Landscape Biodiversity and Biological Health Risk Assessment: The Map of Italian Nature

Giovanni Zurlini, Orazio Rossi, and Vittorio Amadio

INTRODUCTION

Ecosystem health is related to the system's capability to maintain some degree of biophysical integrity while supplying humans with valuable services (Rapport, 1995). Thus, the functional relationship between the diversity of organisms and the set of ecological services on which humanity depends must be addressed (Perrings et al., 1995). Signs of dysfunction, either structural or functional, associated with particular stresses can be identified by suitable indicators in the biophysical domain of ecosystems themselves. In the Mediterranean regions, where ecosystems have been shaped by the millennial historic and evolved interactions between man and nature, many forms of human disturbance are recognized to be important sustaining components of natural systems (Pickett and White, 1985); consequently in the Mediterranean, but not only there, we have often to deal with the question of defining both the extent to which ecosystem services start to be impaired by either natural or anthropogenic perturbation, and the extent up to which the services themselves are unimpaired, or even sustained, by human disturbances.

Studies of natural, managed, and disturbed or impacted ecosystems have shown that ecosystems under stress appear to keep more of their functional performance than their species composition (Holling et al., 1995), as processes are buffered by species redundancy. Thus, species composition appears more sensitive than ecosystem processes since it responds more quickly and recovers more slowly (Angermeier and Karr, 1994). Changes in species composition may also significantly alter ecosystem performances (Naeem et al., 1994), like the resilience and stability of the ecosystem to several sources of disturbance.

However, giving equal emphasis to every piece of biodiversity would be ecologically incorrect and practically unachievable (Walker, 1992). Indeed, one of the fundamental aims of conservation management and reserve design is often not just the preservation of maximum species diversity per se, but the preservation of the diversity of species "typical" (or rare) of the habitat or habitats within a reserve (Usher, 1991), also classified into functional, structural, and compositional groups using a "guilding" concept (O'Connell et al., 1998).

This chapter addresses risk assessment of biological diversity at the landscape level, associated with ecotypes or ecotype mosaics, by a simple multiscale conceptual model incorporating metrics related to current human disturbance, based on native species most threatened with extinction and reduction. We consider all native vertebrates threatened according to the International Union for

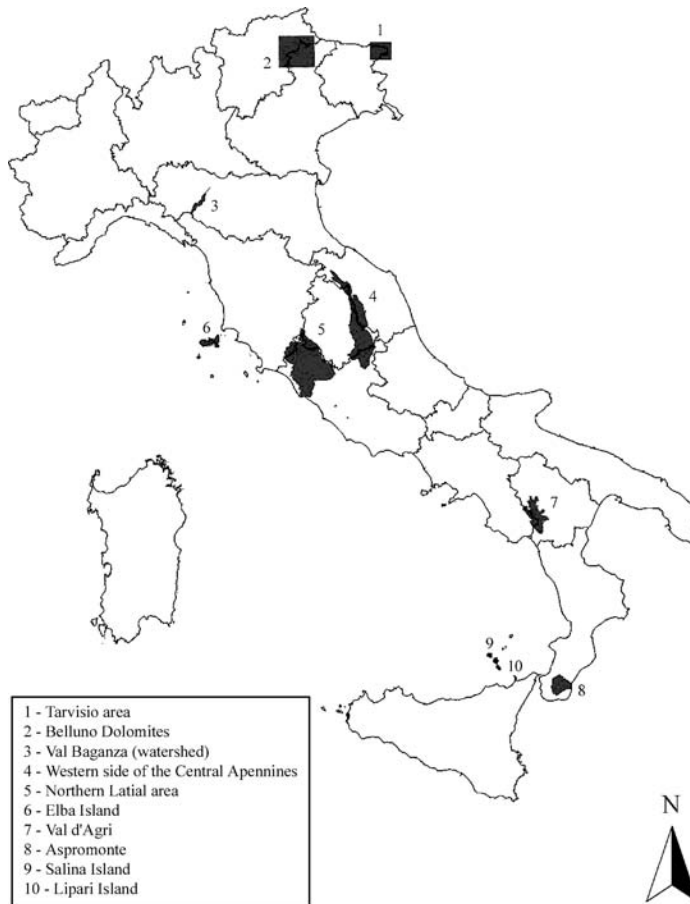

Figure 66.1 Distribution of the current study sites of the Map of Italian Nature, accounting for almost 1,500,000 ha.

Conservation of Nature and Natural Resources—The World Conservation Union (IUCN) (1996), and European Directive 92/43/EU, following Pinchera et al. (1997) updates, overlapping with their distribution range at least 10% of the area considered by the Map of Italian Nature project (Rossi and Zurlini, 1993, 1998; Zurlini et al., 1999). This project accounts for 1,500,000 ha (Figure 66.1), started as a result of the Italian national law 394 (1991) on reserves and protected areas (Ministry of Environment, 1992). Vertebrates considered are mostly at the top of their natural food webs and are end points to a number of ecological processes. They tend to be rare animals with slow rates of population growth, particularly susceptible to overexploitation or habitat loss, and are expected to reduce populations or disappear first, as disturbance intensifies, because of their sensitivity. They are supposed to be reliable witnesses of the ability of ecosystems to maintain their characteristic patterns and rates of process in response to disturbances and to the variability inherent in their climate regimes (Walker, 1992).

While risk and conservation value assessments for a pilot study area already have been presented elsewhere, together with overall data processing procedures (Zurlini et al., 1999), this chapter presents primary results based on real Map of Italian Nature sites with particular regard to the Aspromonte area (Area 8, Figure 66.1). Biological health issues are also addressed, where health stands for health condition or well-being in the native biodiversity structure of ecosystems (Wickert and Rapport, 1998; Zurlini et al., 1999).

In the last centuries, due to anthropic pressure on Mediterranean ecosystems and abandonment of intense agricultural and pastoral practices, Mediterranean plant communities have been shaped into a mosaic-like pattern composed of different human-induced degradation and regeneration stages (Naveh and Liebermann, 1994; Pignatti, 1994). Such mosaics can be physically recognized as composites of CORINE habitats (European Union Directorate General XI, 1991), and risk assessments are made at a nominal scale of 1:50,000, to provide focus and direction for proactive land management activities. Digital thematic maps are generated as geographical information system (GIS) coverages in polygonal (vector) format of (1) existing land cover habitat types and biodiversity component distributions and (2) different kinds of human-induced disturbance.

The project, akin to the Gap Analysis Program (Scott et al., 1996), aims at identifying gaps in the existing reserve network to establish new reserves and protected areas to obtain a more representative network of regional biological diversity, based on (1) their natural values and (2) fragility. The project operates in a multiscale perspective (O'Neill et al., 1986; Allen and Hoekstra, 1992), dealing with scales in which humans generally influence the condition of the landscape. Activities are currently enlarging to cover another 6,000,000 ha, and accounting for almost one fourth of the entire Italian territory (about 30,000,000 ha).

A SEMANTIC RATIONALE FOR THE MAP OF ITALIAN NATURE

While the Italian law deals with values as components of the national natural heritage including different biological, ecological, geological, anthropological, archaeological, and historical issues, the project focuses on biophysical and ecological components. Here values are in reference to biodiversity, biological integrity, and biological and ecosystem health. Biodiversity refers to the variety of components at every level of biotic community organization, whereas biological integrity is reflected in both biotic elements and processes that generate and maintain those elements (Angermeier and Karr, 1994). Biological integrity is “the capability of supporting and maintaining a balanced, integrated, adaptive community of organisms having a species composition, diversity, and functional organization comparable to that of natural habitat of the region” (Karr and Dudley, 1981) prior to industrial settlement by humans. Exotic species also are taken into account by biological integrity. A site can be high in biological diversity, but not have biological integrity if exotics are common, making up a significant percentage of diversity (Karr and Dudley, 1981). Ecosystem health can be deemed as a condition of normality in the linked processes and functions that constitute ecosystems (Rapport, 1995), and defined in terms of vigor, resilience, and organization (Mageau et al., 1995). Ecosystem health and biological integrity are related, since a sure way to maintain ecosystem health is to maintain biological integrity (Karr, 1995), but not vice versa. Along the same line, we might state that biological health and integrity also are related, since a sure way to maintain biological integrity is to maintain biological health, albeit this would not guarantee the maintenance of processes. Thus biodiversity, biological integrity, and biological and ecosystem health, while related, are not identical. It is generally recognized that biological integrity is primary as a conservation value (Angermeier and Karr, 1994).

Fragility relates to the degree of change observed in species abundance and composition following disturbance (displayed fragility, cf. Nilsson and Grelsson, 1995). However, Ratcliffe's (1977) definition seems more useful to provide direction for land management and planning; it states that fragility “reflects the degree of sensitivity of habitats, communities and species to environmental change, and so involves a combination of intrinsic and extrinsic factors.” Fragility can be estimated as intrinsic fragility, which relates to intrinsic factors like broad biological differences among taxa, such as the size of the species range, their trophic status, their habitat fidelity, and other aspects related to feeding, breeding, and reproductive strategies. Extrinsic factors are represented by human and naturally induced stresses. The amount of stress, coupled with those intrinsic factors, determines fragility. The type, magnitude, and timing of the stressor; the exposure

of the species; and the species' inherent or intrinsic fragility (sensitivity) have important interactive relationships that determine the overall fragility.

CORINE HABITAT MOSAICS

The basic data produced by the Map of Italian Nature project concerns mosaics of contiguous patches (Figure 66.2) corresponding to the different habitat types in the CORINE biotopes classification (European Union Directorate General XI, 1991). The CORINE classification system aims to compile an inventory of biotopes (habitat) of major importance for nature conservation in the European Union, providing a unique basis for evaluation of conservation management issues. The CORINE habitat classification, through satellite, airborne, and ground data, permits the biophysical identification of ecosystems, as defined by Tansley (1935), as patches, based on vegetation covers, physiognomy, soil types and landforms, and an integration of related abiotic and biotic components, like habitats and syntaxa (Usher, 1991). CORINE biotopes, called habitats, are coded at different levels of a hierarchical system of mosaics of patches within patches, that can go from very broad

Figure 66.2 From the Map of Italian Nature, distribution of CORINE habitat mosaics (1:50,000) for the Aspromonte area (Area 8 from Figure 66.1) where a total of 168 patches belonging to 30 habitat types were identified. The following primary CORINE habitat types were identified: (1) Sila and Aspromonte Laricio forests (CORINE code 42.651); (2) Aspromonte beech forest (CORINE code 41.185); (3) Meso-Mediterranean holm-oak forests (CORINE code 45.31); (4) Illyrian holm-oak woodland (CORINE code 45.319); (5) Tyrrhenian broom fields (CORINE codes 31.844, 32.21, and 32.23); (6) Thermo-Mediterranean brushes, thickets, and heath garrigues (CORINE codes 32.23, 32.21, and 34.5); (7) Mediterranean xeric grasslands (CORINE codes 34.5 and 32.21); (8) Southern Italian mat-grass swards communities (CORINE code 35.72); (9) Chestnut woods (CORINE code 41.9); (10) Eucalyptus plantations (CORINE code 83.322).

Table 66.1 An Example of the Hierarchical Classification of Habitats within the CORINE Biotopes Classification Scheme

CORINE Habitat Classification	Description	CORINE Code
Sclerophyllous scrub	Mediterranean and sub-Mediterranean evergreen sclerophyllous bush and scrub maquis, garrigue, matorral, recolonization and degradation stages of broad-leaved evergreen forest, supra-Mediterranean garrigues, pseudo-maquis, Macaronesian xerophytic communities	32
Arborescent matorral	<i>Quercetalia ilicis</i> , <i>Pistacio-Rhamnetalia alaternii</i>	32.1
Thermo-Mediterranean shrub formations	<i>Pistacio-Rhamnetalia alaterni</i> , <i>Oleo-Ceratonion</i> , <i>Asparago-Rhamnion oleoidis</i> , <i>Periplocion angustifoliae</i> , <i>Rhamno-Quercion cocciferae</i> , <i>Juniperion lyciae</i> , etc.	32.2
Meso-Mediterranean silicicolous maquis	<i>Cisto-Lavanduletea</i> , <i>Pistacio-Rhamnetalia alaternii</i> , <i>Ericion arboreae</i> ; shrubby formations, often tall, on most siliceous soil of the meso-Mediterranean zone of the Iberian peninsula, France, Italy, and the large western Mediterranean islands, degradation stages of evergreen oak forests; very similar formations of the thermo-Mediterranean zone and of the eastern Mediterranean are included	32.3
High maquis	Highest formations, with a tall stratum of <i>Erica arborea</i> , <i>Arbutus unedo</i> , <i>Quercus</i> spp., but few or no emergent oaks, in contrast to 32.1	32.31

Note: The high maquis (code 32.31) belongs to the meso-Mediterranean silicicolous maquis (code 32.3), which, in turn, belongs to sclerophyllous scrub (code 32) (modified from European Union Directorate General XI, 1991).

Modified from European Union Directorate General XI, CORINE Biotopes Manual, Habitats of the European Community. A Method to Identify and Describe Consistently Sites of Major Importance for Nature Conservation, EUR 12587/3, Brussels, 1991.

syntaxa at the landscape level down to alliances and associations. This is a provisional classification open to further clarification and precision. An example of hierarchical classification for habitats within the CORINE biotopes classification (European Union Directorate General XI, 1991) is highlighted for the *high maquis* in Table 66.1. In the classification, the brief description of habitats, the list of plants, and the phytosociological terms included are intended first to facilitate identification by data collectors, and second to draw attention to sensitive taxa harbored by the concerned habitat. A habitat is defined as:

1. A patch differing from its surroundings in nature and appearance at the finest resolution of the available spatial data
2. Capable of covering large enough surfaces to be important habitat for animals
3. Physiognomically significant in the landscape
4. Essential to the survival of sensitive or rare plant and animal species
5. A necessary element of a larger ecosystem
6. Remarkable because of either ecological processes or its aesthetic value

Map of Italian Nature uses the Landsat Thematic Mapper (TM) to derive digital maps of habitats (Figure 66.3). First, the images are used to identify and mask out urban areas, villages, and sparse agricultural settlement areas. The TM imagery is then used to focus on the habitat patterns of the remaining more naturalistic areas.

An airborne multispectral infrared and visible imaging spectrometer (MIVIS), available from the Italian National Council of Research (CNR), is also used on some areas of interest to generate images with 102 spectral bands in four spectral ranges (0.43 to 0.83, 1.15 to 1.55, 2.0 to 2.5, 8.2 to 12.7 μm), allowing a spatial resolution up to 3 m for the further identification of structural and functional indicators, subtle gradients, and structures like ecotones and riparian corridors.

Figure 66.3 Satellite image of the Aspromonte area from the Map of Italian Nature (Landsat TM5, July 1996).

Preprocessed seven-band TM data are used to delineate areas of relative homogeneity and these are then labeled into classes, defined by the CORINE habitat classification. We use true and false color digital TM scenes, together with other available information sources such as MIVIS hyperspectral imagery, air photos, and other existing maps, to create an integrated visual interpretation of habitat patterns. CORINE habitat patterns also are delineated by supervised classification (Colwell, 1983), by selecting known representative CORINE habitats (training areas) and deriving discriminant functions based on their spectral properties. In practice, the final delineation of habitat mosaics on comparable rendering maps is an iterative process based on integrated evidence from processed satellite imagery, true and false color TM scenes, aerial photos, MIVIS imagery, existing vegetation, other coverage maps, and field reconnaissance.

An example of the decision rule for the CORINE classification can be made in reference to olive trees (*Olea europaea*). When sparse, they are evaluated together with other plant species and habitat physical traits and considered within a specific plant syntaxa (e.g., olive-carob forests). When they dominate, accounting for more than 80% of the vegetation cover, they are classified as olive groves if the peculiar habitat traits of this agroecosystem also are met.

About 10,000 CORINE habitats in Italy, representative of habitat and biotic heterogeneity at the national level, have been identified to date at different scales, mainly 1:50,000 (typical project scale), but also at 1:25,000, accounting for 1,500,000 ha.

CORINE habitat mosaics can be regarded as integrators of many of the physical and biological properties of an area. Each habitat type represents a list of typical plant and animal species linked to it (e.g., invertebrates; Council of Europe, 1996), as well as species shared with other habitat types. Since the urgency for conservation action can often be so great that the lack of detailed

inventories for most taxa becomes of secondary importance, CORINE habitats could be extended, as a coarse filter approach (Noss, 1983), to threatened and nonthreatened species with no actual recorded distribution data. Of course, no coarse filter can be regarded as a complete substitute for biological health and integrity protection status. In Map of Italian Nature habitats, species passing through the mesh of the coarse filter, such as very narrow endemics or wide-ranging animals, can be recorded in the data bank and are not lost for mapping. They can still be recovered by higher- (or lower-) resolution assessment of potential high-priority biodiversity areas in the embedded hierarchy of organization levels provided by CORINE habitats (Zurlini and Rossi, 1995). For the Map of Italian Nature, the habitat level (coarse filter) protection can be a complement, not a surrogate, for protection of individual species at risk. Thus, the Map of Italian Nature intends to protect landscape mosaics at the broader scale, based on gaps in protection and threats, while including finer scale data on threatened species and habitats to make sure they do not fall through the cracks.

BIODIVERSITY COMPONENTS AND CONSERVATION VALUES

With regard to habitats, digital and alphanumeric data were acquired at a scale of 1:100,000 from the Nature 2000 national network of special areas of conservation (SAC) according to Directive 92/43/EU, listing habitat types whose conservation demands consideration for SAC designation, and whose animal and plant species require similar attention by member states. Nature 2000 information layers were generally enlarged to a scale of 1:50,000 and cross-validated by CORINE habitat mosaics below. Existing national and regional park and reserve areas also were acquired as digital data.

As a rule, priority is given only to officially recognized and geo-referenced data available on threatened species. At this first broad analysis level of the Map of Italian Nature, our analyses were restricted to threatened vertebrates, although we are currently enlarging vertebrate data and collecting distribution data on invertebrates and plants, officially provided by scientific societies.

Of 551 terrestrial vertebrate species present, even if only in Italy seasonally, 398 are native reproducing species while 153 are exotics and not reproducing species (Pinchera et al., 1997). Eighty-eight native species are classified in the threatened categories according to IUCN (1996) and Directive 92/43/EU, following Pinchera et al. (1997) updates. Digital maps of observed distribution for the 88 threatened terrestrial native vertebrates were acquired from the Italian Ministry of Environment data bank (Boitani et al., 1993), based on current agency records and reliable records from research and conservation institutions. Digital maps were selected for 31 vertebrates (Table 66.2) with their distribution range included for at least 10% within the 1,500,000 ha currently investigated. Maps were enlarged to 1:100,000 and intersected with CORINE land use maps (Heymann et al., 1993) and digital elevation model (DEM) coverages. Habitat suitability for each species, either within (expected) or outside the observed distributions (potential), was derived by rules of combination for intersecting areas, based on different land use suitability and the elevation range of species distribution. Suitability was expressed as positive or negative scores (3, 2, 1, -1, -2, -3) according to whether it was high (+) or low so that avoidance might occur (-), with unknown suitability equal to zero (Figure 66.4). These digital maps refer to CORINE land use coverages (1:100,000), and represent to date the best current knowledge, providing predictions of encountering an animal in a particular area. The digital maps were carefully enlarged by experts to CORINE habitat mosaics (1:50,000), so that species could be attributed to patches as small as 5 ha (minimum mapping unit). For some species, such a resolution may be desirable to allow more precise estimation both of habitat area and of the wildlife and habitat relationship model (WHRM). For others, such small patches may be biologically meaningless. Most terrestrial vertebrates considered by the project depend on multiple habitat types and sizes for their life history. In order to establish a WHRM for wide-ranging animals, CORINE habitat mosaics summarized at the landscape or at

landscape systems level are going to be considered together with corridors (Corsi et al., 1999) and estimates of species home range size.

For freshwater vertebrates in Italy, the status of the native fish (45 species of 71) is seriously compromised; only 17% of the original fauna (mostly endangered diadromous species) have not been involved in human manipulations and trans-introductions (Bianco, 1995). Most native species have been subjected to authorized or clandestine trans-introductions; only 36% have not been contaminated by trans-introductions of conspecific populations or transplanted to localities outside their original range. Today there is no way to trace the original range of any primary freshwater species (Bianco, 1995). Thus, Italian freshwater systems appear, as a whole, to have quite poor biological integrity, according to the definition of Karr and Dudley (1981).

Strategies and planning for conservation at the ecosystem and regional level, rather than the species-by-species approach focusing strictly on target or endangered species, may protect up to 85 to 90% of species by conserving representative natural communities without a separate inventory of individual species (Noss, 1987). We generated integrated conservation value distributions by intersecting several maps based on habitat and threatened species distributions. Intersection of

Figure 66.4 Example of vertebrate distribution range map for the wolf (*Canis lupus*) in the Aspromonte area from the Map of Italian Nature. The area within dotted boundaries represents the present observed distribution. The wolf's distribution range for Italy is given in the small map. Habitat suitability of CORINE land use covers is provided through positive (good suitability) and negative scores; unknown suitabilities are equal to zero (see text).

habitat coverages produced a GIS composite coverage (hypercoverage) where each habitat received a score according to the different information layers to which it belonged (Zurlini et al., 1999). Scores were assigned to each CORINE habitat: (a) for its occurrence as habitat per se in the Directive 92/43/EU, (b) for its inclusion within park and reserve areas, or within SAC sites, and (c) for the presence of threatened vertebrates, from observed range distribution maps. An example of map-based conservation value of threatened vertebrates distribution is given in Figure 66.5 for the Aspromonte area. Ranked scores were derived for either absolute species occurrences or species per unit of habitat surface (threatened species concentration), with five ranks based on histogram equalization of data frequencies at the current broadest (1,500,000 ha) analysis level. Multivariate scaling techniques were then applied and, by simple inspection of cluster vector means, it was possible to order habitat clusters according to either absolute conservation values (Figure 66.6) or conservation value concentration (Zurlini et al., 1999).

DISTURBANCE

Since disturbance is currently considered to include every process altering birth and mortality rates of individuals present in a patch (Petraitis et al., 1989), it is difficult to separate its intrinsic and extrinsic factors (Nilsson and Grelsson, 1995). Therefore, it seems more appropriate to consider a combination of those factors as provided by fragility.

We considered two main types of human disturbance: (1) human interference activities and (2) pollution. The former refers to interferences from all human activities that transform, interrupt, and fragment the environment, together with noise and other controlled and uncontrolled presences. The latter refers to pollution activities, which in our case are represented by organic load into the watershed from industry, agricultural practices, human residential impact, and tourism.

Human interference was assessed using GIS to read and quantify the length of networks given by state and regional roads, highways, and railways. Road lengths in kilometers crossing and partially or completely delimiting each CORINE habitat were calculated. In addition, habitat edges with agricultural, urban, and industrial areas were considered. For each habitat, the overall amount of exposure length (roads plus edges) in kilometers per unit of habitat surface were calculated and

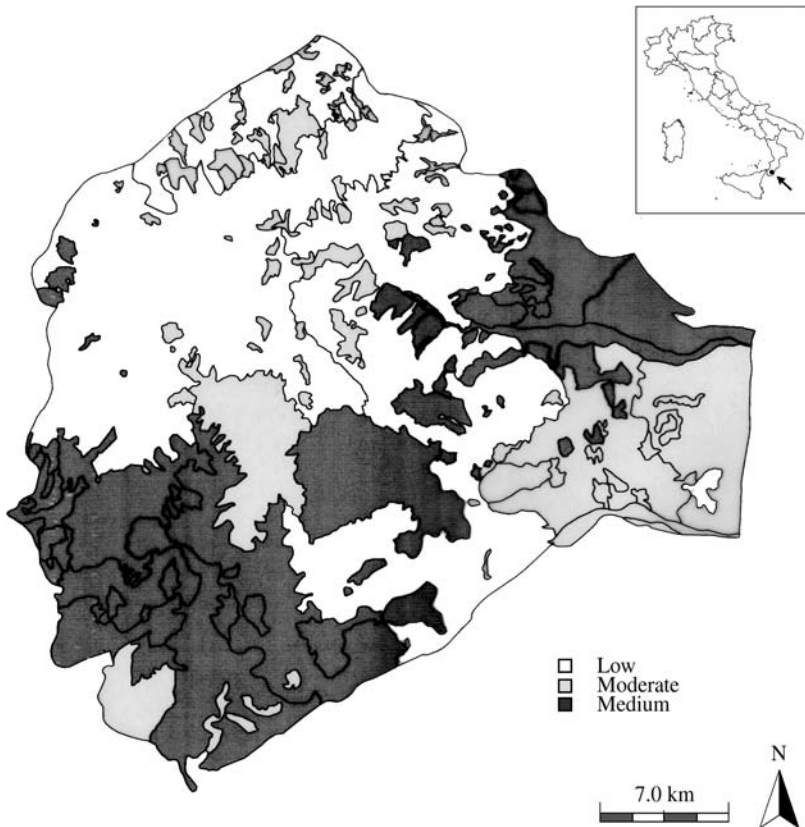

Figure 66.5 Distribution map of habitat conservation values according to the occurrences of threatened native vertebrates for the Aspromonte area from the Map of Italian Nature.

ranked to provide a disturbance exposure index (DE) with the first rank expressing slight or very low disturbances (Zurlini et al., 1999). An example of DE distribution is given in Figure 66.7 for the Aspromonte area.

Pollution was based on (a) the number of residents of each municipality, (b) the number of employees in agriculture, (c) the number of employees in industry, based on estimates from the 1991 census of the Italian National Statistical Institute. Numbers were transformed into inhabitant-equivalents by coefficients varying according to the categories (a), (b), and, within (c), to the type of industry, as established by the National Water Research Institute (IRSA) (Marchetti, 1998), to estimate potential pollution for residents (RWL), agriculture (AWL), and industry (IWL), respectively.

An overall estimate of agricultural pollution into bodies of water was obtained by taking the AWL and adding 5% of pollution from animal breeding (BWL). BWL was weighted differently following IRSA procedure based on the number of breeding animals (cattle, sheep, pigs, etc.) present. From these basic metrics, different indices could be derived. A simple metric of pollution stress to bodies of water at the watershed level could be obtained by ranking the metric $WL = AWL + BWL + RWL + IWL$ per unit of surface in five ranks. The remaining 95% of pollution due to animal breeding (BL) is assumed not to go into bodies of water (Marchetti, 1998), but to the portion of agricultural land falling in each watershed. This was done using GIS by intersecting digital watershed maps with municipality boundaries and agricultural land use areas. This resulted, for each municipality, in a ranked estimate of organic load for agricultural use per unit of surface

Figure 66.6 Distribution map of overall absolute conservation values of CORINE habitat mosaics in the Aspromonte area from the Map of Italian Nature.

(AL). All anthropogenic disturbance indices were ranked by histogram equalization of all data frequencies at the broadest analysis level (Zurlini et al., 1999).

A SIMPLE MODEL FOR FRAGILITY

At each hierarchical level within the Map of Nature, fragility of an environmental system at time t depends on both the sensitivity of the system and overall disturbance, expressed by natural disturbances plus the intensity and frequency of human activities.

A simple conceptual (linear) model can be expressed by the following equation:

$$Fr = K + \alpha(U) \tag{66.1}$$

where Fr is the degree of fragility on an arbitrary, semiquantitative scale; K is a constant; α is a coefficient of sensitivity; and U represents overall disturbance, radically different from the natural regime, and linked to unexpected events not embodied by the system through homeostatic or homeoretic adaptive mechanisms (Figure 66.8).

Model 66.1 is a specific case of a more general model adopted within the project:

$$Fr = K + \alpha(U)^\beta \tag{66.2}$$

where β takes into account that in a given situation the increase of Fr with U may be different from that expected from a linear relationship. When $\beta = 1$ Model 66.2 reduces to Model 66.1; when β

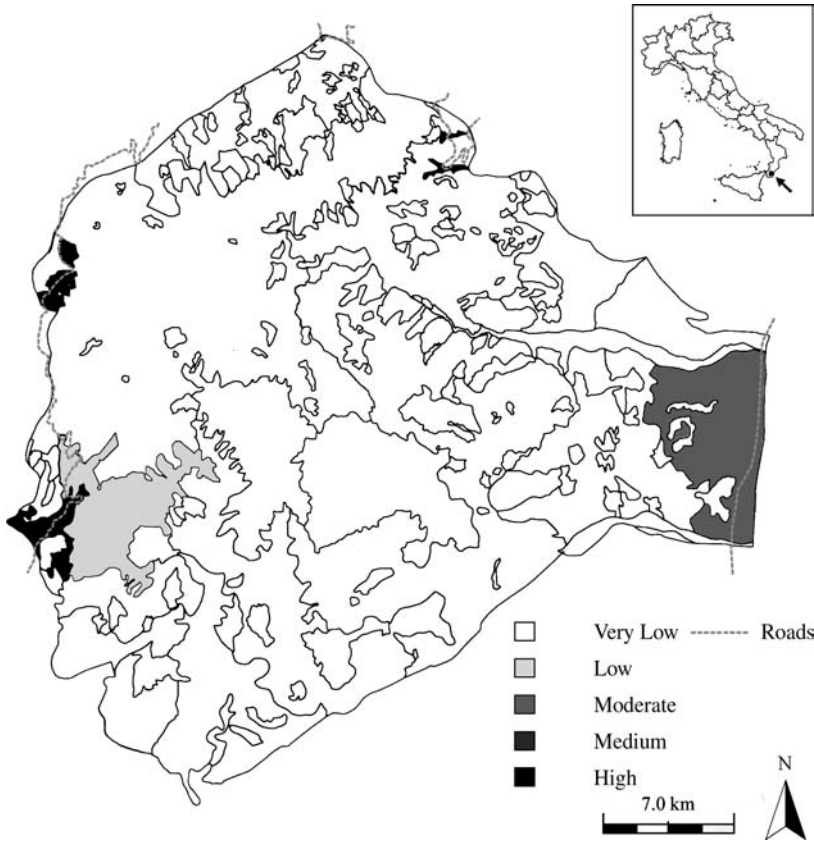

Figure 66.7 Distribution map of the disturbance exposure index (DE) for the Aspromonte area from the Map of Italian Nature.

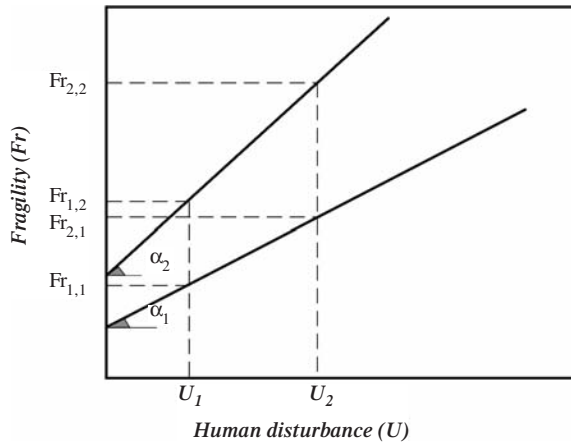

Figure 66.8 Graphic representation of the simple conceptual model for estimating fragility from the Map of Italian Nature. Fr = degree of fragility, α = coefficient of sensitivity, U = overall disturbance.

> 1 Fr increases more than expected according to Model 66.1; for $\beta < 1$ Fr increases less than expected according to Model 1. For $U = 0$, K expresses background fragility typical of the hierarchical level considered. Such fragility is related to specific adaptive mechanisms to expected disturbances, embodied into the memory of the system itself, characterizing the system with relative frequencies in time and space (Norton and Ulanowicz, 1992), and including human disturbances that mimic or simulate natural disturbances. We used Model 66.1 as a first approximate model.

DERIVING SENSITIVITY, FRAGILITY, AND BIOLOGICAL HEALTH IN PRACTICE

Fragility has been often obtained by scores on a semiquantitative scale (Nilsson and Grelsson, 1995), but invariably human disturbances were not explicitly considered. Although empirical, this way of quantifying fragility can be useful since it meets the need to compare habitats, planning intervention, and maintenance measures.

To identify and evaluate fragile habitats, it is important to compare distribution maps of threatened native species. The study area is assumed to be partly or fully covered by species distribution maps as CORINE habitat mosaics. Intersecting areas with one or more threatened species are then considered to be *critical* areas for conservation. However, two critical areas with the same degree (n) of threat, where n is the number of threatened species present, can be different due to the *quality* of threat to the species. Different extinction threat categories for each species, as provided by IUCN (1996) and Pinchera et al. (1997) for vertebrates, must be taken into account. Thus, for threatened vertebrate species in an area, n_1 are critically endangered, n_2 are endangered, and n_3 are vulnerable.

