these locations at a later date (Myers and Rothman, 1995). Even if not successful as eradication, population outbreaks and further spread of gypsy moths are reduced by spray programs. Slowing the spread is an alternative to eradication for introduced species (Myers et al., 2000). Attempted eradication of the gypsy moth is more about trade and trade barriers than biology.

CODLING MOTH

Codling moth (*Cydia pomonella*) is the most serious pest afflicting apples worldwide. It is native to western Asia and eastern Europe but occurs now in all apple-growing areas. The amount of damage caused by codling moths is partly influenced by the number of generations that occur each year, a figure that can vary from one to three. Soon after hatching from the egg, codling moth larvae enter the fruit where they feed on the seeds. When fully developed they burrow out through the fruit. In British Columbia the crop may be downgraded at the packing house if more than 0.5% of the fruit is damaged by worms. Codling moth is particularly troublesome for organic fruit growers.

In the 1970s, a pilot project was undertaken by the Canadian Department of Agriculture in the Similkameen Valley in the southern Okanagan region of British Columbia to investigate the feasibility of eradicating codling moth through the use of sterile male release (Proverbs et al., 1975, 1982). This project was carried out in a 500-ha apple-growing area over 3 years. By the end of the program most orchards in the area had no codling moths, but 7 of the 476 orchards had apple damage above the acceptable level. The cost of the program was \$225/ha/year compared to normal investment of \$95/ha/year for insecticide control. The conclusion at the end of the project was that eradication would not be feasible, even considering that insecticide use was reduced for several years. Further expansion of the program was not recommended.

Rather surprisingly, in the late 1980s, renewed interest was expressed by Agriculture Canada in initiating a codling moth eradication program for the whole Okanagan Valley, from Kelowna in the north to Keremeos in the south (Myers et al., 1998, 2000; Winston, 1997). Agriculture Canada and the B.C. Fruit Growers Association became partners in the program that was funded by the federal and provincial governments and by special taxation on both orchardists (approximately \$195/ha) and urban and rural landowners (\$45/ha). To sell a special tax to the taxpayers required a very positive spin to be put on the project, and the cost-benefit analysis was very optimistic as a result. The aim was initially to eradicate codling moths first from the southern end of the valley and eventually to expand the program to the north. The economic analysis amortized costs over a long period of time and this enhanced the financial benefits side of the equation. The proponents underestimated some costs in the analysis, such as the enormous cost required to initially reduce the moth population with spray programs, fruit culling, and removal of abandoned and urban fruit trees. The costs of monitoring and evaluation were minimized, and other technologies, such as mating disruption and the possible development of viral sprays, were initially ignored. Critical comment on the program was ignored or suppressed. People were easily convinced because everyone wanted the program to succeed. Everyone wanted to reduce insecticide use, and the sterile insect release (SIR) causes no negative environmental side effects.

A state-of-the-art moth rearing facility was built and the program began. Five years into the program the feasibility of eradicating the codling moth was evaluated. One of the major problems influencing the success of the SIR was the failure of the first generation of sterile males to fly actively and to compete for mates with wild males. The initial reduction of wild populations was slow and expensive. Growers began turning to other controls, such as mating disruption or even chemical sprays. Between 1995 and 1998, the percentage of orchards with no codling moth damage increased from 42 to 84%, and the percentage of traps with wild moths declined from 98 to 60% (Anonymous, 1999). But clearly, eradication remained allusive. In the winter of 1998–1999 the program goal was changed from eradication to area-wide suppression with the long-term goal of eventual eradication (Fisher-Fleming et al., 1998). By the summer of 2001, codling moth densities were very low in the southern Okanagan Valley (Edwards, L., personal communication).

Eradication of the codling moth in the Okanagan Valley is an unrealistic goal for several reasons. For one, land use in the area is heterogeneous. In addition to commercial orchards, the region contains urban lots with backyard apple trees and abandoned orchards. Part of the area is in native land reserves under a separate jurisdiction. Reintroduction of moths to treated areas is difficult to stop unless the movement of fruit bins is very carefully controlled. The value of apples has been declining because worldwide production is high and therefore prices are low. Maintaining a program that is more than twice as expensive to the growers as chemical control must show rapid results or support declines. On the other hand, the high capital cost for the rearing facility and the optimistic promises of the program team make the eradication program difficult to stop.

The advantage of the sterile insect release approach to eradication is that it is species-specific and environmentally friendly, although high levels of insecticides are initially required to reduce moth populations. The greatest long-term costs of the failure of this program are the growers' increased mistrust of scientists' advice and the poor value for taxpayers' dollars. Whether it is economically feasible to use SIR as part of an integrated pest management strategy remains to be seen.

THE NORWAY RAT ON LANGARA ISLAND

Langara Island (3100 ha) on the northwest tip of the Queen Charlotte Islands was formerly one of British Columbia's largest seabird colonies with six species of burrow-nesting birds. Between 1971 and 1980, four of these bird species became extinct and populations of the ancient murrelet were greatly reduced. The Norway rat (*Rattus norvegicus*) is known to have a large impact on colonial seabirds and even displaced black rats from Langara Island during the seabird decline (Bertram, 1994; Bertram and Nagorsen, 1995). Diet analysis indicated that Norway rats did attack ancient murrelets (Drever and Harestad, 1998). By 1992, experimentation had shown the effectiveness of a new anticoagulant rat poison, brodifacoum, for eradicating rats from small islands in New Zealand (Taylor and Thomas, 1989). The advantage of this poison is that it kills the rat after one dose, but it is slow acting, which has implications to the social system of rats. In 1993, \$2.5 million became available for seabird enhancement as mitigation for the Nestucca oil spill. In hopes of restoring Langara Island as a successful breeding colony, a rat eradication project was undertaken. In 1994, a pilot project was carried out on Lucy Island, a small, nearby island. The use of fixed stations baited with poison pellets was successful in removing rats from Lucy Island, and the next year a large-scale program was launched on Langara Island. In July 1995, the eradication of rats from Langara Island began. Bait stations were placed at 100-m intervals with the aim of having one in each rat home range. In total, 3905 bait stations were used. By August 1995 most rats were gone, and none was captured between 1996 and 2001 (Kaiser et al., 1997; Taylor et al., 2000; Kaiser, G.W., personal communication).

The poisoning program had some impact on other animals on Langara Island (Howald, 1997). Ravens learned how to extract the poison pellets, and approximately 50% of the raven population was killed. Eagles would not feed on dead rats but did eat poisoned ravens and also suffered some mortality. Raven populations have since recovered through immigration from other islands. Ancient murrelets do not breed until the age of 3 or 4 years, so recovery will be slow. The continued success of this program depends on preventing a reintroduction of rats. Because Langara Island is isolated and the sites visited by humans are localized, that may be possible.

The factors that contributed to the success of the program included the effective poison, the territorial behavior of the rats, the isolated nature of the island, and the fact that the rats were not thriving because food was limited. Seasonal laborers and volunteers enabled this program to be carried out on such a large scale. This successful program is also well documented.

CONCLUSION

Eradication programs are difficult to evaluate because little information is available in the published literature. Monitoring is often not carried out in a rigorous manner, and the desire for success is strong. Therefore, undesirable or compromised results are not welcome. In eradication programs of insects, such as those for the gypsy moths, numbers of male moths trapped may be recorded, but the number of traps used is not. Such limited documentation undermines the ability to compare the numbers caught in different areas and in different years. Evaluation of the growth or decline of populations is difficult. Eradication programs are always very expensive, and the large scale of projects sometimes influences the impetus to maintain the project.

Programs can be classified into three categories: (1) those called eradication for the purpose of preventing trade barriers (gypsy moth eradication); (2) those called eradication of well- and widely established native or exotic organisms (usually insects) that should truly be called area-wide management (codling moth eradication); and (3) those that target the removal of a species from a defined area for which eradication is possible (Norway rat eradication). I believe that eradication should be attempted only in very restrictive situations in which it can be complete and permanent. That will occur in situations in which the distribution of the organism is limited, either because it is newly introduced and concentrated in a particular area, or because it is on an island with limited access. Vertebrates are likely to be more susceptible to eradication because they are more readily detected than invertebrates, they may have limited breeding seasons, and baited poisons have been developed that have been shown to be effective.

Programs should be undertaken only following realistic economic evaluation and should be carried out only when the benefits are sufficiently great to warrant what may have to be an extended and expensive program. Having an emergency response plan in place for dealing with introduced species that may become pests is important. A model that could be emulated by other countries is that of Hosking (2001). This document outlines six response phases: (1) detection, (2) evaluation, (3) the response decision, (4) the operation phase, (5) the monitoring stage, and (6) the review stage. In the early stages of a program, communicating honestly with members of the public who will pay the cost of the program is most important. Program directors should realize that in the long run the truth will emerge. If an eradication program is not successful, the credibility of the scientist usually suffers if unrealistic promises have been made. It is best to call area-wide management by its name rather than proposing that a widespread or frequently introduced organism can be successfully eradicated. Slowing the spread might be an alternative to an eradication program (Sharov and Liebhold, 1998) with more achievable goals. And finally, the monitoring and review stages are most important in evaluation of eradication success or reasons for failure. These should not be forgotten.

Why Not Eradication?

Daniel Simberloff

INTRODUCTION

Eradicating a population — removing every last individual — is a seductive but highly controversial idea. Some question the value of attempting eradication of well-established, widespread populations (e.g., Dahlsten, 1986; Rejmanek in Borenstein, 1999). Probably some of the skepticism arises from several highly visible, costly failures (Newsom, 1978). Perhaps the worst was the attempt to eradicate the imported fire ant (*Solenopsis invicta*) from the southeastern U.S. (Davidson and Stone, 1989). This was such a catastrophe in terms of collateral damage (impacts on nontargets, including humans) and expense (over \$200 million) that E.O. Wilson has termed it the *Vietnam of entomology* (Brody, 1975).

Part of the controversy surrounding eradication can be traced to the fact that the term is used colloquially and imprecisely to mean partial removal of a pest species and control at some lower, acceptable density. This usage is common among politicians (e.g., Chiles, 1996) but also among scientists (e.g., Langland and Sutton, 1992). Thus, a program not really designed to eliminate every individual of a population can be said to have failed even if it confers substantial control. Of course, if a management program aiming at complete elimination — an eradication campaign — uses the same methods that would have been used had the goal been to lower densities to an acceptable level, even a failed campaign can be useful. No harm need be done even if the species is not eradicated (Simberloff, 1997), and substantial control can be achieved, as in the current campaign to eradicate *Spartina* spp. from New Zealand (Nicholls, 1998).

However, if different means are used in an eradication attempt than would have been used for maintenance control, a real problem can arise (Dahlsten, 1986). Consider, for example, a major premise of biological control: the maintenance of both a pest and its natural enemy at low levels, with a homeostatic relationship between them such that an increase in pest density triggers a rapid increase in that of the natural enemy. An eradication project that attempted to kill every pest individual but failed could nonetheless leave pest densities so low that natural enemy populations are extinguished, and subsequent increase of pest densities would be unimpeded.

One typical approach in insect eradication projects is massive use of chemical pesticides, generally ones that are not highly specific. For example, the chemicals used to attack the imported fire ant are widely believed to have exacerbated the problem, at least partly, by lowering populations of competing ants more than that of the fire ant itself (Davidson and Stone, 1989). The effectiveness of a complex of native natural enemies of the introduced spotted alfalfa aphid (*Therioaphis trifolii*) in California was compromised by broad-spectrum pesticides that attacked native predators and

parasites (Smith and van den Bosch, 1967). And use of massive amounts of chemicals in an eradication attempt can have far-reaching ripple effects, such as secondary pest outbreaks associated with the destruction of natural enemies of other species that had been successfully held in abeyance (Perkins, 1989). Further, of course, broadscale application of generalized pesticides often has generated substantial collateral damage to nontargets, including biological magnification and human health risks. Finally, insects have evolved resistance to many initially promising insecticides.

SUCCESSFUL ERADICATION PROJECTS AND TECHNIQUES

An early remarkable success was the complete eradication of an African malaria vector, the mosquito *Anopheles gambiae*, from a large area of northeastern Brazil (Soper and Wilson, 1943; Davis and Garcia, 1989). Although this insect was recorded in 1930, the eradication campaign did not commence until devastating malaria outbreaks in 1938, by which time it had spread to a much larger geographic area. The project began in earnest in 1939, when the Brazilian government gave full control of the project to the Rockefeller Foundation, with almost dictatorial powers to Fred Soper of the foundation. Separate chemical treatments for adults and larvae achieved the complete eradication of *A. gambiae* by the end of 1940. Several features of the mosquito's life history, including its relatively poor dispersal in Brazil and the fact that its microhabitat requirements were satisfied in Brazil almost exclusively in human habitations, contributed to the success of the campaign. Also, the cost to workers exposed to the chemicals was substantial. Nevertheless, this project yielded potential lessons. First, if really substantial resources are devoted to eradication, even an entrenched, widespread pest may be vulnerable. In this instance, both the Brazilian government and the Rockefeller Foundation provided the resources. Second, the campaign was mobilized quickly and put under a unified command that enforced rapid cooperation among all relevant organizations and agencies. Finally, draconian powers were granted to the campaign, and individuals could not exempt themselves from its mandates.

The concept of eradication of pest insects received a tremendous boost from the work of E.F. Knippling, who developed the sterile-male technique that succeeded in completely ridding the island of Curaçao of the screw-worm fly (*Cochliomyia hominivorax*) in 1954–1955 (Baumhover et al., 1955) and aided in the eradication of the fly from the southeastern United States in 1958–1959 (Perkins, 1989). The method subsequently has been successfully applied in a few instances to other insects. For example, the melon fly (*Bactrocera cucurbitae*) was eradicated from Rota Island by this technique.

Steiner et al. (1955, 1965, 1970) pioneered in developing the male annihilation method to rid islands of fruit flies, such as the Oriental fruit fly (*Dacus dorsalis*) from Rota and Guam. Most recently, the melon fly was eradicated, island by island, from the entire Ryukyu Archipelago, including Okinawa, between 1972 and 1993 (Iwahashi, 1996; Kuba et al., 1996) by the sterile-male technique combined with the male annihilation method.

In the public mind, the sterile-male technique seems the quintessence of surgical removal, as it is autocidal and does not directly affect other species. However, it is often not employed alone. Knippling (1966) suggested that insect eradication programs should use a combination of techniques carefully designed to deal with the entire pest population. In the Ryukyus, male annihilation was used: absorbent materials were impregnated with a lure/toxicant, then aurally distributed by helicopter and manually hung in residential areas (Koyama et al., 1984).

Knippling was particularly enthusiastic about the sequential use of pesticides and the sterile-male technique. He reasoned that insecticides can efficiently kill insects when populations are large but are often inefficient when they are small, whereas the sterile-male technique can be highly efficient against small populations but is inefficient against large ones. This sequence of an insecticide (malathion) followed by sterile males is exactly the one envisioned in the California medfly campaign, although in the 1989 and 1990 program the sterile-male technique had to be abandoned

because too few flies were available, and pesticide spraying was substituted (Penrose, 1996). However, even the initial use of pesticides could, in theory, lead to the sorts of problems indicated above: nontarget impacts, secondary pest outbreaks, and evolution of resistance.

Another set of potential problems with the sterile-male technique concerns evolution. Mass-rearing (domestication) of both vertebrates and insects often leads to a deterioration of quality, the exact nature of deterioration depending on the selective regime induced by the culture conditions. For example, low dispersal ability and decreased longevity may result (Boller and Chambers, 1977). In the Ryukyu melon fly eradication program, mass-reared males (which were sterilized) were shown to have evolved lower sexual competitiveness, while wild females evolved discriminatory mating behavior against mass-reared males (Iwahashi, 1996). The existence of these evolutionary processes implies that the initial inundative release of sterile males must be sufficiently large and widespread to prevent an opportunity for evolution to occur.

Several brute-force chemical and manual eradication programs have succeeded against recently introduced species that had not dispersed far. For example, the Asian citrus blackfly (*Aleurocanthus woglumi*) was found in Key West in 1934 and was eradicated over 3 years by spraying with a mixture of paraffin oil, whale oil, soap, and water (Hoelmer and Grace, 1989). It never reached other islands. Eradication of a subsequent invasion by the same species failed for a much larger region centered on Fort Lauderdale.

The giant African snail (*Achatina fulica*) was brought to Miami from Hawaii by a tourist in 1966 and liberated in a backyard. The resulting infestation, encompassing about 42 city blocks, was first discovered in 1969, and another infestation was quickly discovered 40 km away. An eradication campaign employing a granular chemical bait plus handpicking was quickly mounted by the Florida Division of Plant Industry (DPI) (Mead, 1979), entailing quarantining of many properties and a heavy publicity campaign. Despite some setbacks, including the discovery of three other infestations as far as 5.6 km from the original one and perhaps 2 to 3 years old, the DPI persisted in its campaign. At a cost of more than \$1 million, success was achieved by 1975, though frequent surveys, baiting, and carbaryl drenches continued for many months afterwards. The snail has not been seen in the region since, and this project served as the inspiration for the only other successful eradication of the giant African snail in Queensland, Australia (Colman, 1978). The fact that these invasions were caught quickly was crucial, as was the fact that *A. fulica* does not self-fertilize.

As noted in the mosquito example above, insects can be eradicated over large areas, if sufficient resources are committed to the attempt, if organization is sufficiently strong, and if rules are universally enforced. The medfly was eradicated from Florida at least once and possibly twice (references in Simberloff, 1997). In 1929, the medfly was found in Orlando and nearby rural areas, eventually spreading to 20 counties. An 18-month, \$1.7 million campaign employed 6000 personnel, a strict quarantine with National Guard roadblocks, destruction of produce and plants, trapping, and insecticide sprays. The insect was not seen again until 1956, when 28 counties from Miami to Tampa-St. Petersburg were infested. A \$10 million campaign ensued, again with quarantines, roadblocks, insecticide-spraying, and extensive trapping. Victory was declared, although the situation bears some resemblance to that in California. The medfly recurred occasionally in the 1960s (each time it was targeted for a mini-eradication), was not seen in the 1970s, and appeared rarely in the 1980s. Two infestations of 1997 and 1998 may have not even been of the same origin (Prasher, 1999).

Nonindigenous vertebrates, at least when restricted to relatively small areas, are generally easier to eradicate than insects. They are usually more visible and far less numerous. New Zealanders are adept in this area, having extinguished various combinations of 12 mammals that include the house mouse (*Mus musculus*), black rat (*Rattus rattus*), Norway rat (*R. norvegicus*), and European rabbit (*Oryctolagus cuniculus*), and feral pigs and goats from many small islands using a variety of techniques such as chemicals and hunting (Veitch and Bell, 1990; Veitch and Henry, 2002). But they are hardly alone in successful eradication of this sort. For example, black rats were recently

eradicated from Great Bird Island, off Antigua, in the northeastern Caribbean by rodenticide baiting (Day and Daltry, 1996a, b), followed by subsequent eradication from four other islands in a *rolling front* operation to prevent recolonization of Great Bird Island (Day and Daltry, 1996b; Varnham et al., 1998) that resembles the sequential eradication of the melon fly from islands in the Ryukyu Archipelago (Kuba et al., 1996). A similar project is under way and apparently successful on White Cay in the Bahamas (Day et al., 1998). Likewise, trapping and poison were used to eradicate the Norway rat from seven islands in the Sept-Îles Archipelago off the coast of Brittany (Pascal, 1996; Pascal et al., 1998), and several small islands in the Mascarenes have been cleared of various combinations of house mice, black and Norway rats, black-napped hares (*Lepus nigricollis*), and feral cats (Bell, 1999). Finally, various combinations of feral cats, Norway and black rats, house mice, European rabbits, goats, sheep, and burros have been eradicated from nine islands in North-west Mexico in an ongoing project (Donlan et al., 2000).

Several small, isolated fish populations have been eradicated, as have small plant populations (references in Simberloff, 1997). Some larger plant infestations have been eradicated, including *Hydrilla verticillata* from 64-ha Lake Murray (California) over 16 years and entailing the use of a quarantine, chemicals, divers with suction dredges, and a massive drawdown (Simberloff, 1997). In Western Australia, a 9-year project to eradicate the agricultural weed *Kochia scoparia* from over 3200 ha is very close to success (Randall, 2001).

The islands cleared of mammals in the West Indies, Northwest Mexico, the Mascarenes, New Zealand, and Brittany are small, as are most sites from which plants have been eradicated. But with sufficient resources and assiduity, much larger sites could possibly be cleared. Inspirational in this regard is the successful 10-year effort to eradicate the South American nutria (*Myocaster coypus*) from England, where it had been established for 50 years and had reached 200,000 individuals (Gosling, 1989). Key to the success, achieved primarily by trapping, was exhaustive scientific study of the natural history and population biology of this mammal in England. A current attempt to replicate this success in Maryland is advised by the director of the English project (Bounds, 1998). This is probably the most ambitious mammal eradication program yet. Since the 1950s nutria have been in Maryland, where they occupy thousands of hectares of wetlands and are remarkably fecund. In one 4000-ha area alone they have expanded from 150 individuals to between 35,000 and 50,000 individuals in 30 years. Nutria are established in at least 15 states, including Virginia and Delaware bordering Maryland, but the Virginia population is isolated from the Maryland one, while the Delaware population is simply an extension of the Maryland one and can easily be incorporated in the project (Colona, 1999). Thus, though the mainland is surely easier to recolonize than is an island, once cleared, this region could quite possibly be kept free of nutria. A partnership of 21 federal and state agencies and private organizations has secured extensive funding and commenced a large study of the biology of the local population, the necessary precursor to eradication. A test project on one 2500-ha site will initiate the eradication attempt.

Possibly the largest plant eradication project is the elimination of witchweed (*Striga asiatica*), an African root parasite of several grass-plant crops, from the Carolinas. Using herbicides, soil fumigation, and stringent regulation of movement of equipment and crops, this project has reduced witchweed from 162,000 ha in the 1950s to approximately 2800 ha now (Cross, 1999).

WHEN TO TRY ERADICATION, AND WHEN TO AVOID IT

The fact that eradication is feasible does not automatically mean a campaign should be mounted, particularly if resources are insufficient to surmount all environmental problems that have been identified. The key factors to consider are likely costs and benefits, as well as probability of success (Simberloff, 2002). A survey of many campaigns suggests some factors that should always be considered (cf. Myers et al. 1998, 2000; Simberloff, 2002).

Perkins (1989) points out that regional eradication efforts, by their nature, go against the grain of American conceptions of the relationship of the individual to the government (especially federal government) and of personal responsibility. The general alternative to insect eradication, integrated pest management (IPM), can usually be used on a field-by-field basis by individual farmers, granted that often its rewards are far greater when accompanied by widespread cooperation. On the other hand, eradication often requires absolute cooperation by all parties on a scale that can be organized and enforced only by the government. Voluntary cooperation is unlikely to suffice. Because costs are very widely shared but benefits often accrue disproportionately to certain segments of society, the matter of perceived equity is a difficult and delicate one. For example, aerial spraying of malathion in medfly eradication projects engendered extensive public hostility in California (Penrose, 1996) and Florida (Anon., 1997). Much of the public was doubtless hostile because they perceived themselves as suffering both the economic costs of the program plus whatever human health consequences might ensue, while the agriculture industry reaped the benefits. Similarly, in Florida, a campaign to eradicate a new infestation of citrus canker has met with armed resistance (Sharp, 2000).

No doubt public education about the costs of a pest to all of society (if such costs really do exist) and ways in which all would benefit from an eradication (if such benefits can be demonstrated) can facilitate the acceptance of a regional eradication plan. When human health is at stake, as in the malaria mosquito example, expense and the heavy and mandatory intervention of government are less controversial than when the target is an agricultural or environmental pest. However, the obligatory nature of eradication activities, the nature of certain techniques, and the key role of government will generally combine to generate a substantial social cost. For instance, animal-rights concerns impeded the successful British nutria eradication, and the nascent Maryland nutria project will surely face similar objections. Nevertheless, if a broad swath of the public can come to see themselves as stakeholders in the operation, a small degree of opposition may not suffice to torpedo a project.

Eco-terrorism may be a problem (Perkins, 1989), as demonstrated by the reintroduction of northern pike (*Esox lucius*) into Lake Davis after its costly but apparently successful eradication (Anon., 1999). This reappearance is probably the result of human activity (Moyle, P., personal communication, 1999). Because eco-terrorists can be single individuals (e.g., Davis, 1990) and such activities do not necessarily require major resources or sophisticated technology, eco-terrorism — or, in some instances, plain carelessness — will be a persistent threat to many eradication programs. On the other hand, eco-terrorism is not as relevant to maintenance control programs, under which low-level ongoing populations will remain.

Even aside from eco-terrorism, reinvasion is an important consideration in whether to undertake an eradication program. Under certain circumstances, particularly where agricultural pests are targeted, an eradication effort may be appropriate even if quick reinvasion is likely (Simberloff, 2002). However, if the probability of reinvasion is very high, a successful eradication could be a wasted effort, and development of a maintenance control method at the outset would have been more productive. In Washington, 130-ha Long Lake was the target of an intensive eradication campaign, mixing mechanical and chemical methods, to eliminate Eurasian water milfoil (*Myriophyllum spicatum*) (Thurston County Department of Water and Waste Management, 1995). This operation achieved success, but reinfestation quickly occurred at a public boat ramp, and the county now controls this plant at an acceptably low level by hand-pulling (Swartout, 1999). Reinvasion is less likely on islands than on mainland, although vagile organisms can often move from mainland to island or island to island surprisingly readily. This is the rationale of the rolling front technique described above.

Unforeseen new impacts may arise after the eradication of a species (references in Towns et al., 1997). For example, eradication of Norway rats from Mokoia Island was followed by greatly increased densities of mice. In many instances, control of top predators at densities far short of eradication has led to proliferation of intermediate predators with ripple effects throughout the

community. Herbivores may also rebound with disastrous impacts. The removal of Pacific rats (*Rattus exulans*) from Motuopao Island to protect a native snail led to great increases in an exotic snail, to the detriment of the native one. Paradoxically, great increases in a native species after eradication of a nonindigenous one can also impede restoration. For example, when Pacific rats were eradicated from Burgess Island in the Mokohinau Islands, the existence of rank pastureland permitted the rapid proliferation of an endemic chafer beetle, *Odontria sandageri*, which in turn almost eliminated an endemic shrub, *Hebe aff. bollonsii*. Often, removal of an introduced herbivore leads to proliferation of exotic weeds rather than an increase in the native vegetation. On Motunau Island, eradication of rabbits fostered proliferation of exotic boxthorn (*Lycium ferocissimum*) that apparently had been suppressed by the rabbits. On Santa Cruz Island, removal of large grazers led to dramatic proliferation of fennel (*Foeniculum vulgare*) and other exotic weeds (Dash and Gliessman, 1994).

Finally, even aside from the danger of reinvasion, uncertainty remains about whether restoration is feasible once a species is eradicated, and whether the effort needed for restoration is a serious option. Removal of undesirable species does not by itself automatically constitute restoration (Towns et al., 1997). The original community may be so heavily changed that nothing approximating it can ever be achieved. For example, one or more of the original key species may be extinct. Sometimes related functional equivalents are seen as acceptable substitutes (Atkinson, 1988); other times, no such species exist. Often restorations are unsuccessful and we do not understand why. Forest and prairie restorations sometimes have been impeded by the mysterious absence of natural densities of ants that disperse some species and generate crucial small-scale disturbances (references in Simberloff, 1990). To date, all attempts to reintroduce stitchbirds (*Notiomystis cincta*) to islands following eradication of predators on small New Zealand islands have failed; reasons are unclear (Towns et al., 1997). Perhaps process restoration is the most critical requirement for successful restoration of functional ecosystems (Simberloff et al., 1999), but the technology of reintroducing many ecological processes is new and often rudimentary. In some instances, key processes (such as hydrological cycles) cannot be reestablished without costly, even regional, efforts that are not economically and politically feasible.

CONCLUSION

Eradication is a useful technique, but it should be attempted only in certain circumstances. Islands and other settings in which reinvasion is less likely are propitious. However, with sufficient resources, organization, and mandatory powers granted to an eradication campaign, large areas may be successfully cleared of a pest if its biology renders it vulnerable. Even on islands, the precise goal and feasibility of achieving it must be carefully considered before one embarks on an eradication campaign. Half-hearted efforts may not only waste money, but can also worsen a conservation problem. Particularly worthy of attention are eradication programs in which the techniques employed can either hinder maintenance control of the target pest or, even if successful, cause other species to become more pestiferous.

Eradication of Introduced Marine Pests

Armand M. Kuris

INTRODUCTION

The ecological and economic impacts of introduced marine species have attracted considerable recent attention. A substantial research effort is under way to prevent further introductions, study the spread of these invaders, and assess their effects on native organisms (Carlton and Geller, 1993). In some parts of heavily invaded ecosystems, exotics comprise over 90% of the biomass (Cohen and Carlton, 1998). However, unlike terrestrial and freshwater introduced pests, remarkably few attempts, with little evident success, have been made to control or eradicate marine pests once they have become established. Typically, news of their establishment engendered responses such as, “We will just have to learn to live with them.” Recently, this defeatist fatalism has been pierced by theoretical arguments, indicating that classical biological control may be possible in a marine environment (Lafferty and Kuris, 1996; Meinesz, 1999; Kuris and Lafferty, 2000), and by the development of sustained concerted research efforts to control or eradicate introduced marine pests. Notably, these include the green crab (*Carcinus maenas*) in North America and Tasmania, the sabellid worm pest of abalone (*Terebrasabella heterouncinata*) in California, the north Pacific starfish (*Asterias amurensis*) in Australia, and the alga (*Caulerpa taxifolia*) in the Mediterranean and California (Lafferty and Kuris, 1996; Thresher, 1997; Culver and Kuris, 1999; Kuris et al., 1996; Goggin, 1998; Meinesz and Thibaut, 1998; Meinesz, 1999; Thibaut and Meinesz, 2000). The establishment of the Centre for Research on Introduced Marine Pests (CRIMP) by the Commonwealth Scientific and Industrial Research Organization (CSIRO) Marine Division in Australia, dedicated to the prevention, eradication, and control of non-indigenous marine species in Australia (Thresher and Martin 1995) has brought a sustained and coherent approach to these problems and raised them to a national priority.

In this chapter, I will make a few comparisons of the problems associated with eradication of introduced marine versus terrestrial and freshwater pests. I will then describe two recent apparently successful efforts to eradicate well-established introduced marine pests. I will comparatively analyze these two histories to seek the factors that promoted success in these two cases so that other introduced pests may be better evaluated for possible eradication.

Detection of introduced marine species is generally more difficult than detection of terrestrial or freshwater exotics. The sea is relatively inaccessible (except for species-poor sandy beach habitats). Few observers can actually recognize a species as nonnative, because most importantly, even intertidal species are exposed for only a few hours daily, and subtidal species are only seen by a few divers and by blind sampling (e.g., trawls, fishing lines). Early detection is widely acknowledged to be essential for the development of an eradication campaign. This will only rarely

be achieved in the marine environment because very few monitoring programs are capable of detecting a new invader. Hence, detected marine exotics are likely to be well established, with large and increasing populations of reproductive individuals, sustained by further recruitment of young.

TWO RECENT ERADICATION SUCCESSES

Case History 1: The Sabellid Polychaete Worm Pest of Abalone and Other Gastropods

In 1993, a previously unknown and undescribed sabellid polychaete worm was detected in abalone mariculture facilities in California. Investigations demonstrated that it had been accidentally imported with South African abalone for commercial research purposes in the 1980s (Culver and Kuris, 1996; Kuris and Culver, 1999; Ruck and Cook, 1998). Recently described as *Terebrasabella heterouncinata* (Fitzhugh and Rouse, 1999), this worm had a unique and remarkable biology. It preferentially settled in the apertures of abalone and many other species of gastropods, evaded the fouling defenses of the host, and guided the mantle tissue to promote a laminar calcification process that formed a tube for the sabellid within hours of settlement of the worm. The sabellid develops in the tube, feeds with a tentacular crown through the opening of the tube on the outer surface of the host shell, and reproduces. Unlike most sabellids, these worms were hermaphroditic and produced benthic crawling larvae that were soon competent for settlement on a new host (Kuris and Culver, 1999). Heavily infested hosts could not secrete the outer prismatic shell layer and growth slowed or ceased as the laminar secretions were added in thickening layers to form the worm tubes. This soon deformed the aperture and weakened the shell structure so that it became brittle and friable (Kuris and Culver, 1999). The potential to affect growth, survival, and appearance of many abundant native gastropods meant that the sabellid was a sufficiently serious pest to enact regulations to prevent its establishment in nature and to eliminate it from culture facilities (Culver et al., 1997; Kuris et al., 1998).

Some relevant life history features of the sabellid made its establishment, if released in appropriate habitat, seem likely. Its hermaphroditism, competent larvae at or soon after release from the parental tube, wide host range, abundance of susceptible hosts, and short generation time (1 to 2 months) (Fitzhugh and Rouse, 1999; Kuris and Culver, 1999) were all features that promoted its establishment. Fortunately, many infested abalone mariculture facilities did not discharge their outflow in appropriate habitats, and the sabellid's lack of a planktonic stage meant that once established locally it would spread relatively slowly to distant sites.

Ultimately all 18 abalone mariculture facilities became infested. The infested abalone were sent to other states, Mexico and Chile, and the outflow from these facilities posed a significant risk of release and establishment in the natural environment. These fears were realized when, in 1995, we discovered a substantial naturalized population at Cayucos, CA, below the seawater outflow of a mariculture facility that discharged into a rich rocky intertidal zone habitat (Culver and Kuris, 1999). Fortunately, in the 2 years since its discovery in the mariculture facilities, sufficient knowledge of its biology was available to estimate its abundance at this infested site, and to devise an eradication program (Culver and Kuris, 1999).

Sabellid worms were being released from the culture facility in abundance in the shells of live escaped cultured abalone, empty shell debris (cultured abalone shells can be recognized by their light green color), and in the shells of kelp snails (three species), brought into the facility with kelp harvested for abalone food. These infested hosts were readily found over an 80-m-long stretch of rocky intertidal zone habitat in the vicinity of the outfall. Examination of upper and midintertidal zone snails disclosed that the very abundant snail, *Tegula funebris*, and also *T. brunnea*, had become infested. Since *T. funebris* was not present in the culture facility, transmission of worms to this host had to have occurred in the wild.

Using marked sentinel host *T. funebris* from elsewhere, we began a regular monitoring program to estimate infestation rates at Cayucos. In the initial survey, 32% of the sentinel snails were infested in the six-week monitoring period, demonstrating a very high rate of transmission and population increase of the sabellid at this site. The infestation was spreading throughout the *T. funebris* population at an epidemic outbreak level.

At our recommendation, the facility screened the outflow to prevent further release of live molluscs and shell debris, and a cleanup of cultured abalone, kelp snails, and their debris from the intertidal zone was conducted. A subsequent sentinel snail release indicated the rate of new infestations had decreased, but new infestations were still occurring. This indicated that the sabellid population was established because wild *T. funebris* were now the primary source of new infestations.

Using conservative estimates of host abundance, prevalence of the sabellids in these hosts, and intensity of the worms on the infested hosts, we estimated that this established population included at least 2.2 million worms.

We rejected an eradication strategy based on detection and removal of infested snails. The worms were too small to be readily detected on the black *T. funebris* shells without microscopic examination, there were too many snails to examine, and estimates of the prevalence of the worms indicated that the number of infested snails was in the range of 1.5 to 2 million.

Since the sabellid was (1) highly habitat specific (as an epibiont on the shells of gastropods), our previous research (Kuris and Culver, 1999; Culver, 1999) had demonstrated that (2) *Tegula* species were highly susceptible, and (3) large individuals were much more susceptible than were small individuals, we were able to devise an eradication scheme based on the Kermack–McKendrick Threshold Theory from epidemiology (McKendrick, 1940; Bailey, 1957; Stiven, 1964, 1968). The incidence of new infestations increases with the density of susceptible hosts. Hence, the threshold density of new infestations drops lower than the replacement rate necessary to maintain the population of parasites. If this low host density can be maintained for a sufficiently long period of time, the number of infected hosts will dwindle to zero.

With the staff of the Abalone Farm culture facility (Cayucos, CA), California Department of Fish and Game (CDFG) biologists and student volunteers from the University of California, Santa Barbara, and Cuesta College, at least 1.6 million large (> 10 mm) *T. funebris* and *T. brunnea* were removed. Repeated monitoring using sentinel snails (with a high degree of sensitivity, 1×10^{-9}) has not detected a newly infested snail over the 2 years since the removal of large numbers of susceptible hosts (Culver and Kuris, 1999).

At this point it appeared likely that the once-abundant Cayucos population of the sabellid has been eradicated. This success provided a strategy should other infestations be discovered. In addition to release from other culture facilities, it is also possible that infested abalone stock were outplanted as part of a program to recover overfished abalone populations in the 1980s and early 1990s.

Case History 2: The Brackish Water Black-Striped Mussel

A team of introduced marine species detection specialists from CRIMP conducted a port survey in Darwin Harbor in the Northern Territory in the spring of 1999, as part of a program to survey all of Australia's international ports. During the survey, the team discovered the brackish water black-striped mussel, *Mytilopsis sallei*, in abundance (Bax, 1999). Their previous survey, 6 months earlier, had not detected this species, so it was evidently a recent introduction and was clearly established. Most of the population was in Cullen Bay, a yacht harbor with a narrow seaward entrance protected by a locked gate to cope with the extreme tidal amplitude at Darwin.

This mussel had high pest potential as it has spread to other tropical harbors (Singapore, Suva, Fiji), forming monospecific clumps up to 15 cm thick and weighing as much as 100 kg/m² (Bax, 1999).

At the time of its discovery, the mussel had already reached densities as high as 60,000/m² in Cullen Bay, and its total population was many millions. The scientific and regulatory response was

rapid. CRIMP determined lethal dosage levels for chlorine and CuSO_4 . The Museum of the Northern Territory promptly identified the invader as *M. sallei*. The government of the Northern Territory quarantined and locked the gates of Cullen Bay 5 days after the discovery of the mussels. Just 9 days after discovery of the mussels, Cullen Bay was treated with 160 t of bleach and 54 t of CuSO_4 (including applications to localized infestations elsewhere in Darwin harbor). Collateral damage was great, but localized; all living things in this 600-Ml marina were killed. Repeated monitoring over the next few weeks failed to recover any living mussels, and Cullen Bay was reopened to boat traffic. The eradication appears to be a success.

KEY FEATURES OF THE SUCCESSFUL MARINE PEST ERADICATION PROGRAMS

The history of the campaigns against the sabellid pest and the black-striped mussel offer some interesting points of comparison. While they shared important features, they differed in many biological and strategic aspects. This implies that targets for future eradication efforts do not have to meet a very narrow set of criteria, and more introduced marine pests might serve as appropriate targets for eradication campaigns than are under consideration at present. Table 58.1 summarizes these comparative aspects.

Although rapid detection is generally considered a paramount precondition for an eradication effort, the sabellid was likely established for a few years before its discovery. The black-striped mussel was very rapidly detected after its establishment, which is fortunate given its explosive population growth at Cullen Bay.

Both pests were very well established with populations in the millions. Both were also reasonably localized, although other populations of each may be present but not yet detected. The localization of each of these pests was certainly important in the initial decision to develop an eradication plan and likely a key factor in the success of these programs because a relatively small monitoring effort could effectively evaluate the status of the eradication effort.

Both pests were rapidly evaluated as exotics. Since the sabellid was an unknown and undescribed species, California experienced a brief period in which some abalone aquaculturists challenged its nonnative status. If it was an undescribed native species (Culver et al., 1997), no environmental risk could be claimed, and it would have been merely an economic pest in the facilities (as it is in South Africa) (Ruck and Cook, 1998).

Regulatory authorities did not call for a comprehensive risk assessment for the impact of either pest. If such had been required, then the geographic scale and abundance of the pests would have been so great that consideration of eradication would have been precluded, and other forms of

Table 58.1 A Summary of the Features of Successful Marine Pest Eradication Programs

	Sabellid	Black-Striped Mussel
Time to detection	A few years?	<6 months
Estimated population size	Minimum 2.5 million	Millions
Evaluation as an exotic	Rapid; unambiguous	Rapid; unambiguous
Species identification	New species; described after eradication under way	U.S. sea grant non-indigenous species Web site information
Impact assessment	Experimentally evaluated	Assumed
Basis for eradication plan	Host-specificity studies; epidemiological theory	Toxicity studies; brute force
Stakeholder involvement	Decision making: yes implementation: yes	Decision making: yes implementation: no
Government regulation	Minimal; informal	Extensive; formal; swift
Collateral damage	Localized; minimum 1.6 million native snails of two species	Localized; extreme; all taxa
Cost	~ \$3000 (U.S.)	\$1,200,000 (U.S.)

control would have been much more difficult. This has been the sad history of some other major marine pests such as the alga, *Caulerpa taxifolia*, in the Mediterranean (Meyer et al., 1998; Meinesz, 1999). *Caulerpa taxifolia* was discovered at Monaco in 1984. Its eradication was called for in 1991 when it still was localized and its removal could have probably been achieved. It has since spread from Spain to Croatia, and eradication is no longer an option. The recent arrival of the green crab, *Carcinus maenas*, on the Pacific coast of North America, provides a case in point. As it spread north, each regional Sea Grant program established the effects of the crab as the principal issue to be studied. The director of the University of California program, James Sullivan, mandated a 3-year moratorium on biological control grants to await results of the impact studies (Sullivan, J., personal communication). Over those 3 years, the green crab spread from being localized in South San Francisco Bay to settling in large numbers in Humboldt Bay, 400 km to the north. In the next 3 years, it reached the outer coast of Vancouver Island, Canada.

The potential impact of the sabellid pest in nature had been partially assessed because it was under study for its effect and control within the aquaculture facilities (Culver et al., 1997). Considerable information on its host range, and on the process of deformation of infested shells, indicated the worst-case potential impact would be severe. However, no studies were directly made to assess its effect in the wild before the eradication program was conceived. Likewise, the eradication plan against the black-striped mussel was conceived, planned, and initiated on the general principle that a very abundant, filter-feeding, fouling organism would have a great impact on both benthic communities and plankton, as well as on maritime activities (e.g., boat fouling, pipe clogging).

Cultural differences also play a role in impact assessments of nonindigenous species. Potential economic impact is generally needed to initiate regulatory action in the United States, whereas its ecological impact is fully sufficient to trigger a regulatory response in Australia (Thresher, R., personal communication).

The development of an eradication strategy against the sabellid pest was firmly based in epidemiological theory. The campaign was designed to break the threshold of transmission for a sufficiently long time for sabellid transmission to damp out to the extinction point. The use of this theory required specific knowledge about host species specificity and the much greater susceptibility of large hosts. Armed with this information, it was relatively easy to design, implement, and monitor the eradication effort.

The environmental configuration of the Cullen Bay Marina was probably key to the eradication campaign against the black-striped mussel. Since it could be effectively closed off and quarantined, it was possible to use chemical control, albeit on a rather grand scale. The preliminary toxicology studies to determine lethal dosages were obvious, rapidly conducted, and conservative, as the kill of the mussels appears to have been attained at a lower chlorine concentration than predicted by the laboratory studies (Bax, 1999).

For both these eradication efforts, the private stakeholders were involved in the decision-making processes. In the case of the sabellid, stakeholders provided much of the labor to remove the large, susceptible *T. funebris* snails.

The Australian and Northern Territory governmental regulatory response was rapid and courageous, as quarantining the major yacht harbor in the territory, with little time to alert and educate the public, certainly carried political risks. The decision to use massive amounts of highly toxic chemicals would have likely met strong public outcry in other countries and could have required extensive deliberation that would have likely been fatal to the successful eradication effort. In contrast, the decision to attempt the sabellid eradication was done by the aquaculture facility and university researchers. The regulatory agency, CDFG, was merely informed and then cooperated in the eradication effort.

Collateral damage in both of these eradication programs was substantial. The estimated 1.6 million *T. funebris* (and some *T. brunnea*) removed were long-lived snails. Almost all were at least 10 years old, based on their size and growth rates determined elsewhere (Frank, 1985). It is

worth emphasizing that these snails were not eliminated at this site. They were still plentiful enough to be routinely collected on the posteradication monitoring transects (Culver and Kuris, 1999).

Although the collateral damage in the chemically based eradication of the black-striped mussels was largely confined to the gated Cullen Bay Marina, it was severe. All living organisms (including vertebrates) in this large marina were killed. In some cultures, this expected prospect would probably have encountered vigorous public opposition.

The cost of the sabellid eradication program was minimal, and no specific funds for its implementation were sought. The eradication of the black-striped mussel was considerable (\$1.2 million U.S.). As with the other elements in the decision-making process, the rapid release of substantial funds for this campaign was noteworthy.

CONCLUSION

The eradication of the sabellid can be attributed to a theoretically based plan, local initiative, and private action with government cooperation. In this sense, it was firmly based upon a strong American cultural imperative of individual action and problem solving. In contrast, a nationally coordinated port survey program (Hewitt and Martin, 1996) and a strong organization (CRIMP) with a coherent plan to identify and manage introduced marine pests (Thresher and Martin, 1995) were essential to the scope, cost, and rapidity of the program against the black-striped mussel in Darwin Harbor. The background for this achievement seems clearly derived from an acute Australian cultural awareness of the effect of introduced species on the native biota, and a willingness to take a proactive stand against such pests.

Taken together, these two recent and apparently successful campaigns strongly suggest that other introduced and established marine pests may be vulnerable to eradication. However, these must be appropriately scaled, and a well-conceived plan with a theoretical basis should be developed. In addition, posteradication monitoring must be a key element in the program. Awaiting results of extensive studies of the effects of an exotic marine pest, and the potential for its further geographic spread, will likely foreclose a successful eradication plan because such studies will consume too much time. Instead, an assessment of impact based on knowledge elsewhere, ecological theory, studies of comparable organisms, and common sense should be the basis for eradication campaigns. Eradication programs in any ecosystem may have controversial, social, and ecological ramifications, so it is necessary to evaluate their political and environmental acceptability as well as their ecological feasibility (Myers et al., 2000). In the U.S., the establishment of a coherent scientific program, such as CRIMP in CSIRO of Australia, would aid the prospect for timely and effective responses against introduced marine pests. A possible candidate for urgent consideration of an eradication effort as part of a control program is the Asian veined rapa whelk, *Rapana venosa*, in Chesapeake Bay because it is a large generalist predator that is currently not abundant, but is becoming widespread (Harding and Mann, 1999; Mann and Harding, 2000).

ACKNOWLEDGMENTS

I thank Carrie Culver, Ron Thresher, and Nic Bax for discussion of the two eradication programs. This chapter was funded by a grant from the National Sea Grant College Program, National Oceanic and Atmospheric Administration, U.S. Department of Commerce, under Grant NA36RGO537, project number UCSG-27 through the California Sea Grant College system and by CRIMP of CSIRO Australia. The views expressed herein are my own and do not necessarily reflect the views of NOAA or any of its subagencies. The U.S. government is authorized to reproduce and distribute this for governmental purposes.

SECTION II.5

Landscape Health Assessment

Overview: Landscape Health Assessment

Ganapati P. Patil

LANDSCAPE ECOSYSTEM HEALTH ASSESSMENT USING REMOTE SENSING DATA

Ecosystem health entails both status and trends. Ecosystem processes operate in space and time, so it matters not only what is observed and how it is observed, but also where and when the observations are made. Ecosystems are open systems with various processes functioning in gradients over a range of spatial and temporal scales. Ecological hierarchy theory implies that observations made in a particular spatial and temporal frame of reference will find certain processes more strongly expressed than others.

Ecosystem health has been evolving over the past decade from explorations of the possible relevance of the health concept at the ecosystem and landscape scale (Nielsen, 1999), to the exploration of the concept in the monitoring and assessment of large-scale ecosystems (Rapport et al., 1995), to an ever-widening range of considerations. These include incorporating societal values (Rapport et al., 1998) at ecosystem and landscape scales, economic and social determinants and consequences of ecological conditions (Buckingham, 1998; Rapport et al., 1998), and the increasing dependence of human health on ecosystem conditions (Epstein, 1995; Epstein and Rapport, 1996; Huq and Colwell, 1996; Karr, 1997; McMichael, 1997). It also includes the encouragement of appropriate techniques for rapid, accurate, and economically feasible methods for regional scale assessment of ecological conditions, including developments in geographic information system (GIS) and remote sensing (Rapport, 1999).

We focus on the new generation of techniques and analyses that permit broadscale geographically based assessments of environmental and ecological conditions. These techniques, including recent advances in applications of GIS and remote sensing imagery, will prove invaluable for advances in ecosystem health. For example, these tools may be the basis for assessing ecosystem health parameters (e.g., biotic community structure, biotic cover, primary productivity) in relation to the provision of ecosystem services at regional scales (e.g., nutrient flux in watersheds, sediment loads to drainage basins, biodiversity as expressed in quantities and ranges of habitat, etc.). These techniques will drive the next generation of quantitative assessment of ecosystem health at regional scales (Patil and Myers, 1999; Rapport, 1999).

While considerable effort has been devoted to identification of stressors and development of indicators, protocols for framing observations spatially and temporally are less well established. No one has yet been heroic enough to attempt delineation of ecosystems, but there are several competing strategies for ecological mapping that can help to segregate areas with respect to degree

of coupling among biophysical processes. All such mapping strategies lead to hierarchies of zones nested over several levels of spatial detail. Successful application of such ecological mapping strategies requires information on distribution of natural and anthropogenic features across landscapes. Making *in situ* determinations everywhere is infeasible, so remote sensing constitutes the only available recourse by which to establish geographic context and achieve spatial integration. Landscape ecology provides increasingly mature guidance regarding spatial organization among ecosystems, and how remotely sensed data can be used to understand such organization in a particular geographic setting.

Resolution, frequency of coverage, cost, and procurement are not the only concerns with respect to use of remotely sensed data for assessment of ecosystem health. Remotely sensed data seldom constitute a complete information source for ecosystem analysis. Improvements in these respects will not necessarily translate to substantially improved monitoring and assessment unless we learn better ways of incorporating pixelized spectral data into multitiered analysis that integrates intensive site studies, distributed sample plots, and various partial coverages from remote sensors at different resolutions and different times. In the remote sensing community, this is known as the challenge of data fusion. The statistical, environmental, and ecological communities know the problem by a

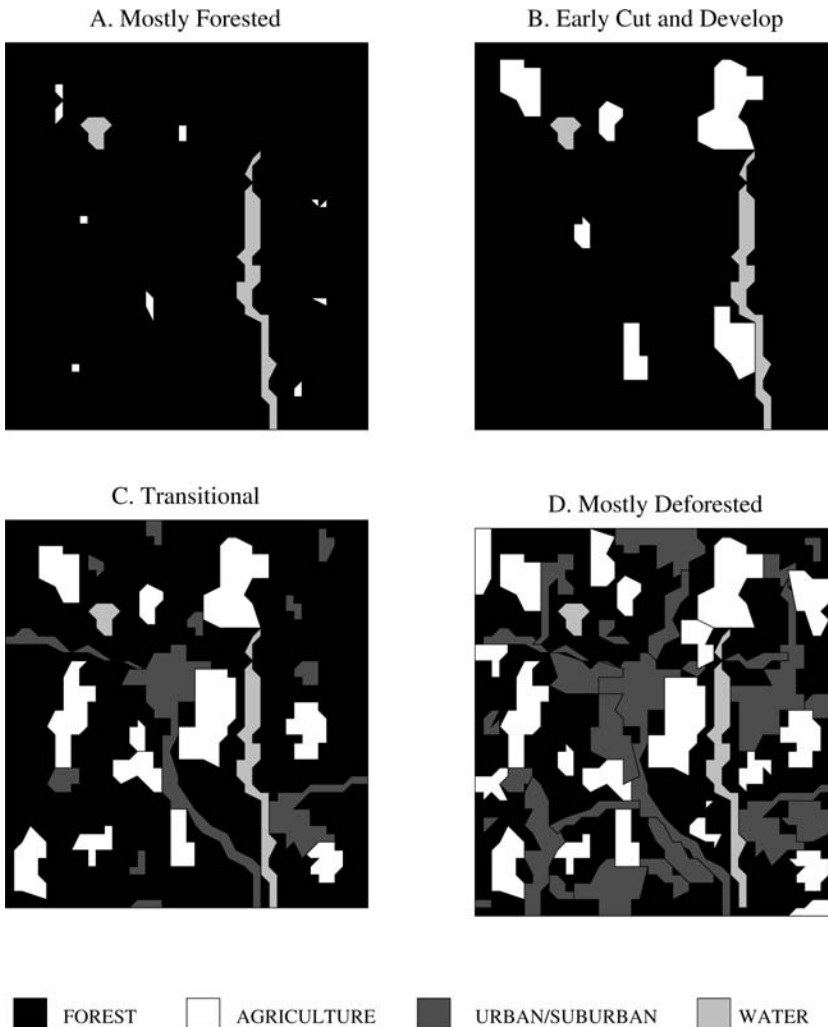

Figure 59.1 Stages in forest defragmentation.

variety of other names. Remotely sensed data is also problematic in the sense that the variates (spectral bands) are not measures that speak to a particular focus of interest like variables conventionally measured in field surveys. They literally constitute a picture of the landscape, and many different sorts of things can be seen from the same picture. Extraneous information is noise to a particular analysis, and segregation of relevant variability from irrelevant variability often requires sophisticated methodology that is the special domain of image analysis. Contemporary improvements in sensors tend to compound such difficulties.

A related concern is for parsimony. Since a massive infusion of high resolution hyperspectral image data could swamp most environmental data analysis facilities, it becomes important to exploit opportunities for compression. Furthermore, the remote sensing community is only beginning to address spatial analysis explicitly in its routine work with image data. Ironically, the spatial structure of image data may ultimately be of most importance for ecosystem analysis.

While compilations of land-use and land-cover maps by remote sensing have a long history, even this basic process is seldom easy or even satisfying with respect to desired detail and accuracy of classification. Determining occurrence and character of landscape change has proven equally problematic. The specific issues are deep, but concrete and finite.

WATERSHEDS, LANDSCAPE PATTERNS, AND THEIR COMPARISON

When a landscape is represented by multiple land-cover types, instead of just forest and nonforest, the challenge is to define a measurement of landscape fragmentation that can be applied to any defined geographic area. Such a measurement would ideally allow quantitative decision making for determining when a landscape pattern has significantly changed, either within the same geographic extent over time, or among different locations within a similar ecoregion. It can also be important to identify ecosystems, such as those that may be delineated by watershed boundaries and are close to the critical point of transition (Figure 59.1C) into a different, possibly degraded, ecosystem where the landscape matrix has become developed land (Figure 59.1D), supporting only small sparsely scattered forest islands that do not provide sufficient forest interior habitat. Along with the collapse of forest-interior species richness, degradation may also be attested to by increasing environmental contamination that is also associated with intensive land development.

Such a measurement of landscape fragmentation can then be a primary component of an ecosystem risk assessment in a manner addressed by Graham et al. (1991). Identifying areas whose landscape level ecosystems are poised for a great reduction in overall species and the elimination of critical functional groups is of utmost concern because such areas may still be salvaged with intervention by proper land-use planning. Meanwhile, other areas that have crossed the line but are not too far beyond the critical point may still be reversible. Indeed, ecosystems that are near critical transition points present both risks and opportunities.