Extinction threats to IUCN threatened species categories are based on the reduction probabilities (p) in the wild within 10 years or three generations, whichever is longer (International Union for Conservation of Nature and Natural Resources–The World Conservation Union, 1996; Walter and Gillet, 1998): critically endangered species (CR) with $p_1 = 0.80$; endangered species (EN) with $p_2 = 0.50$; vulnerable species (VU) with $p_3 = 0.20$. The IUCN criteria which led to extinction threats are given in Table 66.3.

IUCN Red List criteria and categories are applicable to all taxonomic groups, except micro-organisms (International Union for Conservation of Nature and Natural Resources–The World Conservation Union, 1996; Walter and Gillet, 1998). The Map of Italian Nature project needs, however, to produce extinction probabilities for a time interval smaller than 10 years. By using extinction curves provided by Akcakaya and Ginzburg (1991), it is possible to estimate extinction probabilities within a 5-year period.

Table 66.3 Criteria Adopted by IUCN (International Union for Conservation of Nature and Natural Resources) for Extinction Threats to Threatened Species Categories

Criteria for Estimating Extinction Threats to IUCN-Threatened Species Categories	Threatened Species Designation		
	Critically Endangered (CR)	Endangered (EN)	Vulnerable (VU)
Observed, estimated, or projected reduction in wild population within 10 years or three generations, whichever is the longer	80%	50%	20%
Extent of occurrence or	<100 km ²	<5000km ²	<20,000km ²
Area of occupancy	<10 km ²	<500km ²	<2000km ²
Population of mature individuals estimated to number less than:	250	2500	10,000

International Union for Conservation of Nature and Natural Resources–The World Conservation Union, 1996 *IUCN Red List of Threatened Animals*, Gland, Switzerland, 1996; and Walter, K.S. and Gillet, H.J., Eds., 1997 *IUCN Red Lists of Threatened Plants*, compiled by the World Conservation Monitoring Center, International Union for Conservation of Nature and Natural Resources–The World Conservation Union, Gland, Switzerland and Cambridge, 1998.

Risk can be defined as the probability of suffering harm from a hazard. A complete technical analysis of risk describes (1) a hazard that is a substance or an action that can cause harm, (2) the events or conditions that create the possibility of harm, and (3) a statistical estimate of the likelihood that harm will occur. A hazard (risk agent) can be a chemical substance, biological organism, radioactive material or other potentially hazardous substance, or a disturbance activity. Under plausible circumstances, a risk agent can cause harm to human health and ecosystems. A baseline risk assessment estimates current risks to organisms and ecosystems resulting from direct and indirect exposure to risk agents in the absence of any remediation.

The likelihood (**I**) that a given area will lose one or more threatened native species in a fixed time interval (Δt) tends to increase with $n_1 + n_2 + n_3$, but it also depends on the categories of threat to each species. Therefore:

$$\mathbf{I} = (p_1 \cdot n_1) + (p_2 \cdot n_2) + (p_3 \cdot n_3). \quad (66.3)$$

Thus, **I** takes threat weights into consideration, using p -values, and gives the minimum number of threatened native species expected to become extinct in a fixed time interval (Δt) for a given area. Differences in **I**-values between areas can be considered to be proportional to the differences in sensitivity of those areas, because we define sensitivity as a condition due to the presence of threatened species and a trait of the area itself.

I-values do not necessarily correspond to the condition of ecological processes that maintain conservation values or species richness as **I**-values do not directly address functional traits; neither do they reflect patterns of genetic variation within and among population variability that may illustrate the relative risk of extinction among populations (Dunham et al., 1999). Nevertheless, a large number of the threatened vertebrates are considered at the top of their natural food webs, and they are end points to a number of biological and ecological food web processes. Therefore, when comparing areas, **I**-values can represent the baseline intrinsic risk to native biodiversity, because **I**-values incorporate current intrinsic traits of native species (events or situations creating the possibility of harm). Following the IUCN criteria, these intrinsic traits can be given by:

1. Observed, estimated, or projected population reductions, including demographic stochasticity (Caughley, 1994)
2. Extent of occurrence
3. Area occupancy (the ability of a species to occupy a larger or smaller fraction of its potential suitable habitat)
4. Number of mature individuals (representative of population growth potential)

Fragility is not directly measurable, but can be estimated, using Model 66.1 or Model 66.2 through surrogates for U (risk agents, e.g., DE) and α (sensitivity; i.e., the likelihood that the harm will occur together with the exposure conditions creating that possibility). As a surrogate for sensitivity (α), four ranked **I**-values (**I***) **I***-1 through **I***-4 for threatened native vertebrates were used, based on histogram equalization of data frequencies at the current broadest analysis level.

Two comparable areas can have similar sensitivity but different fragility because of differences in the type, frequency, and extent of the risk agents. Different estimates of current fragility can be made using different kinds of risk agents (disturbances) and their relative impact on the responses of the threatened species in question (receptor). For example, most vertebrates can be assumed to cope immediately with disturbances (e.g., noise) by escaping, whereas for invertebrates with aquatic larval stages, other stressors like water pollution are inescapable and should be addressed. The diverse roles receptor species play in the natural food webs, including producers, decomposers, predators, parasites, herbivores, and pollinators, can also be differently affected by various disturbances.

By comparing habitats within CORINE types and between comparable habitat composites (mosaics) in the landscape according to their sensitivity (I^* -values) at the broadest analysis level, it is possible to perform comparative assessments of biological health by defining well-structured, biologically healthy systems. Habitats that fall outside the current normal bounds and that can become dysfunctional because of different degrees and types of stress also can be identified. In this context, current fragility estimates also can be regarded as baseline risk assessments to biological health.

SOME ILLUSTRATIVE RESULTS

Some examples are given for the Aspromonte area (Area 8 in Figure 66.1, CORINE habitat mosaics in Figure 66.2, and satellite image in Figure 66.3), which is mainly montane, but also contains coastal areas of the Ionian Sea. The montane habitats of the northwest range from 1000 to 1956 m altitude and occupy a metamorphic substrate susceptible to erosion and the typical pedogenesis of acid environments. Climate is Mediterranean-montane type, and morphology is rocky with ridges, slopes, depressions, and streams in sunken valleys; beech woods are prevalent here, with two overlapping associations represented by *Aquifolio-Fagetum* at altitudes up to 1500 m and *Asyneumati-Fagetum* at higher altitudes, belonging to the same CORINE habitat, coded 41.185. *Abies alba* is frequent in the association at intermediate altitudes, but disappears at higher altitudes. *Pinus laricio* woods (CORINE code 42.651) start at lower altitudes on ranker soils. Dependent plant associations are present on rocky outcrops. Coastal landscape habitats, located on the eastern side, are characterized by seasonally torrential streams with very broad beds (*fiumare*), and agricultural practices (citrus orchards) with concentrations of exotic species (*Eucalyptus* plantations). Anthropogenic areas are represented by a few villages and sparse agricultural settlements with negligible industrial activity.

To estimate conservation values, human disturbance indices, and I^* -values, the approach described in previous sections was followed, with rank-values comparable within the current broadest analysis level of the project. Overall, 14 occurrences of threatened native vertebrates were recorded (Table 66.2), including wolves (*Canis lupus*), martens (*Martes martes*), wild cats (*Felix silvestris*), and birds of prey: *Hieraetus fasciatus* (Bonelli's eagle), *Neophron percnopterus*, hawks, and owls (*Bubo bubo*). To find a suitable surrogate for U in Model 66.1, we took into account human residential impact as well as agricultural, pastoral, and forest activities, which are quite significant in the area, whereas tourism and industry are negligible. Thus, terrestrial vertebrates were assumed to be affected mainly by DE, RWL, and by inhabitant-equivalents (employees) for AWL per unit of agricultural land use together with those due to animal breeding (AL). These four single metrics (DE, RWL, AWL, AL) were ranked at the broadest analysis level for the 168 habitat units and 30 habitat types identified at a scale of 1:50,000 in the area, then scaling techniques (principal component analysis) were applied to derive two components explaining most of the variance. Those components were subjected to k -means cluster analysis to identify five main habitat clusters for easier interpretation. By simple inspection of cluster vector means it was possible to order habitat clusters according to disturbances in five ranks. This was called overall disturbance (Figure 66.9).

For sensitivity, we used four I^* -ranks to index threatened vertebrates (low, moderate, medium, high). Fragility scores were transformed into a series of six ranks from very low (1) to very high (6), based on histogram equalization of habitat fragility frequencies. Sensitivity and current fragility distribution maps for the Aspromonte are presented in Figures 66.10 and 66.11, respectively.

Absolute conservation value distributions are presented in Figure 66.6. However, such distributions are biased since Directive 92/43/EU still neglects beech woods in the priority list.

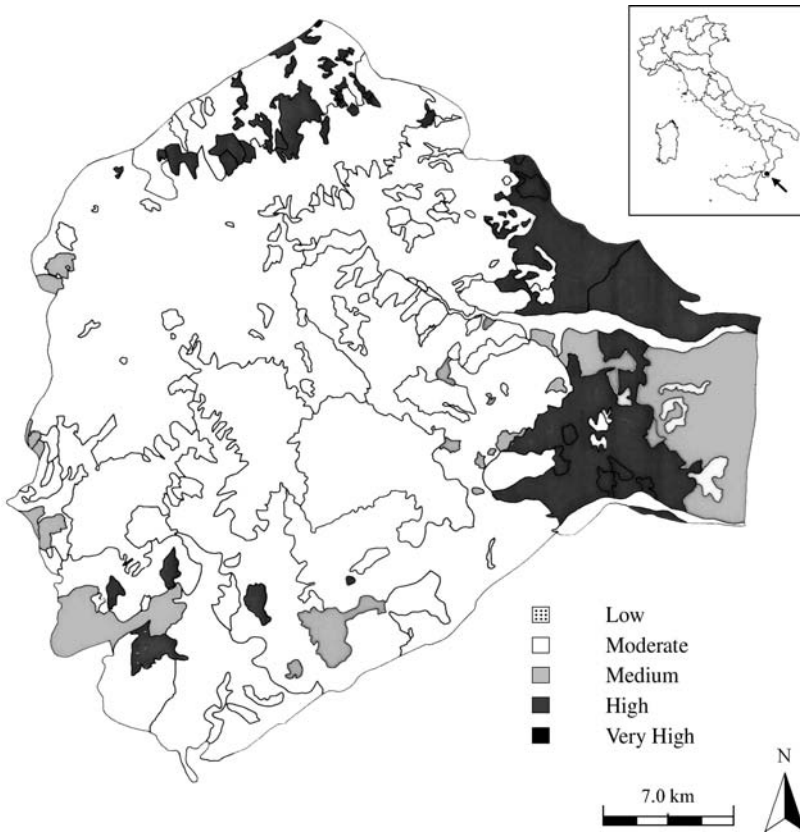

Figure 66.9 Distribution map of the overall disturbance index in the Aspromonte area from the Map of Italian Nature.

At higher elevations, patches with high sensitivities were found embedded within the environmental matrix of beech wood habitats (CORINE code 41.185). *Pinus laricio* woods (CORINE code 42.651) shelter more threatened native vertebrates than beech woods, likely because they are at lower altitudes, and as many as plantations with exotic *Eucalyptus*. By comparing Figures 66.10 and 66.2, we could recognize either similar sensitivity (biological health) levels between different habitat types (e.g., 41.185 and 45.319), or different sensitivity levels within the same habitat type, as illustrated by *Illiryan holm-oak* woods (code 45.319) that at intermediate elevations appear to be a buffer zone between beech woods and anthropogenic coastal areas (Figure 66.2). At the landscape level, sensitivity and fragility distributions were very similar because of relatively low human disturbance in this area compared to other Map of Italian Nature sites. Where sensitivity (biological health) was higher, fragility (risk to biological health) was also higher. The highest fragility and risks to biological health were found for patches of *Castanea sativa*-dominated chestnut woods located in the west (Figures 66.2 and 66.11).

Since landscapes are generally structured according to scaling regions with distinct dimensions connected by transition zones (Holling, 1992), we used fractal geometry to provide a more realistic picture of the geometry of naturally occurring objects. A shift in the fractal boundary dimension, D , might indicate a substantial change in the processes generating and in maintaining landscape patches (Krummel et al., 1987; Sugihara and May, 1990). A procedure based on successive, piecewise, log-log perimeter and area linear regressions (Grossi et al., 2001), where regression slopes are related to D , was applied to CORINE habitat mosaics and a statistically significant discontinuity was detected. This discontinuity separated two distinct scaling regions of habitats in the Aspromonte

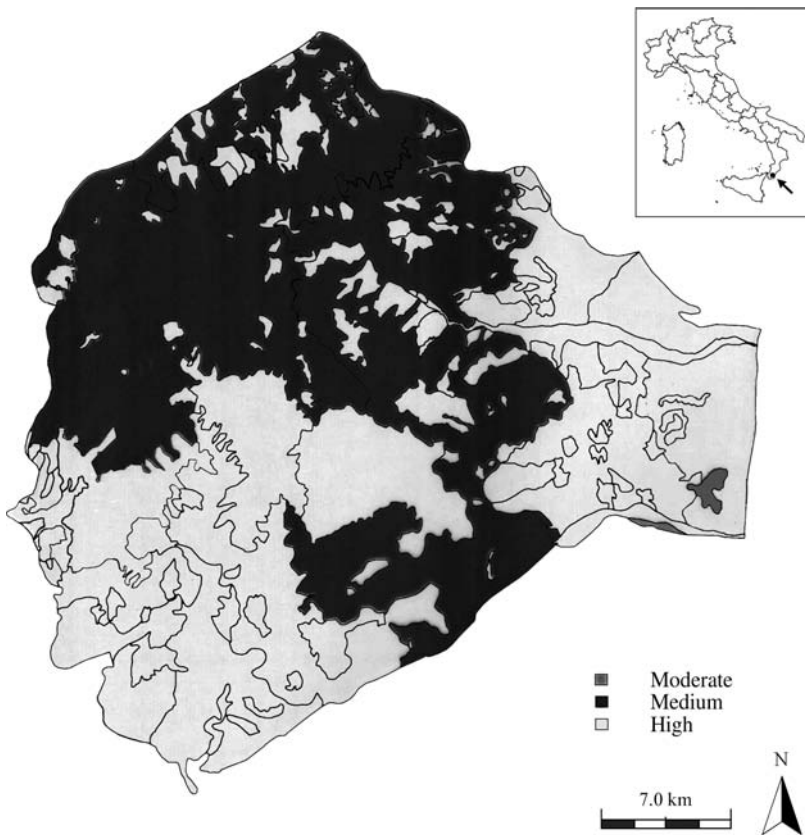

Figure 66.10 Sensitivity distribution map of CORINE habitat mosaics of the Aspromonte area from the Map of Italian Nature. Only ranks present in the area are shown.

area. Habitat patches at higher elevations showed higher fractal D -values, since patch dynamics appear more driven by natural processes, leading to more complex plane-filling fractal edges. In contrast, human and natural (e.g., *fiumare*) disturbances predominate on smaller spatial scales at lower altitudes, making for smoother patch geometry and lower fractal D -values.

CONCLUDING REMARKS

Integrity applies, at one end of a continuum of human influence, to sites with a balanced, integrated, adaptive biota, that is the product of evolutionary and biogeographic processes, with the full range of elements (genes, species, assemblages) and processes that are expected in the region's natural environment (Karr and Chu, 1999). Integrity as a management goal aims at systems looking like this evolved state as much as possible.

Through the kind of approach presented here (but see also GAP analysis, Scott et al., 1996), we are aware we might not preserve the processes that maintain and sustain diversity. Nevertheless, we recognize that ecosystem elements like species and habitat features are used, from the practical point of view, more frequently than processes as indicators of integrity, since they are more sensitive to degradation, more fully understood, and less expensive to monitor (Angermeier and Karr, 1994). In this sense, biodiversity is an important indicator of biological integrity (Angermeier and Karr, 1994). Diversity of threatened native species, CORINE habitats, and patch size and shape relationships are end points to a number of biological and ecological processes

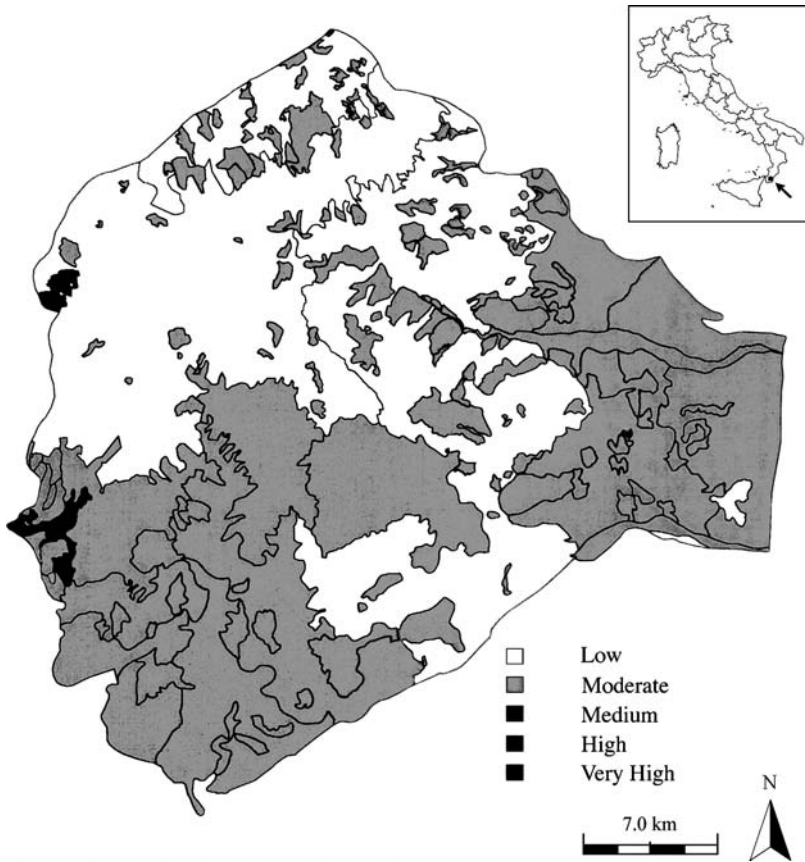

Figure 66.11 Fragility distribution map of CORINE habitat mosaics of the Aspromonte area from the Map of Italian Nature. Only ranks present in the area are shown.

they demonstrate. Indeed, CORINE habitats are not recognized by the Map of Italian Nature as patches themselves, but also for both the ecological processes they stand for, and in the functional perspective of preserving and maintaining habitat-creating processes (Prendergast et al., 1999), including human dynamics.

Albeit we speculatively acknowledge the need and the primacy of integrity as a management goal, we also think that preserving biotic communities, with particular concern for native species populations with their evolved or historic interactions together with their habitat composites, can be still a valuable parallel conservation goal. For example, in regions like the Mediterranean where, due to the millennial synergistic interaction between humans and nature, there might be no easy-to-find historical baseline to judge integrity that predates industrial man. This seems to be the case of freshwater fish communities in Italy (Bianco, 1995). Furthermore, seeking historical benchmarks for evaluating biological integrity addresses elusive issues that must be addressed in planning the restoration of perturbed systems, with regard to the question of resetting the ecological clock, as pointed out by Cairns (1994). Actually, the ecological system, once restored, must be self-maintaining and integrated into the larger landscape where the perturbed patch occurred. When the damage occurred long ago, resetting the ecological clock to predisturbance condition might not always be compatible with the larger landscape where it occurred. Presumably, the larger landscape also has been changing since the patch was perturbed. Therefore, if we want to restore an ecosystem to some approximate earlier condition, at what point should the ecological clock be reset?

Wilderness conservation is dealing with dynamic systems that tend to be more dynamic at interfaces with humans. Under the influence of these human dynamics, conservation has to face an intrinsic paradox (i.e., that we seek to preserve what must change) (Pickett and White, 1985).

The prioritization of areas at risk is a function both of the status of our knowledge and of urgency for conservation management. The Map of Italian Nature is a knowledge system that is evolving and updating due to enlargement, clarification, and increased precision of the data. Ideally, Map of Nature digital maps will never be finished products, since they must continually evolve as new information is gathered at state, regional, and local government levels. Thus, we will prioritize areas at greater risk in a comparative way with approximations based on the best status of knowledge currently available.

Through very simple models and procedures we are generating distribution maps of threatened habitats, plant communities, and animal species. However, our emphasis is on maps of habitat sensitivity and fragility, which can give policy makers and land managers information to foresee the impact their land-use decisions will have on existing risks to ecosystem health.

Assessing the significance of risks to biological health involves judgment and trade-offs to determine what risk level is acceptable. A variety of formal techniques can be used to address this question, including risk–perception analysis, cost–benefit analysis, and decision analysis. However, the use of such techniques to determine an acceptable level of risk is controversial. They provide insight, but also involve uncertainties. Therefore, decision makers, who are going to use the Map of Italian Nature, must be aware that they have also to consider alternatives such as negotiation, consensus building, and other means of broadening involvement in acceptable risk decisions.

ACKNOWLEDGMENTS

The research was conducted under contracts with the Italian Ministry of Environment and the Prime Minister's National Technical Services. We are particularly grateful to G. P. Patil and W. Myers of the Pennsylvania State University for many discussions and helpful comments on this manuscript. Thanks are also given to S. Pignatti, L. Boitani, L. Soliani, L. Grossi, F. Spada, F. Pani, and M. Amadei, as well as a vast number of participants to the Map of Italian Nature project, and an anonymous reviewer. Many thanks are due to N. Zaccarelli for figures and tables.

Interior Columbia Basin Forests and Rangelands, 1930s to Present*

Paul F. Hessburg, Bradley G. Smith, R. Brion Salter, Roger D. Ottmar, and Ernesto Alvarado

INTRODUCTION

Forest and rangeland ecosystems of the interior Northwest U.S. are remarkably diverse and productive, owing to great variety in climate, geology, landforms, floral and faunal species, and ecosystem processes (Bailey, 1995; Franklin and Dyrness, 1988). Recurring disturbances, such as those caused by fires, insects, pathogens, and weather are essential to maintaining this diversity (Agee, 1993, 1994; Arno, 1976, 1980; Hall, 1976; Hessburg et al., 1994; Turner, 1987, 1989). Terrestrial plant communities include dry, short-grass prairies and sagebrush hills; dry ponderosa pine and Douglas fir forests; cool and moist midmontane western hemlock and western red cedar forests; high-elevation whitebark pine and subalpine larch forests, krummholz, and heath. Alpine tundra, rock barrens, and glaciers occupy many of the highest elevations.

Here as elsewhere, vegetation patterns at diverse spatial scales are closely related to underlying patterns of biophysical environments and associated disturbance regimes. Discernible patterns of life-forms and physiognomic conditions arise from broadscale differences in topography, surficial geology, geomorphology, annual temperature, precipitation, solar radiation, and large-scale disturbance. Within the mosaic of coarse patterns, mesoscale patterns result from environmental gradients, patch-scale disturbances, stand development, succession, and other processes.

Natural fire regimes of forests range from frequent, nonlethal surface fires typical in dry ponderosa pine and Douglas fir forests to moderately infrequent, mixed-severity fires, characteristic of some moist grand fir, western hemlock, and western red cedar forests, and infrequent, lethal, stand-replacing fires typical in cold subalpine forests (Agee, 1993, 1994). Likewise, native insect and pathogen disturbance regimes vary in their frequency, severity, duration, and spatial extent. Pandemic bark beetle and defoliator outbreaks occur relatively infrequently in any given geographic area, and when outbreaks occur, often are synchronous with climatic extremes or periods of geographically dominant vegetation structure, composition, or condition resulting from preceding events or trends. Insect or pathogen disturbance associated with endemic populations blends seamlessly with other succession and stand-development processes.

The declining health of forest ecosystems in the Interior Northwest has been the subject of much recent study and controversy (e.g., Everett et al., 1994; Harvey et al., 1995; Lehmkuhl et al., 1994; O’Laughlin et al., 1993; Wickman, 1992). Land use practices of the 20th century altered disturbance

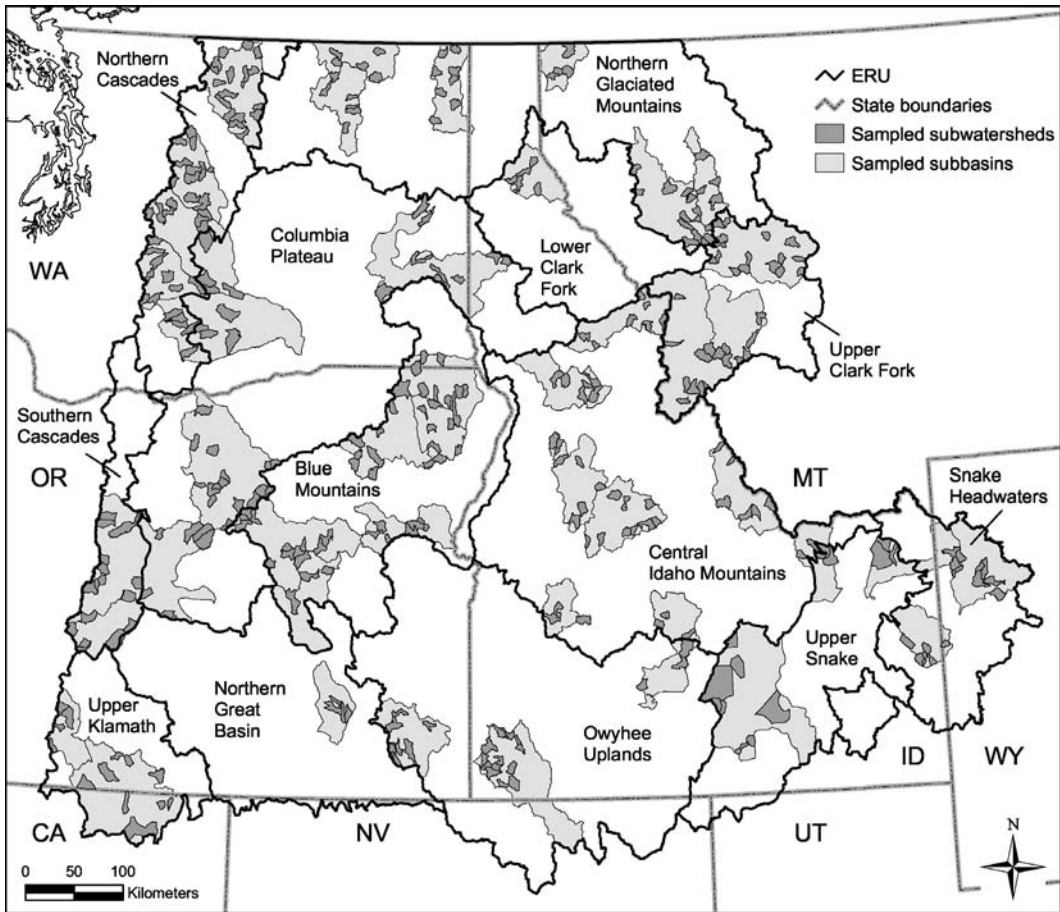

Figure 67.1 Map of Ecological Reporting Units (ERUs), and sampled subbasins and subwatersheds in the midscale assessment of the interior Columbia River basin.

regimes, spatial and temporal patterns of terrestrial habitats and species, and reduced ecosystem resilience to both native and human-caused disturbances (Covington et al., 1994). Fire suppression and exclusion, timber harvest, and domestic livestock grazing have contributed most to increased vulnerability to insect, pathogen, and wildfire disturbance. Concern over declining forest health centers on the perception that management activities have damaged ecosystem structure and function. That perception is founded on a strongly held social value that forest ecosystems should appear natural and function naturally.

This chapter presents results of a study conducted under the aegis of the Interior Columbia Basin Ecosystem Management Project. We report on a mesoscale (map scale = 1:24,000) scientific assessment of change in spatial patterns of forest and rangeland landscapes of the interior Columbia River basin. We also report on associated changes in landscape vulnerability to fire and related PM_{10} (particulate matter <10 μm in diameter) smoke production, and insect and pathogen disturbances, and we discuss management implications of those changes. The study area (58 million ha) included the Columbia River basin east of the crest of the Cascade Range and portions of the Klamath and Great Basins in Oregon (“the basin,” Figure 67.1).

Our study had four objectives:

1. To characterize current structure and composition of a representative sample of forest and rangeland landscapes
2. To compare existing vegetation conditions to the oldest historical conditions we could reconstruct at a comparable scale

3. To link historical and current vegetation spatial patterns with patterns of vulnerability to insect and pathogen disturbances
4. To link historical and current landscape vegetation characteristics throughout the basin with fuel conditions, potential fire behavior, and related smoke production.

Linkages in objectives 3 and 4 would enable us to better understand causal connections among historical management activities and current conditions, and assist in evaluating current air quality and human health trade-offs associated with wild and prescribed fires, and trade-offs associated with alternative insect and pathogen vulnerability scenarios.

METHODS

In the midscale assessment (Hessburg et al., 1999a), we quantified change in vegetation patterns and landscape vulnerability to fire, insect, and pathogen disturbances over the most recent 50 to 60 years. Sampling design and change analysis methods were adapted from Lehmkuhl et al. (1994). Our sample of historical conditions corresponded with the start of the period of intensive timber harvest, road construction, fire suppression, and a period of declining intensity in rangeland management. We based our assessment on a two-stage stratified random sample of 337 of 7496 subwatersheds (10,000 ha average area) distributed in 43 of 164 subbasins (400,000 ha average area) across all ownerships. We reported results of change analysis by ecological reporting units (ERUs; Figure 67.1). ERUs were developed during the broadscale assessment of the basin (Quigley and Arbelbide, 1997) as statistical pooling strata for generalizing results of various ecological, social, economic, and integrated assessments. The ERUs represent land areas that are broadly homogeneous in their biophysical and social ecosystem characteristics.

Forest and rangeland composition and structure were derived from raw data developed from aerial photographs taken from 1932 to 1966 (historical), and from 1981 to 1993 (current). Historical conditions of most forested settings were represented by photography from the 1930s and 1940s, while those of rangelands were represented by aerial photography from the 1950s and 1960s. Areas with homogeneous vegetation composition and structure were delineated as patches to a minimum size of 4 ha. Vegetation cover types, structural classes, and potential vegetation types were classified for each patch using the raw attributes, and topographic or biophysical data from other digital sources of comparable scale and image resolution.

Each patch was assigned a rating for 3 to 7 vulnerability factors associated with each of 21 different forest insects and pathogens, including defoliator, bark beetle, dwarf mistletoe, root disease, rust, and stem decay disturbances. Vulnerability factors were unique for each host–pathogen or host–insect interaction modeled, and included items such as site quality, host abundance, canopy layers, host age or host size, stand vigor, stand density, connectivity of host patches, topographic setting, and type of visible logging disturbance. Patch vulnerability factors were taken from the literature or were based on the experience of field pathologists and entomologists with expertise in specific geographic areas (Hessburg et al., 1999b). Resulting models represent a substantial revision of prototypes described in Lehmkuhl et al. (1994).

Similarly, historical and current vegetation patches were matched to 1 of 192 fuel condition classes (Ottmar et al., 1996; Schaaf, 1996) and assigned a fuel loading level. Fuel loads were used to compute fuel consumption, particulate emissions production (PM₁₀), crown fire potential, and fire behavior attributes for an average wildfire scenario using published procedures (Huff et al., 1995; Ottmar et al., in press). We also modeled fuel consumption and related smoke production for a prescribed burn scenario. Algorithms for estimating fuel consumption for both burn scenarios were taken from the CONSUME (Ottmar et al., 1993) and First Order Fire Effects Model (FOFEM; Keane et al., 1994). Fire behavior attributes were rate of spread, flame length, and Byram's fireline intensity. We computed fireline intensity (Rothermel, 1983), rate of spread, and flame length using

the published equations of the National Fire Danger Rating System (Cohen and Deeming, 1985; Deeming et al., 1977; Rothermel, 1972).

Vegetation and Landscape Pattern Analysis

This assessment was a map-based characterization of landscape patterns and ecological processes across space and time. We used the ARC/INFO (Environmental Systems Research Institute, 1995) geographical information system (GIS) to manipulate and analyze digital maps, and to develop and run spatially explicit insect and pathogen vulnerability (Hessburg et al., 1999b), and fuel consumption and fire behavior models (Ottmar et al., in press). Spatial and statistical analyses characterized change in patterns and quantified the significance of change. FRAGSTATS (McGarigal and Marks, 1995) was used to compute class and landscape pattern metrics directly from ARC/INFO data tables, and we incorporated three additional metrics (N1, N2, and R21; Table 67.1) into the source code. We used S-PLUS (MathSoft, Inc., 1993) to summarize and analyze ARC/INFO and FRAGSTATS outputs. Vegetation maps and raw and derived patch attributes formed the basic data set for all analysis. For spatial pattern analysis, a variety of unique vegetation maps were derived in a GIS by dissolving on single or combined data items. Patch types of a map submitted to analysis could be defined by any raw attribute, such as canopy layers or total crown cover class, or by any derived attribute, such as cover type or structural class, either singly or in combinations.