As a Markov transition model, the landscape fragmentation generating model can be fully described by its transition probability matrices. To simulate the null scenario of a self-similar fragmentation process at each resolution, we may invoke a stationary model whereby the same stochastic matrix applies at each transition. Stationary probability transition matrices are based on characteristics of actual watershed-delineated landscapes that are represented by eight land-cover types at a floor resolution of 30-m pixels. The actual landscape maps are reproduced in Figure 59.2. More detail about the data sources can be found through the Web page, <http://www.pasda.psu.edu>, that includes metadata for the land coverage. The Sinnemahoning Creek watershed is mostly forested, representing a continuum of forest interior wildlife habitat. The Jordan Creek watershed represents a transitional landscape that barely maintains a connected forest matrix that is encroached by agriculture and urban and suburban land use. Meanwhile, the Conestoga Creek watershed represents a landscape that is dominated by open agricultural land and highly aggregated urban and suburban land, with isolated patches of remaining forest. Conditional entropy profiles, measuring landscape fragmentation, appear in Figure 59.3.

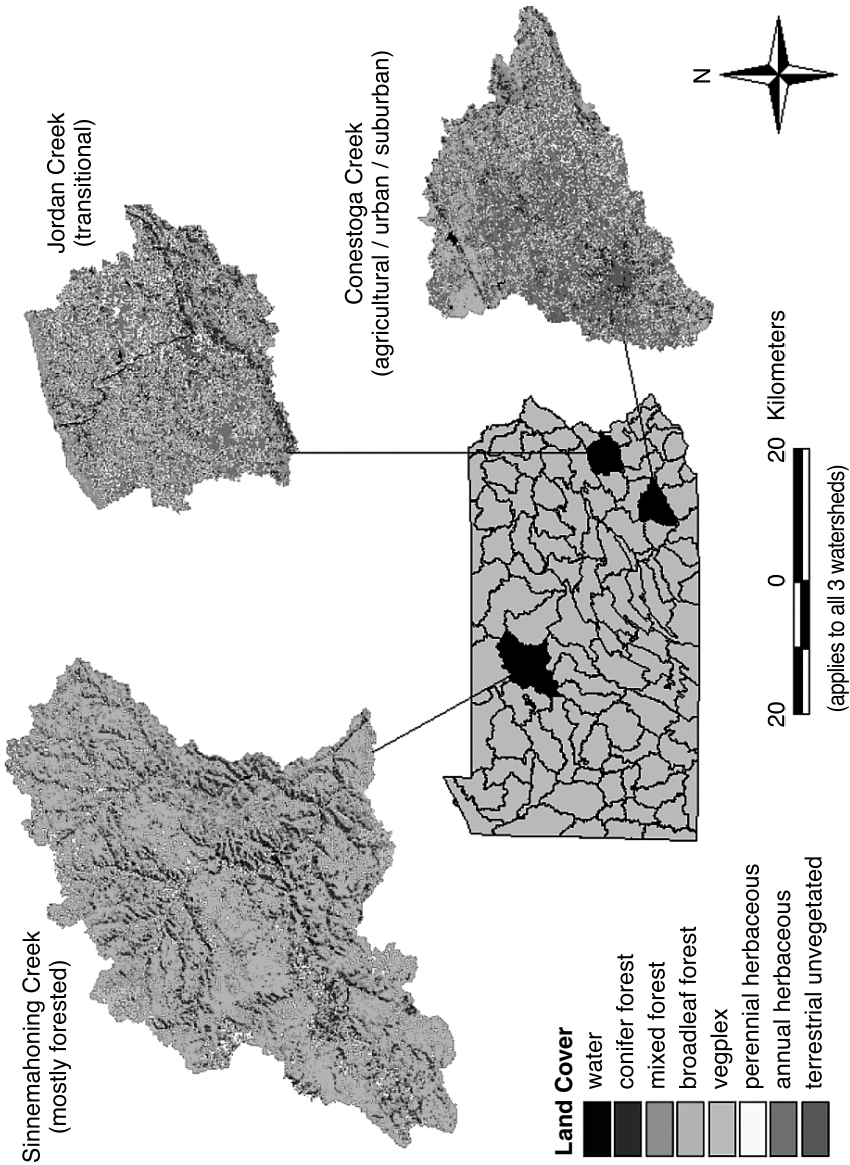

Figure 59.2 Land-cover maps for three watersheds of Pennsylvania.

Figure 59.3 Conditional entropy process files as landscape fragmentation profiles for hierarchical Markov transition matrix (HMTM) models whose transition matrices are obtained from watersheds with three distinctly different land-cover patterns.

The stochastic transition matrices can be modeled as appropriate. For example, null landscape models may be obtained by designating a degree of within-patch coherence by the magnitude of diagonal elements (self-preserving probabilities) in a stochastic matrix. Labeling the diagonal value as λ , off-diagonal elements may then be evenly distributed among the remaining probability mass $(1 - \lambda)$ within each row. The conditional entropy profiles for some examples of such models are presented in Figure 59.4.

The shape of a conditional entropy profile appears to be largely governed by two aspects of landcover pattern, as seen in the floor resolution data: the marginal distribution, viewed as the relative frequency of each landcover, and the spatial distribution of landcover types across the given landscape. For more information, see Johnson and Patil (1998), Johnson et al. (1999, 2000), Myers et al. (1997), and Patil (1998a,b).

Figure 59.4 Conditional entropy process profiles for HMTM models whose hypothetical $k \times k$ transition matrices have the value λ along the diagonal and the value $(1 - \lambda)/(k - 1)$ off the diagonal. Here $k = 8$ and the values of λ are indicated in the legend. The stationary vector is uniform across the k categories and is used as the initial vector in the model. The floor resolution maps G_L were 1024×1024 (i.e., $L = 10$). Large values of λ result in strong spatial dependence (indicated by large profile relief) that persists at larger distances (indicated by a slowly rising profile). All models have the same stationary vector and therefore the same horizontal asymptote.

CONCLUSION

The chapters in this section were invited to help demonstrate environmental and ecological regional policy research with remote imagery and geospatial information. It is clear that the satellite sensors provide databases of the surface of the Earth. Using various technologies, it is now possible to provide snapshots of landscapes indicative of various features of interest pertaining to human societies, plant and animal communities, aquatic networks, etc. The information is synoptic and we are subsequently able to see various kinds of multicategory maps of different kinds of regions of interest, whether political, natural, or methodological. These multicategory maps provide a basis for comparative assessments of regions within a policy-making and implementation context. It is also possible to extract meaningful profiles of management units, such as watersheds, that can be calibrated and compared in order to assess and manage watersheds of a region. These current

developments are in the nature of an environmental and ecological information superhighway, and lead to the cutting-edge frontier of regional policy research with remote imagery and geospatial information with 21st century technology. This frontier initiative can use a focused approach to accomplish the capability and the output within a short time frame.

Multiscale Advanced Raster Map Analysis System for Measuring Ecosystem Health at Landscape Scale — A Novel Synergistic Consortium Initiative

Ganapati P. Patil, Robert P. Brooks, Wayne L. Myers, and Charles Taillie

SETTING THE STAGE

Geospatial data form the foundation of an information-based society. Remote sensing has been a vastly underutilized resource involving a multimillion dollar investment at the national levels. Even when utilized, its credibility has been at stake, largely because of lack of tools that can assess, visualize, and communicate accuracy and reliability in a timely manner and at desired confidence levels.

Consider an imminent 21st century scenario: What message does a multicategorical map have about the large landscape it represents? And at what scale and what level of detail? Does the spatial pattern of the map reveal any societal, ecological, environmental condition of the landscape? And therefore can it be an indicator of change? How do you automate the assessment of the spatial structure and behavior of change to discover critical areas, hot spots, and their corridors? Is the map accurate? How accurate is it? How do you assess the accuracy of the map? How do we evaluate a temporal change map for change detection? What are the implications of the kind and amount of change and accuracy on what matters, whether climate change, carbon emission, water resources, urban sprawl, biodiversity, indicator species, ecosystem health, human health, or early warning? And with what confidence? The proposed consortium research initiative is expected to find answers to these questions and a few more that involve surface maps and multicategorical raster maps based on remote sensing and other geospatial data in measuring ecosystem health and in managing for healthy ecosystems.

INFERENCEAL GEOSPATIAL INFORMATICS FOR ECOSYSTEM HEALTH

The satellite sensors provide databases of the surface of the Earth. Using various technologies, it is now possible to provide snapshots of landscapes indicative of various features of interest pertaining to human societies, plant and animal communities, and aquatic networks. The information is synoptic and we are subsequently able to see various kinds of maps of different kinds of regions of interest. These maps provide a basis for comparative assessments of regions within a policy-making and implementation context. It is also possible to extract meaningful profiles of management units, such as watersheds, that can be calibrated and compared to assess and manage watersheds of a region.

Space Age and
Stone Age Syndrome

- Data: Space Age/Stone Age
- Analysis: Space Age/Stone Age

Data/ Analysis	Space Age	Stone Age
Space Age	+	+
Stone Age	⊕	+

Figure 60.1 Disappointing report (left) and disappointing software (right).

These multidimensional and multidisciplinary approaches call for linkages and collaborations beyond those traditionally applied in ecosystem health research. Thus, we propose that new consortia be forged to capture, analyze, and model whole ecosystems or subsets of them. The results can be applied to holistic ecosystem management strategies. A purpose of this chapter is to identify the timely need for a consortium initiative on environmental and ecological policy research using remote imagery and geospatial information with appropriate multiscale advanced raster map information science and technology to be accomplished within a short time frame.

The proposed consortium initiative will help advance regional policy research and judge the effectiveness and usefulness of potential or actual policies using satellite technology, computer technology, statistical technology, information technology, multimedia communication technology, and landscape ecology. Initial regional policy research will involve issues that are environmental, ecological, and societal, providing multiscale assessments for management purposes. The proposed initiative will begin with selected prototype case studies involving forests, watersheds, coastal areas, and other regions of interest for issues pertaining to biodiversity, watershed integrity, landscape vulnerability, surface water quality, ecosystem health, human health, global change and disturbance impacts, geographic surveillance, and others.

The urgency of the proposed consortium initiative lies in the disappointing software syndrome depicted in Figure 60.1. The program manager finds the report disappointing and wonders about the software used. It is important that we use space-age analysis for space-age data. Several nonstandard problems arise, and these require nonstandard tools (Patil, 1998; Patil and Myers, 1999) in a timely manner. The proposed consortium initiative is expected to be cost-effective in this emergent need for assessment and management for ecosystem health at landscape scale.

MEASURING ECOSYSTEM HEALTH AT LANDSCAPE SCALE

The Middle Atlantic region studies demonstrate the feasibility and practicality of ecosystem health assessments (Brooks et al., 1998, 2001). This area provides an ideal case study because it is an ecoregion that is rich in synoptic data and contains many of the geographical elements found in the eastern U.S., and other temperate regions. Its natural and human-induced landscapes, gradients, and boundaries provide a wealth of options to explore.

For example, Pennsylvania watersheds have been mapped at scales ranging from 102 units for the state water plan to 9855 units for individually named streams. These watershed units have been studied from diverse perspectives including nonpoint pollution, groundwater pollution potential, land cover, and animal habitats (Johnson, 1999; Johnson et al., 1998, 1999a,b, 2001a,b, Chapter 65, this volume; Johnson and Patil, 1998; Myers et al., 2000; Patil et al., 2000a,b). Pennsylvania watersheds vary in their ecology, geology, hydrology, degree of human influence, and other factors.

Representing this complexity synoptically in a format that enables one to address questions of ecosystem health, integrity, and resilience is our key challenge and goal. Using the collective data from the Middle Atlantic region, we confront the following types of questions in this context:

- What is the health status of a particular watershed, and how does this compare with a similar but less stressed system?
- To what degree is ecosystem degradation associated with cumulative effects from population growth and economic development within the watershed?
- Do changes in spatial biocomplexity of key indicators of ecosystem distress serve as an early warning sign of loss of resilience at regional scales?
- Which watersheds show the greatest degree of fragmentation?
- Do these watersheds also indicate a loss of ecosystem services such as water quality and habitat?
- Is the degree of fragmentation within watersheds correlated with the loss of ecosystems goods and services as measured by synoptic data on water quality, soil erosion, biodiversity, and other factors?

Although spatial landscape analyses have been conducted for years, it has been difficult to compare different locations when using multiple indicators simultaneously. However, with the application of insightful and sophisticated quantitative methods, it is possible to create truly integrative measures that characterize the synergistic relationships among landscape patterns and indicators. In particular, we will explore the techniques described here in the multiscale advanced raster map analysis system for addressing multiple indicators, partial orderings, and multicriterion decision support, along with echelons of spatial variation. This approach will allow us to search for and define consistent and recognizable landscape patterns, while allowing us to define a set of reference conditions to understand the consequences, both favorable and unfavorable, that human actions have on biocomplexity.

There are several national and international projects in progress, such as the Atlantic Slope Consortium, that will benefit with their participation in the proposed geoinformatic methods and tools consortium discussed in this chapter. Several of these projects will find this geospatial and temporal quantitative arm useful in their in-house work in progress from day one of their participation. This chapter constitutes a call for this collaborative synergism in the form of a short course, workshop, project collaboration, or proposal preparation.

MULTISCALE ADVANCED RASTER MAP ANALYSIS SYSTEM FOR MEASURING ECOSYSTEM HEALTH

This section briefly describes applications of the emergent methodologies collectively known as the Multiscale Advanced Raster Map analysis system (MARMAP) for landscape health assessments (Patil, 2000; 2001b,c,d; Chapter 59, this volume; 2002a,b; also see <http://www.stat.psu.edu/~gpp/newpage11.htm>).

Modeling and Simulation of Thematic Raster Maps

A raster map depicts the landscape as a grid of uniform cells. Modeling and simulation of raster maps are employed for three general purposes. First, model-fitting provides a set of estimated parameter values characterizing the spatial structure of the map (landscape). Second, simulation yields statistical confidence capability, as well as response sensitivity to variation in the fitted parameter values. Third, model validation provides a check on tendencies to overfit the model. Three classes of map models are available. These address issues important to monitoring and diagnostics to determine and discriminate differing status with regard to degradation of habitat integrity across landscapes. From land-cover maps derived by remote sensing, we examine naturalistic vs. more strongly human disturbed situations through an index of conditional entropy to

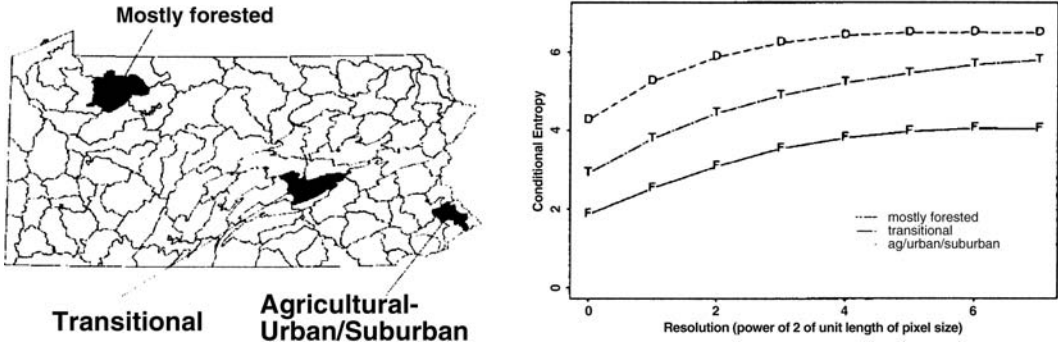

Figure 60.2 Fragmentation profiles for three Pennsylvania watersheds with distinct land cover patterns: mostly forested, transitional and mostly deforested (agricultural – urban and suburban).

obtain profiles of disruption (Figure 60.2). For more information, see Johnson (1999), Johnson and Patil (1998), Johnson et al. (1998, 1999a,b, 2001a), Patil et al. (2000a,b), and Patil and Taillie (1999, 2000a,b,c). The issues of landscape characterization and discrimination, patch structure and patch dynamics, scaling domains, spatial pattern heterogeneity detection, and others arise. The issues of assessment of accuracy and change detection of land-cover and land-use maps also arise for a variety of ecosystems. These issues can be addressed by the methods and tools discussed in the proposed MARMAP System.

Echelons of Spatial Variation, Critical Area Detection, and Delineation

Echelons frame local values of synoptically mapped environmental indicators in regional context for comparative purposes and objective analysis of complex hierarchies in spatial variation across landscapes. The environmental indicators are considered as surface variables in virtual (or real) topographies as depicted in Figure 60.3. Echelons are structural entities consisting of peaks, foundations of peaks, foundations of foundations, and so on in an organizational hierarchy. It is natural to cast the echelon hierarchy as a dendrogram, from which profiles of spatial complexity can be obtained and principal families determined as contiguous areas of criticality from perspectives of either pronounced ecosystem health or pronounced ecosystem distress. Echelons have proven effective for elucidating concentration and connectivity of biodiversity and complexity of landscape change induced by factors such as wildland fire or pattern of propagation for urban sprawl (Myers et al., 1995, 1997, 1999; Kurihara et al., 2000; Smits and Myers, 2000; Patil and Myers, 2002).

Figure 60.3 Echelon decomposition of a surface (left) and associated echelon tree (right).

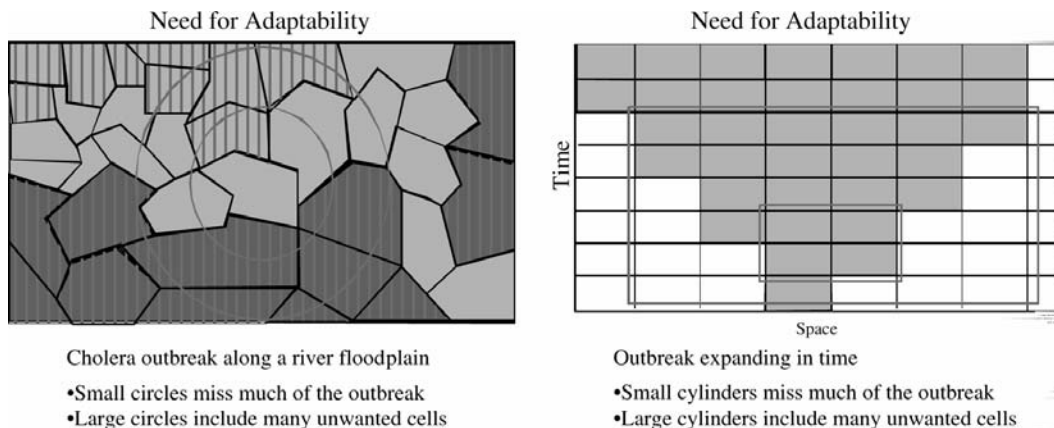

Figure 60.4 Scan statistic zonation (left) and space-time scan statistic zonation (right).

Contemporary study of human disease as a component of ecosystem health entails a spatial scan statistic (Kulldorff and Nagarwalla, 1995) for detecting geographic clusters of disease and other responses that are significantly elevated with respect to the regional setting. In conjunction with the spatial scan statistic, echelon analysis is expected to more clearly delineate the cluster boundaries for focus of investigation (Patil and Taillie, 2001d), as depicted in Figure 60.4.

Pattern-Based Landscape Change Analysis

Landscape change analysis is becoming increasingly important for ecosystem monitoring. Deforestation, habitat fragmentation, and land-use conversion are growing concerns for conservation, landscape ecology, and planning. Effective and parsimonious methods are needed to make the combinatorial challenges of comparative analysis manageable. Composite mosaics of multiple images derived by pattern-based segmentation have proven particularly advantageous for extracting and representing change from remotely sensed image sequences, where previously analysis was largely restricted to consideration of image pairs taken at two times with the same sensor (Myers, 2000; Patil et al., 2000b).

Geospatial Data Compression, Segmentation, and Classification

Remote sensing is generating spatial data at a rapidly increasing rate. The increase in data flow has a threefold nature due to increasing spatial resolution, increasing spectral richness, and more frequent acquisition. These data have potential informational utility that often remains unrealized. Facilitating the realization of such potential informational utility is one of the major challenges facing modern information technology, and provides the underlying motivation for emergence of data mining. Data mining is essentially a search for pattern that may have some interpretability, but it is too often an aimless search that is lacking conceptualization of what constitutes pattern. When dealing with image data, however, space and time offer organizing paradigms that have been underexploited.

From both theoretical and practical perspectives, landscapes have a mosaic nature with particular pattern elements emerging at different scales. This compound mosaic nature is fundamental as a basis for landscape ecology. The process of mosaic pattern extraction is one of image segmentation, where the operative partitioning takes place in the spectral domain. The determination of spatial mosaic segments is a direct consequence of partitioning as spectral subspaces. Accomplishment of such segmentation must take into account both distinctiveness and expansiveness of mosaic ele-

ments. Distinctiveness is most important for perceptual purposes, and the expansiveness for analytical purposes (Myers, 2000).

Geographic Surveillance, Disease Mapping, and Evaluation

Disease mapping is about the use and interpretation of maps showing the incidence or prevalence of disease. Disease data occur either as individual case events or as groups of case events (count data) within areal units, such as census tracts, zip codes, or counties. Any disease map must be considered with the appropriate background population which gives rise to the incidence. Maps answer the question: Where? The maps in conjunction with the underlying data reveal spatial patterns not easily recognized from lists of statistical data (Kulldorff et al., 1997, 1998; Lawson and Williams, 2001). For example, use of remote sensing data and other relevant geospatial data can help evaluate surrounding landscape characteristics that may be precursors for vector-borne diseases leading to early warning, involving landscape health, ecosystem health, and human health.

Urban Heat Islands, Urban Sprawl, and Environmental Justice

The urban heat island may be visualized as a temperature dome on an urban area. It contributes to the formation of ozone, which is a major urban air pollutant that has serious human health consequences. Analysis of thermal energy characteristics helps us understand how we can modify the city landscape to lessen the impacts of the urban heat island and its subsequent effects on air quality (Quattrochi and Luvall, 1999; Quattrochi et al., 2000; Quattrochi and Gillani, 2001). Three main objectives may be involved:

1. Characterization of thermal landscape in the metropolitan area. This aims at evaluating not only the strength of the urban heat island, but also the spatial variance within the heat island.
2. Evaluation of the relative roles of land cover characteristics and urban structures. This involves the quantification of land-cover characteristics and urban structures, such as percent of impervious surfaces, biomass density, urban canyon geometry, and roadway density.
3. Linking localized thermal characteristics to human health outcome. This attempts to directly and indirectly link illnesses, such as pediatric asthmatic attacks and heat strokes, to localized thermal stress.

Multiple Indicators, Partial Orderings, and Multicriterion Decision Support

To prioritize and to rank means to linearize. Rather than derive a composite index, we will prioritize without having to integrate the indicators. This is now possible, and the approach is relatively novel and innovative. We have developed it for nationwide prioritization for the United Nations Environmental Programme with land, air, and water indicators measuring the human environment interface at the national level (Patil 2001a; Patil and Taillie, 2001b, c). For another example, a landscape atlas published by the U.S. Environmental Protection Agency (Jones et al., 1997) considers 33 indicators of ecological condition on 123 watersheds (7-digit hydrologic unit codes [HUCs]) of the Middle Atlantic region and attempts to rank the watersheds using clustering and quintile-frequency methods. We address the question of ranking such a collection of objects when a suite of indicator values is available for each member of the collection. The objects can be represented as a cloud of points in indicator space, but the different indicators (coordinate axes) typically convey different comparative messages, and there is no unique way to rank the objects. A conventional solution is to assign a composite numerical score to each object by combining the indicator information in some fashion. Every such composite involves judgments (often arbitrary or controversial) about trade-offs or substitutability between indicators.

Figure 60.5 The linearizing effect of the CRF operator (left); example of how ties can emerge during linearization (right). A poset is a partially ordered set.

Rather than trying to impose a unique ranking, we take the view that the relative positions in indicator space determine only a partial ordering and that a given pair of objects may not be inherently comparable. Working with Hasse diagrams of the partial order, we study the collection of all rankings that are compatible with the partial order and arrive at the ranking and prioritization as in Figure 60.5, using the cumulative rank frequency (CRF) operator specially developed for the purpose (Patil and Taillie, 2001a).

Hierarchical Structure Analysis

Trees and other nodal graph structures arise in map modeling, echelons, and posets of MARMAP. Also important is the coupling of related structures. For example, when a suite of indicators is partitioned into subgroups (e.g., stressor, integrity, socioeconomic), the Hasse diagrams have a common set of labeled nodes but perhaps different edges (Patil, 2001c,d).

Mining Geospatial Data

Data structures and algorithms are under investigation for exploring associations between ecosystem degradation and spatial patterns employing higher-level models for detecting changes and finding interesting spatiotemporal patterns and trends (Rodriguez, 2001).

Interface Design and Visualization Toolbox

The main goal is to promote the discovery of inherent structures and patterns, enable the study of particular facets and dimensions of data, and provide means to visually assess the utility and accuracy.

PROJECT MARMAP CONSORTIUM: SYNERGISTIC INTEGRATION AND TECHNOLOGY TRANSFER

An essential part of this proposed consortium initiative is to introduce concepts and methods at the core of MARMAP to researchers in ecology, environment, socioeconomic, and the quality of human life. It is timely to think of multidisciplinary groups for ecosystem health measurement at the landscape level. It will be productive and cost-effective to initiate synergistic collaboration, whether in the form of a short course, workshop, project research, or proposal preparation.

The experiences gained from the collaborative studies will feed back into refinements of methods. At the end of the day, the thrust of this enterprise will have quantification of ecosystem

health at landscape scales from subwatersheds to major watersheds as an essential, replicable method of assessing our progress toward sustainability (Rapport et al. 1999). You are invited to visit the MARMAP Web site, <http://www.stat.psu.edu/~gpp/newpage11.htm>, and contact gpp@stat.psu.edu for your participation in this unusual consortium initiative to manage for healthy ecosystems in the spirit of digital governance of the 21st century.

Application of Landscape Models to Alternative Futures Analyses

Anne C. Neale, K. Bruce Jones, Maliha S. Nash, Rick D. Van Remortel, James D. Wickham, Kurt H. Riitters, and Robert V. O'Neill

INTRODUCTION

Scientists and environmental managers alike are concerned about broadscale changes in land use and landscape pattern and their cumulative impact on environmental and economic end points, such as water quality and quantity, species habitat, productivity, erosion potential, recreational value, and overall ecological health (Rapport et al., 1998). They also are interested in predicting short- and long-term future impacts on ecological goods and services based on current land management policies and decisions (Steinitz, 1996). Because we have the means to adjust land management policies, it is worthwhile to develop approaches that can predict the consequences (alternative futures) of different land management policies for different environmental end points. This type of analysis can, for example, allow decision makers in resource conservation and restoration programs to estimate how they can get the most ecological benefit for the least cost (Steinitz, 1996).

Modeling alternative futures can be a simple or complicated process depending on the method employed and the environmental end point in question. The questions and end points of interest are paramount in developing a valid model. Very different models, for example, are needed to predict terrestrial wildlife habitat vs. aquatic conditions. Even within a broad category such as aquatic conditions, different models may be appropriate for different aspects of aquatic conditions (e.g., macroinvertebrate health, pesticide toxicity, eutrophication potential). While different models may be required for different end points, common landscape composition and pattern metrics may be employed in a number of models for a suite of environmental end points. For example, percent natural cover or road density in a measurement unit (e.g., watershed) is an important factor for many environmental end points, including water quality and quantity, wildlife habitat, erosion potential, and recreational value (Burns, 1972; Harden, 1992; Saunders et al., 1992; Kattan et al., 1994; Koopowitz et al., 1994; Short and Turner, 1994; Jones et al., 2000).