To quantify change in individual patch types and patterns of various patch types, we used raster versions of current and historical vegetation maps where patch types were physiognomic conditions, cover types, structural classes, potential vegetation types, or combinations. A raster format was chosen because several useful metrics were only available in FRAGSTATS for raster maps. The appropriate cell (pixel) size was determined by calculating several class metrics in vector and raster form, with cell sizes ranging from 10 to 100 m² (1 ha), in 10-m² increments, and at 141.4 m² (2.0 ha) and 223.2 m² (5.0 ha), and plotting each raster-derived metric value against the vector value. When compared with vector values, raster bias was insignificant with 30-m² and smaller cell sizes, and we used 30-m² raster maps for all pattern analysis.

Sample Statistics

We used percentage of area, patch density, mean patch size, edge density, and mean nearest neighbor class-metrics to describe change in area and connectivity of patch types in subwatersheds of an ERU. We used ten landscape-metrics to describe changes in patch type richness, evenness, diversity, dominance, contagion, interspersion, juxtaposition, and edge contrast (Tables 67.1 and 67.2). For each ERU, means, standard errors, and confidence intervals were estimated using methods for simple random samples with subwatersheds as sample units. Significant ($p \leq 0.2$) change from historical to current conditions was determined by examining the 80% confidence interval (CI) around the mean difference for the ERU. We used a moderately conservative 80% CI because we wanted to be able to detect changes in spatial patterns that were of potential ecological importance. We reasoned that with a more conservative CI, we might increase the probability of Type II error (false positive). When we compared 90 and 95% CI estimates of mean difference with 80% estimates, we noted that important changes went undetected using the more conservative CIs.

To avoid increasing the probability of Type I error (false negative), we supplemented our significance test with two other tests. These enabled us to evaluate the potential ecological importance of change in patch area or connectivity, and the probability of error in rejecting the null hypothesis. First, we estimated a reference variation by calculating for each metric the 75% range around the historical sample median, and then compared the current sample median value with this range. We chose the median 75% range instead of the full range as a measure of reference variation to portray typical variation exclusive of extreme observations. Historical and current data distributions were most frequently right-skewed, the sample median value accurately

Table 67.1 FRAGSTATS Indices Used to Quantify Spatial Patterns of Patch Types in Sampled Subbasins in the Midscale Ecological Assessment of the Interior Columbia River Basin

Abbreviation	Scale	Index Name	Description ^a
%LAND	Class	Percentage of landscape (%)	Percentage of a landscape composed of the corresponding patch type
PD	Class or landscape	Patch density (no. per 10,000 ha)	Number of patches in an area of 10,000 ha
MPS	Class or landscape	Mean patch size (ha)	Average patch size
AWMECI	Class or landscape	Area-weighted mean edge contrast index (%)	Average patch edge contrast as a percentage of maximum contrast with patch edge contrasts weighted by patch area; equals 100 when all edge is maximum contrast; approaches 0 when all edge is minimum contrast
SHDI	Landscape	Shannon's diversity index ^b	Measures proportional abundance of patch types and the equitable distribution of patch type areas; increases with patch richness (PR) and equitability of area
RPR	Landscape	Relative patch richness (%)	Observed number of patch types within a landscape over a realistic potential maximum number of patch types
PR	Landscape	Patch richness	Observed number of patch types within a landscape boundary
MSIEI	Landscape	Modified Simpson's evenness index ^c	Observed distribution of area of patch types within a landscape over evenly distributed area of patch types
IJI	Class or landscape	Interspersion and juxtaposition index (%)	Observed interspersion of edge types over maximum possible interspersion; IJI approaches 0 when patch types are clumped; IJI approaches 100 when all patch types are equally adjacent to all other patch types
CONTAG	Landscape	Contagion index (%)	Observed contagion over the maximum possible contagion for the given number of patch types; approaches 0 when the distribution of adjacencies among unique patch types becomes increasingly uneven; approaches 100 when all patch types are equally adjacent to all other patch types; measures patch type interspersion and patch dispersion
N1	Landscape	Hill's index N1 ^d	A transformation of SHDI, computed as e^{SHDI} ; rare patch types are weighted less in the calculation than in PR
N2	Landscape	Hill's index N2 ^d	A transformation of SIDI, computed as $1/(1 - SIDI)$; rare patch types are weighted less in the calculation than in N1
R21	Landscape	Alatalo's evenness index ^e	Measures evenness of patch types; computed as $(N2 - 1)/(N1 - 1)$, where $PR > 1$; values approaching 0 indicate uneven distribution of patch type areas; values approaching 1 indicate even distribution of area for the given number of patch types

^a See McGarigal and Marks (1995) for algorithms and complete descriptions of all indices, except N1, N2, and R21.

reflected central tendency, and most observations were clustered within the median 75 to 80% range. Second, we determined the largest changes in absolute area of a patch type within a sample using transition analysis. Transition analysis estimates the percentage of sampled area in each unique historical to current patch type transition. We reasoned that the more extreme variation

Forest ofms									0

^a For FRAGSTATS, see McGarigal and Marks (1995).

^b Forest structural classes are: stand initiation (si); stem exclusion open canopy (seoc); stem exclusion closed canopy (secc); understory reinitiation (ur); young forest multistory (yfms); old forest single-story (ofss); and old forest multistory (ofms). See also Figure 67.8 for graphical illustrations of forest structural classes.

^c Range of possible values is 0 to 1, with increasing values representing greater edge contrast.

resulted from either unique contexts or environments, or from rare events. By imposing the contrast between current median values and a typical range of historical conditions, we retained the ability to detect conditions resulting from management activities, rare or chance events, or perhaps climate change that were unique in some aspect.

RESULTS

Trends in Physiognomic Conditions

Significant changes in physiognomic types occurred throughout the basin. Cover of forest increased significantly in the Blue Mountains, Columbia Plateau, and Upper Snake ERUs (Figure 67.2, Table 67.3). Transition analysis showed that effective fire prevention, suppression, and exclusion allowed the expansion of forests into areas that were formerly fire-maintained shrublands, herblands, or areas created by early logging. Connectivity (spatial aggregation) of forest increased in the Central Idaho Mountains and Upper Snake ERUs (see Hessburg et al., 1999a). Increased connectivity was the result of expanded forest cover on former shrubland areas (Table 67.3). The Central Idaho Mountains contain large wild and roadless areas. Transition analysis of cover type changes indicated that increased connectivity of forests resulted from effective fire suppression and fire exclusion. We note that in a few subwatersheds increased forest connectivity resulted from regrowth of forest in areas that had experienced large-scale stand replacement fires.

Both area and connectivity of forest cover declined in the Upper Klamath ERU (Figure 67.2). Upper Klamath forests are naturally quite fragmented because broad grassy valley bottoms or grasslands on dry southerly aspects often separate forested slopes. High timber harvest levels and juniper woodland expansion into the ponderosa pine cover type were responsible for the observed reduction, and we suspect that domestic livestock grazing was indirectly involved as well. Observed reductions in area of forest were readily explained via transition analysis of historical and current physiognomic and cover type maps, and through analysis of patch density

Figure 67.2 Change in percentage of area in the forest physiognomy for selected ERUs. ERU abbreviations are: SC = Southern Cascades; BM = Blue Mountains; UK = Upper Klamath; CP = Columbia Plateau; US = Upper Snake. Asterisk (*) denotes significant difference at $P \leq 0.2$.

and mean patch size trends. Figure 67.3 illustrates altered physiognomic conditions in sampled subwatersheds of the Blue Mountains (Figure 67.3 [top]) and Upper Klamath (Figure 67.3 [bottom]); see color figure following p. 668) ERUs.

Woodland (sparsely wooded rangeland) area increased in 7 of 13 ERUs and declined in none (Figure 67.4). Transition analysis revealed that fire suppression, fire exclusion, and domestic livestock grazing enabled mostly juniper woodland expansion at the expense of hermland and shrubland area. The associated regional decline in area of shrublands was the most dramatic of all changes in physiognomic conditions (Table 67.3, Figure 67.4). Transition analyses showed that losses of native shrublands resulted from forest and woodland expansion (Blue Mountains and Northern Great Basin ERUs), cropland expansion (Northern Great Basin ERU), and conversion to seminative or nonnative herblands (Owyhee Uplands and Snake Headwaters ERUs). Figure 67.5 (see color figure following p. 668) illustrates reduced shrubland and increased woodland area in an Upper John Day subwatershed, Blue Mountains ERU.

Conversely, hermland area increased in the Central Idaho Mountains, Northern Great Basin, Owyhee Uplands, Snake Headwaters, and Southern Cascades ERUs and declined in none. In the Northern Great Basin, hermland increased at the expense of shrubland area, which fell by more than 15%. Transition analysis indicated that half of the lost shrubland area is currently occupied by juniper, and the balance supports montane bunchgrasses or exotic grass and forb cover. Herblands and shrublands followed a similar pattern in the Owyhee Uplands. Across the basin, most increases in hermland area resulted from expanding colline (environments occurring below lower treeline), exotic grass, and forb cover with shrubland conversion. Here, we note that the vast majority of native herblands were converted to agricultural production prior to our historical condition. We describe changes to what are essentially relict herblands.

Forest Cover Type Trends

Shifts from early- to late-seral cover species were evident in most ERUs (Table 67.3), but the most pronounced shifts occurred in the Northern Glaciated Mountains (Figure 67.6). In some ERUs, the shift was partially masked by steep climatic gradients. For example, in the Northern Cascades ERU, Douglas fir is early-seral in several mid- to upper-montane series (e.g., western hemlock, western red cedar), but to the east at lower elevations is climax in the Douglas fir series.

Figure 67.6 Change in percentage of area in forest cover types of the Northern Glaciated Mountains ERU. Asterisk (*) denotes significant difference at $P \leq 0.2$.

Western larch cover declined significantly in the Central Idaho Mountains, Columbia Plateau, and Northern Glaciated Mountains, and ponderosa pine cover decreased in the Northern Cascades, Northern Glaciated Mountains, Upper Clark Fork, and Upper Klamath. Increased ponderosa pine cover in the Southern Cascades resulted from regrowth of forests that were tractor-logged prior to our historical photo coverage. Lodgepole pine cover declined in the Snake Headwaters and in six other ERUs. Western white pine cover decreased in the Northern Glaciated Mountains as a consequence of white pine blister rust and mountain pine beetle mortality, and early selective harvesting. It increased slightly in the Northern Cascades as a result of recent reforestation. Whitebark pine-subalpine larch cover declined in the Central Idaho Mountains, Northern Glaciated Mountains, Snake Headwaters, and Upper Clark Fork ERUs and increased in the Blue Mountains and Northern Cascades. Decline in whitebark pine-subalpine larch cover resulted from ongoing blister rust and mountain pine beetle mortality, and expanded area of subalpine fir and Engelmann spruce.

In contrast, Douglas fir cover increased in the Blue Mountains, Columbia Plateau, and Northern Cascades; grand fir cover increased in the Northern Cascades and Northern Glaciated Mountains; Pacific silver fir cover increased in the Northern Cascades; Engelmann spruce-subalpine fir cover increased in the Northern Glaciated Mountains, Snake Headwaters, Southern Cascades, and Upper Clark Fork; and western hemlock-western red cedar cover increased in the Columbia Plateau and Northern Glaciated Mountains (Table 67.3). Engelmann spruce-subalpine fir cover declined in the Blue Mountains, and Engelmann spruce-subalpine fir and western hemlock-western red cedar cover both decreased in the Northern Cascades. Results of transition analysis showed that noted increases in these shade-tolerant cover types were best explained by fire suppression and exclusion, and selective timber harvest activities.

Added to expanded area of late-seral species, average patch sizes of most forest cover species are smaller and current land cover is more fragmented (Figure 67.7; see color figure following p. 668). In the historical condition, spatial patterns of biophysical environments and disturbance regimes created patches of land cover that were large, and overall patterns were relatively simple. In the current condition, highly fragmented land cover mosaics have replaced simpler patterns. In some heavily roaded subwatersheds (Figure 67.7, top), widely applied patterns of small cutting units were responsible for the change. In roadless subwatersheds, fine- to midscale disturbance processes are responsible for reduced connectivity of land cover. For example, subwatershed 55 of the Methow subbasin (Figure 67.7, bottom) resides in the Pasayten Wilderness. Prior to the era of fire suppression (pre-1930s), large-scale stand replacement fires would naturally occur on an infrequent basis, resulting in simple land cover mosaics consisting of a relatively few large patches. Today, the Methow subwatershed exhibits reduced connectivity of land cover, and causative factors were small fires and bark beetle outbreaks.

In the next section, we discuss changes among forest structural classes. Here, it will be important to keep in mind the scale dependence of observations. Immediately above, we reported that land cover mosaics exhibited increased pattern complexity in the current condition. Below, we show patterns of structural classes changing in a different way.

Trends among Structural Classes

In general, the vertical structure of individual forest patches has become more complex, but the overall landscape pattern of forest structural conditions is simpler when compared with historical forests. Landscape area in old forest structures (multistory and single-story) declined in most forested ERUs (Figure 67.8; see color figure following p. 668), but the most significant declines occurred in the Blue Mountains, Northern Cascades, Snake Headwaters, and Upper Klamath ERUs (Figure 67.9, Table 67.3). Landscape area in stand-initiation structures (patches of young, new forest) declined in five of nine forest-dominated ERUs and increased in only one, the Blue Mountains. Area in stand-initiation structures declined in the Central Idaho Mountains,

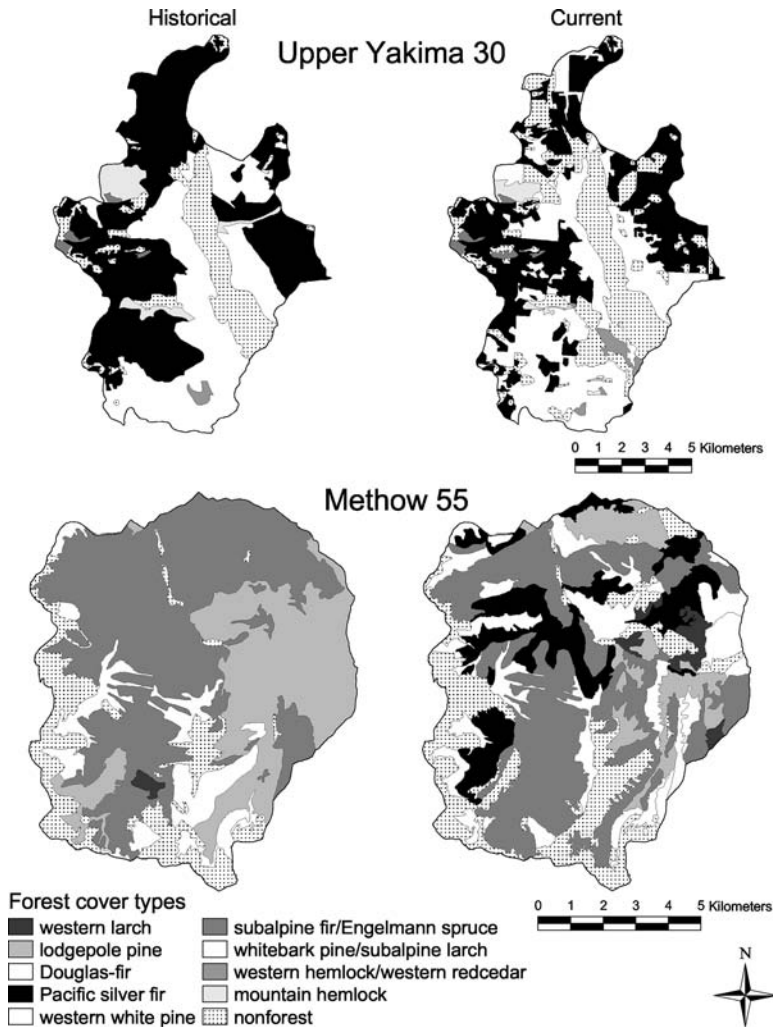

Figure 67.7 Historical and current forest cover type area of subwatershed 30, Upper Yakima subbasin (top); and subwatershed 55, Methow subbasin, North Cascades ERU (bottom). (See color figure following p. 668.)

Lower Clark Fork, Northern Glaciated Mountains, Upper Clark Fork, and Upper Snake ERUs (Figure 67.10). This stands to reason because stand replacement and mixed severity fires were historically dominant in these ERUs across both space and time.

Area and connectivity of intermediate (not new and not old forest) structural classes (stem exclusion, understory reinitiation, and young multistory patches) increased in most forested ERUs. This change toward landscape dominance of intermediate forest structures was the general mechanism of pattern simplification. When viewed simplistically, there is currently less area in stand-initiation and old forest structures, and considerably more area and improved connectivity of intermediate forest structures. The most notable increases in intermediate structures occurred in the Blue Mountains, Central Idaho Mountains, Columbia Plateau, Lower Clark Fork, Northern Glaciated Mountains, Snake Headwaters, Southern Cascades, and Upper Clark Fork ERUs. Area in intermediate structural classes actually declined in the Upper Klamath ERU, where transition analysis implicated extensive past timber harvesting.

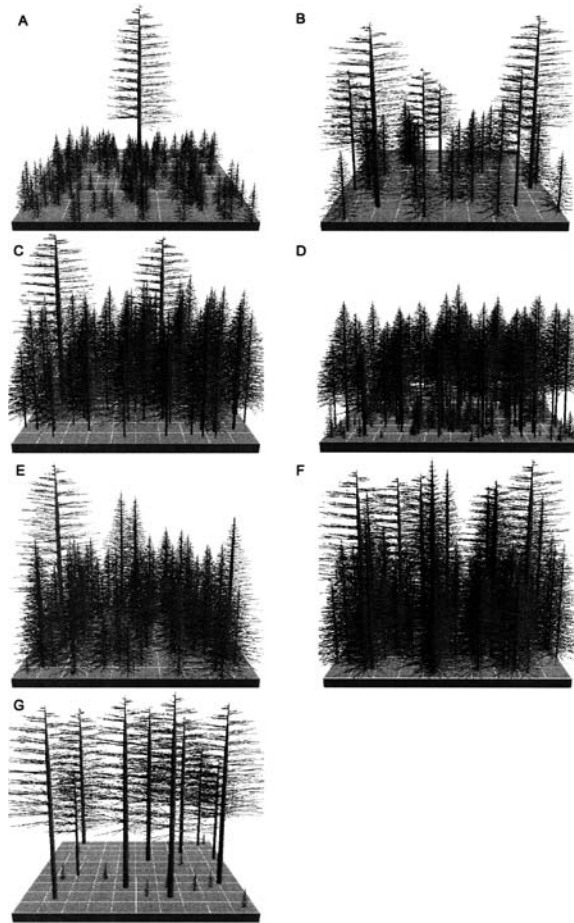

Figure 67.8 Graphical representation of forest structural classes used in the midscale assessment of the interior Columbia River basin: (A) stand-initiation; (B) open stem exclusion; (C) closed stem exclusion; (D) understory reinitiation; (E) young multistory forest; (F) old multistory forest; (G) old single-story forest. Refer to Oliver and Larson (1996) and O'Hara et al. (1996) for expanded descriptions of forest structural classes. (See color figure following p. 668.)

Other Structural Changes

Four additional findings related to forest structural change are worthy of brief mention:

1. In the historical condition, large (>63.5 cm diameter at breast height, d.b.h.) and medium (40.5 to 63.5 cm d.b.h.) trees were once more widely distributed in structures other than old forest as a conspicuous remnant after stand-replacing wildfires. Change analysis indicated that patches with medium and large trees were targeted for timber harvest, regardless of their structural affiliation.
2. Along with other raw attributes interpreted from aerial photos, we estimated dead tree and snag abundance in each forest patch as: none, <10%, 10 to 39%, 40 to 70%, and >70% of trees dead or as snags. Change analysis with these data indicated that dead tree and snag abundance increased significantly in most forested ERUs, but primarily in the pole and small tree (12.7 to 40.4 cm d.b.h.) size classes, because the medium and large trees were depleted by timber harvest.
3. Current forest patches have more canopy layers than were displayed in the historical condition, and understory layers are typically comprised of late-seral species.
4. In the historical condition, forest understories were often absent or they were comprised of shrub and herbaceous species. Current forest understories are less often grass or shrub and mostly coniferous. With livestock grazing and the elimination of surface fires, multilayered conifer understories developed.

Figure 67.9 Change in percentage of area in old forest and other structures for selected ERUs. Asterisk (*) denotes significant difference at $P \leq 0.2$.

Landscape Spatial Patterns

We conducted change analysis with cover type-structural class couplets as patch types. Following, we discuss changes occurring across all ERUs for a given subset of metrics (Table 67.1).

Richness, Diversity, and Evenness

Patch richness (PR), Shannon's (1949) diversity index (SHDI), and the inverse of Simpson's λ (N2; Hill, 1973) provide different views of the diversity of patch types of a landscape. While richness tallies the number of patch types present regardless of their abundance, the SHDI and N2 indices incorporate abundance into the measurement of diversity, but N2 responds to change in the abundance of dominant patch types. Relative patch richness (RPR) relates PR to the total number of patch types (192) present in the basin. The SHDI (or its transformed equivalent, N1; Hill, 1973) is intermediate in responsiveness to abundance changes between RPR and N2.

In general, for the five measures of richness and diversity (RPR and PR, SHDI and N1, and N2), all ERUs displayed a positive mean difference with two notable exceptions (Table 67.4): the Lower Clark Fork and Upper Klamath ERUs exhibited minor declines in PR. Using transition analysis, we could attribute declines in richness to a history of widespread timber harvest activity. Five of 13 ERUs displayed change in PR generally on the order of a 15 to 30% increase, while 8 of the 13 ERUs reflected both increased dominance and diversity (N2). PR values and transition analysis showed that cover-structure patch types not only increased in number, but new patch types (cover type and structural class combinations) occupied considerable landscape area. The ERUs displaying increased dominance and diversity are shown in Table 67.4.

Evenness measures assess how equitably area is distributed among patch types. Both evenness measures (modified Simpson's evenness index, MSIEI, and Alatalo's evenness index, R21) index change in the distribution of area among all patch types. Many ERUs displayed increased diversity, richness, and dominance during the sample period for the diversity measures we used. Such increases typically result in a modest increase in the values of the evenness measures, if any change occurs. Our results confirmed this relation; the MSIEI and R21 indices increased in 6 of 8 ERUs displaying increased diversity and dominance. The Upper Clark Fork and the Central Idaho Mountains were the only 2 ERUs to decline in evenness; the Upper Clark Fork declined in both evenness measures (Table 67.4). To explain changes in evenness, it is helpful to reexamine changes in the area relations of cover types and structural classes. In the Central Idaho Mountains, few cover type changes were significant, but distribution of area in forest structural classes became increasingly uneven (Table 67.3, Figure 67.10). Area in stand-initiation structures declined from 9.7 to 5.9% of the ERU, and area in understory reinitiation structures increased from an average of 16 to 21.4% of the ERU. A similar pattern of change was evident in the Upper Clark Fork; few cover type changes were evident, but distribution of area in stand-initiation, closed canopy stem-exclusion, and young multistory forest structures became uneven (Table 67.3).

Landscape metrics were averaged across sampled subwatersheds, hence, values for all metrics in the historical and current condition reflect the average per subwatershed. But an examination of data in Table 67.4 prompts two additional questions: (1) What is the total richness and diversity of patch types of each ERU, and (2) Have total richness and diversity values for the ERU changed during the sample period? Heltshe and Forrester (1983) describe a jackknife estimator for richness that attempts to estimate total richness for a geographic area of interest. We applied this technique and a related estimator for N2 (Burnham and Overton, 1979) to the historical and current data to estimate difference in total richness and dominance for each ERU (Table 67.5). The jackknife technique results in estimates of the total and standard error. We used these statistics in simple two-way *t*-tests to evaluate significant change in total

^a RPR values represent percentage of relative patch richness where the observed number of patch types (cover type-structural classes) in an ERU is scaled against a realistic maximum number of patch types possible across the entire basin assessment area. PR values simply represent the total number of patch types present within an ERU. N1 is a transformation of SHDI; rare patch types are weighted less than in PR. N2 also counts numbers of patch types like RPR, but N2 gives dominant patch types increased weight and can be considered a count of the average number of dominant patch types in an ERU. With N2, rare patch types are weighted less than in N1. ^b Suffix h = average historical value among subwatersheds of an ERU; c = average current value among subwatersheds of an ERU; and md = mean difference of pairwise comparisons of sampled subwatersheds within an ERU; RPR = relative patch richness; SHDI = Shannon-Weaver diversity index; N1 = Hill's index N1 = e^{SHDI} ; N2 = Hill's index N2 = $1/(1/SID)$; MSIEI = modified Simpson's evenness index; R21 = Alatalo's evenness index = $(N2 - 1)/(N1 - 1)$; CONTAG = contagion index; IJI = interspersion and juxtaposition index; AWMECI = area-weighted mean edge contrast index (see also Table 67.1 and McGarigal and Marks, 1995). ^c Asterisk (*) indicates statistical significance at $P \leq 0.2$.

^d MSIEI is more sensitive to change in abundance among all patch types, whereas R21 is more sensitive to change in abundance of the dominant patch types. Increases indicate that area distributed among patch types is increasingly even. Declines indicate that some patch types are more abundant than others within an ERU. Significant figures are computed to two decimal places.

Table 67.5 Jackknife Estimates of Total Patch-Type Richness and Dominance (N2) for 13 Ecological Reporting Units in the Midscale Assessment of the Interior Columbia River Basin, Where Patch Types Were Cover Type-Structural Class Doublets

Ecological Reporting Unit	No. of Sampled Watersheds	Richness ^a		Dominance (N2) ^b	
		Historical (s.e.)	Current (s.e.)	Historical (s.e.)	Current (s.e.)

Snake Headwaters	15	83 (5.4)	92 (5.9)	30 (3.2)	26 (3.1)
Southern Cascades	16	69 (5.7)	80 (8.1)	15 (1.3)	15 (2.6)
Upper Clark Fork	32	113 (5.8)	120 (4.9)	25 (1.9)	23 (2.2)
Upper Klamath	13	107 (7.0)	100 (5.7)	13 (3.9)	16 (3.0)
Upper Snake	15	67 (8.3)	71 (6.5)	3 (0.4)	3 (0.9)

^a Estimates of total richness and standard error (s.e.) were computed by using the methods of Heltshe and Forrester (1983). Estimates for total richness were rounded to the nearest integer.

^b Estimates of total dominance (N2) and its standard error were computed by using the methods of Burnham and Overton (1979). Estimates for total dominance were rounded to the nearest integer.

^c Asterisk (*) indicates significant difference at $P \leq 0.2$.

richness or dominance. All changes but one were insignificant, but 8 ERUs displayed nonsignificant increases in richness. Jackknife estimates of richness are sensitive to differences in sample size and distribution. In this instance, it is best not to make comparisons among ERUs, but comparisons between current and historical values are appropriate. Jackknife estimates for N2 are not restricted in this way. The N2 values across ERUs range from a low of 1 in the Owyhee Uplands to 36 in the Northern Cascades. We expect forest-dominated ERUs to display much larger values of total dominance than rangeland-dominated ERUs because of their greater patch richness and diversity.

Contagion and Interspersion

Contagion (CONTAG) and interspersion-juxtaposition (IJI) metrics quantify the extent to which pixels of differing type intermix; IJI considers length of edge between contrasting patch types, and CONTAG estimates patch dispersion and interspersion for raster maps. Seven of 13 ERUs displayed significant declines in CONTAG, and all significant mean difference values were negative (Table 67.4). A negative mean difference value of CONTAG indicated that across an ERU, cover-structure patches became smaller and more dispersed. Three of 6 ERUs with nonsignificant mean difference values of CONTAG also exhibited a negative sign. These results suggest a basin-wide decrease in cover-structure patch contagion. With the exception of the Northern Great Basin and Owyhee Uplands ERUs, the magnitude of decrease was small relative to initial average historical values.

Only 4 of 13 ERUs displayed significant mean difference values for IJI; 2 were positive and 2 were negative (Table 67.4). The Owyhee Uplands and Upper Snake ERUs were noteworthy because the magnitude of the mean IJI difference for these 2 ERUs was especially large. Unlike CONTAG, there was no consistent pattern across ERUs for this metric, and most changes were small. We conclude that interspersion changes as measured by this metric are minimal at this scale, but that changes in interspersion and juxtaposition may be better observed at smaller pooling scales where environmental variation is controlled.

Edge Contrast

The area-weighted mean edge contrast index (AWMECI) uses a set of user-defined values ranging from 0 to 1 to represent relative edge contrast (Table 67.2) between patch types, weighted by area, to evaluate change in edge contrast of a sample of landscapes. We based edge contrast weights on physiognomic and structural conditions in deference to edge-sensitive and edge-dependent terrestrial species, and their sensitivity to structural edge differences. An increase in area-weighted mean edge contrast was indicated as the percentage of the total edge that was the equivalent of maximum contrast edge. The greater the difference in structure or physiognomic condition (e.g., an old single-story forest patch adjacent to herbland), the greater the edge contrast weights. Significant increase in AWMECI for a sample of landscapes indicated that greater contrast in structural and physiognomic condition was occurring at patch edges. Six of 13 ERUs displayed such an increase. Most increases were relatively modest except in the Lower Clark Fork where increase in maximum contrast edge averaged 5.1% of the total edge (Table 67.4).

Landscape Vulnerability to Disturbances

Insects and Pathogens

Our analysis indicated that forest landscapes have changed significantly in their vulnerability to major insect and pathogen disturbances. Absent frequent fires and influenced by selective harvesting and domestic livestock grazing, overstory and understory cover of shade-tolerant conifers expanded, forest structures became more layered, and grass and shrub understories were replaced by coniferous understories. As a consequence, the vulnerability associated with shade-tolerant forest area increased substantially. Conversely, because patches with medium and large trees of early-seral species were primarily harvested, the vulnerability associated with mature and old early-seral forests declined. A few examples follow (also see Table 67.6).

In many ERUs, the area vulnerable to western spruce budworm increased, but most changes were not significant at the scale of an ERU. To determine whether the lack of observed significant difference was scale dependent, we summarized statistical results for budworm (and other disturbances) by smaller scale pooling strata. For example, we used subregional groupings of sampled subwatersheds based on similarity of climate and environments, and we were able to readily detect significant change in area vulnerable to budworm defoliation. Results of these analyses suggested that ERUs were too large for detecting these and perhaps other changes, and smaller pooling strata would be more informative. In addition, we noted that the conduciveness of both patch- and landscape-scale vegetation conditions to widespread severe budworm defoliation increased over the sample period. This was due to the increased area and connectivity of patches of shade-tolerant conifers, increased abundance of multilayered host patches, increased contagion of host patches reflected both in increased average host patch size, and in some cases, increased host patch density.

Throughout the basin, area vulnerable to Douglas fir beetle and Douglas fir dwarf mistletoe increased in three important ways: (1) forest landscapes in the existing condition exhibit increased cover and connectivity of Douglas fir; (2) current stand densities are elevated well above historical conditions; and (3) patches today tend to be multilayered, often with several layers of understory Douglas fir. Figure 67.11 (top; see color figure following p. 668) provides an illustration of increased forest area vulnerable to Douglas fir dwarf mistletoe in a subwatershed of the Wallowa subbasin of the Blue Mountains ERU. Conversely, area vulnerable to western pine beetle disturbance of mature and old ponderosa pine (WPB1, Table 67.6) fell because medium and large ponderosa pine were selectively harvested from old forest patches and from other structures (Figure 67.11 bottom; see color figure following p. 668).

^b H = historical condition; C = current condition.

^c Values shown in bold indicate significant increase or decrease ($P \leq 0.2$) from the historical to the current condition.

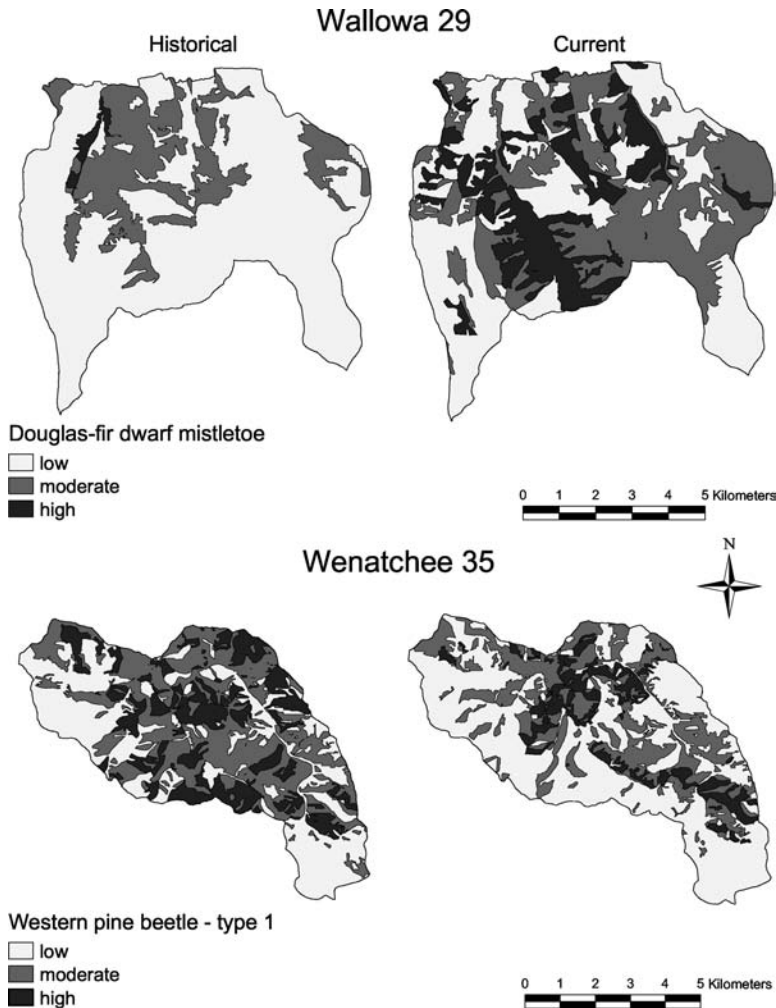

Figure 67.11 Historical and current forest area: (top) vulnerable to Douglas fir dwarf mistletoe disturbance, subwatershed 29, Wallowa subbasin, Blue Mountains ERU; (bottom) vulnerable to western pine beetle disturbance of medium (40.5–63.5 cm d.b.h.) and large (> 63.5 cm d.b.h.) ponderosa pine, subwatershed 35, Wenatchee subbasin, Northern Cascades ERU. (See color figure following p. 668.)

Wildfires, Prescribed Fires, and Smoke Production

Forest landscapes have been significantly altered in their vulnerability to wildfires, increasing the potential for air quality degradation as well. In general, the risk of stand replacement fire has increased throughout the forest-dominated portion of the basin. Elevated risk is indicated by increased ground fuel loads, crown fire potential, flame length, rate of spread, fireline intensity, and smoke production (PM10), each of which are consequences of change in spatial patterns of both living and dead forest cover and structure. Changes in vegetation patterns are the result of effective fire suppression, timber harvest, and fire exclusion. Key factors responsible for fire exclusion were the widespread elimination of flashy fuels through extensive domestic livestock grazing, especially in the first half of the 20th century (Hann et al., 1997, and references therein; Skovlin and Thomas, 1995; Wissmar et al., 1994); reduced connectivity of fire-prone landscapes through placement of extensive road networks; settlement of fire-prone interior valleys and subsequent conversion to irrigated agriculture by European immigrants; and movement of American Indians, who frequently used fire as a management tool on reservations (Robbins and Wolf, 1994).

A number of changes in fuel loading, PM10 smoke production (Table 67.7), crown fire potential, and fire behavior attributes (Table 67.8) were significant at the ERU scale; a few examples follow (see also Ottmar et al. in press). In the Central Idaho Mountains, fuel loads (>45 Mg/ha), smoke production (>448 kg/ha), and flame length (>1.2 m) increased to high levels or above on more than 5% of the area. In the Lower Clark Fork ERU, fuel loads (> 45 Mg/ha), PM10 smoke production (>448 kg/ha) during wildfires, and flame lengths greater than 1.2 m during wildfires increased to moderate levels or above on approximately one third of the ERU area. Crown fire potential increased to high levels or above on 29% of the ERU area. At present, 82% of the area of the Lower Clark Fork ERU exhibits moderate to severe crown fire potential. In the event of a wildfire today, it would be difficult with current technology to suppress expected flames on 94% of the current forest and rangeland area. At present, over 81% of the ERU would exhibit very low smoke production if prescribed fires were implemented in place of wildfires for fuels reduction. Under a wildfire burn scenario, only 14% of the ERU area would exhibit very low smoke production.

Finally, in the Southern Cascades fuel loads (>45 Mg/ha) increased on nearly 5% of the ERU area, rate of spread (>2.4 m/min) during wildfires increased on more than 11% of the area, and extreme fireline intensity (>3459.2 kW/m) increased on nearly 8% of the area. At present, 56% of the ERU area exhibits moderate to extreme crown fire potential, and 82% of the forest and rangeland area would experience flame lengths in excess of 1.2 m during wildfires. In the event of a wildfire, it would be difficult to suppress flames on 8 of every 10 ha. At present, over 75% of the ERU would exhibit very low smoke production if prescribed fires were implemented in place of wildfires for fuels reduction. Under a wildfire burn scenario, 21% of the ERU area would exhibit very low smoke production.

DISCUSSION

The primary utility of landscape assessment is in understanding the characteristics and potential responses of the ecosystems we manage (Morgan et al., 1994). Knowledge of landscape pattern change at regional and subregional scales provides critical context for forest-level planning; watershed analysis and project-level planning; and valuable insight for ecosystem restoration, conservation, and monitoring decisions. Landscape change analysis provides an empirical basis to evaluate the historical and current rarity of landscape pattern features and aids in determining how representative current patterns are compared with historical conditions.

- The basin assessment area is large, and we summarized many changes in vegetation condition and associated vulnerability to disturbance. Here we focus on the most important generalities lest we lose them.
- The most dramatic change in physiognomic conditions that we observed was the widespread decline in shrublands. Losses resulted from forest, woodland, and cropland expansion, and conversion to semi- or nonnative herbland.
- The loss of historical herblands to agriculture was considerably more dramatic, but it had already occurred by the time of our historical sample.
- Shifts from early- to late-seral species were evident in many ERUs. Change in ponderosa pine, western larch, and Douglas fir cover was associated with reduced area with medium and large trees.
- We observed a precipitous decline in area and connectivity of western white pine cover in northern Idaho and northwestern Montana, the heart of the historical range. Losses were attributed to early selective harvesting, an introduced blister rust fungus, and mountain pine beetle mortality.
- Shade-tolerant conifers now dominate interior Columbia Basin forests. Lacking significant pattern restoration, the insects and pathogens that favor shade-tolerant conifers will continue shaping forest patterns by their growth and mortality effects, and by indirect influence on fire regimes.
- Patch area with old forest-structures declined sharply in all ERUs where they historically occupied more than a minor area. The same was true of patches with remnant large trees.

- In several ERUs, area with medium and large trees overshadowed or augmented losses to historical old-forest area. Our results suggested that 20th century timber harvest activities targeted patches with medium- and large-sized trees regardless of their structural affiliation. There are at least two important ramifications: First, it has been broadly assumed that large trees were principally associated with old forests, where they obviously contribute important living and dead structure. In some ERUs, old forest abundance was historically quite minimal (refer to Table 67.3), but medium and large trees were broadly distributed in other forest structures as a remnant after stand-replacing fires. In some cases, large trees comprised as much as 24% of the crown cover of other forest structures, contributing important living and dead late-successional functionality. Second, where old forest area and area with remnant large trees has been depleted, the present and future supply of medium and large dead trees as snags and down logs is substantially diminished. This is especially true of snags and down logs of early-seral species. We propose that terrestrial and aquatic species and processes requiring large dead tree structure may be adversely influenced by this reduction unless the shortfall is remedied through intentional recruitment.
- In several ERUs, we observed a marked reduction in landscape vulnerability to dwarf mistletoes of early-seral species. Comparisons of historical and current subwatersheds showed that timber harvest reduced crown cover of large early-seral trees while one or more shade-tolerant understory strata developed. Wildlife microhabitat ramifications are likely.
- Area and mean patch size of stand-initiation structures dramatically declined where natural stand-replacing fires have been excluded. Such reduction was evident despite widespread timber harvest activity. With recent emphasis on conserving dwindling areas of late-successional and old forests in the Interior Northwest, the role of stand-initiation structures on the landscape may have been underestimated. The immediate effect of stand-replacing fires is to simplify landscape patterns and restore early-seral conditions. After such a fire, forests are regenerated with a new cohort of early-seral seedlings, saplings, grasses, and shrubs. Subsequently, environmental and disturbance gradients interact, recreating some of the lost pattern complexity, but expanses of interior forest emerge as a reminder of prior disturbance. Absent disturbances of this magnitude, what will create the interior forests of the future?
- The absence of wildfires has had profound effects on forest and woodland area and connectivity at subwatershed to regional scales. The history and legacy of fire suppression and prevention programs is well known, but fire exclusion effects have been more difficult to pin down because many interacting factors played a role. As a result, fire prevention and suppression efficacy may have been overstated, and the role of factors responsible for exclusion of fire understated. Basic ecological studies are needed that explore in greater detail effects of road networks and domestic livestock herbivory on historical *and* current exclusion of fires and accretion of trees.
- Patches of current forest cover types and structural classes are more fragmented than before. Patch densities are now higher, mean patch sizes are smaller, the largest patch of any given cover or structural class is smaller, and edge density is greater. These combined outcomes point to reduced landscape contagion as a consequence of timber harvest and road construction. Landscape pattern metrics confirmed the presence of highly fragmented landscapes in the current condition and pointed to increased pattern complexity among patch types in managed landscapes, and decreased complexity in roadless and wilderness-dominated landscapes.

Management Implications

Several important management implications emerge from our assessment of basin conditions, but before we discuss implications, we summarize what was learned from assessment. First, we showed that spatial patterns of historical landscapes were indeed variable, and that those patterns reflected variation resulting from patterns of environments and natural disturbance regimes. Second, we showed that ground fuel and fire behavior conditions can be explicitly linked to vegetation conditions, that fuel and fire behavior conditions changed throughout the basin, and that landscapes varied in the direction and magnitude of changes. Finally, we showed that fire, insect, and pathogen disturbances were commonly associated with historical landscapes, but that the area and pattern of area that was highly vulnerable to disturbance, and the degree of spatial isolation has changed. In

Fire rate of spread classes (m/min): very low = 0.0–0.6; low = 0.7–2.4; moderate = 2.5–9.1; and high >9.1. Flame length classes (m): are: very low <0.6; low = 0.7–1.2; moderate = 1.3–1.8; high = 1.9–2.4; very high = 2.5–3.4; and severe >3.4. Crown fire potential classes are a relative index.

this section, we highlight several key issues surrounding current public land management of Interior Northwest forests and relevant implications from this assessment.

Fuels and Fire Behavior — Examining and Isolating the Risks

Throughout the basin, there are currently many large, spatially continuous areas that display elevated ground fuel conditions and increased severity in fire behavior attributes. Prior to the 20th century period of active management, areas that were normally influenced by infrequent lethal fires and those of a mixed lethal–nonlethal type also displayed relatively high fuel loads, crown fire potential, rate of spread, flame length, and fireline intensity. Active management has not made the entire landscape wildfire-prone; rather, it has removed the degree of spatial isolation that patches prone to stand replacement once enjoyed (Figures 67.12A to H; see color figure following p. 668). A reasonable target of restoration would be to restore more typical patterns of spatial isolation to affected landscapes.

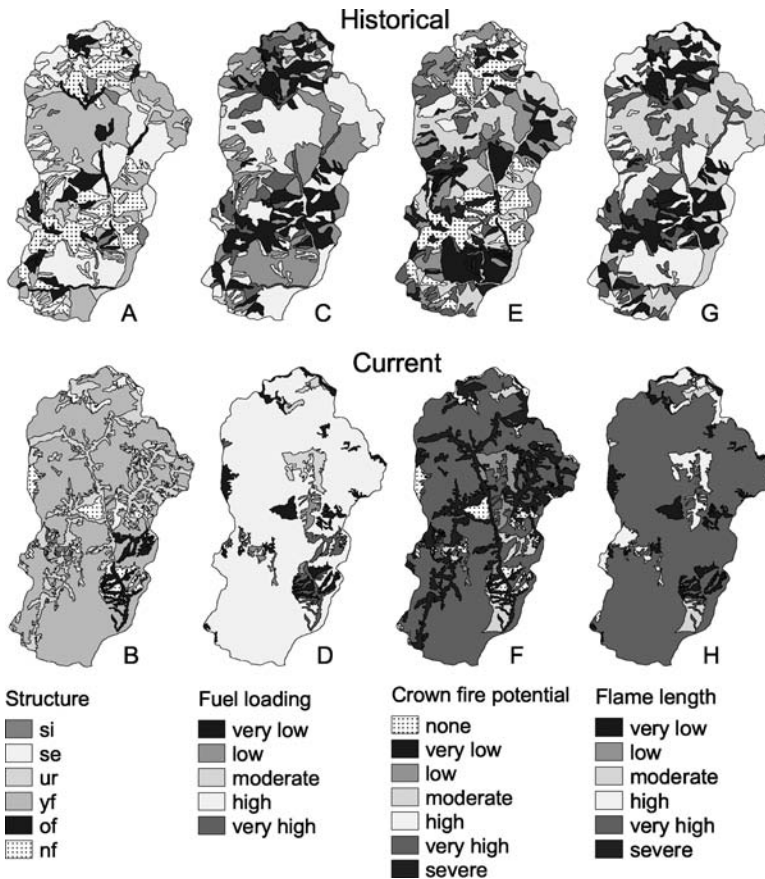

Figure 67.12 Maps of subwatershed 55, Lower Grande Ronde subbasin, Blue Mountains ERU, displaying historical and current structural classes (A and B), fuel loading (C and D), crown fire potential under wildfire conditions (E and F), and flame length under wildfire conditions (G and H), respectively. Structural class abbreviations are si = stand-initiation; se = stem exclusion (both open and closed canopy conditions); ur = understory reinitiation; yfms = young multistory forest; of = old multistory and single-story forest; and nf = nonforest. Fuel loading classes are very low < 22.5 Mg/ha; low = 22.5–44.9 Mg/ha; moderate = 45–56.1 Mg/ha; high = 56.2–67.3 Mg/ha; and very high > 67.3 Mg/ha. Crown fire potential classes were a relative index. Flame length classes were: very low < 0.6 m; low = 0.7–1.2 m; moderate = 1.3–1.8 m; high = 1.9–2.4 m; very high = 2.5–3.4 m; and severe > 3.4 m. (See color figure following p. 668.)

The Wildland–Urban Interface

Most people who live adjacent to National Forest lands of the basin live on or adjacent to dry woodlands, or dry to mesic forests. These specific settings have been most altered by 20th century management activities. As a result, surface fire regimes that once affected lands of the current wildland-urban interface have become lethal or at best mixed regimes, and forest residents are at risk at each outbreak of fire. In the context of declining fire suppression effectiveness, public land managers might consider, as a first priority, restoring vegetation and fuels patterns in the wildland-urban interface. In addition, managers might consider working with local citizens and communities to halt what is currently a rapidly expanding zone of interface. The tacit assumption of citizens who take up private residence in the forest is that the public land manager will come to their aid at the outbreak of fire. At some point, the rescue role of public land managers must be clearly enunciated and the total extent of a wildland-fire interface zone defined. The safety and management implications of not doing so are large.

Fire and Smoke — How Much and When?

Stated simply, the question before public land managers is not whether there will be fire and smoke in their future, but how do citizens want their fire and smoke. As Ottmar et al. (in press) and Huff et al. (1995) have shown, the air quality and smoke production trade-offs between wild and prescribed fires are highly significant; prescribed burning can eliminate 50% or more of the particulate emissions generated by wildfires, and the timing, movement, and disposal of smoke released to the airshed is managed. According to Hann et al. (1997), it is unlikely that fire suppression efficacy will improve given current vegetation and fuels conditions. Provided there is sufficient management latitude, it will be up to resource managers to restore patterns of living and dead vegetation to conditions that are more attuned with natural fire regimes and biophysical environment conditions. In this scenario, citizens would learn to live with some measure of smoke on a regular basis as an alternative to uncertain fire- and smoke-free intervals punctuated by periods with extreme fires and smoke emissions of unchecked magnitude, distribution, and effect.

Insects and Pathogens — Which Ones and How Much?

In the same way that fires visit healthy forests in many areas, some native insects and pathogens also visit healthy forests. Insect and pathogen disturbances motivate forest succession, especially in the fire-free interval. Under natural disturbance regimes, these disturbances produced semi-predictable outcomes, and more importantly, insect and pathogen disturbances were either attuned with biophysical environment conditions and natural fire regimes, or they recalibrated them. Such is not the case today. Owing to effects of past management, current patterns of forest vegetation are out of synchrony with natural fire regimes, and current insect and pathogen disturbance regimes are anomalous. There is no way to eliminate insect and pathogen disturbances from basin landscapes, and we would undoubtedly not wish to do so even if we were able. The by-product of most insect and pathogen disturbances is microhabitat (snags, down wood) of varying quality and residence time essential to a variety of terrestrial and aquatic species. Management, by altering spatial and temporal patterns of vegetation structure, composition, and growing conditions, can influence the suite of agents operating on a landscape, but it cannot, and from a purely ecological point of view, should not attempt to eliminate these disturbances.

Dynamic and Reserve Systems

In the Pacific Northwest, the Northwest Forest Plan (NWFP) defines a network of late-successional reserves throughout the Cascade and Coast Ranges of Oregon, Washington, and

California. While these lands are not explicitly set aside for custodial management, that is how they are managed. It is likely that such an approach may be implemented west of the Cascade crest where most fire regimes are lethal; fire-free intervals may last 250 to 800 years or more; and the most common disturbances, which are caused by native insects and pathogens, result in relatively small canopy gaps. East of the Cascade crest where this assessment has taken place, the picture is different. Wildfires and large-scale insect outbreaks are relatively common, and escaped wildfire frequency is increasing as a consequence of past management (Hann et al., 1997).

Results from the interior Columbia Basin assessments (Hann et al., 1997; Hessburg et al., 1999a; Ottmar et al., in press) suggest that a two-pronged, mixed dynamic and reserve system management approach may be needed to ensure recovery of the northern spotted owl and associated species. In the short term (e.g., 50 to 100 years), it is likely that areas currently functioning as late-successional and old forest habitats will be maintained with only limited success. Risk of disturbance and uncertainty of outcomes will be high. Over that period, some areas will be affected by stand-replacement fires, and will cease to function as late-successional habitat. For example, since 1994, 10 of the 140 to 180 (6 to 7%) northern spotted owl nest stands and neighborhoods were lost to uncontrolled wildfires on the Wenatchee National Forest alone. Patterns of structure and composition within the NWFP reserve network will continue to change as a result of uncontrolled fires, insect outbreaks, and other processes.

What may be needed is an approach that marries a short-term system of reserves with a long-term strategy to convert from a reserve system to a continuous network of landscapes with dynamic properties. In such a system, late-successional elements with semipredictable environmental settings (*sensu* Camp et al., 1997) are continuously recruited, but shifting in landscape position across space and time. Patches of late-successional and old forest structure are ephemeral landscape elements; they have specific contexts in space and across time. Future old forest will grow from some other condition; current old forests will become something else. Taking hold of this notion enables one to identify the dilemma of strategies that rely on a reserve system without backup. Because of the unfortunate legacy of past management actions, late-successional reserves must represent a special case for management. But the special case is an unforeseen consequence of past events, and in the interior, the long-term likelihood of success is low.

Healthy Fish and Healthy Forests

Can there really be an aquatic conservation strategy separate from a landscape pattern restoration strategy? One conclusion of the interior Columbia basin aquatic (Lee et al., 1997) and landscape assessments (Hann et al., 1997) is the notion that disturbance regimes and succession processes associated with terrestrial and aquatic environments are inextricably intertwined. For example, in forested catchments, hydrologic regimes are naturally governed by spatial and temporal patterns of vegetation and disturbance. Wildfires and timber harvest activities have a direct bearing on the timing, purity, temperature, and flow of water through catchments. Disturbance in upland settings can result in either positive or negative effects on aquatic conditions. Disturbances associated with native regime attributes tend to result in the renewal and redistribution of essential aquatic habitats. Disturbances of unprecedented frequency, intensity, distribution, and duration tend to result in habitat damage and losses to fish production. Likewise, by specifying standardized buffer zones and long-term custodial management of riparian zones, aquatic conservation strategies have a direct bearing on spatial and temporal patterns of vegetation. But in neither case are the effects of either strategy jointly considered. While the tug-of-war between healthy aquatic systems and healthy forests is to be expected initially, reason suggests that as the debate comes of age, scientists and managers would pursue strategies that jointly consider long-term spatiotemporal patterns of upland vegetation and disturbance, *and* consequences to hydrologic regimes and aquatic habitats.

ACKNOWLEDGMENTS

The U.S. Department of Agriculture, Forest Service, through the Pacific Northwest and Rocky Mountain Research Stations, and the U.S. Department of the Interior, Bureau of Land Management, provided financial support for this study. We are grateful to John Lehmkuhl, Sandy Boyce, Ann Camp, and two anonymous reviewers for helpful comments and suggestions on an earlier draft.

SECTION II.6

Communities, Politics, Culture, and Tradition

Overview: Communities, Politics, Culture, and Tradition

Alexander H. Harcourt

The three main themes of this section are the issues of multiple users, means of assessing environmental health, and cooperation to mitigate adverse effects on environmental health. The regions covered extend from the Americas, east through Europe and the Middle East, and then to Bhutan, in the northeast of the Indian subcontinent. The size of the regions ranges from multicountry in North America and the Middle East, to multistate within the U.S., to single countries (Mexico, Netherlands), to a single county in a state in the U.S. (in California), to a single city (Brussels), and to communal pastures in two districts of Bhutan. The features assessed or managed encompass the total environment, both physical and economic (Netherlands); the natural environment (Mexico); water quality in the whole Great Lake catchment basin of Canada and the U.S.; desertification (Middle East); the effects of urbanization on the environment (U.S.); the effects of change in transportation use on air quality (Brussels); agricultural environment and native biota (Yolo County, CA); and pasture and livestock health (Bhutan). The levels of cooperation examined include international treaties, interstate agreements in the U.S., governmental and NGO (nongovernmental organizations associated with the United Nations) coordination in Mexico, cooperation among disciplines in the Netherlands, and communal use of pastures in Bhutan.

To ensure a healthy environment despite increased use, we need to know who the users are, and how they will be affected by measures aimed at the maintenance of environmental health. In all the cases in this section, public land is, effectively, the environment under discussion. Multiple users are therefore involved, with the number of users ranging from a few score people and a few hundred livestock in a communal grazing pasture in Bhutan (Ura) to millions of users in the Great Lakes region of Canada and the U.S. (Bertram et al.), and in the Middle East (Christiansen). With so many users, the types of use are, of course, varied and variably conflicting. Little to no common ground exists between the biologist and the urban developer, especially where most of the natural environment has disappeared already, as in Mexico, leaving set-aside as often the only way to preserve natural environments (Ezcurra). By contrast, cleaner fuel and improved public transport could result in a cleaner, quieter city despite increased urban sprawl and commuting (Safonov et al.).

However complex the multiple use, we obviously have to understand which environmental variables are crucial, and how to measure them. Bertram et al. describe the 80 indicators of environmental health being used by Canada and the U.S. in the Great Lakes region, 19 of which involve water quality. The indicators are biotic (parasite and waterfowl numbers, area of natural habitat) and chemical (phosphorus and acid concentrations), and also include ecosystem function

(resilience to disturbance) and health of the users (contaminants in breast milk). The Great Lakes protocol essentially uses the indicators separately, but Zhang et al. describe their attempt to produce a single index of environmental health for Yolo County, CA, that incorporates not only indices appropriate to sustainable agriculture in the county, but also to protection of wildlife. In recognition of the importance of the economics in determining almost all aspects of policy, an assessment protocol developed in the Netherlands involves integration of measures of both environmental and economic health. Furthermore, the protocol includes, most crucially, assessment of progress toward achievement of goals (Verkaar et al.). The sense of the future inherent in such assessment is paramount in the analyses by Matheny and Endres and Safonov et al. of the effects of urbanization on environmental health. Matheny and Endres, for instance, examine the possibility that telecommuting in the eastern U.S. would allow smaller or fewer new offices, resulting in less environmental degradation than traditional commuting would cause. And Safonov et al. start with socioeconomic analyses in order to predict trends in urbanization and consequent trends in transportation, which they then use to predict changes in air quality under a variety of scenarios for urbanization in the region of the European Union capital, Brussels.

Turning to the issue of cooperation, Bertram et al. describe what must be one of the larger attempts at collaborative management in the world, the Great Lakes Water Quality Agreement between Canada and the U.S. They also describe the sort of small-scale cooperation that is a necessary part of the large-scale collaboration. The new Brantford office complex of Union Gas Ltd. in Ontario, Canada, has been designed to be environmentally friendly and, more visibly, the company restored the surrounding lands to nearly their natural prairie state. The local community is using the prairie as an outdoor classroom, and Union Gas itself benefits both from the goodwill so generated, and from the low cost of upkeep of a natural landscape. (Prairies don't need fertilizer.) If only more companies were so farsighted. Perhaps the most ambitious cooperative achievement sought is peace in the Middle East by cooperation among the nations of Egypt, Israel, Jordan, the Palestinian Authority, and Tunisia through concerted research and action on control of desertification (Christiansen). However, the multiorganization involvement in conservation of the natural environment in Mexico (Ezcurra) is the scale to which most of us are probably accustomed.

All themes of the section — multiple users, environmental assessment, and cooperation in maintenance of environmental health — come together in Ura's account of traditional grazing practices in Bhutan. For hundreds of years, common grazing grounds have been sustainably and equitably used through institutionalized assessment of pasturage quality, distribution of grazing rights, and insistence on maintenance duties that accompany the rights. With open and fair assessment, and adherence to rules that work, Ura stresses that a tragedy of the commons can be avoided.

Gambling for Sustainability — Local Institutions for Pasture Management in Bhutan

Karma Ura

INTRODUCTION

Each summer, on the 18th of the 7th lunar month of the Bhutanese calendar, the pastoral communities of the villages of Gechukha, Chumpa, and Chempa in Northwestern Bhutan assemble at their community shrine. The gathering is a scene of day-long prayer sponsored by the community. Supernatural influence is invoked for favorable outcomes. This daylong ritual is just a prelude to the actual business, a brief, statistical affair, that takes place in the evening. Die is cast to allocate the communal pastures to groups of herders for the coming year. The group with the highest score gets first choice, the second highest gets the second choice, and so forth. Until they meet again, 1 year later, herders will be dependent on the allotted pastures to provide their yaks with sufficient feed.

Viewed as rules of the game, a local institution of the type mentioned above is crucial for equitable access to one of the major resources in agropastoral communities because it provides a mechanism for the allocation and division of pastures among herders. But this institution is also important for the many other functions it plays. A tentative outline of these can be made:

- First, an institution is very often eco-specific and therefore it may reflect sustainable uses of resources within that eco-niche. This could also mean that the institution could express accumulated indigenous knowledge about sustainable resource use within that eco-niche.
- Second, an institution, since it is correlated to an eco-niche, is adaptive over eco-niches. Institutional diversity and ecological diversity, therefore, go hand in hand.
- Third, an institution defined as “rules of the game” regulates the behavior of the individual members of an organization, be it formal or informal. In this sense an institution acts as coordinator of collective activities and obligations of the membership of that community or organization.

My intention in this chapter is to explore briefly these three aspects of local institutions with references primarily to pasture distribution rules in Bhutan.

PASTURE DISTRIBUTIVE RULES FOR COMMUNAL YAK PASTURES IN GECHUKHA, CHUMPA, AND CHEMPA IN HAA

Communal pasture is a more usual form of usufruct ownership than private pastures in Haa. The communities of Gechukha, Chumpa, and Chempa in upper Haa have collective usufruct rights

over summer and winter pastures for their yak herds. Grazing months are divided equally between these seasons; the period from November to April is spent in winter pastures, and from May to October in summer pastures. These pastures form a contiguous area, but each is divided into five (more or less) equal patches. Boundaries among these patches often follow natural landmarks such as streams, rivers, ridges, watersheds, etc. and these are likely to provide practical and useful perimeters for both herders and yaks.

When herders meet they first reach consensus on the boundaries, then preferential ranking of each of the five patches of summer and the five patches of winter pasture is done. This ranking of the carrying capacity of the patches is based on the herders' knowledge about the quality and area of each. Their understanding of the local ecology, geography, and wildlife is today an exclusive knowledge base about these high mountain and low subtropical pastures. Even indigenous doctors in Bhutan depend upon local yak herders to find rare alpine medicinal plants. It is this experience and knowledge about the local ecology that enables them to rank the 10 patches of pasture.

When consensus has been reached on a ranking, the pairing of the summer and winter patches is done. (See Table 69.1 for the ranking and pairing.) The best patch of summer pasture is paired with the worst patch of winter pasture and so forth. Twinning of winter and summer patches in this manner was aimed to equalize the access to pastures. Pairing the most preferred summer pasture with the least preferred winter pasture is a mechanism that compensates the loss a herder may find in winter months by gains in the summer. Within the competing herders' group, the triumph of getting Jatekha, the best of the summer pastures, is tempered by the prospect of herding in Richey, the worst of winter pastures. Equity and fairness is built into the way herders pair off winter and summer pastures.

Since there are five patches of summer pastures and five patches of winter pastures, the yaks of the Gechukha community are also grouped into five equal herds. No differentiation is made between calves and adult yaks. Every yak, whether cow, oxen, or calf is taken as one unit. Thus, corresponding to the five herds, five groups of herders are formed.

With the formation of five groups of herders and five pairs of winter and summer pastures, the stage is set for the actual allocation of pastures. In turn, a representative from each of the five herders' groups casts three die. The herder who scores highest makes the first choice among the pairs of winter and summer pasture patches. The second choice is given to the herder who scores the second highest and so forth.

Because pasture patches are ranked and paired prior to allocation, all are ignorant about who will get a particular pair of pastures. Anonymity of the recipient at that time ensures that there will be no personal incentives to mismatch the summer and winter pastures in any biased way.

This ritual of casting die randomizes the allocation of pasture in a most ingenious manner, ensuring that the knowledge of all the herders is combined to identify the fairest distribution of communal pasture possible.

Table 69.1 Paired Ranking of Summer and Winter Pastures Communally Owned by Chumpa, Chempa, and Gechukha Villages in Haa, Bhutan

Summer Pastures Ranked by Preference	Winter Pastures Ranked by Preference
1. Jatekha	5. Richey

PASTURE DISTRIBUTIVE RULES FOR COMMUNAL PASTURES IN URA, BUMTHANG

We now move our examination of the rules of dividing pastures to Ura village in Central Bhutan where the design of equitable division of winter pastures shows significant differences from that in Haa. Like the villages in Haa, Ura is a pastoral community. Unlike these villages, Ura depends predominantly on cattle rather than yaks. The cattle of Ura village are grazed in a subtropical belt for over 8 months from October and November to April and May. Almost all the summer and winter pastures are communal, and the division of pastures requires a fair method acceptable to all cattle herders. The rules they use for sharing and dividing pastures have not altered in living memory and are used every year. Surprisingly, cattle herders are of the opinion that neither the quality of the pastures (and their stocking capacity) nor the total population of the cattle grazing these pastures has changed very much. Thus, they find that the validity of the rules has not diminished.

There are 22 winter pastures in subtropical regions, which collectively belong to cattle herders of Ura. The herders and herds descend toward these pastures within weeks of each other. Although some herders may drive their herds a bit earlier than others toward these pastures, unilateral entry is forbidden. They must await the arrival of all the other herds. Finally, all the herders and their herds camp in a spacious meadow for a few days, usually in early November. Here, they convene daylong discussion on allotment of pasture. In practice, this is usually done throughout the night because the day is taken up by chores.

Communal pastures of herders in Ura are, as far as possible, allocated by consensus. But disputes can rarely be resolved through discussion when it comes to good pastures that are vied for by many herders. It is then that the herders resort to allocation by lottery. The names of the pastures are written down on pieces of paper and thrown in a jumble in a bag. Who gets what depends on blind chance. A large number of herders from Bhutan, who own communal pastures, use this particular mode of allocation.