Different methods have been proposed and used to predict future conditions, but the basic premise is the same; they are predicated on (1) what land managers and the public want based on needs and values, and (2) the biophysical constraints of the environment (Steinitz, 1996). Models may be developed by establishing trends based on past and present conditions and projecting those trends into the future. They also may be developed empirically by assessing how conditions of

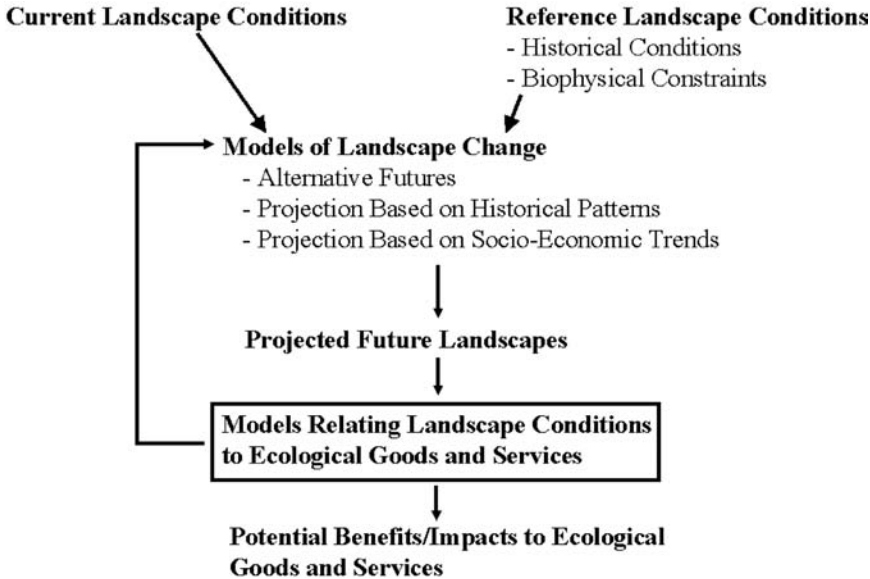

Figure 61.1 The use of landscape models in assessing the consequences of alternative landscape futures.

environmental end points vary with landscape composition and pattern (substituting spatial variability for time) and then manipulating the landscape conditions for different scenarios to project environmental end point conditions based on those different scenarios. Figure 61.1 describes the process used to apply a landscape model to alternative futures analysis.

This chapter will describe a model to predict nitrogen loading, one aspect important to water quality of streams, from a suite of landscape metrics and then will apply this model to a series of alternative future landscapes. This example also will illustrate important issues to consider when developing models for future conditions. Although we will describe only the process for modeling nitrogen loading, the methods presented could easily be applied to other environmental end points. A similar approach, using virtually the same suite of landscape pattern metrics, was used in an assessment relating landscape metrics to breeding bird richness in the Middle Atlantic region (Jones et al., 2000).

BACKGROUND INFORMATION FOR EXAMPLE MODEL

Key to model development was establishing a quantitative relationship between landscape pattern metrics and nitrogen loading to streams. Nitrogen is of particular interest to the U.S. Environmental Protection Agency (EPA) because, as a nutrient, it is essential to the health and continued functioning of natural ecosystems. However, when nutrient inputs exceed the assimilative capacity of a water body system, the system progresses toward hypereutrophic conditions. Excessive nutrient loadings can result in excessive growth of macrophytes or phytoplankton and potentially harmful algal blooms (HAB), leading to oxygen declines, imbalances between prey and predator species, public health concerns, and a general decline of the aquatic resource (U.S. Environmental Protection Agency, 1998).

A number of studies have shown strong relationships between water quality and landscape characteristics. A decrease in natural vegetation indicates a potential for future water quality problems (Likens et al., 1977; Franklin, 1992; Walker et al., 1993; Hunsaker and Levine, 1995; Smith et al., 1997). Many studies have shown that land use within a watershed can account for much of the variability in stream and estuary water quality (Omernik et al., 1981; Omernik, 1987;

Hunsaker et al., 1992; Charbonneau and Kondolf, 1993; Roth et al., 1996; Herlihy et al., 1998; Jones et al., 2001). Changes in landscape conditions in the riparian zone and in areas surrounding water quality sample sites may have a greater influence on water quality than broader-scale watershed conditions (Lowrance et al., 1984). The relationship between intact riparian areas and high water quality is well established, especially in the eastern U.S. (Karr and Schlosser, 1978; Yates and Sheridan, 1983; Lowrance et al., 1984; Cooper et al., 1987). Riparian habitat functions as a sponge, greatly reducing nutrient and sediment runoff into streams (Peterjohn and Correll, 1984; Cooper et al. 1987). Wetlands also play an important role in reducing nutrient loads to surface waters (Weller et al., 1996). High amounts of impervious surface and roads on watersheds also may result in high loadings of nutrients and sediment to streams (Burns, 1972; Harden, 1992; Arnold and Gibbons, 1996), and atmospheric deposition may be a significant source of nitrogen in surface waters (Stensland et al., 1986). Degraded water quality and quantity can, in turn, affect many other environmental end points such as species habitat, productivity, recreational value, and overall ecological health.

In 1996, a regional-scale land-cover database was developed for the five-state area of the U.S. Middle Atlantic region, and this database, along with other regional landscape coverages (e.g., topography, soils, road networks, stream networks, and human population density) were used to assess landscape conditions across the entire region down to a scale of 30 m (Jones et al., 1997). The assessment used a set of landscape metrics (O'Neill et al., 1988, 1997) to evaluate the spatial patterns of human-induced stresses and the spatial arrangement of forest, forest-edge, and riparian habitats. Advances in computer technology and geographic information systems (GISs) have made it possible to calculate landscape metrics over large areas (e.g., regions) at relatively fine scales (e.g., down to 30 m).

Using landscape metric data generated from Jones et al. (1997), and nitrogen loading data provided by the U.S. Geological Survey (USGS) (Langland et al., 1995), we developed a preliminary model predicting nitrogen loading to streams from landscape metrics for a subset of Middle Atlantic watersheds found in the Chesapeake Bay basin (Jones et al., 2001). The analyses presented in this chapter are demonstrative only and should not be construed as an ultimate model for predicting future nitrogen loading. The research to develop predictive nitrogen loading models based on landscape metrics is still ongoing.

METHODS

The obvious first step in developing alternative future models is to collect the appropriate input data for the models. In some cases, the researchers may have the luxury of designing and collecting their own data. In many cases, however, we are limited to existing data, especially if we want to include historical data in our analyses.

In this project, data were compiled from two independent sources. The nitrogen yield data were acquired from the USGS (U.S. Geological Survey, 1995) and the landscape metric data were derived from the data used by Jones et al. (1997).

The USGS calculated annual nutrient and suspended-sediment loads and yields for 148 nontidal streams within the Chesapeake Bay basin. The Chesapeake Bay basin contains more than 150,000 stream miles in the District of Columbia and parts of New York, Pennsylvania, Maryland, Virginia, West Virginia, and Delaware. The basin comprises six major river systems: the Susquehanna, Patuxent, Potomac, Rappahannock, York, and James Rivers (Langland et al., 1998). The USGS annual nitrogen yield estimates were based on the USGS water year which is October 1 through September 30. We calculated a median annual nitrogen yield based on the yields for the years 1989 through 1996. The inputs for the USGS model were measured concentration of nitrogen in milligrams per liter, measured discharge in cubic feet per second, and time measured in decimal years. USGS model methods and results are described in detail in Langland et al. (1998). The USGS

annual loads and yields are based on two different sampling regimes: flow-driven and fixed-interval sampling. In the flow-driven (or total stream flow) sampling regime, samples are collected on the basis of stream flow conditions. Fixed-interval sampling programs collect samples on a regular schedule, usually monthly or quarterly (Langland et al., 1995). Loads are reported by USGS in tons per year. Yields, which have been normalized by watershed area, are reported in pounds per acre. Our analyses were conducted with the yield data only and we combined data for flow-driven and fixed-interval sampling.

Watershed support areas were delineated using Arc/Info GIS software (ESRI, 1996) for each of the USGS water quality monitoring locations so our support areas consisted of only that part of the watershed actually contributing to the water quality monitoring point. For the landscape metrics, we acquired digital coverages of landscape metrics generated by Jones et al. (1997) and then calculated landscape metrics for each of the delineated watersheds. The source of the land cover map from which many of the landscape metrics were derived was the Multi-Resolution Land Characteristics (MRLC) project (Vogelmann et al., 1998). The MRLC data were derived from Landsat Thematic Mapper and had a resolution of 30 m and 15 land cover classes (Vogelmann et al., 1998). However, before calculating the landscape metrics, we used an Arc/Info routine to aggregate the 15 land cover classes into six classes: urban, agriculture, wetland, forest, barren, and water. The landscape metrics used in this analysis are listed in Table 61.1.

Figure 61.2 shows the delineated watersheds used in this analysis in the context of the entire Middle Atlantic region. Although it cannot be detected in Figure 61.2, several of the watersheds are actually nested within larger watersheds. The points on the figure represent water quality data collection sites. Any delineated watershed that did not overlap the Middle Atlantic study area by at least 75%, such as those in the northern portion of the study area, were deleted from the analysis.

Table 61.1. List of Landscape Metrics Compared to Nitrogen Loads^a

Name of Metric	Explanation
Riparian agriculture	Percentage of watershed with agricultural land cover adjacent to stream edge; 1 pixel wide
Riparian forest	Percentage of watersheds with forest land cover adjacent to stream edge; 1 pixel wide
Forest fragmentation	Forest fragmentation index for watershed; of all edges in the watershed involving at least 1 forested pixel, the percent that joins a forest pixel to a nonforest pixel; higher values indicate higher fragmentation
Road density	Road density for watershed expressed as an average number of kilometers of roads per square kilometer of watershed; normalized to approximate scale of land-cover metrics
Forest land cover	Percentage of watershed with forest land cover
Agricultural land cover	Percentage of watershed with agricultural land cover (pasture/crops)
Agricultural land cover on steep slopes	Percentage of watershed with agriculture occurring on slopes greater than 3%
Nitrate deposition	Estimated average annual wet deposition of nitrate
Potential soil loss	Proportion of watershed with the potential for soil losses greater than 1 ton per acre per year
Roads near streams	Proportion of total stream length that has roads within 30 m; normalized to approximate scale of land-cover metrics
Slope gradient	Average percent slope gradient for watershed
Slope gradient range	Percentage slope gradient range (maximum–minimum) for watershed
Slope gradient variance	Percentage slope gradient variance for watershed; normalized to approximate scale of land-cover metrics
Urban land cover	Percentage of watershed with urban land cover
Wetland land cover	Percentage of watershed with wetland land cover
Barren land cover	Percentage of watershed with barren land cover; includes quarry areas, coal mines, and transitional areas, such as clear-cut areas

^a Calculation methods and details of each indicator can be found in Jones et al. (1997). Metrics were calculated for each watershed support area.

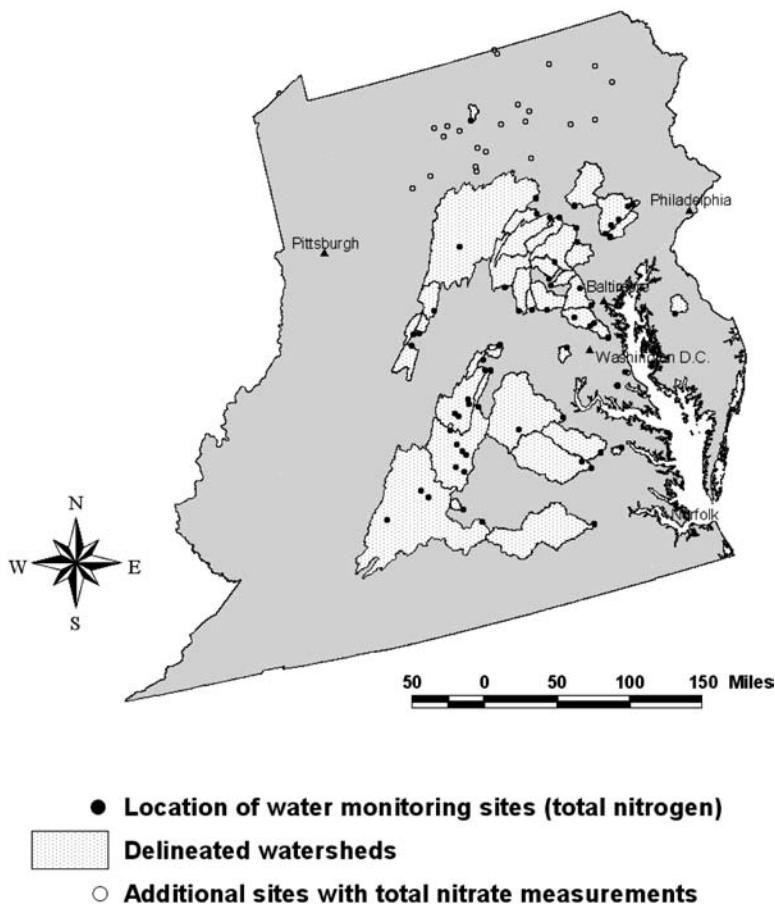

Figure 61.2 Location of water sampling points and their associated delineated watersheds.

We first examined the individual relationships between nitrogen yield (dependent variable) and landscape metrics (independent variables) using individual scatter plots and preliminary regression analyses (SAS Institute, 1990). From our preliminary analyses, we concluded that a log transformation of the nitrogen yield data was necessary. We also performed a square-root transformation of the nitrate deposition landscape variable to linearize the relationship between it and the dependent variables.

We then ran several different regression analyses (SAS Institute, 1990) for nitrogen with the suite of landscape metrics listed in Table 61.1 to help us understand the importance of each variable. We selected a model based on four requirements:

1. The model had to be valid (i.e., basic principles of regression analysis, such as normality, constancy, and independency of error terms were not violated).
2. The model explained a high proportion of the variance in the nitrogen yield.
3. The model included variables over which we may have more control (e.g., selecting riparian forest as a predictor variable over agricultural land cover; agricultural land cover may have explained more overall variance in the model had it been included, but there is a low likelihood of changing the amounts of agriculture in a watershed significantly).
4. The model did not include variables that were highly collinear, as it is difficult to separate the effects of different variables when multicollinearity is an issue.

After selecting the model, we applied it to three future scenarios for all watersheds (defined by USGS hydrologic accounting units) in the Middle Atlantic region. The variables selected for this regression model, based on the criteria discussed above, were amount of riparian forest cover and air nitrate deposition. Amount of riparian forest cover is defined as the percentage of watershed with forest land cover adjacent to the stream edge with a buffer size of 30 m (i.e., one 30×30 m picture element). Air nitrate deposition is a modeled value that represents the estimated average annual wet deposition of nitrate. The resulting model from this analysis was:

$$\text{total nitrogen yield} = \exp[0.9056 - 0.02769(\text{riparian forest cover}) + 0.00168 (\text{nitrate deposition})]$$

This model, based on 69 observations, explained 87% of the variation in nitrogen loading values with 68% explained by riparian forest and 19% explained by nitrate deposition. We next applied this model to the landscape metrics (riparian forest and nitrate deposition) from Jones et al. (1997) for the USGS hydrologic accounting units and manipulated the amount of riparian forest to create three future scenarios for nitrogen loading.

We subsequently applied this model to all the hydrologic accounting units in the Middle Atlantic region based on current conditions of riparian forest and nitrate deposition. We then projected a future scenario if the current amount of riparian forest were increased by an additional 10% to a maximum value of 100%. We also projected a future scenario if the amount of riparian forest was decreased by 10% to a minimum value of 0%. These predictions assume that the amount of nitrate deposition remains constant. This is a simple model and does not take into account several potentially important variables, such as loadings from point sources, hydrogeologic conditions, groundwater contribution, and other highly correlated but important variables, such as total amount of agriculture on the watershed. It also does not take into account other things that could affect future scenarios (e.g., probable population growth patterns).

RESULTS

Figure 61.3 shows nitrogen loading conditions as predicted by current conditions. Figure 61.4 shows a future scenario if the amount of riparian forest were increased by 10%. Figure 61.5 shows a future scenario if the amount of riparian forest were decreased by 10%. These figures demonstrate that by adjusting the riparian forest percentages, we could have a significant impact on nitrogen loading to streams. The pattern of transition from lower to higher nitrogen loadings to streams is clear in these three figures. The cutoff values for each of the five classes shown in Figures 61.3, 61.4, and 61.5 are based on quantiles and were defined from current condition data (Figure 61.3). Cutoff values perhaps would be more meaningful if they were based on some known water quality criteria for nitrogen such as those developed on an ecoregional basis by the EPA (U.S. Environmental Protection Agency, 2000).

A potentially serious limitation of this analysis is extrapolating the model derived from limited spatial coverage (Figure 61.1) to a larger spatial extent. The farther away we get from those watersheds shown in Figure 61.1 (i.e., to the north and the west), the less reliable our model may be. We may be able to justify extrapolating to the north by examining the relationship between total nitrate and the same landscape metrics. We had total nitrate data for 79 sites, including 20 sampling sites to the north of those shown in Figure 61.1. The resulting model, if we regress total nitrate on the same two landscape variables (riparian forest and nitrate deposition), is as follows:

$$\text{total nitrate load} = \exp[0.9621 - 0.0366(\text{riparian forest cover}) + 0.00163 (\text{nitrate deposition})]$$

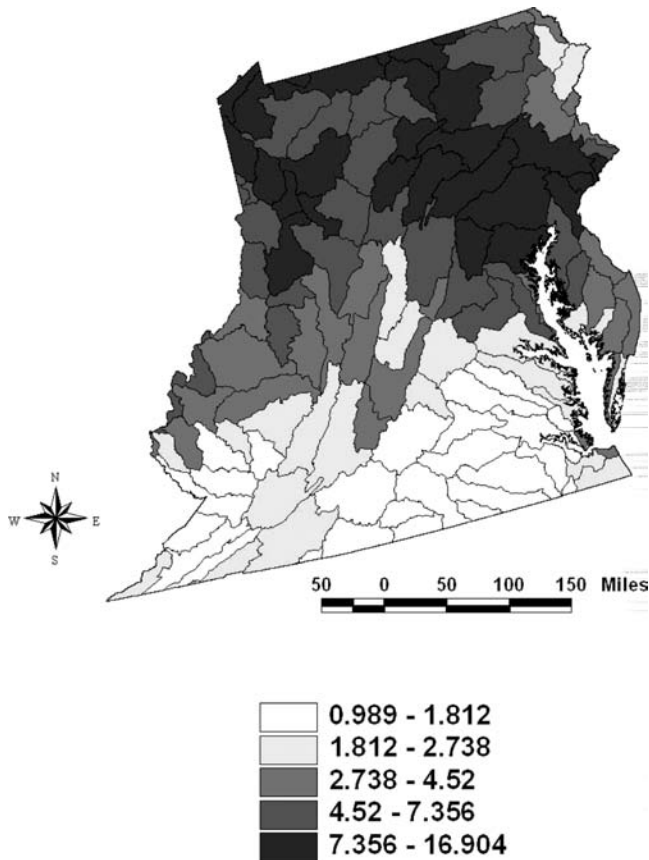

Figure 61.3 Nitrogen loadings (lbs/acre/year) as predicted by present conditions.

This model, based on 79 observations, explained 78% of the variation in nitrate loading values with 55% explained by riparian forest and 23% explained by nitrate deposition. While this model is somewhat similar to the model for total nitrogen, riparian forest explains less of the variation but has a more severe impact on nitrogen loading (steeper regression slope).

Another potential limitation of the model concerns the important issue of scale. The model was developed based on data from multiple scales ranging from very small to very large watersheds; some of these were larger than the USGS hydrologic accounting units and many of them were smaller. The model parameter estimates could be very different if, for example, all the watersheds were based on either very small or very large watersheds.

DISCUSSION

Wall-to-wall landscape data of relatively fine spatial scale (e.g., 30 m), and field sample measurements of a variety of stream chemistry parameters, permit the development of spatially distributed empirical models that can be used to assess potential loadings to streams across an entire region. As demonstrated in this chapter, the development of these models is critical to assess how future landscape scenarios might affect stream water quality across a region. In our study, riparian extent along streams was a strong predictor of nitrogen yield. Because of this relationship, we were able to assess how two future scenarios of riparian habitat condition would affect nitrogen loadings to streams at a watershed or catchment scale. We used two simple

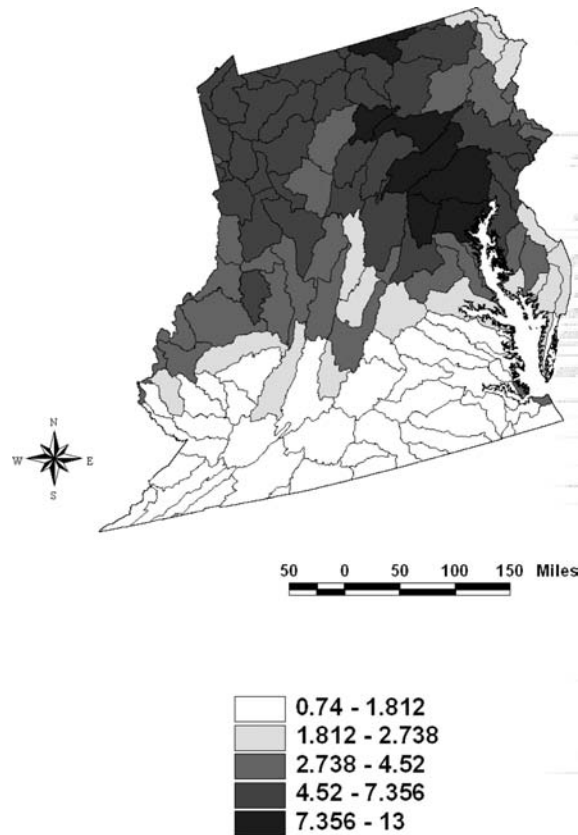

Figure 61.4 Nitrogen loadings (lbs/acre/year) as predicted with a 10% increase of riparian forest.

future scenarios — one with a 10% increase in the amount of riparian habitat at the catchment scale and one with a 10% decrease in riparian habitat — to demonstrate how the approach can be used to target those watersheds that would benefit the most from an increase in riparian habitat (restoration) and those that would be at the greatest risk due to decreases in riparian habitat (catchments needing protection). The decreased riparian habitat scenario is similar to a treadmill stress test in humans (after the ecohealth concept of Rapport et al., 1998). It finds those catchments where streams are most vulnerable to increases in nitrogen load and, therefore, a potential dramatic effect on human (waterborne diseases and drinking water quality) and ecological health (stream biota).

Our modeling approach differs from other watershed or catchment models that predict nutrient loadings in that it considers the spatial pattern and distribution of key landscape features; most existing models only consider the percentage of land cover at the catchment scale (U.S. Department of Agriculture, 1972; Liang et al., 1994). Additionally, most existing models lack riparian and atmospheric deposition parameters. Riparian habitats can be significant filters of nutrient inputs to streams (Lowrance et al., 1984; Peterjohn and Correll, 1984; Cooper et al., 1987) and atmospheric nitrogen deposition can be a significant source of nitrogen input at the catchment scale (Stensland et al., 1986; Appleton, 1995).

Our modeling approach is a significant improvement over the comparative watershed approach used by Jones et al. (1997) and Wickham et al. (1999a) because landscape metrics were quantitatively linked to stream conditions. Jones et al. (1997) and Wickham et al. (1999a) ranked the relative vulnerability of watersheds but did not link their ranking to observed water quality.

Figure 61.5 Nitrogen loadings (lbs/acre/year) as predicted with a 10% loss of riparian forest.

Because our model includes the spatial pattern of key landscape features, it is possible to find those areas that would benefit most from riparian restoration and riparian protection (those catchments at risk under the reduced riparian habitat scenario). Such information can be used by land managers and private landowners to decide where to restore and protect riparian habitats. This is important because budgets for restoration and protection are often limited. Wickham et al. (1999b) used a similar approach to identify those catchments that had the greatest potential to restore forest connectivity. Such targeting approaches are needed to identify restoration and protection opportunities for other ecological goods and services (e.g., flood abatement, wildlife habitat, and forest, rangeland, and agricultural productivity).

The spatially distributed model demonstrated in this chapter can be used to assess the consequences of other landscape scenarios. For example, the model could be applied to assess the potential change in nitrogen loading to streams associated with different land management scenarios generated from public workshops (Steinitz, 1996). It also could be used in combination with socioeconomic, land-cover change models (Wickham et al., 2000) to assess the consequences of socioeconomic futures on nitrogen loadings to streams.

Our modeling approach requires regionally consistent landscape data and a fairly extensive network of water quality samples. Therefore, availability of regional-scale, land-cover data similar to that being developed by the MRLC Consortium in the U.S. (Vogelmann et al., 1998), and stream samples similar to those being collected by the Environmental Monitoring and Assessment Program program in the U.S. and the Waterwatch program in Australia (Waterwatch, 1997), is critical to the use of our modeling approach. Additionally, since quantitative relationships between landscape pattern and stream water quality vary between different biophysical settings (Omernik et al., 1981; Clarke et al., 1991; Jones et al., 2001), water quality sampling must be sufficient to represent different biophysical settings.

ACKNOWLEDGMENTS

We thank Scott Phillips and Judy Denver of the USGS for providing information on nutrient parameters used in this study. The U.S. Environmental Protection Agency (EPA), through its Office of Research and Development, partially funded and collaborated in the research described here. It has not been peer-reviewed by the EPA. Mention of trade names or commercial products does not constitute endorsement or recommendation by the EPA for use.

Echelon Screening of Remotely Sensed Change Indicators

Wayne L. Myers and Francis R. Beck

INTRODUCTION

Tracking of changes on the landscape is central to assessment of ecosystem health and sustainability, although implications of change phenomena are not always straightforward (Costanza, 1991; Jones et al., 1997; O'Neill et al., 1997; Picket and White, 1985). Determining and recording changes on a parcel basis at local scale is a fairly mechanical matter when modern geographic information systems (GISs) are utilized, but becomes much more problematic for large areas when funds are limited. In the latter case, it becomes a practical necessity to exploit remotely sensed data obtained electronically from instrumentation carried by satellites and transmitted to strategically located receivers. Remotely sensed data are typically recorded in a grid arrangement with a set of spectral reflectance readings for each cell of the grid. The readings correspond to energy of selected wavelengths that is integrated (averaged) over the sector of Earth's surface encompassed by the cell. Remote sensing specialists use the technical term *pixel* (for picture element) instead of the more generic cell terminology (Wilkie and Finn, 1996). The area covered by a pixel (cell) is usually too large to provide high resolution regarding geometric detail of objects on the ground (Lillesand and Kiefer, 1994). Differences in landscape features must be inferred from computed differences among spectral readings, as opposed to detailed visual examination.

Computerized methods of detecting landscape changes involve one of two general modes with numerous variations in either mode (Lunetta and Elvidge, 1998). One mode consists of using multivariate statistics to assign each cell to a feature (thematic) class, such as forest or grassland. Specific types of class changes for a pixel between dates of imaging will constitute landscape changes of interest. The utility of this *classification mode* depends heavily on the accuracy of classification. If classifications for two dates both have substantial inaccuracies that occur independently, then derived inference regarding change will be less accurate than either original classification. The second mode involves spatial comparison of spectral readings without performing classifications as an intermediate step. This produces an *index of change* (change signal) with a value for each pixel that is indicative of where change may have occurred when analyzed comparatively across the extent of the image. The index of change can be displayed directly as an image, but decisions must then be made regarding what constitutes background that indicates lack of change vs. highlights that suggest candidate areas where change may have occurred and further investigation is warranted. The typical approach to making such decisions is by establishing a

threshold level in terms of the index. Establishment of the threshold may be done either visually or by a computational heuristic.

Our focus is on the index of change mode, with concern for limitations of thresholds in the context of change detection. Spectral expression of landscape change is given brief consideration in order to provide perspective on the problem. Next, we discuss limitations of thresholds relative to change indicators. We then explain an alternative way of highlighting candidate areas with respect to change. This alternative approach has been called *echelons* (Myers et al., 1997). Echelons overcome many of the limitations for thresholds, and are also applicable to finding areas of prospective interest relative to grid mappings for environmental indexes other than change.