Cattle herders of Ura have a clear idea of how many cows each pasture can and has been supporting in the past. This is a key concept, and also a difficult one, in the allocation of pastures. One would expect that the stocking capacity would generally be decided on the basis of an adult equivalent by taking a number of calves as adult cattle. Oxen in the herd should also be taken into account when calculating carrying capacity. However, among the herders of Ura only cows above 4 years of age are acknowledged for the purpose of allocating pastures. It is as if other animals, not at all productive or at that time unproductive, do not matter in this calculation for finding carrying capacity. Disregard for all other cattle except these cows impart disincentives to keep animals other than adult cows. Oxen, infertile females, and calves are, so to speak, disenfranchised, while the claims to grazing lands are weighed. Denial of suffrage to oxen, infertile females, and calves has environmental justification in subtropical pastures. By contrast, when the pastures are divided among yak herders in Haa, male yaks and calves are not excluded in the head count. This difference will be explained later.

Puzzling though it is, the cattle herders of Ura have a rule of thumb about the carrying capacity of each pasture for cows over 4 years. The convention in Omdaar provides cattle herders with an opportunity to negotiate which of the 22 pastures each would prefer to utilize. These negotiations take place after they have reached agreement about the number of the contenders' cows above 4 years and the carrying capacity of each pasture (defined only with respect to cows above 4 years). The herders know the carrying capacity as a historically and traditionally determined figure, historical and traditional in the sense that the information about the methodology of calculating stocking size is beyond recollection by the present herders. But the number itself is not absolutely sacrosanct. Unexpected changes in the condition of the pastures are surveyed and assessed by the herders before they meet. Possible decline in the quality of pastures could be due to a landslide; encroachment of bamboo forest, which cannot be penetrated by cattle; or lower grass yield due to low rainfall on a slope has been observed by herders. In such pastures, the number of cows would be reduced from the carrying capacity, a fixed number that has been previously determined.

The cattle herders of Ura are expected to occupy the pastures for the winter season after allotment by lottery. During that season, herders have control and utilization of the pasture. They also have obligations and responsibilities to manage the pasture in such a way that its quality is maintained for future herds. A herd's consumption during one season must not deplete the future flow of goods and services, such as grass and fodder and footpaths in the forest. In addition, the herders must use an active form of management termed *brocksel* (i.e., clearing the pasture). It is failure to notice this kind of restorative measure carried out by herders that leads to opinions that herders are environmentally destructive. Migratory livestock farming is part of the forest system since they are both associated in many ways. The species mix and regeneration process is affected by livestock, although not necessarily in the negative way that is widely presupposed in today's antimigratory livestock literature. The replanting of wild fodder trees and plants, the selective thinning of bamboo forest by herders, and the availability of cattle compost as forest plant nutrients are a few of the herders' management activities that have obvious positive effects.

The yield of winter pastures can be reduced because of several factors. As animals graze and fodder is cut, unpalatable plants and shrubs may displace palatable ones. If growth of unpalatable species is not restricted by manual cutting, the species mix is changed in favor of unpalatable ones. If the herder does not carry out restorative measures, especially to reduce the rate of bamboo growth, the situation of the herder who gets that particular pasture the following season will be worsened. Further, the herder may use lops and tops of wild fodder trees and fodder vines, but may not fell them, for this would permanently deprive the succeeding wave of herders who follow him into this pasture. Saplings of wild fodder trees are uprooted from the forest and planted in more convenient places for more intensive care. Herders propagate wild fodder trees and fodder vines that are fed to the cattle only when surface herbage growth is fully consumed. This usually happens by the end of January. From then until the cattle begin their movements toward summer pastures in Bumthang, they subsist heavily on wild fodder trees and fodder vines. Another restorative measure includes repairing the labyrinth of forest tracks that give cattle access to grazing areas in the depth of the jungle.

The obligation to pass on the pastures in a state as productive as when they were received is an ingrained herders' norm, but it is not enforced by explicit sanctions. The propensity to follow the norm is conditioned by the knowledge that mutual cooperation in not overexploiting the pasture will keep the pasture ecology stable. If one herder leaves the pasture allotted to him in a worse state and others are tempted to follow his behavior of negligence toward the pasture every season, it may have a snowball effect and eventually leave the pasture degraded. Such a runaway process could result in environmental disaster where every herder would be worse off.

There are those who tend to predict an almost sure likelihood of an environmental disaster in situations where resources are managed communally, known as the tragedy of the commons. Their apprehension is misplaced in this case. It probably stems from an unquestioned belief that peasants are irrational, a belief that empirical findings could easily disprove, and an assumption in behavioral theories that have long been discarded. That is, individuals will manage resources for their own short-term benefits without taking the future needs of the group, of which they are part, into consideration.

COMPARISON OF THE TWO PASTURE DISTRIBUTIVE RULES

Both systems of pasture distribution show a high regard for an agreed and just principle of transfer of pasture from some herders to others within the same community for a specific period. Both stress establishing broadly equitable access to pastures over both time (winter and summer seasons) and space, in the sense that over the long run the throwing of dice or drawing a lot will assign a herder to any pasture with equal probability. In the long-term perspective, a herder will stay equally long in all the pastures. We find the actual allotment of pastures is determined at

random by the throw of dice or the pick of a lot. At the same time, because each herder has an equal chance to get a specific patch of pasture, herders set egalitarian subrules about how many livestock units can be assigned to certain pasture areas and how winter pastures can be combined with summer pastures.

It was mentioned that while determining the occupancy rate in the winter pastures of cattle in Ura, herders take account of only cows above 4 years old. This generates disincentives for these herders to keep oxen, calves, or infertile cows in the herd. This disincentive compels the herders to export their unproductive cattle, mainly oxen, to other parts of Bhutan. The herds of Ura are therefore dominated by cows. The yak herders of Haa, however, do not differentiate yaks either by age or sex during allocation of pastures. Each yak is taken as a livestock unit during the division of communal pastures. To a certain extent, this lack of disincentive to reduce the number of male yaks is economically justified because they are, unlike oxen, profitable meat animals. Male yaks are slaughtered at about 6 years and their carcasses can be sold for about 8000 Nu each (\$1U.S. = 47 Nu). In late 1992, the price of yak meat was 65 Nu/kg compared with 15 Nu/kg for beef in the Thimphu market.

Pasture distributive rules such as the ones described here are profoundly important as rules of the game, yet both policy makers and researchers might pay insufficient attention to them. While we cannot assume that all existing institutions are completely optimal on both distribution and efficiency grounds, the fact that pasture distributive rules have existed for centuries without damaging the forest calls for greater faith and credibility in the system.

CONCLUSION

The migration of native bovine species, both yak and siri cattle, is a particularly skillful adaptation to ecologically varied niches where biomass varies spatially and seasonally. As a sophisticated social and ecological response to varied niches, different bovine species graze on herbage growing and dying at different rates, at different times, and at different altitudes. Traditional herder management systems embody a dynamic relationship among humans, native bovine species, and heterogeneous mountain niches (subtropical forest pasture and alpine grassland pasture).

The decentralization policy of the Royal Government of Bhutan creates an environment for the survival of diverse institutions, including their rules and the organizational forms, as determined by and for the communities. In our current search for sustainability, there is a case for continually feeding enduring local institutions into national policy, though there are also frequent occasions for doing the reverse. I would submit that the pasture distributive rules governing the use of communal pastures is one such valuable institution. It cannot be regenerated easily once destroyed.

ACKNOWLEDGMENTS

I am thankful to Dasho Shingkar Lam and Tashi Dorji, former gup of Ura for most of the information in the Bumthang section. I would like also to acknowledge encouragement and help received from Dasho Sonam Tobgye, the Chief Justice of Bhutan.

Environmental and Socioeconomic Indicators of Great Lakes Basin Ecosystem Health

Paul Bertram, Harvey Shear, Nancy Stadler-Salt, and Paul Horvatin

INTRODUCTION

The purpose of the Great Lakes Water Quality Agreement (GLWQA) between the U.S. and Canada is to restore and maintain the chemical, physical, and biological integrity of the waters of the Great Lakes basin ecosystem (U.S. and Canada, 1987). The U.S. and Canada have spent billions of dollars and uncounted hours attempting to reverse the effects of cultural eutrophication, toxic chemical pollution, overfishing, habitat destruction, introduced species, and other insults to the ecosystem. Environmental management agencies are now being asked to demonstrate that past remediation programs have been successful and that the results of future or continuing programs will be commensurate with the resources expended (financial and personnel time). The demand for high quality data is forcing environmental and natural resource agencies, which operate with limited resources, to be more selective and more efficient in the collection and analysis of data.

Assessing the health of something as large and complex as the Great Lakes basin ecosystem is a significant challenge. The lakes themselves contain one-fifth of the world's fresh water with over 10,000 miles (17,000 km) of shoreline. The basin consists of over 200,000 square miles (520,000 km²) of land, and about 33.5 million people reside within the basin. The basin is governed by two nations, eight states, two provinces, and hundreds of municipal and local governments. A set of Great Lakes basin ecosystem indicators will enable the Great Lakes community — government and nongovernment organizations, academia, industry, and individual citizens — to work together within a consistent framework to assess and monitor changes in the state of the ecosystem.

In this context, the information collected can be characterized within a series of indicators. An indicator is a parameter or value that reflects the condition of an environmental (or human health) component, usually with a significance that extends beyond the measurement or value itself (Canada and U.S., 1999). An indicator is more than a data point. It consists of both a value (which may be a direct environmental measurement or may be derived from measurements) and a target or reference point. Used alone or in combination, indicators provide the means to assess progress toward one or more objectives: Are conditions improving so that the objective is closer to being met, or are conditions deteriorating? The achievement of these objectives leads toward achievement of higher order goals and vision for the ecosystem (Figure 70.1).

Figure 70.1 Conceptual model of the relationships among indicators, measures, targets, objectives, goals, and visions. (From Canada and the U.S., *State of the Great Lakes 1999*, www.on.ec.gc.ca/solec/ or www.epa.gov/glnpo/solec/98/, Toronto and Chicago, 1999.)

Within the Great Lakes basin, no one organization has the resources or the mandate to examine the state of all the ecosystem components. However, dozens of organizations and thousands of individuals routinely collect data, analyze them, and report on parts of the ecosystem. A consensus by environmental management agencies and other interested stakeholders about what information is necessary and sufficient to characterize the state of Great Lakes ecosystem health, and to measure progress toward ecosystem goals, would facilitate more efficient monitoring and reporting programs. The relative strengths of the agencies could be utilized to improve the timeliness and quality of the data collection and the availability of the information to multiple users.

The State of the Lakes Ecosystem Conferences (SOLEC) were established by the governments of Canada and the U.S. in 1992 in response to reporting requirements of the GLWQA. The conferences are to provide biennial science-based reporting on the state of health of the Great Lakes basin ecosystem.

In the first SOLEC (1994), the governments reported on basin-wide conditions relating to aquatic ecosystem health, human health, aquatic habitat and wetlands, nutrients, contaminants, and the economy. These categories ensured that major components of the ecosystem were assessed, as well as a major component of human activity (the economy). The organizers developed a series of *ad hoc* indicators to provide an assessment of the state of these components and to assess progress toward the goals of the GLWQA. These indicators were based on the best professional judgment of a number of scientists and managers who had prepared background papers on the subject components (U.S. and Canada, 1995). A similar process was followed for SOLEC '96, in which the focus was on the nearshore aquatic and terrestrial environments (Canada and U.S., 1997).

For SOLEC '98, the organizers wanted to support the further development of easily understood indicators that objectively represented the condition of the Great Lakes basin ecosystem, the stresses on the ecosystem, and the human responses to those stresses. These indicators would provide a predictable set of signs of the health of the ecosystem components and the progress being made to remedy existing problems.

INDICATOR SELECTION PROCESS

To guide the development of a suite of indicators for the Great Lakes basin ecosystem, a series of organizing principles was recognized.

- *Build upon the work of others.* There has been a long history of monitoring and of the development of indicators for the Great Lakes. For example, indicators have been proposed in some form by the International Joint Commission, the Great Lakes Fishery Commission, Lakewide Management

Plans, and in the background papers prepared for SOLEC '94 and SOLEC '96. The intent for the SOLEC process was to make use of the work that has gone on before rather than repeat it.

- *Focus on broad spatial scales.* SOLEC indicators are intended to reflect conditions on the scale of the whole Great Lakes basin, whole lake watersheds, and subbasins of the larger lakes. Indicators for local geographic areas are reported through other programs.
- *Select a framework for subdividing the Great Lakes basin ecosystem.* SOLEC indicators were developed within the framework of geographic zones (offshore, nearshore, coastal wetlands, nearshore terrestrial) and nongeographic issues (human health, land use, societal, and unbounded). This framework provides flexibility to incorporate the main elements of other frameworks. For example, physical, chemical, and biological status can be assessed within each geographic zone.
- *Select a system for types of indicators.* There are several classification schemes or models for indicators (for example, GMIED, 1998; IJC, 1991, 1996; Messer, 1992; Regier, 1992), one of which is the State-Pressure-Human Activity (Response) model. This S-P-A model is simple and broadly applicable. *State* indicators address the state of the environment, the quality and quantity of natural resources, and the state of human and ecological health. *Pressure* indicators describe natural processes and the results of human activities that impact, stress, or pose a threat to environmental quality. *Human activity (response)* indicators include individual and collective actions to halt, mitigate, adapt to, or prevent damage to the environment. They also include actions for the preservation and the conservation of the environment and natural resources.
- *Identify criteria for indicator selection.* The primary criteria that were used for the selection of the suite of indicators were: *necessary*, *sufficient*, and *feasible*. For individual indicators, a set of 21 additional criteria was identified. Not all indicators scored high for all criteria. However, for any given indicator, the more criteria that were met, the stronger the case for including that indicator on the proposed SOLEC list (Bertram and Stadler-Salt, 1999).

A group of experts was assembled to review, select, and refine Great Lakes indicators. Some members of this indicators group were also leaders of seven core groups, one for each of the SOLEC indicator categories mentioned above. The core groups were composed of expert panels who participated either directly with hands-on selection and development of indicators, or by reviewing draft products throughout the process. Over 130 people were involved in some way in this project.

The core groups studied documents from multiple sources that identified or discussed ecosystem objectives or environmental indicators. More than 850 indicators were identified through this process. The indicators were then screened according to the criteria, and appropriate indicators were identified. In many cases, indicators from the existing list were modified or combined, or new indicators were developed to create the proposed suite of 80 SOLEC indicators.

For each of the SOLEC indicators, detailed descriptive information was assembled into a meta-database. The information included the following (Bertram and Stadler-Salt, 1999):

- Environmental measurements to be taken
- Environmental components the indicator would be used to assess
- Ecosystem objectives the indicator would be addressing
- Indicator desired end points or reference values
- Descriptions of the indicator's features and limitations
- Illustrations of how the indicator would be presented and interpreted
- Additional comments that would clarify the intent and implementation of the indicator

The list of 80 indicators (Table 70.1) addresses all of the SOLEC categories. Most of the indicators (84%) reflect the state of the ecosystem component or stresses on the ecosystem rather than human activities. The indicators also have applicability to broad environmental compartments (air, water, sediments, land, biota, fish, and humans) and to issues of human concern (toxic substances, nutrients, nonnative species, habitat, climate change, and stewardship). A full description of the indicators can be found in Bertram and Stadler-Salt (1999), which is available online at www.on.ec.gc.ca/solec/solec2000 or www.epa.gov/glnpo/solec/98/.

^a Excluding fish and humans.

^b Including pathogens.

Because SOLEC conferences are multiagency, multijurisdictional reporting venues, the SOLEC indicators require acceptance by a broad spectrum of stakeholders in the Great Lakes basin. The indicator descriptions were widely circulated for review and revision several times, and most proposed indicators have been accepted by consensus. The indicator list will remain dynamic, however, and it will continue to evolve.

IMPLEMENTING SOLEC INDICATORS

As capacity to monitor and report on the 80 indicators builds over the next several years, a more complete answer to the questions posed by the public about the health of the Great Lakes will emerge. For example, 19 of the 80 indicators are directly concerned with the waters of the Great Lakes (Table 70.1). By analyzing the monitoring data of those indicators and aggregating the results, a picture of the health of the waters of the Great Lakes should emerge. Gaps will no doubt be identified that require both an adjustment in the number of indicators needed and a fine tuning of the indicators in order to more fully describe the state of the waters. This will be true for the other environmental compartments and issues as well.

Currently, however, data are not available for all 80 indicators. The example indicators presented here represent each of the SOLEC organizational groupings. For each indicator, a short overview is followed by a description of the indicator, with examples of the data available for that indicator.

Nearshore and Open Waters Indicators

The nearshore waters of the Great Lakes occupy a band of varying width around the perimeter of each lake between the land and the deeper offshore waters of the lake. Also included as nearshore waters are the Great Lakes connecting channels and the lower reaches of tributaries that are influenced by changes in water levels in the Great Lakes. Human activities have substantially altered the Great Lakes basin landscape and the nearshore waters of the basin ecosystem. Some of the most significant stresses include the following:

- High density patterns of settlement, development, and population growth leading to the release of contaminants and nutrients, as well as habitat loss
- Agricultural development in the southern portion of the basin, which created an abundance of food and fiber leading to increased nutrient and pesticide loading
- High usage of surface water for drinking, manufacturing, power production, and waste disposal into tributaries
- Navigational structures such as dams and canals
- Nonnative species invasions, often facilitated by the construction of canals
- Development of sheltered areas into marinas and deepwater ports

The open waters of the Great Lakes are all of the waters beyond the lakeward edge of the nearshore waters (Edsall and Charlton, 1997). The offshore waters of the Great Lakes are also subject to many of these same stresses plus some unique offshore issues, such as atmospheric deposition of contaminants, the alteration of fish communities, and loss of biodiversity associated with overfishing and fish stocking practices.

Sea Lamprey

This indicator estimates the abundance of sea lampreys in the Great Lakes, which has a direct impact on the structure of the fish community and health of the aquatic ecosystem. Populations of large, native, predatory fishes can be diminished by sea lamprey predation.

The sea lamprey (*Petromyzon marinus*) is a parasitic aquatic vertebrate native to the Atlantic Ocean that is able to spawn and live entirely in fresh water. It has invaded all the Great Lakes in a span of 110 years, 1835 to 1946 (Mills et al., 1993).

The sea lamprey is not selective in its feeding as it preys on all species of large fish including salmon, lake trout, whitefish, walleye, and chubs. During its adult stage, it is possible that an individual sea lamprey can cause the death of more than 40 pounds of fish. Control measures managed by the Great Lakes Fishery Commission and supported by federal, provincial, state, and tribal governments has brought the lamprey population under control in most areas (Klar et al., 1996).

The information presented in Figure 70.2 shows sea lamprey populations (in their spawning phase) throughout the Great Lakes. During the past 20 years, Lake Superior populations have remained at levels less than 10% of peak abundance. For Lake Michigan, populations have been relatively stable, but an increase has been seen in northern sections of the lake due to the large population in Lake Huron moving into Lake Michigan. Lake Huron populations have remained at very high levels since the early 1980s because of large spawning populations in the St. Marys River. An integrated control strategy was initiated in the St. Marys River in 1997 which includes

*Note scale change for Lake Erie

Figure 70.2 Total abundance of sea lamprey in each of the five Great Lakes estimated during the spawning phase. (From Canada and the U.S., *State of the Great Lakes 2001*, www.binational.net, Toronto and Chicago, 2001.)

the targeted application of a new bottom-release lampricide, enhanced trapping of spawning animals, and sterile-male release. In Lake Erie, lamprey abundance has increased since the early 1990s. Sources of this increase were several streams to which treatment has been deferred due to low water flows or concerns for nontarget organisms. Lake Ontario populations have remained constant in recent years because of adequate control.

Future pressures include the increased potential for sea lamprey to colonize new locations due to improved water quality in Great Lakes tributaries. Additionally, short lapses in lamprey control can result in quick increases in abundance. Significant additional control efforts, like those on the St. Marys River, may be necessary to maintain reduced lamprey populations.

Phosphorus Concentrations and Loadings

This indicator, which assesses total phosphorus levels in the Great Lakes, is used to support the evaluation of trophic status and food web dynamics in the Great Lakes. Phosphorus is an essential element for all organisms and is often the limiting factor for aquatic plant growth in the Great Lakes.

Sewage treatment plant effluent, agricultural runoff, and industrial processes have released high concentrations of phosphorus into the lakes (IJC, 1996). Strict phosphorus loading targets implemented in the 1980s have been successful in reducing nutrient concentrations in the lakes (Figure 70.3), although high concentrations still occur locally in embayments and harbors (Canada and U.S., 1999).

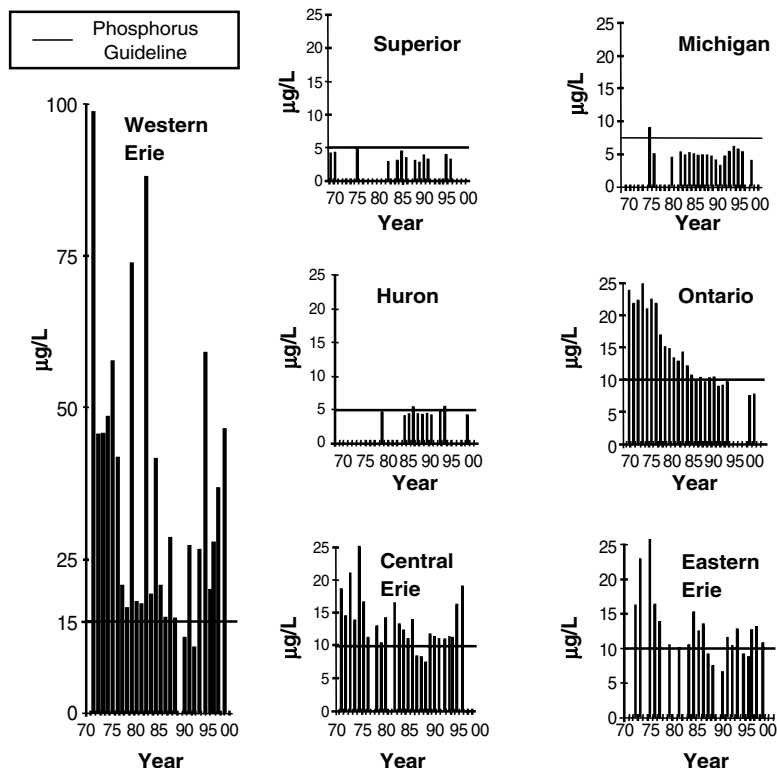

Figure 70.3 Total phosphorus trends in the Great Lakes 1971–2000. Data reflect samples collected at the surface from offshore waters during spring. Blank indicates no sampling (From Canada and the United States, *State of the Great Lakes 2001*, www.binational.net, Toronto and Chicago, 2001.)

Concentrations of total phosphorus in the open waters of the Great Lakes have remained nearly stable since the mid-1980s. Concentrations in the open waters of Lakes Superior, Michigan, Huron, and Ontario are at or below guideline levels. Concentrations in all three basins of Lake Erie exceed phosphorus guidelines, and recent data suggest an increasing trend. This trend may be related to the large populations of nonnative zebra mussels (*Dreissena polymorpha*) and quagga mussels (*Dreissena bugensis*).

With the anticipated human population growth in the basin over the next 25 years (up to 2 million in Canada alone), the nutrient loads to the lakes from this population will be significant and they will require additional treatment, particularly at sewage treatment plants. The phosphorus indicator will be of value in helping governments track trends in nutrients in the lakes and adjust management strategies accordingly.

Coastal Wetland Ecosystem Indicators

Wetlands are important ecologically, socially, and economically and are one of the most productive ecosystems in the world (Maynard and Wilcox, 1997). Despite these values, coastal wetlands are in trouble. Threats include regulation of lake water levels, land-use change, nonnative species, and toxic chemicals.

To select indicators of the health and integrity of coastal wetlands, the following criteria for coastal wetland health were used:

- Capability to self-maintain assemblages of organisms that have a composition and functional organization comparable to natural habitat
- Resiliency to natural disturbances
- Risk factors or human-induced pressures at an acceptable level

There are few existing monitoring programs for Great Lakes coastal wetlands. Efforts are being made to select indicators for which there are existing data and monitoring programs, although many of the indicators will require new or improved monitoring programs.

Wetland-Dependent Bird Diversity and Abundance

Assessments of the diversity and abundance of wetland-dependent birds in the Great Lakes basin, combined with an analysis of habitat characteristics, are used to evaluate the health and function of wetlands.

Birds are among the most visible and diverse groups of wildlife in Great Lakes coastal wetlands. Because breeding wetland birds require an appropriate mix and density of vegetation, sufficient and safe food resources, and freedom from predation and other disturbances, their presence and abundance provides information that integrates the physical, chemical, and biological status of their habitats.

Patterns in the species composition and numbers of breeding wetland birds may reflect changes in the condition of breeding habitats. Five years of Marsh Monitoring Program (MMP, www.bsc-eoc.org) data provided information on numbers of marsh nesting birds. Basin-wide increases were observed for Canada goose, mallard, chimney swift, northern rough-winged swallow, common yellowthroat and common grackle (Table 70.2). Basin-wide declines were observed for pied-billed grebe, blue-winged teal, American coot, and black tern. Each of the declining species depends on wetlands for breeding, but because they use wetland habitats almost exclusively, the pied-billed grebe, American coot, and black tern are particularly dependent on the availability of healthy wetlands.

Continuing and future pressures on these bird species include the continued loss and degradation of wetlands, water level stabilization, sedimentation, contaminant and nutrient inputs, and the invasion of nonnative plants and animals.

Table 70.2 Estimated Annual Percent Changes in Population Indices of Marsh-Nesting and Aerial Foraging Bird Species Detected on Great Lakes Basin Marsh Monitoring Program (MMP) Routes, 1995–1999

Species	% Change	95% Confidence Limits
Canada goose	20.2	4.9, 37.7
Mallard	29.2	17.0, 42.6
Chimney swift	15.8	1.7, 31.8
Northern rough-winged swallow	20.1	0.8, 43.1
Common yellowthroat	6.8	2.0, 11.7
Common grackle	42.5	27.1, 59.7
Pied-billed grebe	-11.8	-19.9, -2.5
Blue-winged teal	-13.2	-24.3, -0.5
American coot	-22.1	-34.7, -7.2
Black tern	-20.2	-28.7, -10.8

Population indices are based on counts of individuals inside the MMP station boundary and are defined relative to 1999 values (see Canada and U.S., 2001).

Nearshore Terrestrial Ecosystem Indicators

The nearshore terrestrial environment is an integral part of the Great Lakes basin ecosystem, the extent of which is defined by the lakes themselves. A description of these areas and major stresses on these natural communities are described in *State of the Great Lakes 1997* (Canada and U.S., 1997).

Thirteen indicators of nearshore terrestrial ecosystem health have been developed to fulfill the need for a cost-effective and easily understood set of measures that will describe how nearshore ecosystems across the basin are changing, identify what is causing the changes, describe the current status of these ecosystems and component parts, and evaluate how effectively humans are responding to the changes.

Area, Quality, and Protection of Alvar Communities

This indicator was designed to measure the area, quality, and protected status of the alvar communities occurring within 1 km of the shoreline. Alvar communities are naturally open habitats occurring on flat limestone bedrock. The information collected to satisfy this measure may also help to identify the sources of threats to these ecologically significant habitats, as well as the success of management activities associated with the protection status.

More than 90% of the original extent of alvar habitats has been destroyed or substantially degraded. Emphasis is focused on protecting the remaining 10%. Approximately 64% of the remaining alvar area exists within Ontario; 16% in New York State; 15% in Michigan; and smaller areas in Ohio, Wisconsin, and Quebec. Less than 20% of the nearshore alvar acreage is currently fully protected, while over 60% is at high risk (Figure 70.4). Michigan has 66% of its nearshore alvar acreage in the fully protected category, while Ontario has only 7%. In part, this is a reflection of the much larger total shoreline acreage in Ontario.

Continuing pressures on alvars include:

- Habitat fragmentation and loss
- Trails
- Off-road vehicles
- Resource extraction uses such as quarrying or logging
- Adjacent land uses such as residential subdivisions
- Grazing or deer browsing,
- Plant collection for bonsai and other hobbies
- Invasion by nonnative plants

Figure 70.4 Protection status of Great Lakes nearshore alvar communities, 2000 (Canada and the U.S., *State of the Great Lakes 2001*, www.binational.net, Toronto and Chicago, 2001.)

Land-Use Indicators

Changing patterns of land use are a major ecosystem stressor for the Great Lakes basin and its nearshore areas. The many forms of development — including industrial, commercial, residential, agricultural, and transportation-related activities — carry specific, significant, and cumulative impacts for the natural world and particularly for Great Lakes water quality. These activities take place throughout the basin, but their most immediate and direct impact on the Great Lakes appears to be on lands proximate to the lakes themselves and their tributary waters. These nearshore areas suffer from a particular and disproportionate environmental burden because of their unique and sensitive environments and proximity to development.

Sustainable Agricultural Practices

This indicator assesses the number of environmental and conservation farm plans and environmentally friendly practices in place, such as integrated pest management to reduce the unnecessary use of pesticides, conservation tillage and other soil preservation practices to reduce energy consumption, and prevention of ground and surface water contamination.

Agriculture accounts for 35% of the land area of the Great Lakes basin and dominates in the southern portion of the basin. In the past, excessive tillage and intensive crop rotations led to soil erosion and the resulting sedimentation of major tributaries. Agriculture is a major user of pesticides with an annual use of 26,000 tons. These practices led to a decline of soil organic matter. The adoption of more environmentally responsible practices has helped to replenish carbon in the soils to 60% of turn-of-the-century levels. The following are two examples of voluntary programs to encourage the development and implementation of environmental farm plans.

In Ontario, farmers can complete an Environmental Farm Plan identifying environmental areas of concerns on their farms and note activities and specific actions they will take to remediate them. For example, ensuring that farm manure is managed to avoid contaminating surface water courses and groundwater is critical to maintaining safe and clean drinking water for the farmer as well as preventing contamination of downstream water or aquifers. The farm plan will identify the possibility of contamination and identify preventative or remedial solutions and actions. The farm plan then becomes a stewardship guidebook for environmental management by the farmer and a reference document for further remedial or preventative actions. Figure 70.5 depicts the percentage of acreage with approved Environmental Farm Plans in Ontario.

The U.S. Department of Agriculture (USDA) offers landowners financial, technical, and educational assistance to implement conservation practices on privately owned land and promote sustainable agricultural practices. The Conservation Reserve Program (CRP) reduces soil erosion, protects the nation's ability to produce food and fiber, reduces sedimentation in streams and lakes, improves water quality, establishes wildlife habitat, and enhances forest and wetland resources. It

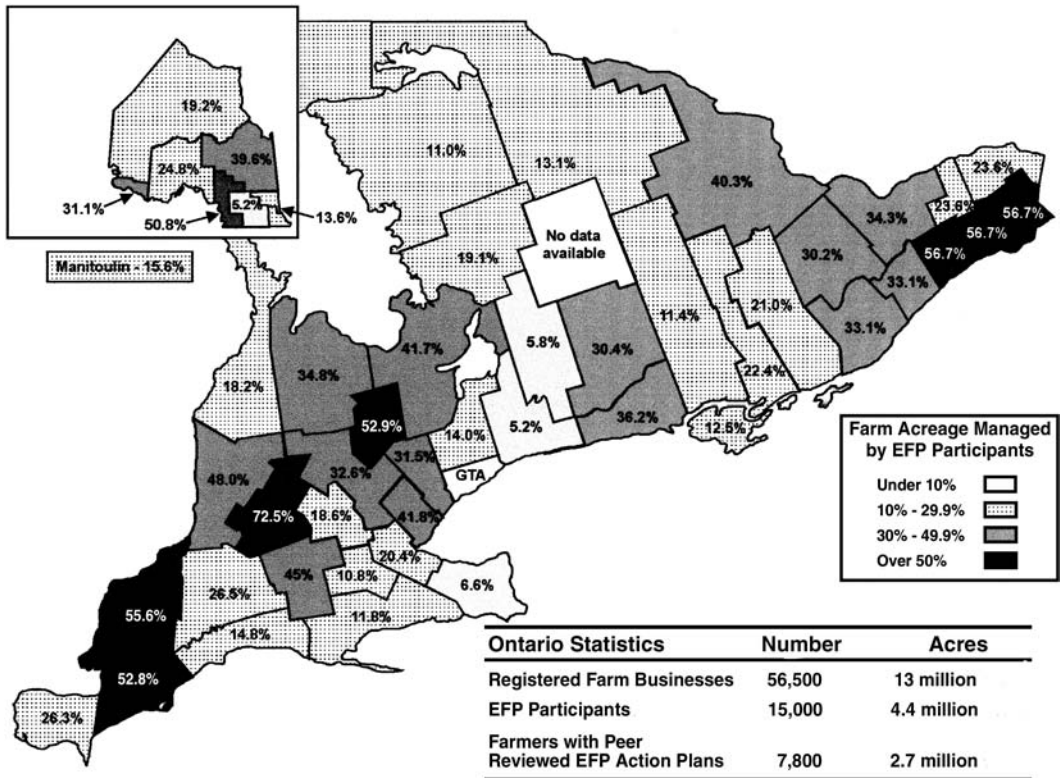

Figure 70.5 Ontario Environmental Farm Plans (EFP). (From Canada and the U.S., *State of the Great Lakes 2001*, www.binational.net, Toronto and Chicago, 2001.)

encourages farmers to convert highly erodible cropland or other environmentally sensitive acreage to vegetative cover, such as tame or native grasses, wildlife plantings, trees, filter strips, or riparian buffers. Figure 70.6 shows the number of acres with conservation planned systems in place.

Human Health Indicators

Many people consider the protection of human health to be one of the more important goals of environmental management. Consequently, there is interest in indicators of changes in human health, or changes in factors that affect health, as they relate to the Great Lakes environment. The premise is that as social, economic, and environmental conditions change in the Great Lakes basin, so could the health of the population. Indicators are also needed to assess the effectiveness of social, economic, health, and environment policies and actions to protect or improve the health of the Great Lakes basin population.

Because the ability to relate the state of human health in the Great Lakes basin to components of the Great Lakes ecosystem per se is difficult at best, the effort to develop human health indicators has focused primarily on exposure to environmental contaminants and pathogens. The indicators include contaminant levels measured in human tissues, such as breast milk or blood; estimates of daily intake of persistent contaminants by the Great Lakes population (e.g., via fish consumption); and contaminant levels in air, drinking water, and recreational water. The contribution of these exposures as causative factors in disease, such as cancer and birth defects, can be difficult to identify. Using an indicator that analyzes geographic patterns and trends in incidence rates, however, can serve to identify potential areas of concern and may lead to testable hypotheses regarding the correlation of environmental exposure with human disease.

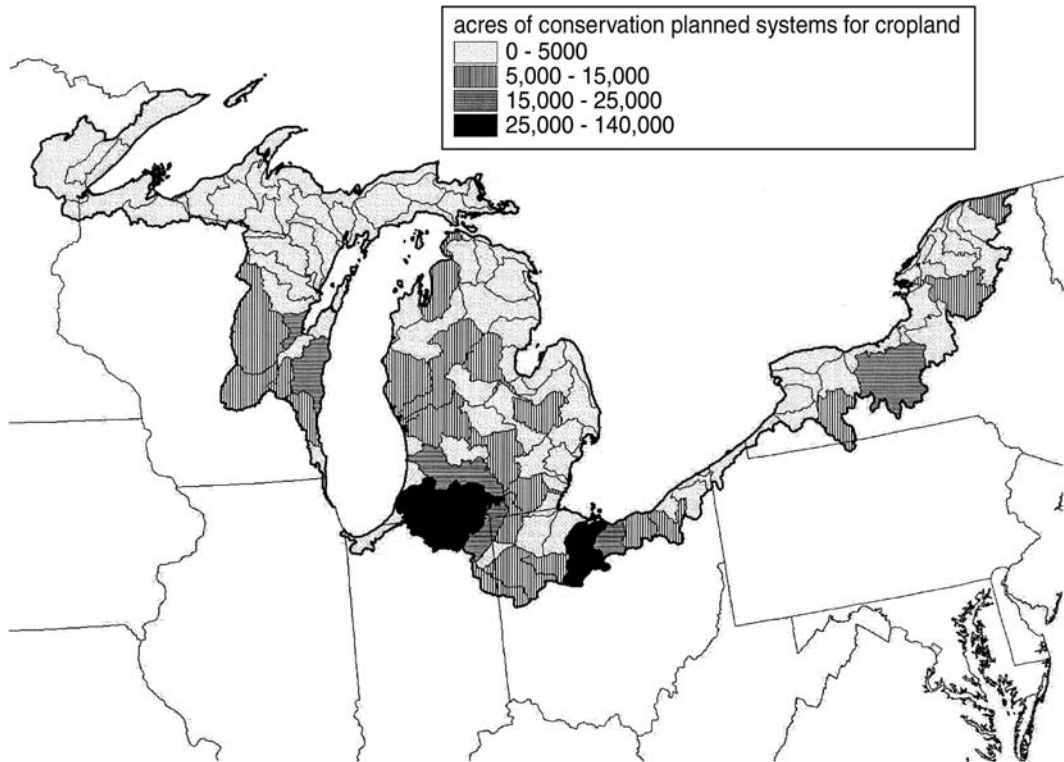

Figure 70.6 Annual U.S. Conservation Planned Systems for 2000. (From Canada and the U.S., *State of the Great Lakes 2001*, www.binational.net, Toronto and Chicago, 2001.)

Escherichia coli and Fecal Coliform Levels in Nearshore Recreational Waters

This indicator assesses *E. coli* and fecal coliform abundance in nearshore recreational waters, acting as a surrogate indicator for other pathogen types, and it is used to infer potential harm to human health through body contact with nearshore recreational waters.

Recreational waters may become contaminated with animal and human feces from sources such as combined sewer overflows that occur in certain areas after heavy rains, agricultural runoff, and poorly treated sewage. Gastrointestinal disorders and minor skin, eye, ear, nose, and throat infections have been associated with microbial contamination. Children, the elderly, and people with weakened immune systems are those most likely to develop illnesses or infections after swimming in polluted water.

Survey reports of U.S. beach advisories during the 1998 swimming season (June, July, and August) show that 78% of the reporting beaches were open for the entire 1998 season. Results were similar for Canadian beaches where 79% of the reporting beaches were open the entire season (Figure 70.7). Survey reports of U.S. beach closings or advisories during the 1999 season show that 65% of the reporting beaches were open the entire 1999 season. Several factors may have influenced the apparent increase in percentage of beach closings in 1999 compared with 1998:

- Fewer beach managers responded to survey questionnaires in 1999
- A different mix of beaches was reported in 1999
- More beach managers were using *E. coli* testing in 1999 than in 1998
- An improved system for accounting for beach advisory days was used in 1999

Figure 70.7 Comparison of the frequency of U.S. and Canadian beach advisories for Great Lakes beaches, 1998. The swimming season was defined as June, July and August. Data were obtained from voluntary responses by beach managers to annual requests for information. (From Canada and the U.S., *State of the Great Lakes 2001*, www.binational.net, Toronto and Chicago, 2001.)

While the actual water quality near beaches may not have changed, the increase in beach advisory days is believed to be more protective of human health.

Societal Indicators

Human society is part of the ecosystem, and integrated environmental management requires human activities to be respectful of other ecosystem components. For example, the creation and discharge of waste materials by humans may have an impact on both the habitat and the health of plant and animal species. A responsible society will recognize its collective impact on the surrounding environment, and it will seek to sustain ecosystem integrity indefinitely.

Within the suite of proposed Great Lakes indicators, sustainability is implicit throughout. A set of indicators to assess human activities and other societal issues, however, would reflect our individual and collective actions to halt, mitigate, adapt to, or prevent damage to the environment. Socioeconomics, urban issues, societal responsibility, and other social aspects of Great Lakes communities are not easy to monitor due to the complexity of the relationships between jurisdictions and the lack of coordinated monitoring programs. The SOLEC process is being used to engage a variety of agencies and organizations in the Great Lakes basin to participate in the further selection and implementation of clear, understandable societal indicators.

Economic Prosperity

This indicator assesses the unemployment rates within the Great Lakes basin and, when used in association with other societal indicators, infers the capacity for society in the Great Lakes region to make decisions that will benefit the Great Lakes ecosystem. During periods of low unemployment and economic well-being, public support for environmental initiatives by government agencies may be increased.

By most measures, the binational Great Lakes regional economy is reasonably healthy. The unemployment rate for the Great Lakes states was less than the U.S. national average for most of the 1990s. Canadian and Ontario economic recoveries unfolded later than the U.S., but Ontario unemployment rates in 2000 were at the lowest level since 1990.

Both sides of the border reflect a manufacturing intensity greater than their national economies. The Great Lakes states represent about 27% of national output in manufacturing, whereas Ontario's percentage is twice as large. The manufacturing sector has many cross-border linkages, particularly

for the auto industry. About one half of the billion dollar-a-day U.S.–Canada trade is tied to the Great Lakes states, with Ontario as the most prominent province in this relationship.

The overall message is mixed. Good economic times can translate into high levels of consumer spending and home buying, which can lead to increased household waste generation, increased air pollution, and accelerated land use changes.

Unbounded Indicators

Several proposed indicators do not fit neatly into any of the other SOLEC ecological categories. These indicators may have application to more than one of the other organizing categories, or they may reflect issues that affect the Great Lakes but have global origins or implications. For example, indicators related to climate change will affect all the groups yet truly belong in none of them.

Nonnative Species

Currently, this indicator reports introductions of aquatic organisms not naturally occurring in the Great Lakes basin, and it is used to assess the status of biotic communities in the basin. The indicator will expand to terrestrial organisms in the future.

Since the 1830s, there have been 63 nonnative aquatic animal (fauna) species introduced into the Great Lakes that have maintained permanent, breeding populations (Figure 70.8). In almost the same time frame, 83 nonnative plant (flora) species were introduced and established residency.

Some of the main entry mechanisms include ship ballast water, the deliberate release of fish and other faunal species, and releases from hobby aquaria. Some plant species have escaped from cultivation. Even with voluntary and mandatory ballast exchange programs recently implemented in Canada and the U.S., newly introduced species associated with shipping activities have been identified.

Introductions of nonnative species are expected to continue because of increased global trade, new diversions of water into the Great Lakes, aquaculture industries, and changes in water quality and temperature. Even the presence of some key nonnative species could make the Great Lakes more hospitable for other nuisance species.

CONCLUSION

The process for selecting and developing indicators of the health of the Great Lakes basin ecosystem has been open but rigorous, engaging the participation of a wide variety of stakeholders.

Figure 70.8 Cumulative number of nonnative species introduced into the Great Lakes since the 1830s (From Canada and the U.S., *State of the Great Lakes 2001*, www.binational.net, Toronto and Chicago, 2001.)

Informal consensus on the suite of indicators has been actively sought, and it continues to be important as the indicators are reviewed and refined. The indicators have been extensively reviewed, but the list continues to be dynamic, and individual indicators are subject to testing and further revision.

Based on the overall criteria of *necessary* and *sufficient*, the suite of SOLEC indicators addresses most of the Great Lakes ecosystem components. Some additional indicators may be added as information gaps or other managerial needs for data are identified. Some indicators may also be removed from the list if they no longer provide useful information.

Monitoring and reporting on the state of ecosystem components is not a new concept to Great Lakes programs. The value added by the SOLEC process is the deliberate selection of information requirements and the translation of those requirements into a comprehensive suite of indicators for multiple users. The data collected from collaborative monitoring efforts and the subsequent interpretation of the data should be useful for environmental managers at all levels of government as well as for researchers, industry, and private citizens. The suite of indicators can also be used by the governments of Canada and the U.S. not only as a basis for reporting on progress toward the goals of the GLWQA, but also as a basis for engaging additional monitoring and research.

Several challenges remain to implement fully the SOLEC indicators and the SOLEC reporting venues. They include the following:

- Periodically reviewing and refining the indicator list.
- Gaining acceptance of the list by federal, state, provincial, and municipal partners who have the potential to monitor these indicators.
- Nesting local and lake-wide indicators within basin-wide indicators.
- Building appropriate monitoring and reporting activities into Great Lakes programs at the federal, provincial, state, Tribes/First Nations, and industry levels, including agencies that have not traditionally provided monitoring data.
- Reporting on indicators at future SOLEC conferences and in printed reports or other media in a format that will meet the needs of multiple users.

As more of the underlying data supporting the indicators become available, more audiences can be served, including the general public, local decision makers, and the scientific and engineering community. A well-informed public should facilitate the management decisions and actions that are needed to continue progress toward the goals of the Great Lakes Water Quality Assessment.

Control of Natural Resource Degradation to Restore Ecosystem Health and Help Secure Peace in the Middle East

Scott Christiansen

INTRODUCTION

The Multilateral Middle East Peace Process called for, among other things, strengthening regional cooperation to control desertification. The World Bank was instrumental in facilitating the process of preparing and implementing the approved program, the *Initiative for Collaboration to Control Natural Resource Degradation (Desertification) of Arid Lands in the Middle East*, which has been recently shortened to *Regional Initiative for Dryland Management* for Phase II of the project, scheduled to continue through 2003. The initiative involves regional cooperation in technology sharing, application of research findings, provision of training, and preparation of pilot investment priorities. The World Bank, Switzerland, Luxembourg, Japan, the U.S., the Republic of Korea, and Canada provide funding that is complemented by in-kind and financial inputs by the participating countries: Egypt, Israel, Jordan, the Palestinian Authority, and Tunisia. The International Center for Agricultural Research in the Dry Areas (ICARDA) is responsible for program execution through a facilitation unit hosted in the ICARDA-Cairo offices.

This chapter presents a summary of the project setup and achievements in Phase I and outlines how it has been redesigned to better achieve its goals in Phase II. The Phase I program (1995–2000) was subject to an external program review and an external financial audit, both serving to strengthen the project. The Phase I matrix setup (Table 71.1) gave way to a more objective-oriented approach in Phase II, namely: (1) natural resource conservation and watershed development using water harvesting techniques and suitable plant resources for the benefit of the local communities within selected national development projects; (2) treated wastewater and biosolids management, reuse, and guidelines; and (3) identification of policy options for reversing natural resource degradation and reducing poverty.

Administrative Structure and Participating Institutions

A steering committee of donors meets annually and sets policy guidelines; approves work plans; reviews annual reports and budgets; supervises the facilitation unit; approves accounting, procurement, and auditing reports; and evaluates the program overall. It comprises representatives of contributing donor organizations or countries, country counterparts, an international facilitator, an

Capacity building	—	—	—	—	—	Focal point

^a Countries leading regional support programs (RSPs) are indicated in bold. Each of the five countries was required to carry out projects within its territory, known as national support activities (NSAs). In addition, the Palestinian Authority was assisted in capacity building through support for the establishment of the Palestinian Environmental Authority (PEnA), subsequently merged with the Ministry of Environmental Affairs (MEnA). For example, Jordan is to carry out NSAs within its territory and provides regional support to all the other countries in the RSP for the rangeland management theme. NSAs were planned as research and development projects while the RSPs are used for coordination, training, and communication.

ICARDA representative, the World Bank supervisor, and a World Bank steering committee chairperson. The conception and implementation of work programs and budgets are the responsibility of the national agencies in cooperation with the facilitator.

Phase I of the initiative was implemented during 1995–2000, a period during which the political environment and the institutional arrangements were under severe stress. For example, the regional dimensions of the initiative were completely frozen from March 1997 until summer 1999, and the mechanisms for cooperation under the Multilateral Middle East Peace Talks were mostly ineffective. Despite these stresses and some financial constraints, however, the project evolved from its original design into a reasonably effective state, but with limitations on regional cooperation.

PROGRESS UNDER PHASE I

The initiative began in earnest during 1995 with the setup of the facilitation unit and organization of national work plans. The partner countries deployed these technical solutions at specific sites with varying degrees of success (see Boxes 71.1 to 71.3). The original structure elaborated by the project designers (Table 71.1) began to evolve into the current form of the initiative from the 1997/1998 to 1999/2000 agricultural seasons (Table 71.2). When activities failed to occur, or when work plans were weak, team leaders were encouraged to consolidate and refocus their programs. In fact, some activities will not continue into Phase II because of the lack of a supporting national development project, which was a prerequisite for continuation of the work.

THE RATIONALE FOR CONTINUATION

A Vision for Phase II

Phase II of the initiative focuses almost exclusively on regional collaboration, underpinned by national-level activities in the domain of natural resource management. The activities of Phase II build on the achievements of Phase I. Greater attention is given to the role of poverty as a causal factor in environmental degradation. Major efforts are being made to capitalize on strong knowledge bases within the region on runoff farming and agricultural reuse of treated wastewater and biosolids

Box 71.1 Accomplishments — Plant Genetic Resources

EGYPT: A systematic plant collection effort in the Sinai characterized and documented the best sites for conservation, providing a useful guide to rangeland scientists, ecologists, botanists, and taxonomists. The work in the northwest coast deserves credit for the manner in which the initiative worked with Matrouh Resource Management Project (MRMP), the Agricultural Research Center, the Desert Research Center, ICARDA, and consultants to review the recommended plant genetic resources considered appropriate for the region. This teamwork resulted in a widescale change in the genetic resource offerings recommended for propagation in more than a dozen private greenhouses working with MRMP, each with a capacity of approximately 100,000 seedlings per year.

ISRAEL: Israel carried out research for elucidating drought resistance of forage plants from the desert and nondesert transition zone of Israel. A postdoctoral fellow developed a climatological index to characterize annual fluctuations in aridity of this transition zone, a report that is available in the scientific literature.

JORDAN: Activity focused on promotion, conservation, and utilization of medicinal and herbal plants of Jordan. Work is now expanded for fenugreek, anise, and fennel. It was found that growing thyme under plastic house conditions maximizes yield and return, while for sage open-field conditions are recommended. For chamomile, the management target is to develop techniques to extend flowering time to increase yield. Arak, mellisa, and roselle can feasibly be grown under conditions of high heat and salinity, particularly when mulched. The project provided the foundation for a Global Environment Facility (GEF) Project Development Facility Grant of \$350,000 (U.S.) that started in 2000.

PALESTINIAN AUTHORITY: A 15-ha botanical garden in Jericho is established. The area is fenced and has plants established around the entire perimeter. The land was cleared of plastic, cultivated, and tested for chemical and physical properties. A drip irrigation system is installed on nearly two thirds of the area. In 1999, eight plastic houses were used for seed production of local vegetable varieties (tomatoes, cucumbers, pumpkins, etc.) in association with a local NGO. A four-room office building (including storerooms) is functional. About two thirds of the area is already planted with trees and shrubs. The vegetable program is based on the technical input from local NGO experts working with about 200 farmers on conservation of 23 local vegetable varieties from 11 main crops. The various units of the garden include herbs and medicinal plants, wild plants, shrubs and forages, citrus, palms, forest species, and cropland races.

TUNISIA: The activities of the germ plasm group were to promote on-farm conservation and propagation of new types of useful arid land germ plasm (shrubs, trees, grass) that can be used to stabilize the fragile ecosystem of the Zammour Valley within the Matmata Mountains. The project has attracted a credible volunteer participation in the program by members of the community. The NGO *Les Jeunes de Zammour* with IRA-Médenine have developed a proposal on the use of medicinal and herbal plants to further enrich the selection of plants with potential economic value that would allow for the development of a project through GEF. A booklet is currently under preparation containing an inventory of plants with pictures and descriptions of the target herbal, aromatic, medicinal, and culinary species with economic potential.

Note: Because of the similarity of the “germ plasm” for arid lands and the “economic forestry and orchards” themes, the accomplishments are consolidated in a single box.

because of their potential to add value to land, permitting the intensification of agriculture through the introduction of trees and other higher value crops. These subjects provide excellent areas for cooperation between Arab and Israeli partners owing to their potential to share knowledge and provide outputs that could have significant sociological and economic impacts. Greater attention is devoted to the sharing of knowledge on policy issues common to the region, especially in terms

Box 71.2 Accomplishments — Rangeland Management

EGYPT: Committed interactions and a high degree of communication are taking place among the initiative, ICARDA, the International Plant Genetic Resources Institute (IPGRI), Matrouh Resource Management Project (MRMP), and the GTZ/Qasr Rural Development Program (QRDP). A range strategy was written during a meeting held October 17–19, 1998 and a study to investigate the potential of rangeland improvement in the wadi tips has culminated in a successful demonstration in the field. Adapted plant materials, good quality seedlings grown in private nurseries, and well-supervised transplantation techniques can result in successful intensification of rangeland on private land where the farmers have shown willingness to protect the transplanted seedlings. This activity requires follow-up if it is to be expanded to other wadis to assure the success of plantations in the first year (watering when absolutely necessary, monitoring survival, and checking farmer compliance to prohibit grazing). The program covers approximately 35 ha at 10 Wadi Ramla sites using approximate 50,000 plants and representing five adapted species.

ISRAEL: The Israelis have invested a large amount of effort in securing national support to carry out their combined NSA on rangeland and economic forestry. The JNF is now a full partner and a site is identified within the Israeli side of the Yatir Forest to monitor the effect of forests on hydrology, productivity, and biodiversity in the watershed. Bedouin farmers from neighboring countries will visit and share experiences with Bedouin in Israel.

JORDAN: The Ministry of Agriculture (MOA), the Royal Society for the Conservation of Nature (RSCN), the Canadian International Development Agency (CIDA), and the Canadian contractor AGRODEV manage the Sustainable Rangeland Management Project (SRMP), which is established in Faysaliya and Buseira and will now expand to another agroecological zone in Muaggar. The Jordanians agreed to expand a 1-ha spineless cactus nursery in Mujib to a much larger area. The initiative team in Jordan enrolled six of its staff in a master of science rangeland program at the University of Jordan set up through collaboration of the initiative and CIDA/AGRODEV. A successful SRMP “cut and carry” operation was achieved on 40 ha at the 5-year-old Faysaliya range reserve with benefits for the villagers and positive public awareness spin-off for the project. The government has expressed its desire to expand this system of management to four additional rangeland reserves of the MOA in the country.

PALESTINIAN AUTHORITY: The main achievements of the project were to introduce a variety of plants to improve production, minimize land degradation, and diversify feed sources. So far, the team has planted *Atriplex halimus*, *A. nummularia*, *Acacia cyanophylla*, *Cassia sturiti*, and cactus on 25 ha of land at three locations, which currently are perceived by local people as islands of plant conservation that are managed by farmers. The project also assists to establish wells or rehabilitate Roman cisterns.

TUNISIA: The initiative’s activities in the activities on rangeland and forestry are complementary activities conducted in an area about 50 to 60 km west of Gabès. The collaboration is synergistic in that the initiative provides operational support in assisting the communities through the provision of added inputs such as 500-l water tanks (20 for 1999) and other supplies as incentives to improve the effectiveness of the Forestry Department in the MOA. In 1998/99, 300 ha of degraded rangeland were planted with adapted trees and shrubs in the Henchir Snoussi community using a participatory approach and 500,000 plants/year produced in the Oued Zayed nursery near Menzel Habib. In addition, 300 ha of olives were planted and irrigated. The farmers appreciate the olives, because even when the trees are planted at a low density, the farmers are convinced that the olives will provide better income than might be achieved with fodder shrubs alone.

of improving policy performance when policies are already in place and are not properly implemented. Finally, a concerted effort is being made to create a mechanism to allow national leadership to surface in the various activities of the initiative through delegation of responsibility to the people actually doing the work.

Box 71.3 Accomplishments — Marginal Water and Saline Soils

EGYPT: An integrated farm management system using drainage water, treated wastewater, and fresh water as sources of irrigation was applied to crops grown within a rotation sequence. Since this study began in 1997, the crop sequence was wheat, soybean, sugar beet, sunflower, and canola. The plots were irrigated under both surface and drip irrigation with five sources (fresh, treated, treated alternated with fresh, drainage, and drainage alternated with fresh). In addition to the large plot field trials the same crops were grown concurrently in a set of lysimeters under more controlled conditions. Five field days for farmers and four training courses for extension agents and technicians were hosted.

ISRAEL: No activity to report within the initiative. Israel has many important activities that could be incorporated into Phase II if resources were mobilized for such efforts.

JORDAN: A fodder-growing demonstration is established on a 2-ha site near the Madaba water treatment plant that previously had problems with soil management, irrigation practices, weed control, and agronomy. Cooperating farmers have now established a green cut fodder cooperative for dairy cattle feeding. The project demonstrated proper ground leveling, preparation of soil basins, and management techniques using ryegrass and sudangrass. Plots are irrigated using secondary treated wastewater. Soil moisture and chemical composition are monitored and a similar demonstration is established on a farmer's field. The main aim of the trials at both sites is to provide year-round green forage and to demonstrate better varieties, crops, and management practices to local farmers. The MOA and the Ministry of Water and Irrigation (MOWI) have agreed to cooperate formally through the initiative to fulfill the government of Jordan's policy on reuse of treated wastewater.

PALESTINIAN AUTHORITY: The Ministry of Environmental Affairs has worked diligently during the past 2 years to create a duckweed demonstration at Al-Arroub Agricultural School. The activity was expanded in the past year from a small exploratory trial, and several technical difficulties were overcome. The technical staff diagnosed and solved a problem related to high levels of biological oxygen demand in the influent wastewater that affected the growth of the duckweed. Through discussions with the World Bank modifications were introduced that solved the problem, this teamwork provided the staff with a practical learning experience. A detailed report has been prepared by the team leader summarizing the experience of the past 2 years including a survey of public attitudes concerning agricultural reuse of treated wastewater.

TUNISIA: A continuing program exists to grow tree seedlings (4000 for 1999) at the Gabès wastewater treatment plant for distribution to communities and schools. The partnership with the Association Tunisie Méditerranée Pour le Développement Durable (ATUMED), an NGO, has proved beneficial. The Commissariat Régional de Développement Agricole (CRDA) in Gabès is in the process of training young farmers who will receive land in a perimeter to be irrigated with secondary treated wastewater. A pilot tertiary treatment facility is being developed at the Gabès wastewater treatment plant to reduce pathogens and suspended solids from the treated effluent. This work is undertaken in close cooperation and cofinancing with the Office National de l'Assainissement (ONAS). Important regional workshops were held in Israel, the Palestinian Authority, and Tunisia in 1999 and 2000.

Beyond Phase II

The vision for some 10 to 15 years from now includes:

- Reduced degradation of the natural resources of the region
- Higher per capita incomes for the rural poor
- Fuller integration of all stakeholders in efforts to control desertification
- Fuller economic integration among the countries of the region by harmonization of their economic science, and technology policies
- A more deeply rooted peace process in the region

Table 71.2 The Actual Deployment of National Support Activities (NSAs) at the End of Phase I

RSP Theme	National Support Activities (NSAs)					Palestinian Authority 17 to 19
	Egypt Activities 1 to 5	Israel 6 to 8	Jordan 9 to 13	Tunisia 14 to 16		
Germ plasm for arid lands	1. Germ plasm diversification in the NWC 2. Collection in the Sinai	6. Various semiarid to arid sites north to south in the Negev	9. Medicinal plants countywide with focus at NCARTT's Mushaqqar, Maru, Ghor Safi, and Khaldieh stations	14. Zammour Valley Germ plasm resources Orchards and range	15. Khenchir Snoussi and Menzel Habib Forestry and range	17. Botanical garden near Jericho
Economic forestry and orchards	3. Fruit tree diversification and integrated watershed management in the NW coast	7. Avdat and Mashash sites in the Negev Desert	10. MOA Mastaba and Khushaibah	11. Wadi Araba with RSCN, CIDA, and AGRODEV		
Rangeland management	4. Range species for use in the NW Coast: "Intensification of Private Range"		12. MOA Ma'in and Faysaliya			18. Samou'a: Shrubs for rehabilitation of eastern slopes
Marginal water and saline soils	5. Kafr El Sheikh and Abou Rawash	8. Several sites in Israel (closed down in 1999)	13. MOA Madaba and Al-Samra	16. Gabès wastewater treatment (WWT) plant, schools, and nonmunicipal WWT		19. Al-Arroub duckweed pond

The Mission to Rehabilitate or Maintain Ecosystem Health

The mission of Phase II is to promote regional technical collaboration within the framework of national pilot development efforts, as an instrument to arrest natural resource degradation of arid lands in the Middle East. If successful, the pilot program will contribute to the strengthening of the peace process among all countries of the region and have a lasting effect into future generations.

Strategic Objectives

1. To focus regional cooperation more effectively on the application of available technical solutions for poverty reduction in rural areas and refugee camps as a means to reduce natural resource degradation.
2. To make use of pilot projects to demonstrate what can be accomplished through country-to-country collaboration, with the eventual goal of upscaling these projects into larger country programs, focusing the technical themes on runoff water harvesting and reuse of treated wastewater and biosolids.
3. To broaden the impact of the initiative by linking its activities to other relevant ongoing activities to combat desertification in the region, namely, the Sub-Regional Action Plan for West Asia through the United Nations Convention to Combat Desertification (UNCCD).
4. To develop an intercountry dialogue on policy issues shared among the partner countries to reduce poverty and natural resource degradation in the region.
5. To sustain and further the goals of the Multilateral Middle East Peace Process by promoting dialogue and common vision among technical people of the region.

The Structure of Phase II

The scope of activities in Phase II is more focused and institutional arrangements for implementation more clearly defined. Work is primarily focused on regional activities. On-the-ground efforts are anchored in relevant national development projects aimed at reducing rural poverty and arresting natural resource degradation. Efforts are incremental to national efforts, adding regional value to existing work. Activities have the potential for upscaling into larger investment programs, thus increasing the level of national financial resources allocated to the sectors. Phase II has three components, as discussed below.

Regional Support to National Development Programs

Each of the participating countries has a number of development activities under implementation, either ongoing or proposed. Each participating country has at least one development project to serve as the foundation for its regional component.

The regional teams of specialists, each selected by the participating countries, add incrementally to national efforts, filling specific gaps and needs for specialized technical assistance. The designated regional team works jointly with the national team, adds value to the output of the national pilot program, and contributes to its potential for subsequent upscaling. These teams share experiences, transfer state-of-the-art knowledge, and contribute to capacity building and strengthening of private and public institutions. These interactions build bridges for future expansion of collaboration, ensure sustainability, and consolidate the peace process.

Policy Fora

Efforts to counter land degradation processes cannot be achieved through technological improvements alone. Policy changes and effective participation of local communities are equally important. The capacity of national institutions to define their policy agendas and mobilize the

List 71.1 National Management Committees and National Development Projects Identified for Phase II of the *Regional Initiative for Dryland Management*

Egypt

- (a) Ministry of Agriculture and Land Reclamation (MALR), including the Agricultural Research Center (ARC) and the Desert Research Center (DRC); Egyptian Environmental Affairs Agency (EEAA); Ministry of Housing (Authority for Sewage Water); Land Reclamation; Private Sector; and the University of Zagazig.
- (b) The Matrouh Resource Management Project on the northwest coast of Egypt is a large development project sponsored by the World Bank and the government of Egypt. Additional collaboration exists with the On-Farm Water Management (OWSOM) Project in Kafr El-Sheikh.

Israel

- (a) The Blaustein Institute for Desert Research (BIDR); Ministry of Agriculture and Rural Development (MA&RD); Ministry of Environment (MOE); Keren Kayemet Le'Israel, also known as the Jewish National Fund (JNF); and Mashav (Ministry of Foreign Affairs).
- (b) The Yatir Forest in Israel, a site of afforestation in the semiarid drylands in the northeast Negev planted by the JNF (~250 mm annual precipitation). The work is complemented by training and demonstration sites at the Evenari experimental farm at Avdat, a resurrected ancient Byzantine farm in a hyperarid zone in the highlands of the central Negev (~90 mm annual precipitation) and Mashash Farm, a runoff farming research site. Wastewater treatment and biosolids reuse takes place at Hamaapil on the coastal plain and Ruchama, Nirim, Nir-Am, and Shual in the western Negev in association with the MA&RD and MOE.

Jordan

- (a) Directorate for Rangeland, in the Ministry of Agriculture; The National Center for Agricultural Research and Technology Transfer (NCARTT); NGO — The Royal Society for the Conservation of Nature (RSCN); The Agricultural Union in Madaba; and the Women's Union in Madaba.
- (b) An area east and west of Madaba serves as the base for work in Phase II. The CIDA/AGRODEV/MOA/RSCN Sustainable Rangeland Management Project, supported by the government of Canada, has been central to the achievement attained in Phase I, and it is planned to reinforce the Range Department of the MOA in the years ahead. A Global Environment Facility (GEF) project for herbal and medicinal plants is the national development project located in Wadi Mujib that will be implemented by NCARTT in cooperation with the MOA and RSCN.