IMAGE EXPRESSION OF LANDSCAPE CHANGE

In an oversimplified manner of statement, a change will be most evident if the conditions before and after have a strongly contrasting appearance. Conversely, the appearance of low contrast changes will be subtle and subdued. *Appearance* is a word that may be somewhat misleading in this context because remotely sensed data usually incorporate infrared wavelengths that are invisible to the unaided human eye. Nevertheless, extending the idea of appearance informally to encompass response of an electronic sensor should convey the intended impression. Building a four-lane highway through a forest thus constitutes a high contrast change, whereas partial regrowth of trees in a brushy forest clear-cut constitutes a change having low contrast.

The task of change detection becomes more complicated because high contrast changes are not all of interest, and not all changes of interest have high contrast. The crop grown in an agricultural field is often changed from year to year for maintenance of fertility and reduction of pest problems. If the successive crops have different tillage and harvest schedules, the resulting appearance of change may exhibit high contrast while being just temporal variants of a consistent and sustainable agricultural cropping regime. On the other hand, exposed earth due to construction may have an appearance similar to former agricultural plowing, which gives rise to a change of low contrast but considerable importance with respect to ecosystem health.

Spatial continuity and extent of change may also be more important than its degree of consistency. A small forest opening due to demise of a couple of trees affecting one pixel may be quite inconsequential, but a pest infestation or fire with varying degree of impact over a larger area becomes something of major concern. High contrast changes are spotty in the latter situation, but these spots connect across bridges of lesser change to form a change complex encompassing substantial area.

LIMITATIONS OF THRESHOLDS FOR CHANGE INDICATORS

In an ideal change detection scenario, a change signal grid would contain a patchy mixture of two populations. One population would have low values of the change index and would represent areas where change had not occurred. The other population would have high values of the change index and would represent areas where change had transpired. It would then be straightforward and appropriate to fix a threshold in the mid-zone between high- and low-change values, choosing an intermediate value that is absent or has the fewest occurrences. Unfortunately, however, such a scenario is practically never encountered for the reasons given above. Consequently, the choice of threshold becomes somewhat arbitrary and inadequate in several respects.

Figure 62.1 poses a hypothetical profile along a transect line through a grid of change index values. The horizontal dashed lines depict possible positions of a threshold to illustrate the attendant problems. The threshold at level A gives the impression that change only occurs in isolated spots, concealing both the substantial extent of change and differing degrees of spatial coherence in the

Figure 62.1 Hypothetical profile of a change signal (+) with illustrative thresholds (-) at levels A and B.

change. The threshold at level B begins to catch somewhat more of the spatial extent for change, but still gives an erroneous impression that there is one larger patch and two smaller ones. Both A and B thresholds miss the lower level of more subdued change.

As the example thresholds serve to illustrate, there is an inherent arbitrariness to the setting of thresholds when change occurs in a graded manner. Furthermore, no single threshold can adequately capture spatial pattern of graded change that is not disjunct.

ECHELONS AS AN ALTERNATIVE TO THRESHOLDS

What is needed is to capture emerging components of spatial structure in the change grid as a threshold is lowered progressively from highest peak to lowest point. This is effectively what *echelons* accomplish. Echelons partition a surface variable into peak and foundation components with records of major characteristics for each component.

The peaks are first located as primary components, and the peaks are numbered in order of decreasing summit level. Each peak extends downward and outward from the summit until a saddle is reached on any side of the peak, whereupon the respective peak terminates. The foundation components are then located in order of decreasing upper level as secondary components. As with a peak, a foundation spreads downward and outward until a saddle is encountered on any side. The foundations are numbered in sequence, starting with the next available number after that allocated to the lowest peak. The echelon components of Figure 62.1 are depicted in Figure 62.2, with dashed lines indicating saddles instead of thresholds.

Our usual analogy for echelons is drainage after submersion by floodwaters. The peaks are components that break the water surface to emerge as islands. New foundations are initiated whenever two or more current islands merge to become a larger composite island. There is also

Figure 62.2 Echelon partition of illustrative change signal from Figure 62.1, with dashed lines at saddles.

an ordering scheme for echelons that is useful in the change detection context. Peaks are of first order, as for instance components 1 through 5 in Figure 62.2. A foundation that supports two or more first-order echelons is of second order, with echelon 6 in Figure 62.2 providing an example. A foundation of a given order can also support one other echelon of like order, as does component 7 in Figure 62.2. A foundation becomes third order if it supports two or more second-order components. In general, the order of a foundation depends on the maximum order of components supported and the number of such maximum-order components. If there are two or more maximum-order components, then the foundation is of next order. The order of the grid as a whole is that of its highest-order component.

Echelon organization also entails a family tree of foundation relations. The peaks are *terminals* of the tree. Second-order foundations supporting only first-order components are *twigs* of the tree, as exemplified by component 6 in Figure 62.2. A *stem* is a foundation that is induced only by first-order components, but is more complex than a twig. Component 7 in Figure 62.2 is a stem because its formation is due to presence of the first-order component 4, although it also supports a second-order component 6. Twigs are locally prominent upper structures of a change surface. Terminals supported by stems are bumps on sidehills of change, and are thus somewhat subordinate components of change. An echelon supported by a foundation is called an *ascendant* of the foundation, and a foundation is called the *founder* of a component that it supports.

Software written in C language with a command line interface for computing echelons is available via the Internet at <http://www.orser.psu.edu>. Computation of echelons proceeds in stages with one program module for each stage. The first two stages serve to determine all first-order echelons. There is a capacity limit of 65,280 echelons for any single grid. If there are more than 65,280 first-order echelons, then the change surface must be simplified (smoothed) in order to proceed. Initial smoothing is accomplished by eliminating single-pixel blips. The most similar immediate neighbor replaces a blip to be eliminated. If there is still insufficient capacity to accommodate first-order echelons, then a median filter is used to further simplify the change grid. When first-order computation is achieved, the results can be displayed to determine whether additional smoothing should be done. If so, then small first-order echelons are shaved off according to size criteria.

Foundation echelons are determined in another stage. Whereas determination of first-order echelons is fairly rapid, foundation echelons are more time-consuming to compute. If computation of foundations becomes unduly protracted, provision is made for controlled termination and subsequent work with partial echelons. Since determination of foundations works progressively downward, the upper echelon components are determined in the beginning. Focal areas of change can be detected by combining first-order echelons with upper foundations. After foundations are determined (whether wholly or partially), a table of echelon properties still must be completed with the appropriate program module.

A fairly sophisticated capability is provided for preparing echelon-based display layers that are compatible with several commercial and no-cost viewers intended for GIS and remote sensing applications. This facility allows one echelon property to serve as a base, with other properties having roles as modifiers. It is recommended that *echelon precedence* be used as a base and rendered as grayscale. Precedence is derived from the order in which echelons have been determined. The first modification is to use the color red for rendering first-order echelons having twigs as foundations. The second modification is to use yellow for rendering first-order echelons having stems as foundations. It may also be desirable to suppress small first-order echelons that lack a foundation by rendering them in the same manner as the (black) background. Modifications involve recoding with a program module, and then editing a textual color lookup file.

Displays using this coding scheme are readily interpreted. Red areas are the strongest indications of change. Red areas situated in whitish or light gray surroundings represent locally strong change that is also spatially coherent but of variable intensity over a vicinity. Yellow colors situated in light gray surroundings are subordinate peaks on sidehills of change. Light gray areas

lacking embedded red and yellow highlights are peaks of change having a base below the level to which partial echelons were developed. The lighter ones of these latter areas represent changes of relatively strong contrast, whereas the darker ones represent changes of relatively weak contrast. An example of this presentation scheme is not provided here because color is key to achieving the desired visual effect.

SUMMARY

Capability for detecting spatially coherent areas having changes of varying intensity is a special advantage of echelons. Echelons likewise pick up all sorts of local peaks, many of which would be missed by usual placement of a threshold. Echelons further offer several options for filtering on the basis of multiple criteria in order to suppress certain types of changes that may not be of interest. Finally, the utility of echelons for screening of surface variables is not limited to the change detection context. Potential for characterizing and distinguishing spatial patterns among surface sectors lies in the capacity of echelons to capture spatial organization of a surface in dendrogram mode. In order for this potential to be realized, further research is needed on methods for comparative analysis of dendrograms.

Grassland Bird Communities and Environmental Health: The Role of Landscape Features

Douglas H. Johnson, Sharon F. Browder, and Maiken Winter

INTRODUCTION

Ecosystems throughout the world are imperiled by myriad anthropogenic factors. It is critical to develop tools for evaluating and monitoring the health or integrity of various ecosystems. Because of the broad scale of the problem, the urgency to address informational needs, and the limited financial resources committed to the problem, relatively inexpensive tools that encompass large areas are especially desirable. Remote sensing offers possibilities for such large-scale evaluation and monitoring. With aerial or satellite imagery, vast quantities of information from very large areas can be collected periodically.

Before remote sensing can be employed to assess ecosystem health on an operational basis, however, two fundamental questions must be addressed: (1) How do features that can be remotely sensed relate to the health of the ecosystem being evaluated? (2) How can remotely sensed measures be validated with on-the-ground assessments of the ecosystem? Here we address those questions in the case of grasslands and grassland birds in the northern Great Plains of the U.S.

We first describe the importance of grassland systems, notably to bird populations, and why their health or integrity needs to be evaluated. Next, we discuss birds of the grasslands and offer reasons birds are useful as measures of ecosystem health. We then address question 1 above by demonstrating that a variety of features that can be sensed remotely are in fact associated with the health of the ecosystem, as reflected in bird communities and their population dynamics. Much of that material is drawn from Johnson and Winter (1999) and Johnson (2001). We then face question 2 by indicating how a measure of ecosystem health for grasslands relates to a community metric based on breeding-bird populations. Those results are based on Browder (1998) and Browder et al. (submitted).

GRASSLANDS OF THE NORTHERN GREAT PLAINS

Three broad provinces of grassland in the Great Plains are generally recognized, which correspond to a gradient of increasing precipitation from west to east: shortgrass prairie in the west, mixed-grass prairie in the center, and tallgrass prairie in the east (Risser et al., 1978). Prior to settlement by Europeans, the northern plains were a vast grassland; trees were scarce or absent (e.g., Bragg and

Steuter, 1995). Grasslands were maintained by periodic drought, fires, and, especially in the west, grazing by large herds of herbivores such as bison (*Bison bison*). These forces created mosaics of habitat ranging from heavily grazed to undisturbed (England and DeVos, 1969).

Much of the grassland in the northern Great Plains has been cultivated for crops. This conversion is nearly total in the eastern Great Plains; tallgrass prairie is one of the most threatened habitats in the northern plains, with only scattered fragments remaining (Samson and Knopf, 1994; Noss et al., 1995). A smaller proportion of mixed-grass prairie has been cultivated, largely because the terrain is rougher and precipitation is lower and less predictable. The proportion of shortgrass prairie that has been tilled is even lower, although much of it is intensively grazed by domestic livestock. Cultivation, however, has increased in the past few decades in the mixed-grass and shortgrass prairies due to the advent of sprinkler irrigation using water from ancient aquifers. Settlement of the northern plains by Europeans also brought major increases of woodland, with tree claims planted to protect farmsteads from winds, shelterbelts established to reduce soil erosion, and increased woody vegetation resulting from fire suppression by settlers (McNicholl, 1988).

Grasslands of the northeastern Great Plains are dotted with innumerable depressions, called prairie potholes, that formed when glaciers retreated about 10,000 years ago. Individual wetland basins contain water for different lengths of time in most years (Stewart and Kantrud, 1971). This variation among wetlands in hydrological regime induces variation in water chemistry, vegetation, nutrient cycling, and invertebrate communities (van der Valk, 1989). This results in a rich diversity of birds and other vertebrates (Igl and Johnson, 1998).

Like grasslands, prairie wetlands have been altered, notably by drainage intended to increase the area under cultivation. Losses of wetlands from settlement to 1980 were 27% in Montana, 49% in North Dakota, 35% in South Dakota, 42% in Minnesota, and 89% in Iowa (Dahl, 1990). Siltation of wetlands due to agricultural activity has had adverse effects on remaining wetlands.

BIRD POPULATIONS OF THE NORTHERN GREAT PLAINS

Many bird species breed in the northern Great Plains. The avifauna includes species of boreal, eastern, southern, and western origins (Johnsgard, 1979; Stewart, 1975). Despite these varied origins, the regional avifauna is distinctive. Only 29% (56 out of 190) of the breeding species in North Dakota are associated with the north-central, mixed-grass avifauna, but those species make up 80% of the total breeding bird population (Stewart, 1975).

Quantitative information about changes in populations of grassland birds exists only for the period since the mid-1960s, 75 to 100 years after most of the major habitat changes on the northern Great Plains occurred. A systematic survey (the North American Breeding Bird Survey, or BBS) was initiated in 1966 (Robbins et al., 1986). BBS results indicate that grassland-nesting birds as a group have suffered more serious population declines than other groups of birds (Peterjohn and Sauer, 1999). From 1966 to 1994, declines in the Midcontinent Region were reported for common yellowthroat (*Geothlypis trichas*), dickcissel (*Spiza americana*), grasshopper sparrow (*Ammodramus savannarum*), bobolink (*Dolichonyx oryzivorus*), Baird's sparrow (*Ammodramus bairdii*), northern harrier (*Circus cyaneus*), loggerhead shrike (*Lanius ludovicianus*), and lark sparrow (*Chondestes grammacus*). Increasing populations during that time were reported for upland sandpiper (*Bartramia longicauda*), ferruginous hawk (*Buteo regalis*), and sharp-tailed grouse (*Tympanuchus phasianellus*) (Johnson, 1996).

In addition, a statewide survey of North Dakota birds conducted in 1967 (Stewart and Kantrud, 1972) and repeated in 1992 and 1993 (Igl and Johnson, 1997) provides a useful contrast between those two time periods. Numbers of chestnut-collared longspurs (*Calcarius ornatus*), western meadowlarks (*Sturnella neglecta*), Savannah sparrows (*Passerculus sandwichensis*), and Baird's sparrows declined by 39% or more; clay-colored sparrows (*Spizella pallida*) and bobolinks declined at lesser rates (Igl and Johnson, 1997). Of the 12 species with significant decreases during that

period, 11 were grassland or wetland dependent. Conversely, 24 of the 34 species that significantly increased were those associated with woody vegetation or human-made structures.

Metrics based on bird communities can provide useful indicators for monitoring ecosystems for several reasons (Browder et al., submitted):

1. Bird species are associated with particular habitats (see, e.g., Johnson and Igl, 1998, for grassland species).
2. Birds occur across a broad gradient of anthropogenic disturbance, from wilderness to urban areas.
3. Groups of bird species can be used to develop associations with cover types that relate to the level of anthropogenic disturbance (Bradford et al., 1998; Croonquist and Brooks, 1991; Szaro, 1986).
4. Most birds live only a few years, so changes in species composition and abundance can be detected in a relatively short time period.
5. Systematic bird surveys, such as the BBS, are currently conducted across the U.S. and southern Canada. These surveys can provide information for use in bird-community metrics.
6. Birds are important to a large segment of the public, which may relate better to concerns about changes in bird communities than to those of other taxa, such as plants or invertebrates.

REMOTELY SENSED FEATURES AND GRASSLAND BIRDS

We now consider how some features of the ecosystem that can be remotely sensed influence the numbers or population dynamics of grassland birds. These features are characteristics of both the grassland patch and the landscape in which the patch is embedded.

The size of a grassland patch and its surrounding landscape markedly influence the use of that patch by grassland birds. Some patches may be too small to be colonized by certain species, or birds using smaller patches may suffer more from competition, predation, or brood parasitism than do birds in larger patches. Also, smaller patches have a relatively greater proportion of their area near an edge, so edge effects can be greater in smaller patches (e.g., Johnson, 2001). Edge effects are phenomena such as avoidance, predation, competition, or brood parasitism, which operate at different levels near a habitat edge than in the interior of a habitat patch (e.g., Faaborg et al., 1993; Winter and Faaborg, 1999). Isolation from other grassland patches is a landscape feature that can affect either the use by or fate of birds in a patch.

Each of these factors, patch size, amount of edge, and isolation, can be assessed remotely and can affect (1) the occurrence or density of birds using a habitat patch; (2) reproductive success, through either predation or brood parasitism; or (3) competition with other species. The following overview of studies that examined these relationships is based on Johnson and Winter (1999) and Johnson (2001).

Patch Size Effects: Occurrence and Density of Birds

Species that are absent from or have lower densities in small habitat patches are referred to as area-sensitive species (Robbins, 1979). Species with large home ranges, such as greater prairie-chicken (*Tympanuchus cupido*), upland sandpiper, and northern harrier, are typical area-sensitive species that are rarely present in small, isolated habitat patches. But even species with territories much smaller than a habitat patch can be area sensitive.

Several grassland passerines, which typically have territories of only a few hectares, have been identified as area sensitive in different geographic areas. Among these are the sedge wren (*Cistothorus platensis*) in North Dakota and Minnesota (Johnson and Igl, 2001), but not in Illinois (Herkert, 1994), and clay-colored sparrow (Johnson and Igl, 2001). The widely distributed grasshopper sparrow (*Ammodramus saviannarum*) has been shown to be area sensitive in several regions (Bollinger, 1995; Herkert, 1994; Johnson and Igl, 2001). The Baird's sparrow was suggested to be area sensitive by Johnson and Igl (2001). Also noted as area sensitive were the following:

- Henslow's sparrow (*Ammodramus henslowii*) (Bollinger, 1995; Herkert, 1994; Winter, 1998)
- Savannah sparrow (Bollinger, 1995; Herkert, 1994; Johnson and Igl, 2001; Johnson and Temple, 1990)
- Vesper sparrow (*Pooecetes gramineus*) (Bock et al., 1999)
- Bobolink (Bollinger, 1995; Herkert, 1994; Johnson and Igl, 2001)
- Eastern meadowlark (*Sturnella magna*) (in Illinois [Herkert, 1994] but not New York [Bollinger, 1995]).

These studies demonstrated that several bird species prefer grasslands of much larger areal extent than their territories.

Patch Size Effects: Reproductive Success

In a Missouri study, Burger et al. (1994) found that artificial nests survived at a higher rate in larger than in smaller prairie patches, although artificial nests may not accurately reflect what happens to real nests (Davison and Bollinger, 2000). Results from Johnson and Temple (1990) indicated an effect of patch size on nest success of Savannah sparrows. Winter (1998) showed that dickcissels reproduced more successfully in larger than in smaller prairies in Missouri.

Edge Effects: Occurrence and Density of Birds

Reduced densities of several species near edges have been reported. In Wisconsin, Wiens (1969) indicated that Savannah sparrows and grasshopper sparrows tended to avoid forest edges. Delisle and Savidge (1996) found in their Nebraska study that few grasshopper sparrow nests were located within 60 m of a habitat edge. Helzer (1996) also reported that grasshopper sparrows in Nebraska avoided woody and cornfield edges, and that Bobolinks avoided woody edges. Bock et al. (1999) indicated that Savannah sparrows, grasshopper sparrows, vesper sparrows, bobolinks, and western meadowlarks avoided edges associated with suburban development in Colorado.

Edge Effects: Reproductive Success

Nests of bobolinks and western meadowlarks in Minnesota that were far from a habitat edge were more successful than those that were closer (Johnson and Temple, 1990). Burger et al. (1994) reported a similar finding for artificial nests in Missouri. Winter et al. (2000) reported that predation rates on Henslow's sparrow and dickcissel nests in Missouri were higher near shrubby edges, probably due to greater activity by mid-sized carnivores near edges. In contrast, Delisle and Savidge (1996) found no edge effect for grasshopper sparrows in Nebraska.

Brown-headed cowbirds (*Molothrus ater*) are brood parasites, which lay their eggs in the nests of other species, and thereby reduce the productivity of the hosts. Johnson and Temple (1990) detected higher brood-parasitism rates of nests within 45 m of forest edge for the clay-colored sparrow and western meadowlark in Minnesota. In Missouri prairies, Winter et al. (2000) found higher parasitism rates for nests near shrubby edges.

Isolation Effects

The array of suitable and unsuitable habitats within a landscape can affect the use of individual patches and the reproductive success of birds in those patches. Effects of fragmentation may not occur until the amount of habitat in a landscape is reduced to 10 to 30% of the original (Andr n, 1994), but less vagile species that require larger territories are likely to exhibit a response earlier. Landscape effects have been demonstrated most clearly in forest systems (Donovan et al., 1997; Freemark and Collins, 1992); evidence in grasslands is ambiguous (Winter, unpub. data).

These examples clearly show that landscape features can markedly influence the well-being of grassland birds. We now turn to the question of how grassland bird communities reflect the health of the landscape.

BIRDS AS INDICATORS OF GRASSLAND HEALTH

Concerns about the effects of anthropogenic changes to various ecosystems have encouraged scientists to develop measures to assess biotic integrity over large geographic areas (reviewed by Browder et al., submitted). Such measures were initially proposed for fish assemblages in streams (Karr, 1981, 1991; Karr et al., 1986), and have been developed for birds (Bradford et al., 1998; Canterbury et al., 2000), other vertebrates, and invertebrates. None had been developed for grassland birds until recently.

Browder et al. (submitted) proposed the following measure of grassland integrity (GI):

$$GI = \%Grassland - \%cropland - \%woodland - \%odd\ area$$

This measure is intended to apply at scales ranging from about 1 ha to several square kilometers which encompasses the typical territory areas of grassland birds.

The cover types included in the measure were chosen because of their structure, functions, and influences in grassland ecosystems. Grassland obviously provides habitat structurally most similar to an intact grassland ecosystem. Cropland, woodland, and odd areas (e.g., farmsteads and rock piles) were considered detractors to grassland integrity because they represent effects of anthropogenic changes to the original structure of a grassland ecosystem and have the potential to exert the most negative influence on grassland birds. We summarized these effects for woodland, showing that nearby woody vegetation reduces the value of grassland to breeding birds. Habitats in the odd area category are likely to function similarly, because they may harbor predators and competitors, or offer perch sites for brood parasites. Cropland, with its frequent and intensive agricultural activities, may preclude successful nesting, and pesticide and herbicide applications might affect adjacent habitats.

Browder et al. (submitted) developed four regression models to predict the GI measure described above from either the presence and absence or the abundance of particular bird species. The models were developed for the prairie pothole region of North Dakota. Species presence and absence and abundance data were obtained from roadside surveys encompassing 889 points in 44 study plots in 1995 and 1996. The plots were 4050-ha hexagons, systematically distributed across North Dakota, east and north of the Missouri River, following the sampling scheme designed for the Environmental Monitoring and Assessment Program (U.S. Environmental Protection Agency, 1993).

Browder et al. (submitted) identified cover types using digital aerial photography and quantified them with geographic information systems. Each area of homogeneous habitat was assigned to one of the following classes: cropland, grassland, patch (field borders, rights-of-way, etc.), wetland, woodland, barren land (road surfaces, buildings, etc.), or odd area (farmsteads, rock piles, and other small areas that did not fit any other category). See Browder (1998) for further details about the classification. Areas of patch, wetland, and barren land were not included in the measure of GI because they were expected to exert fairly neutral influences. Two scales were used; one included all habitats within 200 m of the point from which birds were counted, and the other included all habitats within 400 m of that point.

Bird species selected for analysis included grassland species and other species that occurred commonly. Browder et al. (submitted) constructed preliminary models with data from 1 of the 2 years, and then tested the predictive ability of the models by cross-validation with data from the other year. Cross-validation tests indicated that the index consistently predicted GI. The four final

models developed involved 11 species that were statistically significant ($p \leq 0.05$) in all preliminary models. Species that had positive coefficients in all models were:

1. Chestnut-collared longspur
2. Baird's sparrow
3. Grasshopper sparrow
4. Western meadowlark
5. Sedge wren
6. Savannah sparrow
7. Clay-colored sparrow (*Spizella pallida*)
8. American coot (*Fulica americana*)
9. American bittern (*Botaurus lentiginosus*)

The first seven are recognized grassland-dependent species (e.g., Johnson and Igl, 1998). The final two are wetland-obligate species. Thus, these nine species are reasonable indicators of relatively intact grassland-wetland ecosystems.

Two species entered in the models with negative coefficients were the vesper sparrow and horned lark (*Eremophila alpestris*). Both species favor bare ground (e.g., Owens and Myres, 1973) such as cropland provides, and indicate the presence of cultivated areas as opposed to intact sod.

Accordingly, Browder et al. (submitted) concluded that the presence of several grassland- and wetland-obligate bird species, combined with the absence of those species associated with cropland, correlates well with their proposed GI measure. Although the development of those indices was labor-intensive, the indices themselves can be applied relatively inexpensively to monitor grassland integrity over a large geographic area. That fortunate situation is due to the annual collection of bird information through the BBS (Robbins et al., 1986). The BBS program includes data collected annually since 1966 on numerous roadside routes (2812 in 1999) in North America. Although the density of routes varies geographically, at least one route occurs within each 1° block of latitude and longitude across the U.S. and southern Canada. Hence, indices could be applied to a specified region using only data that are collected operationally under the BBS program.

SUMMARY

Remote sensing offers opportunities to measure landscape features associated with grasslands (and wetlands), such as size of the habitat patch, amount of edge, extent of bordering by woody vegetation, and isolation from similar habitats. These features have been shown to influence the use of grassland habitats by breeding birds and the reproductive success of those birds. In turn, results of an ongoing operational program, the BBS, can provide a useful measure of the integrity of the grassland-wetland ecosystem in the northern Great Plains. These two sets of relationships offer complementary views of the connections between a landscape and some of its biotic resources. Indices such as those proposed here, in combination with BBS data, could be enlisted to provide a valuable assessment of the health of landscapes, with respect to breeding birds, over large areas and through time. Conversely, remotely sensed data can be applied to determine the potential of grassland habitats in a landscape to support viable populations of breeding birds.

ACKNOWLEDGMENTS

We are grateful to Robert R. Cox, Jr. and Diane L. Larson for comments on this chapter and to our colleagues who have contributed to our understanding of the issues discussed here.

An Ecosystem Approach to Human Health

Lada V. Kochtcheeva and Ashbindu Singh

INTRODUCTION

The health and well-being of humans are intricately linked to the natural environment, which provides both sustenance and hazards. Not all risks and threats to the health of the population arising from the degradation of the environment are the result of human activities. Many of the hazards are an intrinsic part of ecosystems themselves. The challenge lies in maintaining people's health while simultaneously improving the health of the ecosystem as a whole.

The ecosystem health approach may be defined as a comprehensive approach to the diagnostic, preemptive, and predictive aspects of ecosystem management, and to the understanding of relationships between ecosystem health and human health. It seeks to understand and optimize the intrinsic capacity of an ecosystem for self-renewal while meeting reasonable human goals. This approach encompasses the role of societal values in shaping our conception of health at human and ecosystem levels.

Health problems resulting from ecosystem degradation vary dramatically from region to region, reflecting geography, climate, and a region's level of economic growth and policy preferences (World Resources Institute, 1998). The total impact of the transformed environment causes considerable harm to natural life-support systems and a threat to the sustainability of human health (Rapport et al., 1998).

Human health problems connected to environmental causes can be understood as coming from (1) lack of development, defined as inability to cope with natural hazards and/or lack of access to essential environmental resources, and (2) unsustainable development, which causes ecosystem degradation (World Resources Institute, 1998). Environmental changes, societal advance, as well as characterization of both biological and chemical environmental hazards are, thus, critical items to be analyzed.

The goal of this study is to establish whether there are strong and direct links between degradation of ecosystems and human health. Therefore, the main objectives are (1) to conceptualize issues of human health and ecosystem health, (2) to review key emerging and reemerging threats to human health on global, regional, and local levels due to ecosystem degradation, and (3) to explore causal links between ecosystem degradation and human health.

METHODOLOGICAL APPROACH

The basic methodology used in this research is a literature search and a critical analysis of the impacts of the transformed ecosystem on the health of population. Environmental conditions that

foster the transmission or spread of diseases and exposure to harmful chemicals and hazardous physical conditions are reviewed. By compiling examples and grouping them in accordance with specific regional natural conditions and ecological characteristics, this chapter intends to establish a basis for a global data collection, as well as to communicate the importance of the interrelationships between human health and the state of the ecosystem.