Palestinian Authority

- (a) Ministry for Environmental Affairs (MENA); Ministry of Agriculture (MOA); The Water Authority (PWA); The Palestinian Hydrology Group (PHG); NGO — Palestinian Agricultural Relief Committee (PARC); and An'Njah and Hebron Universities.
- (b) Principal focus will be the Qa'abnah site, an area with customary rights held by the Arab al-Kaabneh tribe, working in collaboration with the MOA/UNDP Rangeland Project; the MOA/UNDP Agro-Biodiversity Project; the MOA/UNDP Land Reclamation Project; and the MOA Green Palestine Project funded by the Dutch. The location of the treated wastewater and biosolids reuse work will be in association with the Gaza Wastewater Treatment Plant in Wadi Gaza and the Al-Bireh Wastewater Treatment Plant in the West Bank.

Tunisia

- (a) From the Tunisian Ministry of Environment (Ministere de l'Environnement et de l'Aménagement du Territoire (MEAT)): Centre International des Technologies de l'Environnement de Tunis (CITET) serving as the Focal Point and the Office National de l'Assainissement (ONAS). From the Ministry of Agriculture (MOA): Commissariat Régional de Développement Agricole (CRDA) in Gabès; Direction Générale des Forêts (DFG); Institut National de Recherches Genie Rural Eaux et Forêt (INRGREF). NGO partnerships: Association Tunisie Méditerranée Pour le Développement Durable (ATUMED) in Gabès.
- (b) The Menzil Habib project site covers about 300 ha, 50 to 60 km west of Gabès, and is traditionally owned by the Henchir tribe of the Snoussi confederation. A degraded rangeland and agricultural site was protected and planted with adapted trees and shrubs in Phase I. For treated wastewater, the Dissa Project irrigated site covers 400 ha near Gabès. All farmers are identified and participate in the implementation of the project.

^a Institutional composition of national management committee

^b National development projects

necessary means to implement these policies is one of the most critical factors that will affect the future of the region. Key socioeconomic policy issues, such as those bearing upon off-farm determinants of the rural poor's access to resources, markets, and product prices, are key to the management of natural resources. Equally, the organizational and policy practices of relevant institutions, and the nature of the institutions that administer the arid lands, represent an important

domain for contributing to the goals of the initiative. Policy dialogues among institutions operating in the region are developing a better understanding of the issues surrounding the management of arid lands. Priority attention is given to issues identified by the partner countries, such as exchange of experiences related to land management by Bedouin, and standardization of legal frameworks for treated wastewater and biosolids reuse.

Capacity Building

Given the young age of its institutions and the importance of the Palestinian Authority in the peace process, the objective of this component is to provide capacity building activities, primarily in support of Palestinian institutions responsible for management of its arid lands. Activities provide financing that leverages contributions by other programs executed by bilateral and multilateral institutions operating within the Palestinian territories.

The approach to be deployed under this component is to identify critical gaps in existing programs that support capacity building in the pertinent institutions. Identification of these gaps is accomplished by the national steering committee, which is composed of ministries, nongovernment organizations, and universities with the objective of identifying the most rational deployment of the initiative's limited resources in areas with the highest payoff. The facilitation unit cooperates with the respective ministries to convene consultation meetings to identify the critical gaps and the modalities for addressing them. With these determined, the facilitation unit establishes contacts with participating countries to identify their potential support to the respective institutions in the Palestinian Authority.

CONCLUSION

The initiative successfully carried out activities during a transitional period from October 1999 to July 2000. Phase II is under way with the involvement of the institutions identified in List 71.1. Regional activities are anchored in selected national development programs that address natural resource management issues within the framework of rural poverty reduction and promote dialogue on common technical, scientific, and economic policy issues that are critical to natural resource management in the region. The facilitation unit assists regional cooperation for capacity building, with particular emphasis on the needs of the relevant institutions of the Palestinian Authority. The facilitation unit also assumes responsibility for monitoring activities and organizing periodic reviews and thematic evaluations. The World Bank assumes leadership for mobilizing the necessary resources from current and potential donors and playing an active role in linking Phase II efforts to investment projects in the partner countries. Emphasis has shifted from research to development, focusing on a strategy that allows for the introduction of rainfall runoff farming and reuse of treated wastewater and biosolids as core elements of the technical package in each of the national development projects. These themes in turn provide the platform in each country upon which incremental regional work can be programmed and financed through the initiative.

Biological Conservation in Mexico: An Overview

Exequiel Ezcurra

INTRODUCTION

The Mexican highlands, and especially the Basin of Mexico, are among the regions of the world that have suffered some of the greatest environmental alterations in history. When the Europeans arrived in Mexico in 1519, the region was already greatly transformed by agriculture, water projects constructed for the development of *chinampa* agriculture, deforestation, and faunal extinction (Ezcurra, 1992). The rate of environmental change, however, has increased continuously since then, and, with the growing ecological deterioration, the awareness of the problem by different social groups has increased accordingly.

The development of the Spanish colony in Mexico hinged on an intentional transformation of the environment to adapt it to the introduced European crops and animals, and to new means of transportation. Toward the end of the 18th century, Alexander von Humboldt, in the *Political Essay on the Kingdom of the New Spain*, expressed serious concern about the future effects of the rapid deforestation that was taking place in the slopes of the Mexican highlands. In the early 20th century, Miguel Ángel de Quevedo campaigned for the planting of trees in Mexico and predicted that large-scale environmental degradation would ensue if deforestation continued at the rapid rate it was undergoing at that time. Unfortunately, Humboldt's and Quevedo's fears proved to be correct. Environmental degradation progressed rapidly during the 20th century, and induced a growing series of responses from both government and nongovernmental organizations (NGOs). Conservation in Mexico is especially important in the context of developing countries, because the country harbors an immense biological diversity, and also because Mexico's industrial growth is typical of many of Latin America's emergent economies (Williams-Linera et al., 1992).

BIOLOGICAL CONSERVATION: A GROWING CONCERN

In spite of the early and dire forecasts of Humboldt, Quevedo, and many other early visionaries, general consciousness about the problem of environmental degradation began to expand only in the late 1970s. The economic development of Mexico during the mid-20th century was conducted essentially with nonsustainable use of natural resources, and with no awareness of the negative environmental consequences that would follow. In the Mexican tropics for example, programs were developed to slash tropical forests and to transform them into grasslands. A national commission promoting deforestation (*Comisión Nacional de Desmontes*) existed within the Secretariat of Agri-

culture until the late 1970s. Actions were driven by the need to industrialize and develop, with few restrictions and no planning for a sustainable future.

GOVERNMENTAL ACTIONS FOR PROTECTION OF BIOLOGICAL DIVERSITY

By the mid-1970s many Mexicans became aware of the accumulation of environmental problems that needed to be confronted. The conclusions of the 1972 U.N. Environmental Conference and the attention drawn by some books, such as Rachel Carson's *Silent Spring*, confirmed the truth of the growing perception that the environment was quickly deteriorating. During the 1970s both the governmental authorities and Mexican society started to react — first around issues of urban pollution, and later with a growing concern for deforestation and biological extinction. Simultaneously, governmental reports and regulations started to emerge, with the aim of curbing the perceived environmental degradation (e.g., DOF, 1971, 1984, 1988; CONADE, 1992).

In 1992, the United Nations Conference on Environment and Development (UNCED) took place, and the Mexican government participated actively in the preparatory meetings of the previous years and in the final writing of Agenda 21. Following the paradigm of sustainable development that UNCED attempted to implement at a global scale, the Mexican Federal Administration started to regard environmental degradation as a problem related to social and economic development, linked to the problem of poverty and lack of social progress. Also as a result of UNCED, the federal government took an active interest in the protection of the natural heritage of Mexico, and created the National Commission for the Knowledge and Use of Biological Diversity (CONABIO) in early 1992, an organization devoted to the survey of the biological richness of Mexican ecosystems. The federal environmental authority (now known as *Secretaría de Medio Ambiente, Recursos Naturales y Pesca*, or SEMARNAP) also started to implement environmental projects with the World Bank, including a donation from the Global Environmental Facility (GEF) to support the operation of ten priority Mexican Biosphere Reserves (BRs).

In that same year, Article 27 of the Mexican Constitution (see *Constitución Política de los Estados Unidos Mexicanos*, 1995) was modified, ending the process of agrarian reform and land allotment — and opening the possibility of ending the communal ownership of the land under the *ejido* (communal land) system for those *ejidos* and indigenous communities wishing to do so. The overexploitation of natural resources in excessively subdivided communal lands was one of the arguments put forth. Although the new version of Article 27 states that one of its objectives is to preserve the environmental balance, Mexican conservation groups are concerned that this constitutional change has exerted pressures to privatize and sell lands that are potentially valuable and still well preserved, such as tourist areas or pristine forests ecosystems.

The federal environmental authority proposed, among other things, to decentralize decision making in environmental matters. Many attributions that were previously held by the federal government in Mexico City were passed to the state and municipal governments (INAP, 1991). In the early 1990s, many state governments enacted their own environmental laws and regulations, and some started to operate programs that had been previously operated by the federal administration (SEDESOL, 1994b). As an example, during this period the state of Campeche started managing the natural protected areas within its territory, including Calakmul, a federal BR.

The new emphasis led to the publication of 58 official standards dealing with different aspects of the environment, including Mexico's first comprehensive listing of endangered species (SEDESOL, 1994a). The publication of these standards opened for the first time the possibility of governmental control on the trade of endangered species within Mexico, as a complement to the obligations assumed in the international sphere with the signature of the Convention on International Trade in Endangered Species of Wild Flora and Fauna (CITES). These standards also established a formal regulatory framework for environmental impact studies and ecological planning. Additionally, these new regulations brought into the governmental discourse the use

of new analytical techniques in decision making and priority setting, such as risk assessment and cost–benefit analysis.

In December 1994, shortly after assuming office, the Zedillo administration created a new secretariat (DOF, 1994) to encompass all federal environmental functions, including those dealing with brown ecology (environmental pollution), and green ecology (natural resource management). The Secretariat of Environment, Natural Resources and Fisheries (SEMARNAP) included functions that were previously dispersed in different federal agencies, including the protection and management of natural resources such as water, forests, and fisheries; waste management and pollution control; the management of national parks and other protected natural areas; and environmental law enforcement. Deconcentrated governmental agencies dealing with environmental matters all shifted to the jurisdiction of this new federal secretariat. The creation of this strong ministry reflects the ever-increasing importance that federal authorities are now giving to the environmental problems of Mexico. It also underscores the perceived need to institutionalize sustainable development initiatives by integrating governmental activities that may affect the environment and that were previously separated, such as forestry, fisheries, and conservation, or energy use, transportation, and urban design (DOF, 1996).

Furthermore, in this new organization, the management of natural protected areas became separated from the management of wildlife, and acquired a higher status as a coordination unit in 1996, and as a national commission in 2000. SEMARNAP faced its great responsibilities and the financial difficulties engendered by the policies of governmental reduction established in 1995 by looking for even stronger programs of decentralization than those implemented by the *Secretaría de Desarrollo Social* (SEDESOL) on the one hand, and by trying to develop alliances with NGOs and the private sector to manage specific aspects of the environmental policies on the other. An ambitious program of decentralization of governmental functions to the states was discussed and established in the early stages of SEMARNAP's creation (SEMARNAP, 1996a, c). More specifically, a program was conceived by SEMARNAP to decentralize the administration of the National Parks, and to cooperate with NGOs and research institutions in the management of BRs (SEMARNAP, 1996b, c). For this purpose, SEMARNAP created an independent Advisory Council on Protected Areas, and worked closely with NGO representatives to convert the GEF \$25 million U.S. donation to Mexico into a private trust fund.

NONGOVERNMENTAL ORGANIZATIONS AND THE PROTECTION OF BIOLOGICAL DIVERSITY

NGOs also have changed rapidly and profoundly during the last three decades (Sandoval and Semo, 1985; Ezcurra et al., 1999). Although much of the ecological activism in the 1960s and 1970s hinged on the growing urban problems of Mexico City, some groups started to work from the late 1970s in the protection of biological diversity and opposing the growing deforestation of the Mexican tropics. Under the direction of Gonzalo Halffter, the Instituto de Ecología (Institute of Ecology) — a research center — started promoting the concept of BRs in Mexico. While fairly accepted at present, the idea, which had been developed by a group of ecologists in United Nations Educational, Scientific, and Cultural Organization's (UNESCO) Man and the Biosphere Program (MAB), was radically new in 1975. Biosphere reserves were conceived as natural protected areas where the indigenous populations living inside the area or in the surrounding buffer zones were encouraged to use their natural resources in a sustainable manner. Instead of following the paradigm of the natural park concept, in which protected areas were conceived as pristine areas free of human influence, the BR concept involved the maintenance of the local populations under a sustainable management plan. Instead of opposing conservation against human use of the resources, BRs promoted the idea of sustainable use. The Mexican BRs were among the world's first to become

operational, and became integrated into the MAB network of BRs. Many of the concepts discussed in UNCED in 1992 were already operational almost 20 years ago in the MAB concept of BRs:

1. The need to protect biodiversity globally through a network of protected areas
2. The urgency to preserve cultural diversity together with natural diversity
3. The demand to integrate local populations in the protection of biological diversity
4. The promotion of sustainable use of natural resources.

Although the Institute of Ecology is an academic research center and, strictly speaking, not an NGO, its work opened the way for many experiences developed later by NGOs along these basic guidelines.

Similarly, in the 1970s, another research center was created in Xalapa, Veracruz, devoted to research on the use of biological natural resources. The *Instituto de Investigaciones de los Recursos Bióticos* (INIREB; Institute of Research on Biotic Resources) was founded and directed by Arturo Gómez-Pompa, a leading Mexican botanist. Apart from its outstanding research, INIREB played a very important role in drawing the attention of researchers and conservationists to the problem of deforestation in the tropics, and especially toward the logging of the Uxpanapa rain forests. The pioneer work of INIREB opened the way for many NGOs to become conscious of the problem of deforestation in the Mexican tropics, and to organize actions around this problem.

The National University of Mexico (UNAM) also played a very important role in the growth of ecological awareness in Mexico. In the 1970s the Institute of Biology started to manage a tropical rain forest field station at Los Tuxtlas, in Veracruz, followed shortly thereafter by management of a tropical dry-forest field station and nature reserve at Chamela, on the Pacific coast of the state of Jalisco (e.g., González-Soriano et al., 1997). From the Institute of Biology a new Institute of Ecology grew in the late 1980s. Together with the Faculty of Sciences of UNAM these three organizations established a kernel of ecological research and conservation that gave rise to myriad academic organizations in the country interested in ecological conservation.

Toward the end of the 1980s, all political parties in Mexico had included environmental issues in their platforms. By that time, many environmentalist NGOs had merged into a coalition known as *Pacto de Grupos Ecologistas* (Pact of Ecological Groups). Around this time, local chapters of international NGOs were also established in the country, some — such as Greenpeace and Oilwatch — were devoted to the surveillance and monitoring of the attainment of environmental regulations and ecological protection. Other organizations — such as the World Wildlife Fund (WWF) and Conservation International (CI) — were dedicated to the conservation of nature and the protection of biodiversity. These organizations are contributing significantly to link the Mexican environmental groups into the global international perspective.

Environmentally motivated groups have continued to manifest themselves in rural Mexico with an ever-increasing momentum. In 1992, the National Commission on Human Rights (CNDH) published its *Recomendación 100*, calling for federal and state authorities to take urgent action to solve the critical environmental problems confronted by the *campesinos* (peasants) in the Tabasco lowlands, most of them caused by the oil industry. In many parts of Mexico, indigenous groups have started to claim the management of their own natural areas. For this purpose, they have made alliances with urban conservationist organizations, and even with international organizations. Examples of this trend are the *Consejo Regional de X'Pujil* in Campeche, and the *Comité para la Defensa de los Chimalapas* in Oaxaca, among many others. Even the traditional urban environment groups have extended their interests into the conservation of biological diversity in natural ecosystems, bringing the concept of biodiversity into the urban agenda. The *Asociación Ecológica de Coyoacán*, for example, now also hosts a group known as *Comisión de Selvas Mexicanas* (Commission for Mexican Tropical Forests). The *Grupo de los 100* (Group of 100) is a very strong opinion group headed by Homero Aridjis and supported by a hundred leading artists and intellectuals. Although it is still concerned with the environment in general, the organization is now more concerned about

conservation issues such as whales, marine turtles, the trade of endangered species, monarch butterflies, and the management of BRs. Additionally, numerous strong grassroots groups working for the conservation of biological diversity have become established in recent years. Some older NGOs based in Mexico City have established regional chapters, working intensely on local problems. In doing so, these NGOs have decentralized much in the same way as the federal government is trying to do, acquiring in the process a renewed grassroots emphasis.

Other initiatives also have prospered vigorously. Supported by international organizations such as the WWF, The Nature Conservancy, and CI, a trust fund was launched in 1993 with the name *Fondo Mexicano para la Conservación*. This fund has received endowments from U.S. Agency for International Development (USAID) Parks in Peril program, from the Mexican federal government, from the GEF, and from Mexican private funds. Together with other NGOs, the *Fondo Mexicano* has given its advice and support in the actions currently taking place to convert the GEF donation to Mexico into a private trust fund. In 1997, the *Fondo Mexicano* was able to establish a specific fund to support the functioning of 10 selected biosphere reserves. This fund, called *Fondo de Áreas Naturales Protegidas*, operates as a private trust fund the GEF's donation discussed in the previous section. For the first time in Mexico, the NGOs started in the late 1990s to play a central role in the financing of conservation efforts and biosphere reserve management.

THE GROWING ROLE OF CONABIO

From the point of view of biological diversity, the creation of CONABIO can be regarded as a true landmark. CONABIO started funding research on biological diversity and promoting the use of biological collections for decision making. Myriad studies were funded to understand the importance of some crucial taxa, and a growing list of publications started to emerge with information and results from CONABIO's impressive portfolio of projects (see CONABIO Bibliography).

Within these projects, large-scale efforts have been done at a national level to map biodiversity for selected taxa of importance to conservation, such as terrestrial mammals or columnar cacti (Figure 72.1a,b). The resulting maps have highlighted the distribution of hot spots for different taxa

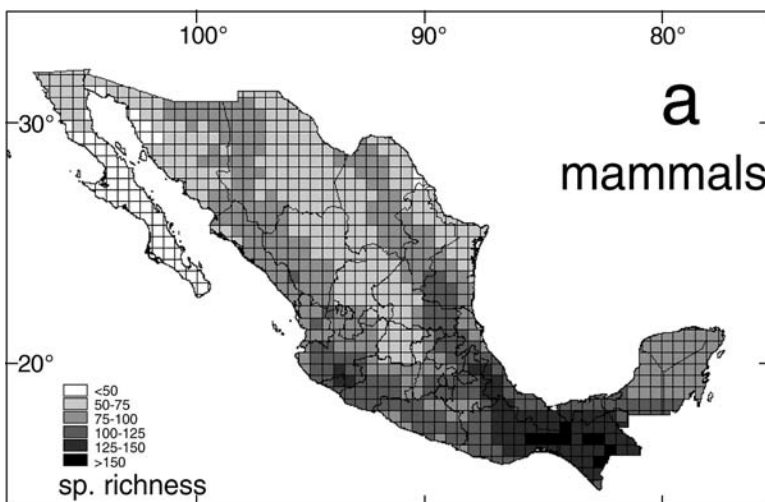

Figure 72.1a Species richness patterns of selected Mexican taxa, developed through CONABIO-funded studies. Mammals (developed by Hector Arita and available at the CONABIO Web site).

Figure 72.1b Species richness patterns of selected Mexican taxa, developed through CONABIO-funded studies. Columnar cacti (Cactaceae, tribe Pachycereeae [Mourelle, 1997; Mourelle and Ezcurra, 1997]). Note the similarity of the patterns and distribution of the high-diversity corridors in 72.1a and 72.1b.

Figure 72.2 Map of priority areas for conservation in Mexico, developed by CONABIO in 1997, with support from PRONATURA, the World Wildlife Fund, the *Fondo Mexicano para la Conservación de la Naturaleza* (Mexican Fund for the Conservation of Nature), The Nature Conservancy, the USAID program, and the National Institute of Ecology (INE-SEMARNAP). This map has been instrumental in defining new conservation policies and establishing new protected areas.

within Mexico, and have led efforts to protect the natural environment in a more effective manner. Based on the emerging results from these largely academic exercises, and also on the experience of hundreds of field biologists and conservationists, CONABIO has been working to identify priority areas for conservation, both in marine and the terrestrial environments, by organizing expert workshops for the identification of hot spots, for the identification of areas providing critically important ecological services, and for setting conservation priorities (Figure 72.2). These immense undertakings have been tackled with the active participation of conservation groups such as PRONATURA, WWF, The Nature Conservancy, or the *Fondo Mexicano para la Conservación de la Naturaleza* (Mexican Fund for the Conservation of Nature). This latter funding agency, in particular, is directing all its financing priorities toward the areas identified through the CONABIO planning exercises.

CONCLUSION

Environmental destruction is still a major problem in Mexico, and biodiversity loss is likely to remain a major problem in decades to come. However, a rapid response is occurring both at the governmental and at the nongovernmental level. Funding agencies that have emerged help ensure the continuous financing of conservation across the changing federal administrations. Biodiversity protection is now part of the jargon of political parties and governments, and it ranks high among the priorities of NGOs and grassroots organizations.

The problem of biodiversity loss should still rank high among the unresolved problems of Mexico, but mechanisms are being established to approach it in a scientific and well-informed manner. Among these mechanisms, the GEF-endowed *Fondo de Áreas Naturales Protegidas* has ensured continuity of funding for critically important biosphere reserves with independence from potential policy changes in the federal government. Additionally, CONABIO has developed an impressive system of biodiversity information and a large portfolio of funded projects. CONABIO's outstanding work has generated a growing series of online accessible databases, documents, ecoregional maps, and applied studies that have been able to generate an ever-improving theoretical framework to prioritize conservation efforts. The results of these projects are in turn starting to guide and influence public policies, as well as help generate funding for new protected areas.

Environmental Impacts of Mobility and Urban Development: A Case Study of the Brussels-Capital Region

Paul Safonov, Vincent Favrel, and Walter Hecq

INTRODUCTION

Aggravation of traffic intensity and air pollution in urban areas requires strategic environmental assessment (SEA) of transportation networks and the integration of land-use planning with transport–environment concerns.

Road traffic in the Brussels-Capital region has increased continuously during the last decade. The reasons for this trend lie mainly in the urban exodus, the growth of employment in the Brussels area and its peripheral region, and the constantly increasing population motorization rate. Recent studies (Plan IRIS, 1989–1995) predict the complete saturation of the road network before the year 2005 in the European capital.

The assessment of the impacts of this road traffic on the environment in general, and on air quality, in particular, helps not only to evaluate the actual situation but also the possible effects of measures toward a more sustainable transport system as an important element of regional sustainable development.

Transport policies alone will not lead to a sustainable level of fuel consumption and emissions. The need to coordinate land-use changes with transport measures in order to achieve an environmentally and economically sustainable transport system is eminent. Transport and land use should be considered as an integrated system. However, as Lobe and Duchâteau (1998) advise, in many urban areas this system resembles a spiral of urban decline, caused by potentially vicious interactions of this system at an urban level.

This chapter presents a study being undertaken in the Center for Economic and Social Studies on the Environment (CEESE) of Université Libre de Bruxelles (University of Brussels, ULB) within a project to analyze the ecological aspects of mobility induced by major regional policy for the case study of Brussels-Capital region (Safonov, 2000). Recognizing the importance of different environmental effects of mobility (such as problems of noise, vibration, and smell, which would stay outside the framework of this study), this project is focused on the assessment of air pollutants emissions [carbon dioxide (CO₂), carbon monoxide (CO), nitrogen oxides (NO_x), sulfur dioxide (SO₂), volatile organic compounds (VOC), particulate matter (PM), as well as others] and the consumption of nonrenewable fuel.

While considering the impacts of air pollution (e.g., in terms of building deterioration, health effects, climate change), the general approach ties to traffic a sequence based on the five steps: human activities, emissions, immissions (pollution concentrations), physical impacts, and external costs. This is the classical approach used in major studies, such as ExternE (European Commission, 1995), for the assessment of externalities in the energy sector, which has recently been updated for its application to the transport sector.

The new model is being synthesized to analyze the influence of recent urban and transport policies on the mobility of people in an urban area. The environmental impacts of such mobility are analyzed on the basis of the information available for the Brussels-Capital region. An integrated modeling approach is proposed, including analysis of socioeconomic factors of mobility, road network assignment model, and estimation of air pollution from traffic. The first version of the model linking urban mobility and emissions from private vehicles is developed using the Professional's Transportation Planning Package (TRIPS, 1999) for network analysis. For possible scenarios of mobility according to the policies defined in the Brussels Regional Mobility Plan (Plan IRIS, 1989–1995) emissions of different air pollutants and fuel consumption were projected and evaluated for the year 2005 as a result of road traffic modeling.

DEVELOPMENT OF THE INTEGRATED MOBILITY MODEL FOR THE BRUSSELS-CAPITAL REGION

Conceptual Structure of the Model and Steps of Implementation

Based on existing experience in modeling different socioeconomic issues of mobility, and its environmental impacts (see Favrel and Hecq, 1998, 2000; and Safonov, 2000; for literature survey), an integrated system of models (Figure 73.1) is proposed, which includes several main components:

1. Urban development model. This will include forecasts of population and employment dynamics, in accordance with different economic and urban development scenarios. Such forecasts should be based on indicators of economic development by main sectors of activities and the respective demand for labor resources, as well as trends in population dynamics and labor resources structured with respect to spatial distribution in the region. Office stock dynamics and other urban factors are also considered.
2. Mobility model. The model provides scenarios of road traffic in the region, according to different origin–destination matrices, generated on the basis of the different urban development scenarios. For transportation network analysis the recent version of TRIPS package (TRIPS, 1999) is used, which provides powerful tools for assignment and graphical presentation.
3. A model linking mobility and air pollution. The focus is mainly on local pollution of CO, NO_x, VOC, and PM. Also consumption of nonrenewable fuels with respect to CO₂ and SO₂ emission is analyzed. The Computer Program to Calculate Emissions from Road Transport (COPERT) methodology (Ahlvik et al., 1997) was used for calculation of the emission functions per kilometer driven, taking into consideration climate, composition of the private car fleet with specific speed profiles, as well as new European/Belgian regulations on vehicles, integrated in COPERT Version III. The emissions are calculated spatially on the transportation network as a function of the assigned traffic intensity, average speed on each link, and length of the trip.
4. In the final stage, as part of the Sustainable Mobility in the Brussels-Capital Region project CESE-ULB is currently developing a methodology for the assessment of the physical effects and external costs caused by air pollution generated by road traffic in an urban area (Favrel and Hecq, 1998, 2000).

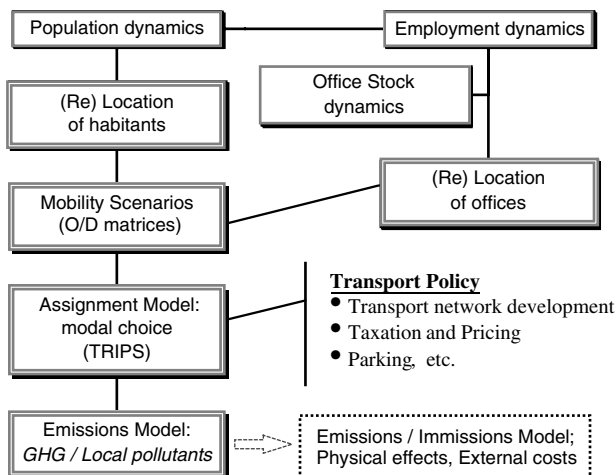

Figure 73.1 General structure of the system of models.

The data necessary for identification of the proposed complex of models are available from various sources, but an in-depth study of the recent literature with a following update of the information base is required along with some additional surveying. Main sources of the data include the National Statistical Institute, administration of the Brussels-Capital region (e.g., Regional Mobility Plan IRIS reports), Brussels office survey (Jones Lang Wootton reports), review of office property (by Brussels-Capital region), and others.

The implementation of the integrated model is planned within several phases. At the initial stage, the mobility demand-related information (socioeconomic, office and dwellings dynamics forecasts) is mainly obtained from the results of previous studies (Plan IRIS, 1989–1995). This enables us to analyze environmental impacts of mobility scenarios within existing urban policy options, along with some additional considerations, such as dynamics of vehicle fleet composition.

As one of the first steps in development of the proposed integrated approach, we have designed a model that allows the assessment of the contribution of mobility by private cars to emission of the air pollutants in the Brussels area. The software was developed to link the mobility model, road traffic assignment, and emissions calculations (Safonov, 2000).

Below we describe the recent situation and the main considerations for the envisaged model design and scenario analysis, and already implemented developments within the proposed modeling approach.

Urban Development

The population of the Brussels metropolitan area has been slowly but regularly decreasing. Households migrating to the close periphery are mainly middle- and upper-class families with a high car ownership level. The decrease in the Brussels-Capital region has been much faster, with an important consequence: the main part of the region’s financial resources comes from the taxes levied on its inhabitants’ income, and these resources are quickly diminishing as a result of both the decrease of the population and also of the average household income. Development in the suburbs cannot be controlled by the government of the Brussels region, because it is located outside of its borders, nor by the federal government, because the land-use planning jurisdiction has been fully decentralized.

During the last 20 years of the 20th century, the economy of the region has undergone a significant mutation. Initially an industrial center, Brussels progressively became an important administrative center and has recently been designated as the European Union capital. Many

Table 73.1 Share of Brussels in the National Economy (%)

	1980	1990	1997
Share of Brussels in the gross national product	15.5	13.4	12.6
Part of Brussels in the global amount of taxable revenue of individuals of the country	11.6	9.8	9.2

Source: Duchâteau (1998), and authors' calculations, based on the data of Banque Nationale (1999).

industrial activities and wholesale enterprises are also migrating toward the periphery, seeking both better accessibility by road and cheaper land (Table 73.1).

It is difficult to identify the cause of such a change, but this process apparently was accelerated by the dramatic improvement of accessibility to the city by road, which resulted from the building of a high standard motorway network during the 1970s.

The structural changes in the economic activities, especially related to technical change, are important factors influencing the mobility. A model of economic dynamics and labor resources in the region, to be implemented as a part of the discussed integrated approach, operates with the information per sector of economic activity. The sectors of services and communication should be considered in greater detail since these are of particular interest for this study as most Belgian offices in this sector are located in the Brussels area.

Several tendencies determine the office stock dynamics and its spatial distribution. Many companies leave city centers for locations that are considered more accessible by their suppliers, clients, and staff members. At the same time, the comparative advantages of housing in cities are decreasing, which reinforces the tendency of more financially secure inhabitants to look for a place to live in the surrounding area of the city, whereas the poorest inhabitants tend to accept housing in the centers. Because of the narrowness of the territory of the Brussels-Capital region, this phenomenon extends beyond the limits of the region, entailing a loss of its substance and a relative impoverishment (Table 73.1). These global trends, as well as the results of the more precise analyses, show that the Brussels-Capital region is seriously endangered by an evolution similar to that of some North American cities, whose centers have been completely deserted by a lot of companies as well as by the middle-class population or the rich.

Mobility

The number of vehicles on the road in Belgium is constantly increasing. In January 1991, the average number of private cars at the disposal of households per 100 inhabitants in the country amounted to 38. The trend of the change observed this last decade suggests that the growth of the motorization rate continues in the coming years, although possibly at a lower rate because of a progressive saturation effect in the demand for vehicles. The general assumption in Belgium is that this saturation point will be reached at 50 vehicles per 100 inhabitants (Duchâteau, 1998). It is relatively modest compared to the levels already reached in North America (nearly 60 vehicles per 100 inhabitants).

The households also took advantage of the new form of mobility that a private car offers in order to change the way they choose where they live. For many households, the comparison of the advantages and the price of a location in the old urban center with those of a location in the suburbs have led to the choice of the latter. The growth of population in the suburbs of Brussels is a consequence of this choice.

The increase of mobility by car also has had indirect consequences on the suppliers of goods and services by extending their market areas, modifying the conditions of competition that they impose on each other, and forcing them to reconsider their location criteria. For some suppliers, especially traders, the location choice is a question of survival, because accessibility to their sale points is a critical element of competition. The increase of jobs in the periphery of the city indicates that decisions against locating in the city were of large scale in the 1980s.

Figure 73.2 Traffic intensity (in vehicle-kilometers) in the Brussels-Capital region, 1985–1998. Calculation based on Recensement de la Circulation, Ministère des Communications et de l'infrastructure, 1998.