ISSUES RELATED TO ENVIRONMENTAL CHANGE AND HUMAN HEALTH: DEFINING THE PROBLEM

The World Health Organization (WHO) characterizes health as “a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity” (Purdum, 1980). Major trends of human health in the world today include the following (World Health Organization, 1996):

- Increase in life expectancy
- Decline in infant and child mortality in most developing countries
- Reduction in incidence of certain vaccine-preventable diseases
- Increased incidence of chronic noninfectious diseases and the spread of HIV/AIDS

Still, avoidable illnesses and premature deaths are occurring in large numbers in many regions of the world, and environmental factors contribute to these deaths (National Environmental Health Association, 1998).

Environmental health refers to conditions and characteristics of the environment, which affect the quality of population health. Ecosystem ills are increasingly at the root of suffering within the human community (Rapport et al., 1998). The decline of human health due to the degradation of the ecosystem may be described as an “illness resulting from disrupted internal balances due to external stresses” (Odum, 1995). The consequences of ecosystem collapse include human dimensions such as biological, physical, social, and economic breakdown (Rapport et al., 1998). Discovering original and improved ways to assess ill health and dysfunction in the ecosystem, which represents the basic functional unit of the natural environment, is the emerging goal of the environmental–health interface. Because human activity sometimes results in unpredictable outcomes, a significant element of health is flexibility or adaptability in the face of unexpected transformations and uncertainty.

The status of human health is a reflection of the complex interactions between the internal biological system and external environmental system. However, certain population groups, because of their lifestyle, occupation, location, or consumption patterns, are differentially vulnerable to specific health risks and threats. This, in combination with differential hazard exposure, may put a group at increased risk (Tata Energy Research Institute, 1998). Health effects of one particular change in the environment should be assessed within the context of other coexisting environmental effects and occurrences, such as rapid urbanization, population density, increasing mobility, increasing movement of produce, resources exhaustion, desertification, and pollution.

During the past 20 years, about 30 new diseases (e.g., Legionella, HIV/AIDS, Ebola, Hantavirus pulmonary syndrome, a new strain of cholera, and a host of antibiotic-resistant pathogens) have emerged, possibly as a result of environmental change (Tata Energy Research Institute, 1998). Emerging diseases can be defined as infections that have newly appeared in the population or have existed, but are rapidly increasing in incidence or geographic range. Environmental changes have contributed in one way or another to the appearance of many such diseases. Human activity, resulting in ecosystem degradation, and human behavioral changes also favor the spread of disease (Tata Energy Research Institute, 1998).

GENERAL CONCEPTS OF THE SUSTAINABILITY OF HEALTH IN THE CHANGING ENVIRONMENT

Sustainability of human health is a priority when the concept of global environmental change is applied to health issues. Indices of the sustainability of health status may be focused on the integrity and stability of the global environment’s ecological systems that maintain the life and health of the population. These indices may not directly measure human biology but may assess the degree to which human biophysical needs are being satisfied by the sustainable use of ecosystem services. Possible indicators may include bio-indices predictive of human disease risk, such as vegetation cover and groundwater levels, in relation to infectious disease vectors, or the degree of balance between population size and available resources (McMichael, 1997).

Ecological approach does not necessarily directly link individual exposure to resulting events or to each other, and is subject to multiple confounding variables. In ecological systems everything is connected directly or indirectly to everything else. An approach that takes into consideration medical and individual data demonstrates the causes of illness cases approach, while an approach that takes into account ecological, ecosystemic, and population variables shows the causes of incidence (Ehrenfeld, 1995).

Interdependence between the state of environment and the status of human health is complex and multidisciplinary in nature, and an often wrongly defined issue with uncertain solutions (Schirnding, 1997). Development, environment, and human health concerns require an integrated approach, where development is a major cause of the environmental change; the environment is a mediator; and health, insuring the ability for the development, is an indicator of these changes. The sustainability of human health is a highly important criterion of successful social and economic policy (Figure 64.1).

The key research issue today is an exploration of the fundamental infrastructural significance of the biosphere’s natural systems, as related to human health. Potential threats and risks from global environmental change differ from well-recognized, locally found, and direct-acting harmful agents. Disruption of natural ecological systems endangers the health of the population by both direct and indirect ways, and immediate and delayed mechanisms (McMichael, 1997).

CONCEPT OF THE ECOSYSTEM HEALTH

Health of the Earth’s Ecosystems

An ecosystem is a functioning unit of nature that combines biotic communities and the abiotic environments with which they interact (LaRoe et al., 1995). The three main features characterizing a healthy ecosystem are vigor, resilience, and organization. A healthy ecosystem is a sustainable component of the biosphere that has the ability to maintain its structure (organization) and function (vigor) in time and in the face of external stresses (resilience) (Mageau et al., 1995). Human community benefits from natural healthy ecosystems, which serve as sources of food, shelter, the capacity to assimilate and recycle wastes, and clean air and water. Ecosystem health is determined not only by the biophysical states of its components, but also by societal values. Still, there is difficulty in characterizing a general index, given the colossal qualitative and quantitative differences among ecosystems. For instance, there are ecosystems in which rich biodiversity is a sure sign of health, and others in which it is a sign of disturbance (Ehrenfeld, 1995).

Figure 64.1 Connection between development, environment, and health.

The concept of the ecosystem distress syndrome was introduced by Rapport and Odum (1985). This syndrome includes such ecosystem disturbances as changes in biotic composition and energy flow, loss of biodiversity and nutrient capital and, in general, the loss of the balance among ecosystem components. Acidified lakes, highly polluted coastal marine systems and estuaries, overgrazed grasslands, loss of valuable fisheries, desertification as a result of overgrazing, and invasions of exotic species are examples of ecosystem pathology that influence human population health and may be readily detected, even by the general public, in all countries (Rapport et al., 1998).

Changes in the distribution and ecological activity of organisms, often resulting from environmental modifications, may give early evidence of environment-related shifts in human health risks. In many cases, the appearance of disease is a symptom of ecosystem dysfunction. Disease, therefore, can be considered a first-recognized impact of an environmental stress (World Health Organization, 1996).

Present State of the Environments and Causes of Ecosystem Degradation

One of the significant aspects of human activity is humanity's total impact on ecosystems, in contrast to the particular contributions that arise from specific pollutants. Recognition of this overall effect is necessary to identify the real problem of ecosystem degradation. From a global perspective, the environment has continued to degrade during the past decade (United Nations Environmental Programme, 1997). According to the United Nations Environmental Programme (UNEP) assessment, different regions in the world experience various environmental concerns. Humans have modified approximately 50% of the land surface, account for more than 20% of the atmospheric carbon dioxide concentration, utilize over 50% of the accessible surface fresh water, and are responsible for about 60% of all nitrogen fixation; the list of such impacts continues (Rapport et al., 1998). The total impact of human activity represents a significant danger to functioning of the natural life-support systems, and to the sustainability of population health. This combination of environmental changes that creates the conditions favorable to disease occurrence is of a significant concern.

Human activities are directly responsible for creating agroecosystems and cultural landscapes at the expense of many natural communities and the reduction in ecosystem services. Serious loss of forest quality and old-growth habitat in many temperate and boreal forests, due to pollution and other injurious agents, and tropical deforestation with current rates averaging about 0.7% per year are problems of significant concern. Desertification and drought are problems of a global dimension that affect more than 900 million people in 100 countries, some of them among the least developed in the world. Approximately 25% of the Earth's land area is being affected by land degradation. Desertification is occurring on 30% of irrigated areas, 47% of rain-fed agricultural lands, and 73% of rangelands. Hydrological and ecological functions of over one half of all wetlands have been altered due to encroachment. Global freshwater biodiversity is declining significantly. Today, about one third of the world's population is living under moderate to severe water stress, most notably in Middle Asia and North Africa. Coastal waters are being contaminated by land-based sources, particularly by municipal wastes, that cause eutrophication. Many fishery resources are classified as overexploited. Stratospheric ozone has decreased since 1979 by about 5.4% at northern midlatitudes in winter and spring, and about 2.8% in summer and fall. The spatial and temporal patterns of precipitation are changing (Watson et al., 1998). These diverse changes are beginning to have adverse consequences for the human population.

There are some fundamental mechanisms and forms of ecosystem degradation that affect human health. According to Karr (1997), there are three major, multidimensional mechanisms of environmental and human systems alteration:

1. Indirect depletion of ecological systems (soil degradation, water supplies degradation, biogeochemical cycle alterations, climate changes, ozone layer depletion, and water, air, and soil pollution)
2. Direct depletion of nonhuman living systems (loss of biodiversity, renewable resources exhaustion, pest outbreaks, spread of alien species)
3. Direct depletion of human systems (epidemics, emerging and reemerging diseases, reduced quality of life, failure to thrive in infants and children)

Environmental changes and ecosystem degradation in particular are the result of many different occurrences in natural and human-made systems. Basic causes of the ecosystem degradation can be divided into two major categories: natural and human induced. Natural induced changes in ecosystems include, but are not limited to:

1. Changes in climate (e.g., ocean functioning, cosmic radiation). According to the Intergovernmental Panel on Climate Change (IPCC), the mean surface temperature of the Earth may increase by approximately 1 to 3.5°C in the next hundred years. Sea level rise due to the climate change may lead to increased erosion in coastal zones and loss of natural protective features, such as dunes and mangroves. Potential health impacts are considered to be cumulative and interact synergistically (World Health Organization, 1996). Changes in climatic conditions would enable mosquitoes and other disease-carrying insects to survive and breed at more northern latitudes and higher altitudes. The distribution of species in an ecosystem may vary due to such changes.
2. Natural disasters (e.g., floods, cyclones, droughts, volcanic eruptions, and earthquakes). Natural disasters may have devastating consequences on both natural and human-managed ecosystems. Severe rains and flooding may cause inundation of a floodplain and lowlands, as well as impair top soil layers and wash out nutrients and microelements. Volcanic eruptions can lead to a collapse of an ecosystem by polluting the air and covering the land surface with lava and ash, destroying vegetative cover. Earthquakes may lead to land degradation and droughts may lead to the loss of biodiversity and species migration.

Human-made causes of changes in ecosystems include, but may be not limited to:

1. Development and intensification of agriculture (World Resources Institute, 1998). The direct result of agricultural practices is the conversion of forest and grassland ecosystem into agroecosystems, which are poorer in biodiversity and consequently less stable and resistant to other interventions. Other effects include soil and water contamination with chemicals and pesticides, land degradation, and salinization.
2. Industrialization, increasing energy use, and urbanization (World Resources Institute, 1998). Industrial development and rising energy use lead to direct changes in, and very often destroys, the ecosystem by simply occupying the space and converting natural environments into industrial sites and urban areas. The results of industrialization include habitat fragmentation and loss of biodiversity; alteration and destruction of vegetative cover; removal and disproportional distribution of species; air, water (fish kills and eutrophication), and soil degradation; pollution; and contribution to the climate change (greenhouse gases). Stratospheric ozone depletion is also considered to be the result of industrial development (World Resources Institute, 1998).
3. Other activities (e.g., construction, forestry, hunting, fishing, recreation). Such activities may lead to the loss of biodiversity, habitat fragmentation, river and stream regime alteration, resource extraction, vegetative cover destruction, disproportional distribution of species, and pollution of the environment.

IMPACTS OF THE ECOSYSTEM DEGRADATION ON HUMAN HEALTH

Human health can be a casualty of environmental degradation and change. Ecosystems that are sufficiently stable and biologically diverse tend to maintain the quality of human health.

Degraded or collapsed ecosystems, both aquatic and terrestrial environments, have a significant impact on human health.

Degradation of Aquatic Ecosystems and Human Health

Water pollution continues to degrade freshwater and marine ecosystems, which in turn causes millions of preventable deaths every year, especially among children (United Nations Environmental Programme, 1998). Water affects disease in many ways, (e.g., drinking contaminated water, contact with aquatic invertebrates, lack of water, infection through vectors). Illness due to consumption of contaminated fish and shellfish is an increasing concern. Harmful algal blooms in coastal regions cause poisoning, neurological disorders, gastroenteritis, and other diseases (United Nations Environmental Programme, 1998; HEED, 1999). Eutrophication, a process of water quality degradation caused by excessive nutrient loads, is depriving lakeside residents of good water quality in many densely populated areas of the world (United Nations Environmental Programme, 1994).

Aquatic ecosystems such as ponds and wells, which are affected by climate change, provide breeding grounds for certain parasites and disease vectors. Changes in water flow in these systems could influence the incidence of a number of diseases. Increased flooding, following changes in precipitation, may cause contamination of water supplies, which leads to greater incidence of fecal-oral contamination (World Health Organization, 1996). Natural networks of rivers, lakes, and marshes play a role in the transmission of water-related and vector-borne diseases as well. Table 64.1 demonstrates categorization of water-related diseases.

Table 64.1 Categorization of Water-Related Diseases

Category	Examples
Diseases carried by water or waterborne infections (microbial and chemical)	Typhoid; cholera; fluorosis; infectious hepatitis; leptospirosis; amebiasis
Diseases related to poor sanitation, lack of water, or water-washed infections	Scabies; trachoma; bacillary dysentery; skin and eye infections; diarrheal diseases; bacillary dysentery
Water-based diseases or infections (penetrating skin; ingested)	Schistosomiasis; guinea worm; echinococcosis
Insect vectors-related diseases (vector bite; breeding in water)	Sleeping sickness; yellow fever; malaria; trypanosomiasis

Source: Adapted from Tata Energy Research Institute (1998) and Wolman (1986).

Degradation of Terrestrial Ecosystems and Human Health Impacts

Expanding agriculture, forest clearing, mining activity, dam building, irrigation schemes, and poorly planned urban development and activities, which change the structure and functioning of terrestrial as well as aquatic ecosystems, pose a number of health concerns. These concerns include increased exposure to toxic substances (e.g., pesticides) and increased exposure to infectious agents. As a result, mosquitoes would have new breeding grounds, causing more people to come into contact with them (Tata Energy Research Institute, 1998).

Loss of species and ecosystem diversity erodes genetic diversity. In addition, many of the 20,000 plant species used as traditional medicines around the world are under threat of overexploitation (United National Environmental Programme, 1993). The genetic diversity of species is not only one of the keys to successful agriculture, which prevents malnutrition-related health problems, but also a sphere of promise for medical research. According to an article in *The Wall Street Journal*, deforestation and hunting bring people into contact with animals, which can lead to transmission of various diseases, including the simian virus closely related to HIV and found in African chimpanzees (Waldholz, 1999). At the same time, animals' disease-fighting immune mechanisms are able to control the virus. By studying these mechanisms, scientists may obtain important clues about how to prevent and treat the devastating infection in humans.

Ebola hemorrhagic fever also may serve as an example of a possibly animal-borne disease; however, the exact origin, location, and natural habitat of the virus remain unknown (Centers for Disease Control and Prevention, 1999). An association between forest fragmentation and Ebola cases is still unclear.

Where forest cover is interrupted, nutrients are released into the hydrological cycle. A net nutrient outflow pollutes local river systems and greatly reduces the productive capacity of the cleared land (World Conservation Monitoring Center, 1992). According to the National Institute of Environmental Health Sciences (NIEHS), deforestation changes natural habitats and creates several human health concerns, such as an increase in infectious diseases and depression. Reports from Southeast Asia say that deliberately set fires have increased pollutants in the air, causing respiratory problems and contributing to global climate change. Forest fires have profound impacts on the physical environment including: land cover, biodiversity, and climate change and forest ecosystems. Health impacts are often serious. Estimates suggest that 20 million people are in danger of respiratory problems from fires in southeast Asia. Large fires also occurred in the Caribbean region, Africa, and in some parts of the former Soviet Union (Levine et al., 1999). Deforestation may continue at high rates until more of us see the value of forests for biodiversity, potential medicines, improved environmental quality, and climate mitigation (National Institute of Environmental Health Sciences, 1999).

Consequences of Climate Change in Human Health

Almost all scientists who study climatic dynamics accept the notion that the increase in, and spread of, many diseases is likely to be the single most dangerous threat that climate change poses to human health (Kingsnorth, 1999).

Temperature and weather changes may have direct and indirect health outcomes. Exposure to thermal extremes and altered frequency of weather events may result in altered rates of heat- and cold-related illnesses, psychological disorders, and death. Results indirectly attributable to the effects on range and activity of vectors, altered food productivity, sea level rise, impacts of air pollution and others may include changed incidence of diarrheal and vector-borne diseases, malnutrition, impairment of child growth and development, asthma, allergic and respiratory disorders, and deaths (World Health Organization, 1996).

Global climate changes may create favorable conditions for disease-carrying insects to proliferate at more northern latitudes and higher altitudes. Malaria, dengue, yellow fever, and some other types of viral encephalitis are likely to increase. According to the World Health Organization (1996), approximately one half of the world population is at risk for insect-borne diseases (Tata Energy Research Institute, 1998). Malaria is an important example because it at present accounts for approximately 350 million cases annually, including about 2 million deaths (McMichael, 1997). The combination of climatic factors contributed to appearances of several rodent-borne diseases, such as leptospirosis and viral hemorrhagic fevers (Epstein, 1997). The impacts of extreme weather events on human health may include death, injuries, stress-related disorders, and other adverse health effects that are associated with social disruption and forced migration. Increased frequency of extreme weather events may also result in increased incidences of infectious diseases, mainly due to poor sanitation and lack of clean, fresh water. For instance, floods often cause increases in incidence of diseases associated with fecal-oral transmission (World Health Organization, 1996).

Significant stratospheric ozone losses have occurred, mainly at middle and high latitudes. Ozone depletion is more pronounced in winter and spring than in summer. An increase in ultraviolet exposure may increase the incidence of skin cancers, the severity of sunburn, skin aging, and eye diseases (e.g., cataracts). The negative effects of ozone layer depletion may also include some suppression of immune functioning, increasing the susceptibility to infectious diseases (McMichael, 1997).

Consequences of Ecosystem Degradation and Human Health at Regional and Local Levels

The extent of environmental threats to human health is distributed unevenly between developed and developing countries. The effects of a degraded ecosystem or transformed environment are exacerbated by inadequate sanitation and nutrition, cultural peculiarities, and demographic features. In areas where environmental threats coincide with poor social and economic conditions, risks and threats to population health increase. In general, countries in Africa and parts of Asia face the highest health threats from the degradation and collapse of the ecosystem.

Table 64.2 demonstrates basic information on the linkage between ecosystems, impact on human health, regional and local examples, and consequences and possible occurrences of the threat and risk to human health.

LINKING DEGRADATION OF THE ECOSYSTEM AND HUMAN HEALTH

The Quality and Quantity of Information

An analysis of the literature on environmental health shows that there are many attempts to find a link between human health and the changing environmental conditions. One of the first and most significant contributions was made by the legacy of Rachel Carson's *Silent Spring*. This book brought a new awareness to the public that nature was vulnerable to human intervention. The threats to human health that Carson had outlined — contamination of the food chain, cancer, and genetic damage — appeared to be too important to ignore.

An important contribution to the literature on environmental health was made by a joint publication of the World Resources Institute (WRI), the UNEP, the United Nations Development Programme (UNDP), and the World Bank (World Resources Institute, 1998). This report clearly explains the multiple causes of environmental change and demonstrated humans' dependence on the natural environment, taking into consideration social, economic, and cultural variables. A number of UNEP reports and publications addressing the environmental health issues provide an excellent source of information on ecosystem degradation due to unsustainable development, emphasizing the importance of maintaining the health of the ecosystem in order to sustain and improve the status of human health (United Nations Environmental Programme, 1993, 1994, 1997).

Research articles and reports on different tropical emerging and reemerging diseases, such as the Rift Valley fever in Kenya, attempt to link the changes between the environment and health, showing the naturally occurring causes of the disease, such as seasonal climate conditions changes (Linthicum et al., 1999).

Many of the parameters associated with environmental change and patterns of disease can be sensed remotely by instruments onboard aircraft and satellites, and modeled spatially with specialized computer software. Remote sensing and geographic information system (GIS) technologies can be used to describe local- and landscape-level features that influence the patterns and prevalence of disease and then model their occurrence in space and time (CHAART, 1999). However, the capabilities of remote sensing technology have not been disseminated to the health investigators and agencies that could be using them. It goes without saying that surveillance, modeling, and early warnings are the main goals of a human health system. However, the research needed to create such a system has not been completely done. Good surveillance means that the factors, such as weather and vegetative cover, places, and other geospatial data to be monitored are well known and identified. In addition, methods of relating these components to demographic information to determine the population risk has to be established. The simplistic logic connecting weather patterns, vegetation, and disease incidence usually lack scientific rigor (Guptill, 1998).

Table 64.2 Ecosystem Degradation and Human Health Consequences at Regional and Local Levels

Ecosystem	Driving Forces and Changing Ecological Patterns	Influence on Human Health and Additional Possible Consequences	Regional and Local Examples
Atmospheric	<p><i>Climate Change</i> Extremes in temperature (excessive heat) increased rainfall; frequency and severity of droughts; changes in temperature and humidity; extension of drought areas; deficiency in micronutrients; variations in temperature, precipitation, and humidity</p>	<p>Malaria; meningococcal disease epidemics; starvation; malnutrition-related diseases; dengue; arboviral infections; excess in the rate of heat-related deaths in summer; physiological disturbance; Hantavirus; respiratory diseases are the fourth leading cause of death Further global mean temperature increase may create ecological conditions conducive to malaria in 60% of the world's land area, compared with current 45%; similar outcomes are possible with schistosomiasis; health consequences may include diseases from a breakdown in sanitation</p>	<p>Rwanda; Ethiopia; East African highlands; Madagascar; Benin; Burkina Faso; Chad; Mali; Niger; Nigeria; Northeast Africa; Australia; Oceania; China; U.S.; Mexico; Argentina</p>
<i>Pollution</i>	<p>Pollution from power plants, metallurgy, the coal industry, the chemical industry, and vehicular emissions; burning of bio- and fossil fuels</p>	<p>Respiratory diseases; eye irritation</p>	<p>A large number of developing and developed countries</p>
Aquatic Marine	<p><i>Biological Contamination, Pollution</i> Oil contamination; water contamination with wastewater; further deterioration of marine ecosystems from a severe imbalance due to severe navigation; sewage discharges; harmful (toxic and nontoxic) algal blooms from the rapid reproduction and localized dominance of phytoplankton; shellfish poisoning; wildlife mortalities; sunlight penetration prevention; oxygen shortages; reservoirs for bacteria</p>	<p>Gastroenteritis; eye and skin infections; decrease in life expectancy; typhoid; malaria; diphtheria; poisonings; diarrhea; dehydration; headaches; confusion; dizziness; memory loss; weakness; gastroenteritis; bacterial infections; swimming-related illnesses; neurological diseases; death; cholera</p>	<p>South Africa; Black and Azov Seas; Caspian Sea; former Soviet Union; United Kingdom; France; Southern and Gulf States; a large number of countries in Latin America</p>
Fresh	<p>Pollution; dam construction; degradation; hydrogeological cycle changes; inundating of lands; contaminated river systems; fecal water pollution; fallen water tables; chemical contamination</p>	<p>Epidemic of schistosomiasis; infection rates in the Diama region went from zero before the dams to more than 90% of the population; fecal infections; intestinal diseases; progressive and irreversible kidney damage; diarrhea; hepatitis; cholera outbreaks; infectious diseases; intestinal parasites</p>	<p>Africa (Senegal River, Manantali and Diama Dams, South Africa) Central Asia; former Soviet Union; Bangladesh; India; Palestine; Israel; China</p>

(continued)

Table 64.2 (continued) Ecosystem Degradation and Human Health Consequences at Regional and Local Levels

Ecosystem	Driving Forces and Changing Ecological Patterns	Influence on Human Health and Additional Possible Consequences	Regional and Local Examples
Terrestrial Vegetation	<p><i>Deforestation, Natural Disaster, Intensified Agriculture</i></p> <p>Soil destabilization; clearing and intervening in the forests; changes in local hydrological cycles; firewood shortage; land degradation; forest and rangeland fires due to high temperature, strong winds, and low soil moisture content; new breeding grounds for insects; agroecosystem development (inundating of lands due to rice growing); conversion of forest into cotton and sugar-cane culture and cattle pasture</p> <p><i>Changed Agricultural Patterns, Desertification, Soil Contamination</i></p> <p>Destruction of the agricultural ecosystem; increased availability of breeding sites for insects; fertilizers and organic manure contamination; transformation of agricultural ecosystems; increase in nitrate level leading to the high levels of nutrients in rivers; mining activities leading to land degradation; soil qualities impairment; contamination with pesticides</p>	<p>Malaria; trauma; allergic reactions; aches; cuts; infections; respiratory diseases; cancer; yellow fever; Ebola epidemics; burns; smoke inhalation; hemorrhagic fever; displacement of population</p>	<p>South Africa, Kenya, Cote d'Ivoire, and some other African countries; Nepal; China; India; Australia; U.S.; Peru; Bolivia; Brazil; Honduras; Central America; Venezuela</p>
Land degradation	<p>Destruction of the agricultural ecosystem; increased availability of breeding sites for insects; fertilizers and organic manure contamination; transformation of agricultural ecosystems; increase in nitrate level leading to the high levels of nutrients in rivers; mining activities leading to land degradation; soil qualities impairment; contamination with pesticides</p>	<p>Malaria; human African trypanosomiasis (sleeping sickness); rising incidence of cancer; birth defects; Lyme disease, lung diseases; possibility of carcinogenesis; infections of respiratory and digestive tracts; population migration; immune suppression</p>	<p>East African highlands and Madagascar; Siberian and Arctic regions; Western Europe; USA; Former Soviet Union; some countries in Latin America</p>

Data from Chen et al. (1997), HEED (1999), Homer-Dixon and Percival (1996), National Institute of Environmental Health Sciences (1999), PAHO (1999), Tata Energy Research Institute (1998), World Health Organization (1996), World Resources Institute (1998).

For most of the potential impacts of the ecosystem degradation on human health, information upon which to build a standard health risk assessment seems to remain inadequate. Most research articles, books, and reports that attempt to connect the deterioration of environment and its impact on human health focus mainly on the social, economic, and demographic consequences of such interactions, rather than on an ecosystem approach. Another problem in connecting human diseases and ecosystem degradation is that these links are not clearly explored. Ecological and medical issues are discussed quite separately, with an emphasis on either, but no connection between the issues.

Reviewed literature shows that there is a continued trend in environmental health publications to connect physical degradation of the Earth with the quality of human health. However, links are generally established through social, economic, and legal spheres (e.g., infirmities in health care, pollution abatement measures, poor sanitation). Declining levels of the world food output is contributing to a reversal in economic progress in many countries, and chemical contamination of agricultural products is often a concern. In addition, many conclusions are built on the inference that the ties between environmental abuse and the population health remain inevitably more presumptive than proven (Feshbach and Friendly, 1992).

Air and water pollution and climate change remain the main spheres, from which the discussion of the human health problems in connection to the ecosystem degradation starts and develops. Moreover, in researching environmental causes of human health, scientists tend to consider the impact of separate substances instead of an aggregate effect.

Many sources provide numerical data on the levels of pollution, health status examples, or medical statistical data, but these sources leave readers with the opportunity to make their own conclusions. Moreover, traditional environmental health risk assessment is based on (1) identifying a discrete health threat, (2) characterizing the resulting health risk, (3) evaluating possible human exposure, and (4) concluding by estimating likely disease outcomes. Such approaches seem to be inappropriate if the health risk is connected to an ecological entity or ecosystem phenomenon, including weather events, quality and quantity of water resources, and vegetative cover (World Health Organization, 1996).

The very concept of an ecosystem is rather broad, taking into account the fact that an ecosystem is a functioning unit of the environment, and can be represented by both a small lake and a watershed. Some sources tend to consider separate parts of the ecosystems. A total reflection of the environmental impact on humans should also consider psychological and mental influences and hazards, even though their precise effects, the magnitude of their influence, or the epidemiology of mental illnesses are not well known (Purdom, 1980).

Environmental health studies do not analyze those causes of ill health that might be attributed to combinations of environmental factors interacting with one another and that are themselves components of complex systems affected by human interventions. Empirical sciences experience difficulties in dealing with the uncertainties arising from such complex systems and the predictive modeling of them. Adequate consideration of the health impacts of ecosystem degradation on human society, and of societal efforts to mitigate or adapt to such change, necessitates multidisciplinary research that draws heavily on the environmental health sciences, epidemiology, anthropology, social psychology, and disciplines (World Health Organization, 1996).

Dealing with the Problem

According to McMichael (1997), better understanding, assessment, and dealing with the problem of the environmental impact on human health requires that three major fundamentals should be accomplished.

1. Practical research into the health impacts of environmental modifications (e.g., dose–response, cause–effect relationships investigations, epidemiological studies, database creation)
2. Environmental modeling for the prediction of the population health outcomes
3. Prediction, forecasting, and estimating of possible future scenarios (e.g., climate change and its influence on human health, geographic range of vector insects)

Public health programs can help to anticipate the health impacts of ecosystem degradation and collapse. Surveillance systems could be improved or installed in sensitive geographic areas. Intersectoral collaboration should be strengthened so that public health considerations are incorporated into the development process through environmental management techniques.

It is worth mentioning that there is no lack of warnings, pronouncements, and declarations on the issue of the human health in connection to the degraded ecosystem from scientists, politicians, humanists, business society, and interested agencies (Rapport et al., 1998). Reports, publications, Internet sources, research articles, and books from UNEP, WRI, the WHO, and other organizations provide the necessary material on the subject of environmental health. The problem is how this information is presented, where the emphasis is placed, and how and to whom the information is disseminated and then used. A proper understanding of the threats from the degraded ecosystem to human health is necessary. Strengthening of collaborative agreements among agencies may help to enhance scientific quality and extend data resources (U.S. Department of Health and Human Services, 1984). Therefore, government agencies that are responsible for health assessment, policy making, regulations, and health quality assurance require an ongoing production, collection, and analysis of information about the impacts of the changed ecosystems on population health (PAHO, 1999).

CONCLUSION

A basic obstacle to the assessment of the human health status, ecosystem health, and the establishment of direct links between ecosystem degradation and human disease lies in coping with the absence of direct, strong, connective mechanisms and scientific uncertainty. For instance, the recognition of the fact that ozone layer depletion, loss of biodiversity, or pesticide accumulation affects human health is based on our understanding that it is the energy or food chain that is affected, often through indirect pathways. Intermediaries connect the change in the ecosystem and human health (Figure 64.2). For example, such environmental changes as climate change, land degradation, pesticide and fertilizer use, and aquifer depletion seriously affect agricultural production. Agricultural production is a major determinant of nutritional status and population health. Hence, human health is affected via processing or consumption of agricultural production and not directly by land degradation or aquifer depletion.

However, there are some environmental changes that directly impact the quality of human health. They include temperature increase, which causes thermal stresses or respiratory problems, and the deterioration of aquatic ecosystems that can subsequently lead to waterborne diseases, while, in general, most of the health impacts of the ecosystem degradation would be mediated by changes in other systems and processes, such as the proliferation of bacteria, distribution of vector organisms, or quality and availability of water supplies. In view of the above, it seems that the problems are relatively well understood. Significant benefits could be achieved if concerns about environmental threats to health are incorporated into development planning at the onset. Changes in health conditions are posing a demand for knowledge and are calling for new solutions in implementation of environmental health policies.

Predictability of Bird Community-Based Ecological Integrity Using Landscape Measurements

Glen D. Johnson, Wayne L. Myers, Ganapati P. Patil, Timothy J. O'Connell,
and Robert P. Brooks

INTRODUCTION

Assessing the ecological condition of large geographic areas is difficult at best. Nothing can replace on-the-ground intensive sampling or surveying by experienced field personnel; however, this is obviously not feasible for areas that are much larger than a site, such as at landscape and regional scales. Remotely sensed data such as land cover maps derived from satellite imagery can provide valuable covariate information. Essentially, local detail is exchanged for spatially synoptic coverage.

The challenge then becomes one of how to analyze remotely sensed data in a way that reflects ecological condition. Many different landscape measurements are available (McGarigal and Marks, 1995) and prior research has been directed toward finding sets of variables that are suitable for distinguishing among different landscape types (Riitters et al., 1995). Meanwhile, Johnson et al. (2001) have assessed the ability to categorize watershed-delineated landscapes in Pennsylvania with respect to landscape patterns.

As part of their study, several conventional landscape measurements were evaluated, along with a new multiresolution characterization of pattern, coined a conditional entropy profile. When applied to actual watershed-delineated landscapes in Pennsylvania, these profiles revealed a valuable graphical tool for presenting a multiscale characterization of landscape fragmentation in a way that is sensitive to pattern changes. Using spatial pattern measurements and land cover proportions, landscapes could be generally categorized according to degree and type of forest fragmentation; however, a more direct characterization of ecological condition was needed for evaluating the performance of these landscape measurements. For this reason, this chapter serves to provide an independent categorization of these watershed-delineated landscapes in Pennsylvania using only bird community data for deciphering categories of ecological integrity.

The ecological data source is a breeding bird atlas (Brauning and Gill, 1983–1989) that is the result of a 5-year field survey performed by trained volunteers. The presence of breeding evidence was recorded for bird species in each of approximately 5000 blocks covering the entire state. Each block is one sixth of a U.S. Geological Survey (USGS) 7.5-min quadrangle. Encountered species were assigned one of four different levels of strength of evidence for breeding. Of these, the three strongest levels were included for this current study: *possible*, *probable*, and *confirmed*. Any species

Figure 65.1 Breeding bird atlas blocks (small squares) superimposed on watershed boundaries (large, irregular polygons) in Pennsylvania. An example is shown of how blocks are selected to represent a watershed according to whether the center of a block lies within the watershed.

listed under one of these evidence categories was treated as *present*. Atlas blocks were assigned to respective watersheds by choosing those blocks whose centers were within the watershed boundary, as depicted in Figure 65.1.

Given a set of atlas blocks for each watershed, where each block contains a species list, the objective is to summarize these data in a way that rationally assesses ecological condition for the watershed as a whole. Simple measurements of species richness and diversity are not sensitive to changes in community composition, and yield little ecological information. This is especially true for geographic areas that are the size of these watersheds. However, if a species list is converted to response guilds that represent structural, compositional, and functional components of an ecosystem, then the guild composition may be used to assess ecological condition (Brooks et al., 1998). What follows are approaches to working with guilding schemes that aim to provide a meaningful ecological assessment for each watershed.

ECOLOGICAL INTEGRITY BASED ON A SONGBIRD COMMUNITY INDEX FROM THE MIDDLE ATLANTIC HIGHLANDS ASSESSMENT AREA

Background

A landscape-level indicator of ecological condition was developed by O'Connell, Jackson, and Brooks (1998a,b) for the Middle Atlantic Highlands Assessment (MAHA) area depicted in Figure 65.2. This indicator is based on the breeding songbird community composition, as obtained through representative field sampling. Their motivation was to characterize ecological condition in the same manner as an Index of Biotic Integrity (Karr, 1991; 1993; Bradford et al., 1998). Here,

Figure 65.2 The Middle Atlantic Highlands Assessment Area, shaded in gray, within Region 3 of the U.S. EPA.

a bird community that reflects high integrity would be dominated by guilds that depend on native system attributes. The indicator incorporates aspects of ecosystem structure (e.g., vegetation), function (e.g., energy flow), and composition (e.g., demographics). The native vegetation matrix for Pennsylvania on a landscape scale is temperate forest. Therefore, specialist guilds, such as obligate tree-canopy nesters, indicate high integrity, while generalist guilds, such as shrub nesters indicate low integrity.

O'Connell, Jackson, and Brooks (1998a,b) initially evaluated their approach using 34 reference sites. First, these sites were grouped into high, medium, and low integrity categories based on the bird community index (BCI). This grouping was then compared to an *a priori* classification of the same sites as pristine, moderate, and disturbed. The independent *a priori* classification incorporated factors, such as sediment deposition, soil properties, plant and amphibian community, a wildlife community habitat profile, and general landscape context. Upon observing satisfactory correspondence between the two independent ranking approaches, a blocked random sample of 126 sites was taken throughout the MAHA area, based on the national Environmental Monitoring and Assessment Program (EMAP) sampling grid (Overton, 1990). Field sampling details are found in O'Connell et al. (1998a).

Each site was represented by a list of guilds, where each guild was represented by the proportion of species observed at the site that were in the respective guild. Since a species could belong to several guilds, the list does not necessarily sum to one, as with a multinomial distribution. The sites were all clustered in guild space using the complete linkage squared Euclidean distance protocol. Each of the guilds was then subject to analysis of variance, using cluster membership as factor levels and species proportions as the response. Tukey's simultaneous confidence intervals ($\alpha = 0.05$) were then used to determine the statistically separable clusters of sites with respect to each guild. This was performed iteratively, combining clusters that were not significantly different from each other along the way. If a guild did not yield at least two statistically distinguishable clusters of sites, then the guild was considered noninformative and therefore eliminated. In this manner, 16 guilds were retained, where each guild revealed two to five statistically separable clusters.

A ranking score was then assigned to these clusters for each guild, whereby if a guild were a specialist, the ranks increased as the species proportions increased and if a guild was a generalist, the ranks decreased as the species proportions increased. Therefore, a set of ranks was obtained for each guild, where each rank corresponded to a range of species proportions, and is presented in Table 65.1. Fractional ranks occur from averaging ranks of statistically indistinguishable clusters. In cases where clusters failed to be statistically distinguishable, yet only slightly overlapped, then separate groups may have still been identified. The final ranking scheme reported in Table 65.1 is actually the result of interactive statistical analysis and expert judgment.

Table 65.1 Biotic Integrity Ranks for 16 Songbird Guilds in the Mid-Atlantic Highlands Assessment Area

Guild Type	Guild	Proportion	Rank	
Structural	Forest birds	0.000–0.280	4.5	
		0.281–1.000	2.5	
	Interior forest birds	0.000–0.010	1	
		0.011–0.080	1.5	
		0.081–0.260	3	
		0.261–0.430	4	
		0.431–1.000	5	
	Forest ground-nesters	0	1	
		0.001–0.020	1.5	
		0.021–0.160	3	
		0.161–0.240	4.5	
		0.241–1.000	5	
	Open ground-nesters	0.000–0.020	1	
		0.021–0.110	2.5	
		0.111–1.000	5	
	Shrub-nesters	0.000–0.210	4	
		0.211–0.330	1.5	
		0.331–1.000	1	
	Tree canopy-nesters	0.000–0.280	1.5	
		0.281–0.320	2	
0.321–1.000		4.5		
Functional	Bark-probing insectivores	0.000–0.060	1.5	
		0.061–0.110	3	
		0.111–0.170	4	
		0.171–1.000	5	
	Ground-gleaning insectivores	0.000–0.050	1.5	
		0.051–0.070	2	
		0.071–0.140	4.5	
		0.141–1.000	5	
	Tree canopy insectivores	0.000–0.030	1.5	
		0.031–0.050	2	
		0.051–0.120	3	
		0.121–0.200	4.5	
	Shrub-gleaning insectivores	0.201–1.000	5	
		0.000–0.140	1.5	
		0.141–0.230	2.5	
		0.231–1.000	5	
	Omnivores	0.000–0.290	5	
		0.291–0.410	4	
		0.411–0.480	3	
		0.481–0.580	1	
Compositional	Nest predator/brood parasite	0.581–1.000	2	
		0.000–0.100	5	
		0.101–0.150	3.5	
		0.151–0.180	2	
	Exotic species	0.181–1.000	1	
		0	5	
		0.001–0.020	4.5	
		0.021–0.050	3	
	Residents		0.051–0.110	2
			0.111–1.000	1
			0.000–0.260	5
			0.261–0.390	3.5
			0.391–0.570	2
			0.571–1.000	1

Table 65.1 (continued) Biotic Integrity Ranks for 16 Songbird Guilds in the Mid-Atlantic Highlands Assessment Area

Guild Type	Guild	Proportion	Rank
Temperate migrants		0.000–0.210	4
		0.211–0.300	2
		0.301–1.000	1
Single-brooded		0.000–0.410	1.5
		0.411–0.450	2
		0.451–0.610	3
		0.611–0.730	4
		0.731–1.000	5

Table 65.2 BCI Scores Corresponding to Qualitative Categories of Ecological Integrity

Highest integrity	60.1–77.0
High integrity	52.1–60.0
Medium integrity	40.1–52.0
Low integrity	20.0–40.0

Each site was then assigned a BCI score by summing the ranks assigned to each guild within the respective site. The logic here is that the BCI reflects biotic integrity because the BCI increases as the ratio of specialists to generalists increases. One can also break down the overall BCI into functional, compositional, and structural scores, a valuable feature of this approach (O’Connell et al., 1998a). The five distinct clusters of sites were ranked according to the relative proportions of specialists and generalist guilds at the sites within each cluster. This ranking scheme allowed the placement of five clusters into four distinct categories of BCI scores, labeled as low, medium, high, and highest. The range of site BCI scores that correspond to each category is presented in Table 65.2. More detailed analysis of individual species proportions in each guild allowed separation of the low-integrity group into low-agricultural and low-urban categories.

Application

Using the same songbird species and the final set of 16 guilds as O’Connell et al. (1998a), data were obtained from the breeding bird atlas (Brauning and Gill, 1983–1989) and applied to each watershed according to the protocol presented below. The cutoff values in Table 65.1 were used to assign species proportions within a guild to a ranking score, and the values in Table 65.2 were used to assign BCI values to an integrity category.

Since the results in Tables 65.1 and 65.2 are based on a representative sample for the MAHA area, we only applied our protocol to those Pennsylvania watersheds that intersected the MAHA region. The native system conditions are expected to be similar at the landscape scale throughout the MAHA area because this area lies within the Appalachian Plateaus and Ridge and Valley physiographic provinces and is affected by common climatic regimes. Note that their sampled sites were 79 ha, whereas an atlas block is approximately 2800 ha, and each was sampled under different protocols. Also, some known sampling bias occurs in both the breeding bird atlas (Brauning, 1992) and the study by O’Connell et al. (1998a). These factors may lead to some anomalous results, but it is anticipated that they will be minimal. Nevertheless, we are presented with a valuable spatially synoptic database that we are analyzing in a logical way to extract ecological integrity assessments for whole watersheds.

Protocol

For each of $w = 1, \dots, W$ watersheds, containing $i = 1, \dots, N_w$ breeding bird atlas blocks, let S_{w_i} be the number of species in the i th block and let $S_{w_{ij}}$ be the number of species in the j th guild of the i th block.

For each block, a guild profile is obtained by computing the proportion of overall species in the block that are members of each of $j = 1, \dots, G$ guilds. Therefore, for the i th block, a species proportion is computed for the j th guild by the equation below.

$$P_{ij} = \frac{S_{wij}}{S_{wi}} \quad (65.1)$$

Note that $\sum_{j=1}^G P_{ij} \neq 1$, or if $\sum_{j=1}^G P_{ij} = 1$, it is only by chance.

Each watershed is then represented by a matrix

$$\mathbf{P}_w = \begin{bmatrix} P_{11} & \dots & \dots & \dots & P_{1G} \\ \vdots & \ddots & & & \vdots \\ \vdots & & P_{ij} & & \vdots \\ \vdots & & & \ddots & \vdots \\ P_{N_w1} & \dots & \dots & \dots & P_{N_wG} \end{bmatrix} \quad (65.2)$$

Each P_{ij} value is then converted to a rank score according to Table 65.1, thus resulting in a matrix of ranks, represented as

$$\mathbf{R}_w = \begin{bmatrix} R_{11} & \dots & \dots & \dots & R_{1G} \\ \vdots & \ddots & & & \vdots \\ \vdots & & R_{ij} & & \vdots \\ \vdots & & & \ddots & \vdots \\ R_{N_w1} & \dots & \dots & \dots & R_{N_wG} \end{bmatrix} \quad (65.3)$$

Each row of the \mathbf{R}_w matrix is then summed to yield a BCI for each block (row), whereby the ecological integrity increases with increasing BCI. The resulting BCI value for each block is converted to one of four categories of ecological integrity — low, medium, high, and highest — based on BCI cutoff values in Table 65.2.

Results for all of the Pennsylvania watersheds that are in the MAHA region are presented in Figure 65.3. Each watershed can now be described by the proportion of land (proportion of blocks) that is in each of the four categories of ecological integrity.

Summarizing General Ecological Integrity for Whole Watersheds

The next question is how to summarize the information in Figure 65.3 so that each watershed can be assigned some overall value of general ecological integrity. It seems most informative to characterize each watershed based on the full spatial distribution of ecological integrity; therefore, the following approach was taken.

All of the MAHA watersheds were clustered using the average Euclidean distance clustering protocol, where the response variables were the proportions of land in each of the four integrity categories (low, medium, high, and highest). Average linkage was used for reasons of robustness and consistency. Further, when Manhattan Distance was evaluated, no differences were seen in the resulting clusters. The clustering was done collectively for all the MAHA-region watersheds, as opposed to separate analysis for the physiographic provinces, because the original study that yielded the P_{ij} and BCI cutoffs (O'Connell et al., 1998a) was performed on randomly sampled sites from

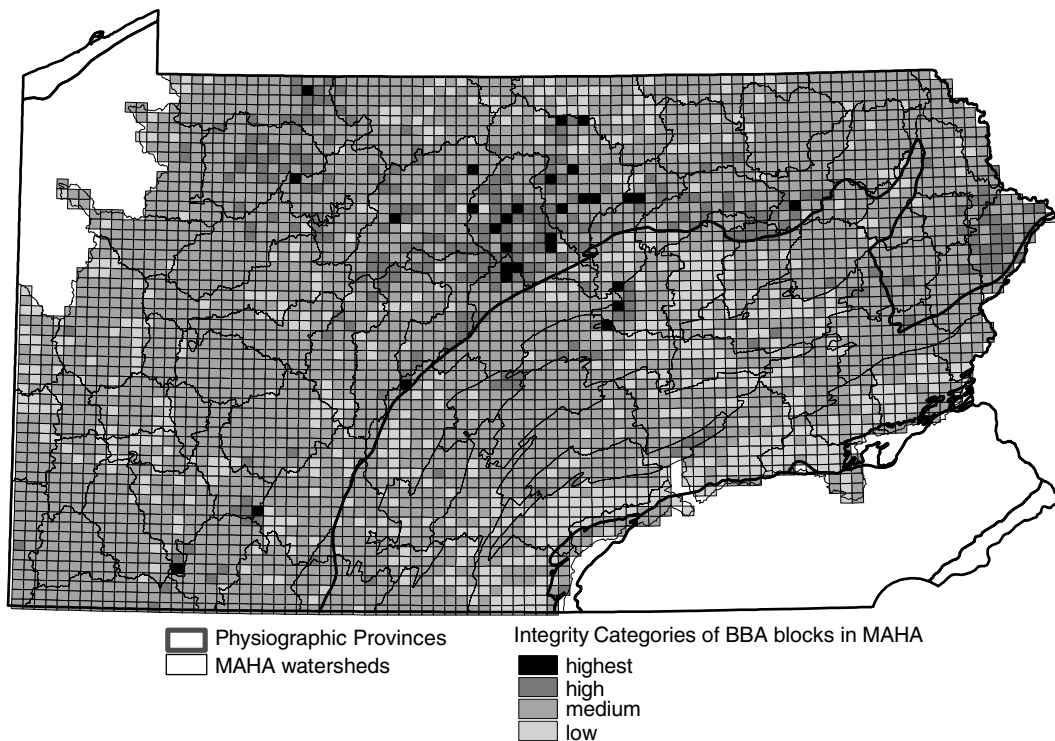

Figure 65.3 Breeding bird atlas blocks coded according to categories of ecological integrity with respect to the songbird community, overlaid with Pennsylvania State Water Plan–based watersheds that are in the MAHA region and the major physiographic provinces of Pennsylvania.

throughout MAHA. The resulting cluster dendrogram is seen in Figure 65.4 and the clustered watersheds are mapped in Figure 65.5. The general category labels for the clusters in Figure 65.4 were based on the distributions of the four integrity categories that are summarized as box plots in Figure 65.6.

All watersheds in cluster 7 have a higher proportion of low-integrity blocks than any watersheds of other clusters. Since cluster 7 also has the lowest distribution of medium- and high-integrity blocks, along with no occurrence of highest-integrity blocks, this cluster is clearly a lowest general integrity group.

At the other extreme, watersheds of clusters 3 and 6 collectively have a higher proportion of high-integrity blocks than any watersheds of other clusters. Since these clusters also yield among the lowest overall proportions of low-integrity blocks, clusters 3 and 6 are clearly in a highest general integrity group.

Cluster 1 is clearly a medium general integrity group, as these watersheds range from having about 85 to 100% medium-integrity blocks, have among the lowest proportions of both low- and high-integrity blocks, and have no blocks that are highest integrity.

Watersheds of clusters 4 and 5 collectively have the second highest proportions of low-integrity blocks. Since cluster 4 watersheds have a relatively high proportion of medium-integrity blocks and also have among the lowest proportions of high-integrity blocks, cluster 4 appears to be in a medium-low general integrity category.

Watersheds of clusters 2 and 5 collectively have the second largest proportions of high-integrity blocks. Since the watersheds of cluster 2 have among the lowest proportions of low-integrity blocks and contain some highest-integrity blocks, yet are predominantly medium-integrity, cluster 2 appears to be a medium-high general integrity category.

Figure 65.4 Dendrogram of watershed clusters in the Pennsylvania MAHA region obtained from applying the average Euclidean distance agglomerative clustering protocol to the proportions of low, medium, high, and highest integrity atlas blocks in each watershed.

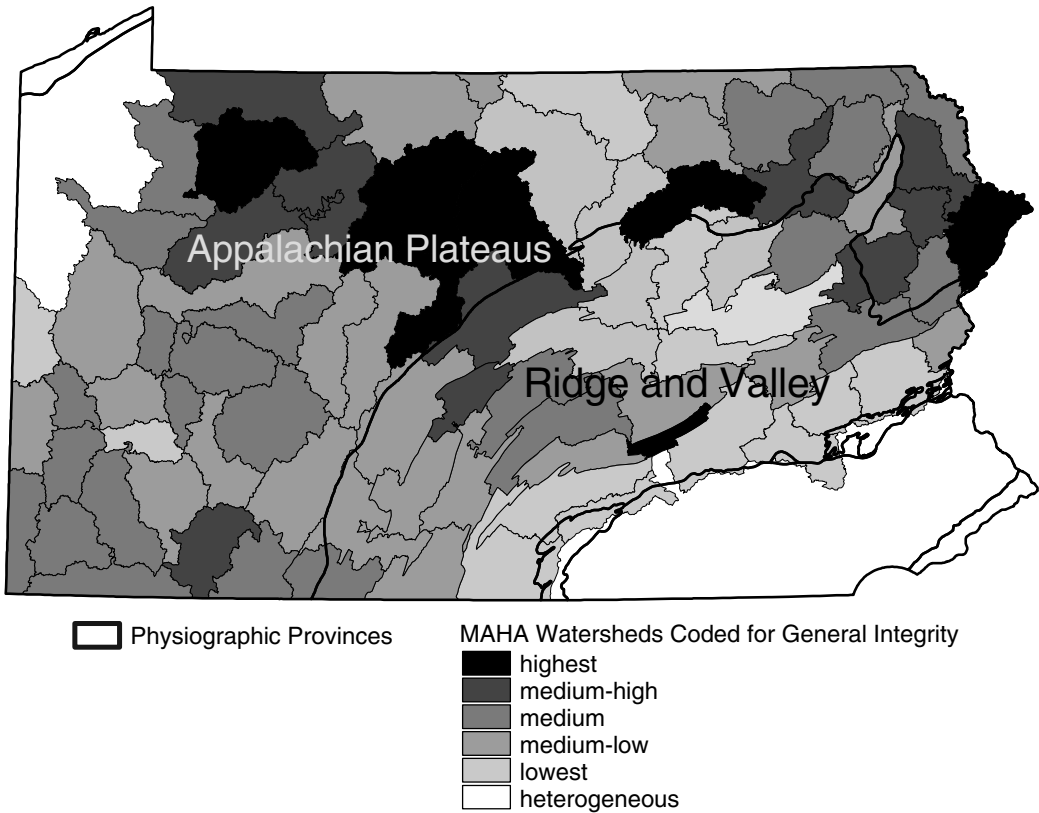

Figure 65.5 Watersheds in the MAHA region coded according to general ecological integrity as determined by cluster membership in Figure 65.4.

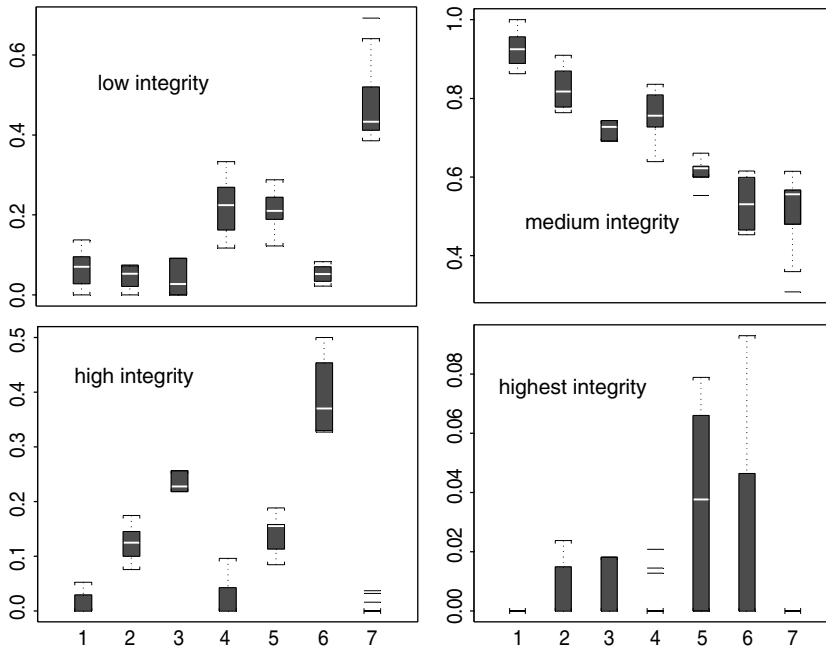

Figure 65.6 Box plots of the proportions of low, medium, high, and highest integrity land in each of the 7 clusters delineated in Figure 65.4. The numbers 1 to 7 appearing along the bottom axes correspond to the labeled clusters in Figure 65.4 as they occur from left to right.

Finally, cluster 5 is labeled heterogeneous because of the simultaneous high proportion of both low- and high-integrity blocks, with some highest integrity. Such heterogeneity can be explained by very different land uses in different areas of the watersheds. Allocating this group into the other categories always resulted in substantially increasing the variability seen in the box plots of Figure 65.6. It was decided to keep these five watersheds in a separate group.

The results mapped in Figure 65.5 generally agree with intuitive expectation based on landscape context, with the only apparent anomaly being the one watershed on the northern border that is labeled as lowest. Based on land cover alone, one may expect a medium classification at worst for this particular watershed (Tioga Creek); however, these results may reflect lower sampling coverage in this area (Brauning, 1992). On the other hand, this protocol did identify one small watershed in the Ridge and Valley province as being in the highest category, and this is indeed expected. This small watershed (Clarke Creek) is completely forested because it is the protected drinking water supply for the city of Harrisburg.

COMPARING LANDSCAPE MEASUREMENTS TO THE SONGBIRD-BASED ASSESSMENTS OF WATERSHED-WIDE ECOLOGICAL INTEGRITY

Now the objective is to determine how well ecological integrity can be predicted by landscape variables on a watershed-wide basis. For this purpose, landscape measurements of both land cover proportions and spatial pattern were evaluated that were previously obtained (Johnson et al., 2001) from an eight-category raster land cover map of Pennsylvania that was in turn derived from LANDSAT™ images (Myers, 1999). Spatial pattern variables were obtained with the FRAGSTATS program (McGarigal and Marks, 1995) for single-resolution maps, and from conditional entropy profiles for multiresolution maps.

Figure 65.7 Conceptual conditional entropy profile and associated parameters.

The conceptual and methodological development of conditional entropy profiles is found elsewhere (Johnson et al., 1995, 1999, 2001; Johnson and Patil, 1998). Basically, the spatial distribution of 2×2 4-tuples of pixels in a raster map is quantified by its entropy in a way that is conditional on values of parent coarser resolution pixels that the 4-tuples are nested within. When computed for multiple resolutions, ranging from the floor that is provided by the original raster map, up to a resolution beyond which conditional entropy does not change much, a profile is traced out that reflects aspects of the underlying spatial pattern. An example profile and its parameterization is seen in Figure 65.7. Essentially, A is the extent of information that is lost from degrading the map resolution, B is the rate of information loss, and C is the asymptotic conditional entropy that is highly correlated with the entropy of the marginal land cover distribution.

Of the measurements obtained by Johnson et al. (2001), we worked with those reported in Table 65.3, which includes a subset of the spatial pattern measurements (both single and multiresolution) that are uncorrelated with each other, along with key land cover proportions. Initial exploratory data analysis indicated that contagion, total forest and total herbaceous land reveal monotonic trends as one moves from the highest to lowest general integrity.

Table 65.3 Landscape Variables Measured for Pennsylvania Watersheds

Variable Description	Code
<i>Single-resolution variables</i>	
Patch size coefficient or variation	PSCV
Landscape shape index	LSI
Double-log fractal dimension	DLFD
Contagion ^a	CONTAG
<i>Multiresolution variables</i>	
Extent of information loss	A
Rate of information loss	B
<i>Land cover proportions</i>	
Total forest cover	TOT.FOREST
Total herbaceous cover	TOT.HERB
Terrestrial unvegetated	TU

Note: Diagonal pixels were included when determining patches.

^a Pixel order preserved when measuring contagion.

Linear Regression Modeling

The relationship between ecological integrity and landscape variables was quantified by regression modeling (ordinary least squares), where several response variables were investigated. The proportion of a watershed that was estimated to be in a particular ecological integrity was considered as a response. Since there were many watersheds with no land classified as high integrity and far less classified as highest, the sum of both high and highest integrity proportions were treated as one response. On the other hand, the majority of watersheds had some low-integrity land, and therefore the proportion of low-integrity land was included. Every watershed had some medium-integrity coverage; however, this category is neutral and therefore was not included. Finally, the raw BCI scores were averaged over the watersheds to provide a rational alternative watershed-wide response.

For each of the different responses, a stepwise selection protocol was applied, whereby the criterion for choosing the best set of predictors was a modification of Mallows’s Cp statistic (Mallows, 1973), known as the Akaike information criterion (AIC) (Akaike, 1974), which is summarized as follows:

$$AIC = RSS(p) + MSE \times 2 \times p \tag{65.4}$$

The term $RSS(p)$ is the residual sum of squares from the new model defined by p terms (k predictors plus the intercept), and MSE is the mean squared error from the original model prior to deleting or adding a term.

Using S-Plus (MathSoft, Inc., 1997), the stepwise selection protocol worked by choosing the set of predictors that minimized the AIC statistic. Critical F values for deciding whether or not to include or remove predictor variables were set at 2. Subsequently, the stepwise selection protocol erred in favor of large sets of predictor variables.

Models were checked by the usual diagnostic graphics. In addition, partial residual plots were obtained for each regressor in a model. Following Montgomery and Peck (1982), the i th partial residual for the regressor x_j is

$$\begin{aligned} e_{ij}^* &= y_i - \hat{\beta}_1 x_{i1} - \dots - \hat{\beta}_{j-1} x_{i,j-1} - \hat{\beta}_{j+1} x_{i,j+1} - \dots - \hat{\beta}_k x_{ik} \\ &= MPE_i + \hat{\beta}_j x_{ij} \quad \text{for } i = 1, \dots, n \end{aligned} \tag{65.5}$$

These partial residual plots display the relationship between the response y and the regressor x_j after the effect of the other regressors $x_i (i \neq j)$ have been removed, therefore more clearly showing the influence of x_j , given the other regressors. Along with providing a check for outliers and inequality of variance, these plots also indicate more precisely how to transform the data to achieve linearity than do the usual residual plots.

A dummy variable was forced to be retained by each model in order to indicate the effect of membership in the Appalachian Plateaus, relative to the Ridge and Valley physiographic province. The set of variables in Table 65.3 constituted the initial set of potential predictors from which an optimal subset was chosen. Although the land cover proportions were correlated among themselves and to some degree with the spatial pattern variables, they were all included in order to see which ones may be retained by a stepwise regression protocol as being most informative. Prior to applying the stepwise protocol, a log transform was applied to the proportion of terrestrial unvegetated land in order to stabilize an extreme outlier.

The sum of both high and highest integrity land did not provide a valid response variable for linear modeling, as evidenced by unacceptable partial residual plots, other diagnostic plots and a very low R^2 of 0.37. Since pairwise plots of high plus highest integrity land with the potential

predictors suggested that a log transform of the response may improve the fit, the response was transformed as $\log(\text{response} + 1)$; however, an improvement was not seen and the R^2 remained essentially unchanged at 0.38.

When the proportion of low integrity atlas blocks was regressed against the set of potential predictors, the resulting set yielded diagnostic plots that were favorable with respect to a linear fit with no overly influential observations and a residual distribution that was approximately normal. The R^2 was only 0.57; however, besides an overall linear fit, the partial residual plots revealed some fairly strong linear relationships once the other predictors were factored into the model. The computed linear coefficients and summary statistics are reported in Table 65.4, where we see the spatial pattern variables that were retained, including both the A and B parameter estimates of the conditional entropy profiles, show fairly strong influence on the proportion of low-integrity atlas blocks in a watershed. Note that standard errors are not reported because the watersheds constitute a population of units; however, p values are reported to show the relative strength of each predictor.

Finally, the raw BCI score, averaged for all blocks within a watershed, was compared to landscape variables by the stepwise regression procedure, resulting in the model defined in Table 65.5. The corresponding partial residual plots for the quantitative predictors revealed some strong linear relationships. Further, the R^2 for this model is 0.69, which is substantially stronger than the model reported in Table 65.4, especially since it contains two fewer terms.

Clustering

In a separate study (Johnson et al., 2001), the watersheds were clustered using a variety of landscape variables that included those in Table 65.3 along with other spatial pattern measurements. However, qualitative labeling of the watershed clusters was subjective, being based on the relative amount of forest fragmentation in the original land cover maps.

^a Symbols for qualitative cluster labels are B = best, MB = medium-to-best, M = medium, MW = medium-to-worst W = worst, H = heterogeneous.

^b Symbols for geographic location, where appropriate are Pitt. = Pittsburgh and near vicinity, lower App. Mtns. and upper App. Mtns. = the lower (southwest) and upper (northeast) Appalachian Mountains, respectively, and lower Gr. Val. and upper Gr. Val. = the lower (southwest) and upper (northeast) Great Valley, respectively.

Clustering of the Pennsylvania MAHA watersheds based on the spatial assessment of ecological integrity using the songbird community data (BCI proportions), as presented in Figures 65.4 and 65.5, was compared to clusters obtained from using all of the landscape measurements, as presented by Johnson et al. (2001). Comparisons for each of the physiographic provinces that overlap both Pennsylvania and the MAHA region are tabulated in Table 65.6. The cluster categories that were based solely on ecological integrity are the same for both physiographic provinces because this clustering is based on all watersheds across the two provinces; however, the cluster categories that were based solely on landscape variables are somewhat different for each province because clustering was applied separately within each province due to very different fragmentation patterns.

These results indicate some fairly strong dependence between the two classification schemes. A formal chi-square or likelihood ratio test is not possible for either physiographic province because of the zero entries in their respective contingency tables, but these zero entries are the result of a dependent structure.

For the Appalachian Plateaus, the landscape measurements alone did an excellent job of identifying medium-low watersheds, as evidenced by complete correspondence with clusters that were qualified as having medium to medium-low ecological integrity, and with the two watersheds that were qualified as having the lowest integrity. The landscape measurements also did a good job of identifying the medium-high and highest watersheds, as evidenced by distributions across the ecological integrity clusters that were biased toward the medium-high and highest clusters, respectively. However, one medium-low and one lowest integrity watershed were each misclassified as highest with the landscape variables.

Meanwhile, for the Ridge and Valley, the landscape variables alone identified the single watershed that was qualified as having the highest ecological integrity (Clarke Creek). A medium integrity watershed was also grouped with the highest watershed, but no gross misclassifications into medium-low or lowest general integrity occurred. The medium-low and lowest integrity watersheds of the Great Valley section were clearly identified by the landscape variables alone. Finally, out of the 21 watersheds identified as medium by the landscape variables, all but 4 were qualified as being in one of the medium-integrity categories, with 3 out of these 4 being labeled as lowest integrity.

Conditional Entropy Profiles

Conditional entropy profiles are reported in Figure 65.8 for those watersheds coded as highest, medium, and lowest in Figure 65.5. The medium-high and medium-low watersheds were not included in order to maintain better graphical clarity.

One observation is that the highest-integrity watersheds lie near the bottom of the profiles. This is because the highest-integrity watersheds are mostly forested, and therefore characterized by large coherent forest patches. This highly contagious pattern results in a very low conditional entropy across the resolutions.

The profiles migrate upwards as the underlying landscape becomes increasingly fragmented and land cover becomes more evenly distributed both marginally and spatially. The increasing fragmentation generally corresponds with decreasing ecological integrity. The lowest-integrity watersheds, however, do not yield the top profiles. This is because watersheds of the very lowest integrity are those that have returned to a more contagious condition, but now it is due to large nonforest patches.

Within Figure 65.8, the very lowest watershed was chosen for each province as the one with the highest proportion of low-integrity blocks, the very highest had the highest proportion of high- plus highest-integrity blocks, and the all medium watersheds were covered 100% by medium-integrity blocks.

Figure 65.8 Conditional entropy profiles of watersheds in the MAHA section of Pennsylvania that were labeled as having highest, medium, or lowest ecological integrity, as assessed from the songbird community.

This shows that as we go from the very highest to all medium to the very lowest watersheds, the profiles increase for all resolutions; however, when all watersheds are viewed, it appears that as the forest is increasingly fragmented, the maximum conditional entropy profile reflects a sort of critical state, beyond which the landscape matrix is nonforest and ecological integrity gets increasingly lower.

ECOLOGICAL INTEGRITY BASED ON ALL SPECIES IN THE BREEDING BIRD ATLAS

An alternative approach to the one discussed in this chapter for assessing ecological integrity is to use all of the breeding bird atlas blocks (as per Figure 65.1), so that an assessment could be made for every watershed. Since the standards established for songbirds strictly in the MAHA region should not be extended beyond MAHA, nor to other species or guilds, a new basis for categorizing watersheds had to be established. Bishop (2000) defined a set of 34 guilds that incorporate all species from the full breeding bird atlas (Brauning and Gill, 1983–1989). Using these guilds and all the species that were listed in the atlas as possible, probable, or confirmed, two variations on a common protocol were investigated.

Initially, reference watersheds were established to represent both the best and worst overall ecosystem condition, based on results from nonpoint source surface water pollution studies (Johnson et al., 2001) and, where appropriate, results from the MAHA songbird evaluation presented earlier in this chapter. Three watersheds from Pennsylvania's northern tier were chosen for the best condition, and four watersheds from the Piedmont Plateau and Great Valley section were chosen for the worst condition, based on the highest and lowest rankings for Agricultural Pollution Potential, respectively (Johnson et al., 2001). The best watersheds with respect to water pollution potential were also categorized as having the highest general ecological integrity based on the MAHA songbirds. Of the worst watersheds with respect to water pollution potential, the one (in the Great Valley section) that lay within the MAHA region was also categorized as having the lowest ecological integrity based on the MAHA songbirds.

For each of the two reference groups of watersheds, a 34-guild mean vector was obtained by averaging the species proportions in each guild over all atlas blocks in the group of watersheds. This included 274 blocks for the three best watersheds and 166 blocks for the four worst watersheds. Given the reference mean vectors for the best \mathbf{P}_b and worst \mathbf{P}_w watershed groups, a vector of weights was established by subtraction: $\mathbf{D} = \mathbf{P}_b - \mathbf{P}_w$. Therefore, each of $j = 1, \dots, G$ guilds is represented by a weight $\mathbf{D}_j \in [-1, 1]$, such that for $\mathbf{D}_j > 0$, the guild is representative of increasingly better ecological integrity as \mathbf{D}_j approaches 1, and for $\mathbf{D}_j < 0$ the guild is representative of increasingly lesser integrity as \mathbf{D}_j approaches -1 ; whereas for $\mathbf{D}_j = 0$, the guild is noninformative.

Now a bird community index can be calculated for each of $i = 1, \dots, N$ atlas blocks across the state by the following sum:

$$\text{BCI}_i = \sum_{j=1}^G P_{ij} D_j \quad (65.6)$$

where, for block i , P_{ij} is the proportion of species in the j th guild.

This protocol was carried out under two different scenarios for calculating the P_{ij} values. First, the P_{ij} was computed as the proportion of species in guild j out of all species in block i . Alternatively, the P_{ij} was computed as the proportion of species in guild j out of all potential species in guild j . The first approach, coined species richness-based, can yield identical multinomial vectors of species proportions for two different blocks, although the overall species richness may be very different between the blocks. Therefore, it has no way of accounting for large differences in species richness that may in turn be due to differing environmental conditions. For this reason, the second approach, coined guild potential-based was evaluated.

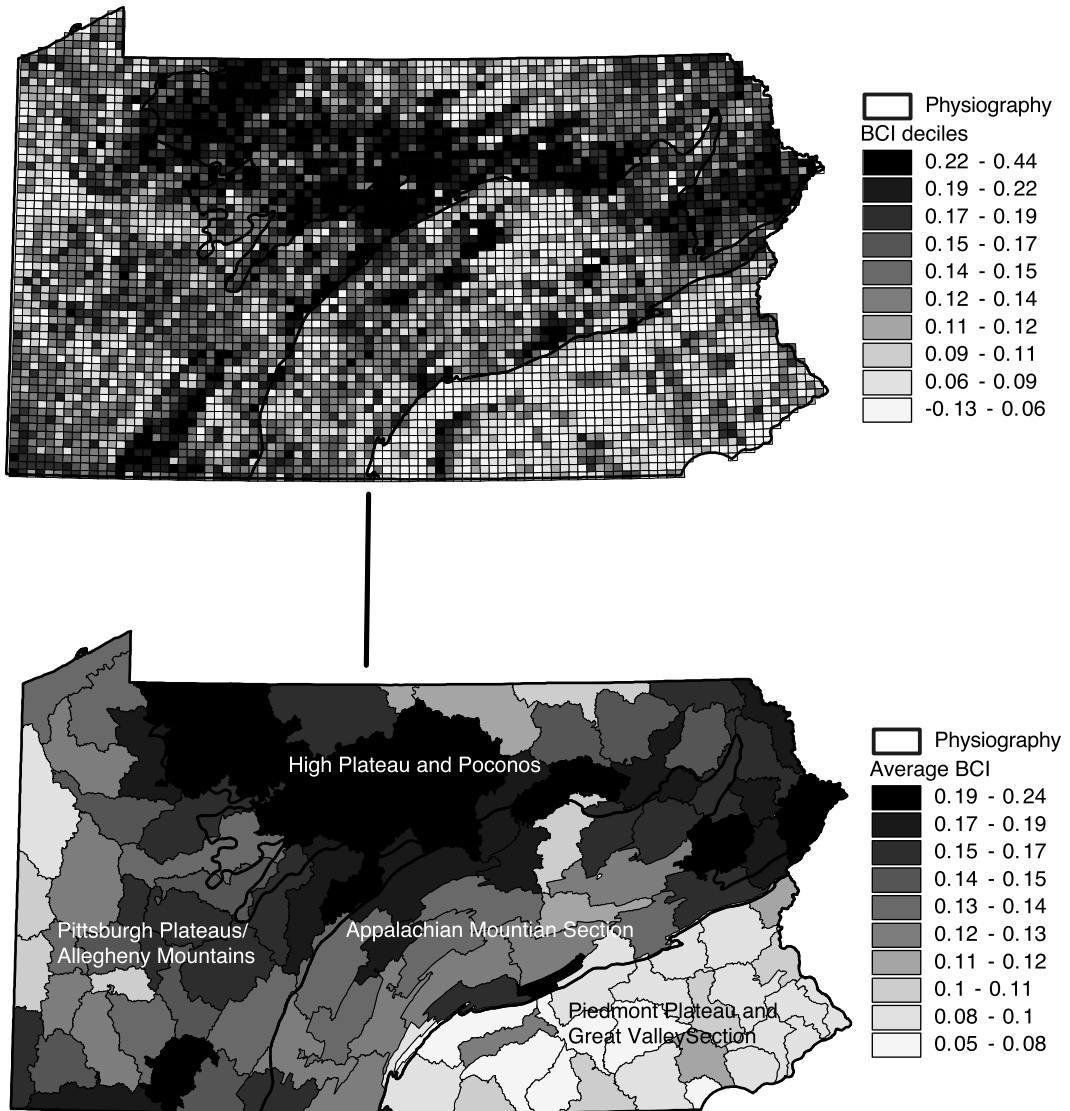

Figure 65.9 Species richness-based bird community index of ecological integrity, presented within each breeding bird atlas block (top) and for blocks averaged within each watershed (bottom). A combination of physiographic provinces and sections have been overlaid to stratify the state into more homogeneous areas of ecological integrity.

The results for both variations on the protocol are presented in Figures 65.9 and 65.10, where the block values of BCI are averaged to obtain a summary BCI value for each watershed. Since there are some gross statewide patterns, the state was stratified by a combination of physiographic provinces and sections to delineate more homogeneous areas using natural boundaries.

Unlike with the MAHA songbirds, there are no preestablished standards for assigning BCI scores to categories of ecological integrity. Conceptually, one may consider clustering the blocks in guild-space; however, with close to 5000 blocks in the state, interpretation would be near impossible at best. Therefore, ecological integrity will be simply represented on the continuous scale of the BCI scores.

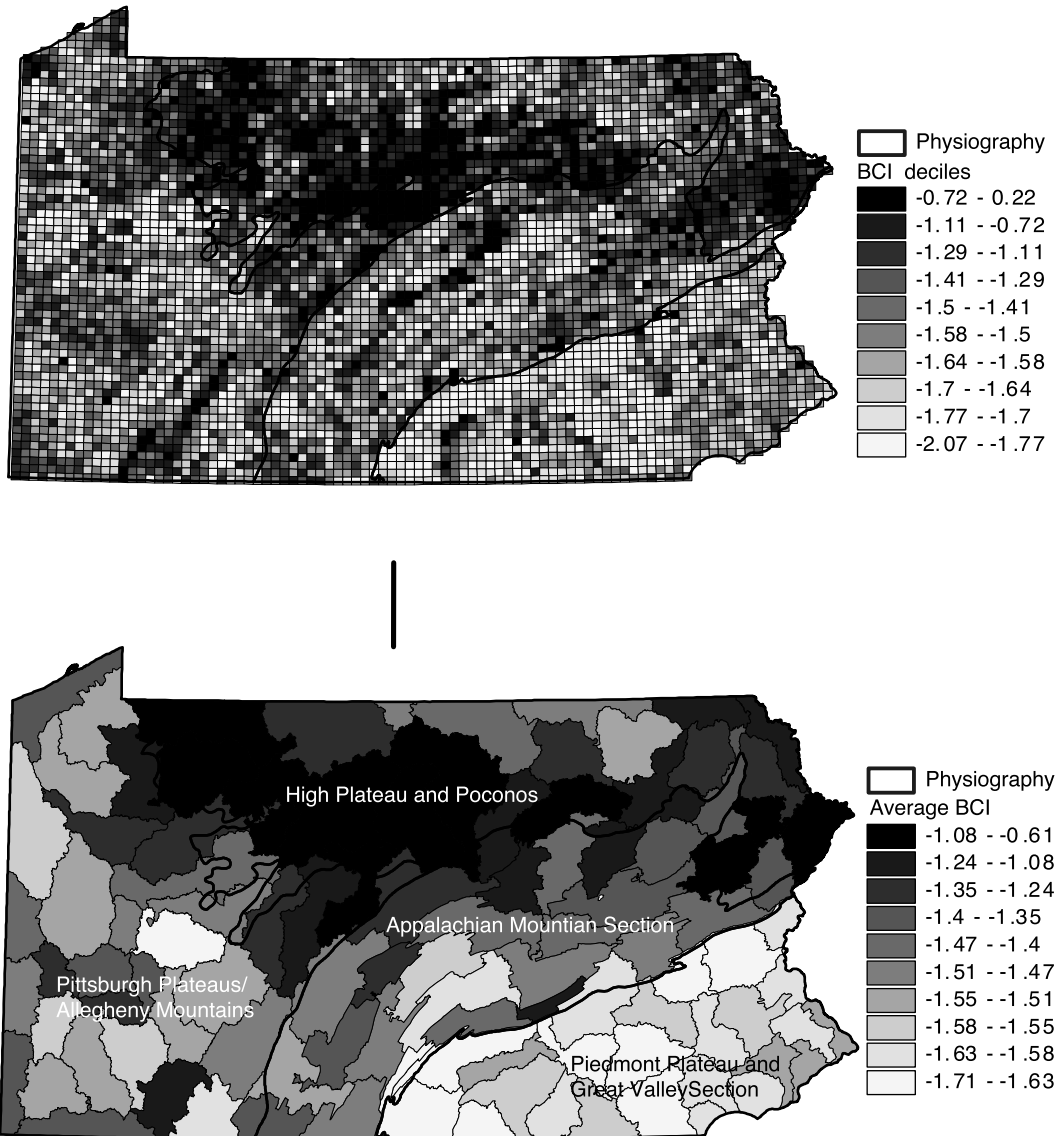

Figure 65.10 Guild potential-based bird community index of ecological integrity, presented within each breeding bird atlas block (top) and for blocks averaged within each watershed (bottom). A combination of physiographic provinces and sections have been overlaid to stratify the state into more homogeneous areas of ecological integrity.

Comparison to Landscape Measurements

Since there is no basis for categorizing the BCI scores, as with the MAHA songbirds approach discussed earlier, a spatial distribution of ecological integrity is not obtainable. Losing this spatial information is a major sacrifice; however, the average BCI scores do lend themselves to regression modeling.

The stepwise selection protocol, as discussed in a previous section, was applied to the same set of potential predictor variables in Table 65.3 in order to assess the strength of relationship between the average BCI value and the landscape variables for the watersheds. Dummy variables indicating physiographic membership of each watershed were forced to be retained by the stepwise

Applied to all watersheds in Pennsylvania. Mean squared error (95 d.f.) = 1.33 and multiple $R^2 = 0.66$.

protocol. Results for each of the two methods yielded favorable diagnostics, including partial residual plots that indicated strong linear relationships. Corresponding statistics are reported in Tables 65.7 and 65.8. Since these regressions were performed on all watersheds in the Pennsylvania population, the final least squares calculations are for actual parameter values, given this particular set of predictors. Significance levels, represented by p -values, are still reported to reveal the relative strength of each predictor.

The species richness-based method of computing BCI yielded the best diagnostics and an R^2 of 0.78 (8 parameters). The guild potential-based method yielded an R^2 of 0.66 (7 parameters). These results, along with favorable model diagnostics, indicate that a fairly strong relationship is obtained with the species richness-based method of computing BCI.

COMPARISON OF THE DIFFERENT METHODS FOR COMPUTING A BIRD COMMUNITY INDEX

Consistency among the three different approaches to computing a BCI of ecological integrity is evaluated in Table 65.9. For each of the watershed clusters that were determined from landscape

Table 65.9 Area-Weighted Bird Community Indices (BCIs) for Three Different Protocols within Each Cluster Defined by Landscape Measurements

Province	Clusters Based on Landscape Measurements	Area-Weighted BCI Based on:		
		Species Richness	Guilid Potential	MAHA Songbirds
AP	High (13) ^a	0.189	-1.019	47.606
	MH ^b	0.163	-1.243	46.045
	ML1 (6)	0.132	-1.437	44.310
	ML2 (19)	0.115	-1.443	42.302
RV	High (2)	0.167	-1.349	46.223
	M1 (13)	0.136	-1.452	43.767
	M2 (8)	0.134	-1.391	42.924

	ML2 (4)	0.091	-1.626	40.466
Pied.	Very low (2)	0.076	-1.678	39.215
	MH (1)	0.046	-1.600	N/A
	M (4)	0.084	-1.570	N/A
	ML (4)	0.066	-1.632	N/A
	Very low (7)	0.086	-1.630	N/A

^a () = number of watersheds in cluster.

^b Symbols for qualitative cluster labels are: MH = medium-to-high, M = medium, ML = medium-to-low. Within the Appalachian Plateaus (AP), ML2 = Pittsburgh and near vicinity, and ML1 = medium-to-low elsewhere. Within the Ridge and Valley (RV), M1 and M2 refer to medium watersheds in the lower (southwest) and upper (northeast) Appalachian Mountains, respectively, and ML1 and ML2 refer to medium-to-low watersheds in the lower (southwest) and upper (northeast) Great Valley, respectively.

measurements alone, as discussed earlier, the average BCI was obtained by taking an area-weighted average BCI of all watersheds in each respective cluster.

Table 65.9 does indeed show that for the majority of Pennsylvania (all of the Appalachian Plateaus and the Ridge and Valley), the average BCI consistently increased for all three methods of computing the BCI as the watershed clusters went from lowest to highest amount of forest cover.

In the Piedmont, the two methods that could be applied did not reveal consistent results and they also did not coincide with apparent decreasing forest cover. This physiographic region, however, presents several limitations for comparing average BCI values among landscape-based watershed clusters. First, there are no watersheds that are mostly forested to provide a background. The one watershed that is labeled as medium-to-high with respect to forest cover is actually not much different from those in the medium cluster. Second, the Piedmont is a small area of Pennsylvania and therefore the sample of watersheds is much smaller than for the other two provinces.

DISCUSSION

For predicting ecological integrity, landscape variables provided fairly strong predictors for each of three different approaches to obtaining a watershed-wide average BCI of ecological integrity. After factoring out physiographic regimes, an objective stepwise model selection procedure retained landscape variables that explained 66 to 78% of the variation in BCI. As expected, for each method of obtaining the BCI response, either total forest or total herbaceous land served as a very strong predictor. However, several measurements of spatial pattern were also retained. Of these pattern measurements, the conditional entropy term that relates the rate of information loss (parameter B) was retained twice and contagion was retained all three times. Contagion was highly significant in all cases and revealed a fairly strong linear relationship to BCI. Since contagion is very highly linearly correlated with the conditional entropy term C, this indicates that only land cover propor-

tions and terms from the multiresolution conditional entropy profiles (A, B, and C in Figure 65.7) can provide a strong capability to predict general landscape-scale ecological integrity.

For the songbird-based approach to obtaining BCI values within the MAHA region, the watersheds could be clustered based on their respective proportions of breeding bird atlas blocks in low, medium, high, and highest integrity. When these watershed clusters were compared to distinct clusters obtained using only landscape variables, a high degree of correspondence was observed, further supporting the claim that landscape measurements alone can characterize landscape-level ecosystem condition.

Improvements can be made for the two approaches to computing a watershed-wide BCI that were based on reference watersheds within the state and incorporated a large set of guilds. As with the initial approach by O'Connell et al. (1998a), the full set of guilds may be reduced to remove redundancy prior to computing a BCI. Also, one can experiment with different choices of reference watersheds.

We look forward to seeing how well landscape measurements alone can predict the condition of landscape-level ecosystems elsewhere.