The combined effect of the dispersal of housing and employment and the increase in motorization of the population has led to a very important increase in automobile traffic both in and around the city. Figure 73.2 depicts the aggregated dynamics of the mobility in the region for private cars per main categories of roads. If this trend continues, and other variables remain unchanged, especially the offer of public transport, congestion of the road network will develop. The result is a doubling of automobile travel time during the morning peak period.

According to Duchâteau (1998), such a development is not realistic because it would lead to an unbearable deterioration of the functioning conditions of the city:

- Urban economic players cannot accept the worsening of their accessibility; if nothing is done to change the situation, their reaction will be to leave the city for a peripheral location.
- The inhabitants will support neither the impediments to mobility due to congestion nor the increase in pollution that will result from it; those who can afford it will leave the city in huge numbers.

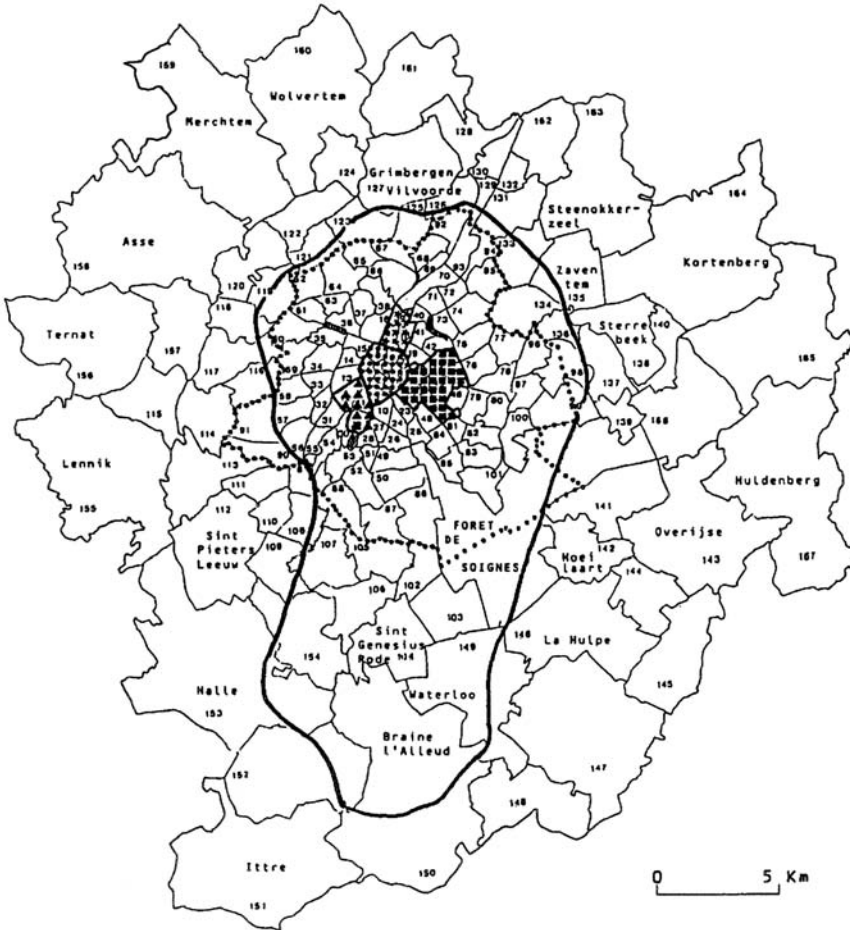

Regional public authorities must react against decline of inhabitants and employers in the city.

Network Model of Private Road Transport

The Brussels-Capital region covers the area of 161 km² with 951,580 inhabitants (1997), in the center of Belgium (Figure 73.3). Administratively, the region is divided into 19 municipalities (communes), but the total area under study (Figure 73.4) comprises a wider territory (covering also nearby districts from which the traffic is most intensive), and it is subdivided into 167 smaller districts. The road network (Figure 73.5), due to further disaggregation of the administrative districts in the central part of Brussels, contains in total of 255 zones, from which trips are generated, with 2545 nodes and 8366 links.

As a basic computer tool for spatial analysis of mobility, the latest available version of the TRIPS package is used (TRIPS, 1999). It includes a set of interrelated modules: highway assessment, public transport assignment, demand modeling, matrix estimation, TRIPS graphics, and TRIPS manager—graphical project management tool. Private car transportation has been modeled (Plan IRIS, 1989–1995) according to the origin–destination matrix (Figure 73.5) for the morning peak hour (7:30 to 8:30) on an average day in 1991. The traffic intensity volumes (number of vehicles), average time, and speed per each link are calculated as a result of traffic assignment with TRIPS Highway Assessment module. The model permits different algorithms of traffic assignment: minimal cost paths (so-called “all-or-nothing” assignment), or multiple paths for each origin and

Figure 73.3 Geographical position of the area under study (an enlarged area of Brussels-Capital region). The outer districts within Belgium (from which passengers' mobility is about 20% of the total Brussels area traffic) are numbered 168 to 184.

- *** Administrative border of the Brussels-Capital region

Figure 73.4 Area under study.

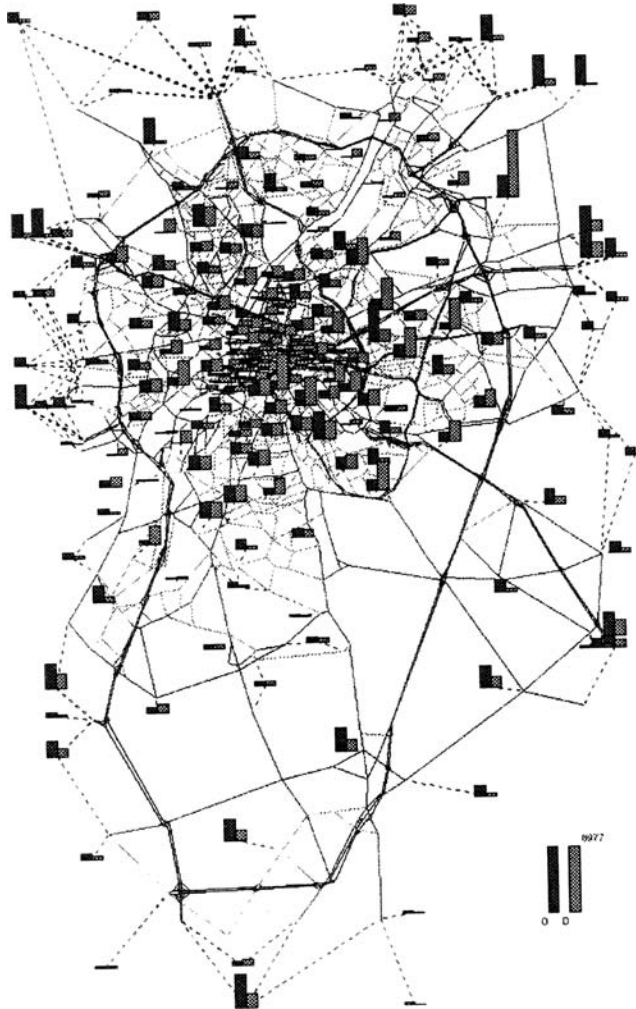

Figure 73.5 Road network and origin–destination matrix for private transport (morning peak hour, 1991).

destination (dial assignment model or Burrell assignment). For this study the Burrell model was used, which provides sufficiently good results from the available data.

Air Pollution

The last step in our modeling scheme is to analyze the impact of mobility on the indicators of air quality. The model considers the following air pollutants: CO_2 , CO , SO_2 , NO_x , VOC , and PM . In this chapter, given the restricted format, we describe only the emission model. Further analysis of concentrations of air pollutants (emissions–immissions link) can be found in Favrel and Hecq (1998, 2000).

Calculation of the emissions from road traffic was based on two types of data. First, the volume of traffic must be estimated, e.g., in the form of vehicle-kilometers driven by the different vehicle categories within the area considered. We used the results of the traffic assignment within TRIPS package and also regional statistics for model validation. Second, suitable emission factors are required for the different vehicle categories circulating in the Brussels area. Average speed-dependent emission factors, proposed in the COPERT II methodology (Ahlvik et al., 1997), have been used.

Table 73.2 Composition of the Belgian Private Vehicle Fleet in 1991

91/441/EEC [1991–1996]	43,733	1.12
94/12/ECE [>1997]	0	0.00
Diesel engines	1,089,055	27.86
<2 Liters	795,512	20.35
Conventional [<1990]	710,628	18.18
91/441/EEC [1991–1996]	84,884	2.17
94/12/ECE [>1997]	0	0.00
>2 Liters	293,543	7.51
Conventional [<1989]	231,081	5.91
91/441/EEC [1990–1996]	62,462	1.60
94/12/ECE [>1997]	0	0.00
LPG engines	22,484	0.58
Conventional [<1990]	20,085	0.51
91/441/EEC [1991–1996]	2,399	0.06
94/12/ECE [>1997]	0	0.00
Total fleet	3,909,065	100.00

COPERT distinguishes for each vehicle category (such as passenger cars, light-duty vehicles, heavy-duty vehicles) different subcategories according to fuel type (petroleum, diesel, and liquid petroleum gases, LPG), cylinder capacity, catalyst type, different legislation and regulations (e.g., Sanger et al., 1997) governing motor vehicle emissions, fuel specifications, and consumption. For the period considered, the Belgian vehicle fleet was distributed according to these subcategories on the basis of the available statistics. An aggregated structure used in the model is presented in the Table 73.2, from which the vehicle fleet of the Brussels-Capital region has been deduced. Using the mileage (number of vehicles multiplied by link length) and the average speed of each vehicle

category on each link of the network, the methodology developed provides the spatially distributed emissions, generated by road traffic in the Brussels-Capital region.

Hot and *cold start* emissions are distinguished. Cold start emissions represent the additional emissions resulting from vehicles while they are warming up or with a catalyst below its light-off temperature. The ratio of cold to hot emissions and the fraction of kilometers driven with cold engines are calculated using the yearly average temperature and an estimate of the average trip length following the COPERT methodology.

The overall calculation of emissions on the region's road network can be summarized as follows:

$$ET_i = ET_{i, \text{hot}} + ET_{i, \text{cold}},$$

$$ET_i = \sum_j \sum_k EF_{i, j, \text{hot}}(S_k) \cdot VM_{j, k, \text{hot}} + \sum_j \sum_k EF_{i, j, \text{cold}}(S_k) \cdot VM_{j, k, \text{cold}},$$

where

i = pollutant index

j = vehicle category index

k = link index

ET_i = emission of pollutant i due to road traffic

$ET_{i, \text{hot}}$ = emission of pollutant i due to road traffic with hot engines

$ET_{i, \text{cold}}$ = emission of pollutant i due to road traffic with cold engines

$EF_{i, j, \text{hot}}$ = emission factor of pollutant i for vehicle category j driven with hot engines

$EF_{i, j, \text{cold}}$ = emission factor of pollutant i for vehicle category j driven with cold engines

S_k = average speed on the link k

$VM_{j, k, \text{hot}}$ = vehicle mileage for vehicle category j driven on link k with hot engines

$VM_{j, k, \text{cold}}$ = vehicle mileage for vehicle category j driven on link k with cold engines

Since each link has its own length, average speed, traffic intensity, and other characteristics, we made an assumption that average emission factors per vehicle can be used based upon COPERT, as functions of the speed on the link. The temperature, the fleet composition (Table 73.2), and the share of cold start and hot emissions were taken as parameters. Given these parameters, the emission functions for an average vehicle can be calculated as functions of the speed only (Figure 73.6).

To calculate the distribution of the emission of the air pollution and the fuel consumption on the road network, an external module was developed (in Visual Basic). This program is linked to the TRIPS project, so that it is possible to spatially visualize the emissions of each pollutant along with the assignment results on the road map of the Brussels-Capital region. For details of the software organization, see Safonov (2000).

SCENARIO SIMULATIONS

The reference calculations with the model have been performed for the morning peak hour on a representative day for the years 1991 and 1996, according to the actual statistical information from the Plan IRIS reports. Possible scenarios for sustainable mobility in the region are discussed in this section. The environmental impacts of urban mobility have been estimated using the emissions model described above.

The urban policies for the Brussels-Capital region defined in the Regional Mobility plan (Plan IRIS, 1989–1995) have been used to build the scenarios of prognostic simulations for the year 2005. Global strategy of Plan IRIS includes six groups of actions (Duchâteau, 1998) aimed at urban

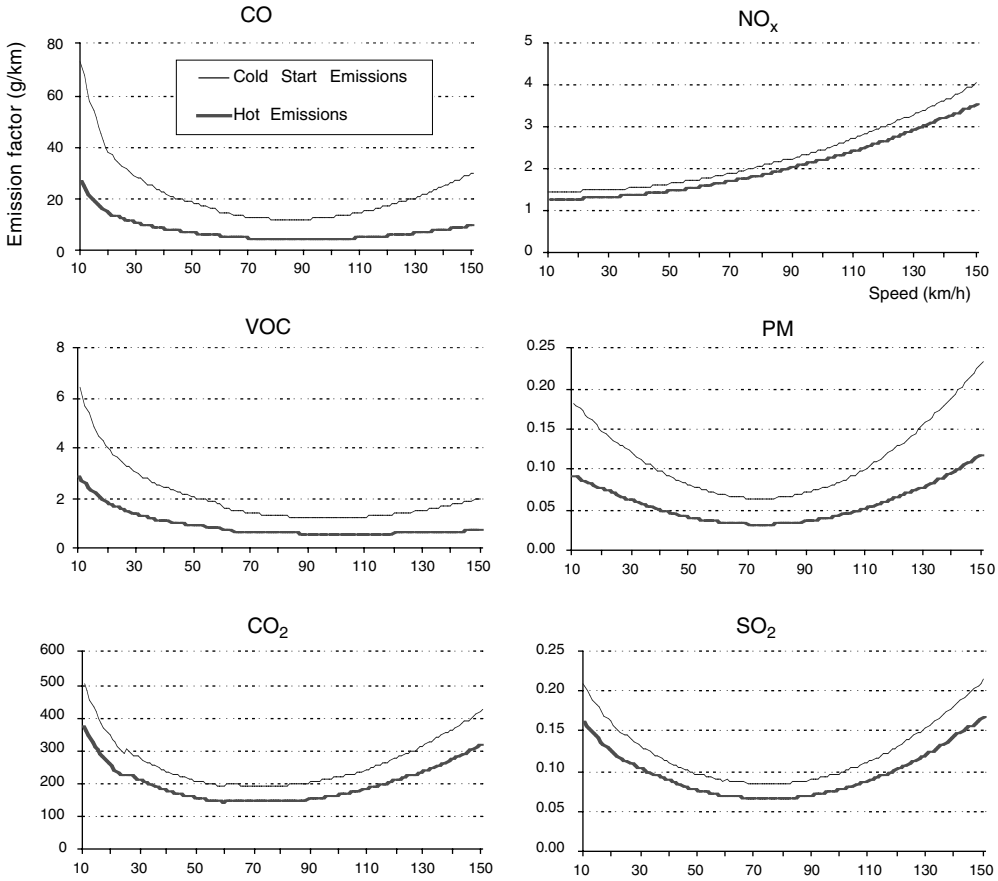

Figure 73.6 Emission functions for an average car in the Brussels-Capital region in 1991 (horizontal axis = speed in km/h, vertical axis = emissions coefficient in g/km).

structure, public transport, car parking, automobile traffic, getting around on foot and by bicycle, and actions on urban road pricing. In particular, the comparison of two scenarios (S1 and S2) that we have developed for the year 2005 are demonstrated below, based on these considerations for possible future actions in order to increase accessibility in the city and reduce the pollution.

Scenario S1

This is the business-as-usual scenario, where the trends are extrapolated from the year 1991 and 1996, from which the latest information is available. The origin–destination matrix for the year 2005 was built upon the forecasts within the Plan IRIS (1989–1995).

The network saturation rate in 2005 increases in comparison to the 1991 situation due to almost 70% growth of total vehicle-kilometers driven on the network. The overcongested links are marked by dark thick lines on Figure 73.7 (saturation rate > 1). This results in a significant decrease of average speed, especially on the ring road and other highways, and brings severe congestion in the center of the city at the peak hours.

It is assumed that the fleet of vehicles develops, proportionally substituting the old cars by the new (Table 73.3), with a growing share (until 1%) of LPG-driven vehicles in the total private car fleet. For this new fleet composition and the climatic conditions (the average temperature is assumed to increase in 2005 approximately to 1.5°C to the level of 1991), the new emission factors were calculated.

Figure 73.7 Network saturation rate (link intensity vs. link capacity), morning peak hour.

Table 73.4 Comparative Analysis of Scenarios

Year	Traffic Intensity Vehicle-km	Air Pollutants Emission						Fuel Consumption		
		CO	NO _x	VOC	PM	CO ₂	SO ₂	Petrol	Diesel	LPG
1991	100	100	100	100	100	100	100	100	100	100
1996	120	86	86	85	99	116	109	103	160	57
2005 (S1)	163	75	80	68	129	179	94	154	255	470
2005 (S2)	124	41	60	40	87	117	69	98	180	346

Due to further expected growth of traffic and respective fuel consumption in 2005, the emissions of CO₂ increase significantly and emissions of PM also grow (see Table 73.4). Emissions of NO_x (which are lower at a slow car speed, Figure 73.6), CO, and VOC decrease, as a result of improvement of vehicle characteristics, such as use of advanced autocatalytic converters. This effect on reduction of PM (which has been observed during the period of 1991–1996) is not enough to compensate for the growth in traffic forecasted within business-as-usual scenario S1. Due to the introduction of fuels with low sulfur content (beginning in late 1996) the emissions of SO₂ also decrease.

Scenario S2

This scenario is based on so-called voluntarist group of scenarios of Plan IRIS (1989–1995), in which several prospective measures and urban policies were introduced:

- Development of the mixed land-use schemes, favoring the localization of offices and residential areas close to the accessibility points
- Improvement of the links in public transport between the city center and the suburbs (suburban metro/suburban express rail system, RER)
- Introduction of parking control, which would favor the switch from roads to public transportation
- Decrease of automobile traffic in residential areas and limitation of the congestion in the city center by means of traffic-flow control measures
- Improvement of the travel conditions of pedestrians and cyclists

The above measures are aimed at reduction of the need for mobility in general, and in particular, stimulate a modal shift from private cars in favor of public transportation (mainly through introduction of RER). In terms of transport model, these changes were introduced mainly in the origin–destination matrix (reduced demand for private car use), as well as in the road network itself (e.g., penalties on particular segments of the roads, link capacities, and times). This information has been provided by the Equipment and Transport Administration (AED) of the Brussels-Capital region, based on the Plan IRIS (1989–1995) assumptions and calculations.

Comparison of aggregated indicators for the above-discussed scenarios is given in Table 73.4. Significant reduction of traffic intensity, coupled with other urban policy measures in scenario S2, result in dramatic abatement of environmental pressure.

Figures 73.8 through 73.10 depict the spatial distribution of several emissions in 2005 for scenarios S1 and S2. Emission levels are proportional to the bandwidth and darkness of the links on the road map. Substantial decrease of emissions in scenario S2 is observed, especially for CO₂, as well as pollution of NO_x and SO₂. As already mentioned above, since NO_x emission is proportional to speed, the higher volumes of this pollution are concentrated on the highways, such as the ring road. Other pollutants concentrate on most busy and congested roads. Projected within scenario S2 is better accessibility by public transportation of some important locations in the city, such as Zaventem International Airport (around which many offices are located), which also helps to avoid outrageous levels of pollution in their neighborhood (Figure 73.9).

Figure 73.8 NO_x emissions (2005), Scenarios S1 and S2.

Figure 73.9 SO₂ emissions (2005), Scenarios S1 and S2.

Figure 73.10 CO₂ emissions (2005), Scenarios S1 and S2.

CONCLUSION

The evaluation of the impact of mobility on air pollution is a multicriteria task. When discussing a sustainable mobility, a compromise should be made between simultaneous achievement of several goals. These goals include providing sufficient transportation services and accessibility to match the mobility demand in the urban area, reasonable travel time from origin to destination, traveling comfort and safety for both those in a vehicle and those on the road, and finally, acceptable emission levels from road transportation. The last two issues (safety and emissions) are linked directly when damage to the health of people in urban areas, as a result of local emissions, is discussed.

Restoring mobility by only decreasing the road traffic congestion, that is, trying to suppress the traffic bottlenecks, increasing the capacity of the main road networks, creating new parking lots, or implementing sophisticated techniques of traffic management, is no longer a realistic strategy in the long term. These are the answers that have been applied for years with only one objective: to increase the flow and fluidity of automobile traffic. They are responsible for their own inefficiency because any possibility of an increase in mobility is used by residential and economic players to increase even further their demand of automobile travel.

Experience has shown that in any city, in which measures were taken to increase the fluidity of traffic, the initial problems reappear some years later in a more acute form. Indeed, in cities where road networks are very congested, such measures only result in a slight shift of the thresholds and a postponement of the critical point. It enables a short-term solution, but does not modify the fundamental causes of the problem, nor create the new conditions required for a sustainable development of cities. In the case of Brussels, it would be particularly harmful as it would favor the centrifugal powers that would empty it of its substance because of the region's small area (Duchâteau, 1998).

As a possible way to solve this problem, an integrated approach to modeling urban development, mobility, and its environmental impacts is proposed and discussed in this chapter. At the first step in its implementation, we have designed a mobility model that allows spatial assessment of the road traffic contribution to air pollutant emissions on a network flow model. In particular, a comparison of two scenarios for the year 2005 demonstrated, based on statistical trends, considerable reduction in pollution with implementation of policies that would increase accessibility in the city, reduce demand for mobility, and favor a shift from private cars to public transportation, or to LPG vehicles. However, it is important to realize that implementation of such scenarios would require, above all, serious behavioral changes in mobility patterns and modal choice.

Further development of the described system of models and of methods used for environmental impact assessment is recently under way with ongoing continuation of this study at the CEESE-ULB in cooperation with the Brussels-Capital region administration.

ACKNOWLEDGMENTS

This chapter is based on a research project financed by the Government of the Brussels-Capital region within a Research in Brussels Actions program in 1999. The authors are thankful to the Equipment and Transport Administration (AED) of the Brussels-Capital region, in particular to Mr. Wouters, Mr. Broes, and Mr. Richel, for the information and technical assistance they provided. Our thanks also go to two anonymous reviewers for their remarks.

Relating Indicators of Ecosystem Health and Ecological Integrity to Assess Risks to Sustainable Agriculture and Native Biota — A Case Study of Yolo County, California

Minghua Zhang, K. Shawn Smallwood, and Erin Anderson

INTRODUCTION

A new holistic, yet quantitative landscape ecology approach to environmental science was born from the availability of spatially referenced data and Geographic Information System (GIS). Scientists have recently begun developing a hierarchically organized, top-down approach for assessing the conditions of, and risks to, ecological resources in large areas (Griffith, 1998). This approach is referred to as the ecological indicators approach. First used in the Netherlands (Rotmans et al., 1994), the ecological indicators approach is now being applied in the U.S. by the U.S. Environmental Protection Agency (EPA) (O'Neill et al., 1994; Schultze and Colby, 1994), U.S. Department of Agriculture (1994), U.S. Geological Survey (Battaglin and Goolsby, 1995), and multiple academic scientists (Rapport et al., 1985; Karr et al., 1986; Bedford and Preston, 1988; Hunsaker et al., 1990; Graham et al., 1991; Cairns and McCormick, 1992). Adopting the approach ourselves, we have gained valuable insight into factors influencing ecological health (Zhang et al., 1997, 1998) and integrity (Smallwood et al., 1998) at the county level. These spatially explicit indicators were relevant to legal compliance issues and useful for focusing planning and regulatory efforts on priority areas in the landscape.

In our study, agricultural chemical application data are integrated and used as an indicator of ecosystem health to examine the risks to ecosystem functions posed by chemical contaminants. Indicators of ecological integrity are developed from habitat quality and landscape contiguity and represent the degree to which functional parts of the landscape are intact from the perspective of biota. The integration of ecosystem health and ecological integrity indicators will become essential for managing agricultural landscapes so that agriculture is sustainable and locally endangered species are conserved.

In this chapter, we present the concept of integrating ecosystem health and ecological integrity indicators to assess agricultural sustainability. We demonstrate the concept by applying the ecological indicators approach to Yolo County, in Sacramento Valley, California, in which we spatially compare the levels of pesticides used to the likely distribution of special-status species. We explore how our indicators of health and integrity may interact and affect each other, and how these most

sensitive and vulnerable parts of Yolo County can be monitored effectively for potential impacts. Our study is intended to serve as an example of how to characterize exposures of special-status species to agricultural pesticides and to prioritize further research and regulatory attention toward the areas with the highest exposure on the landscape.

Yolo County (Figure 74.1) is home to numerous special-status species, some of which were selected as target species by Smallwood et al. (1998) for measuring ecological integrity (Table 74.1). Yolo County is an agricultural county. Farmers in the valley portion of the county grow field crops, such as alfalfa, rice, orchard crops, and wine grapes. These growers use many pesticides to control weeds, insects, nematodes, fungi, and rodents. Each ecosystem element has an inherent sensitivity to disturbance (stress), and each has a vulnerability posed by the implementation of management practices (Zhang et al., 1998). The coincidence of sensitivities and vulnerabilities yields a suite of impacts among the ecosystem elements as well as consequences for the societal goals. By predicting these impacts and consequences, or at least understanding them, we can set about making a proper management response.

Pesticide exposure can be assessed by several means:

1. Measuring the active ingredients within environmental media, including within the tissues of biological species
2. Mapping the amounts of pesticides reportedly used by growers or that are typically associated with each crop
3. Mapping the amounts of pesticides used, their likely pathways through the environment, and their likely fates

The U.S. EPA's BASINS software (Best Assessment Science Integrating Point and Nonpoint Sources) has consolidated monitoring programs for environmental contaminants in the waters of the U.S., thus providing the means to assess exposures as described in (1) above. However, the data resulting from point (1) above lack the resolution of geographic coverage that we would prefer for assessing exposure risk. Assessment approaches (2) and (3) have become more practical now that GIS and spatial data have become more available and the ecological indicators approach has matured. The indicators approach complements the more conventional reductionist approaches by offering a top-down perspective on likely exposures. Using the indicators approach, academic scientists and government regulators can focus on selecting locations within the landscape, the crops associated with the most damaging chemical applications, and the species that may be at the greatest risk.

The toxicity of pesticides varies by biological species, exposure pathway, source term, and interactions among active ingredients. For animals, direct toxic effects can cause mortality, reduce foraging efficiencies, or disrupt reproductive and social performance. Indirect effects are suffered through habitat degradation. Pesticide use may therefore result in reduced numbers and spatial extent of animal species. These impacts can be devastating on landscapes where special-status species persist on remnant habitat patches, constrained to the margins of agricultural fields, roadways, and irrigation structures (Smallwood et al., 1998). Mineau et al. (1999) summarized fatalities of raptorial birds due to dermal contact with labeled pesticides, including five of the special-status species occurring in Yolo County.

The Endangered Species Act (ESA) regulates the taking of threatened and endangered species. Often not considered under the regulations are the effects of exposures to hazardous substances in the environment, such as agricultural pesticides. Remnant aggregations of many special-status species exist in or near agricultural landscapes, however, so such species and the biological elements of their habitats are exposed to pesticides. Under the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) and the Food Quality Protection Act (FQPA), pesticide registration and use are much more regulated. Exploring spatial patterns of ecological integrity and ecosystem health are essential to ecosystem risk assessment relevant to sustainable agriculture. This is especially true in Yolo County where implementation of a proposed Habitat Conservation Plan (HCP) would also force

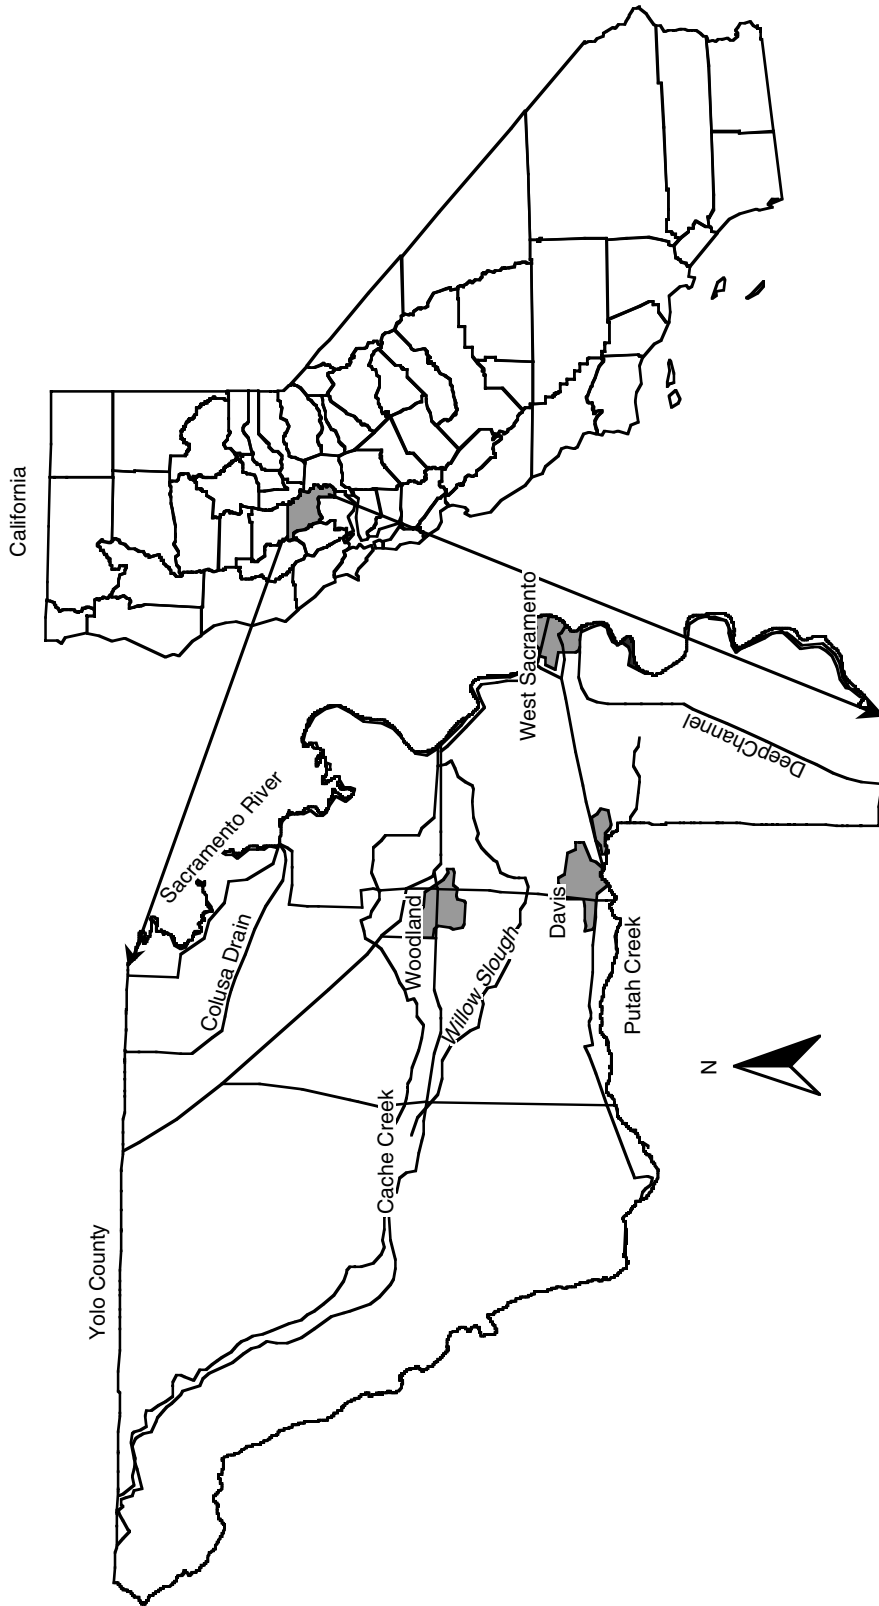

Figure 74.1 Study area in Yolo County, California.

Tricolored blackbird (<i>Agelaius tricolor</i>)	CSC, C2
California yellow warbler (<i>Dendroica petechia brewsteri</i>)	CSC

^a Listed as CE = California endangered; CT = threatened; CSC = special concern (not threatened with extinction, but rare, very restricted in range, declining throughout range, peripheral portion of species' range, associated with habitat that is declining in extent); FE = federal endangered; FT = threatened; PT = proposed as threatened; C1 = category 1 candidate; C2 = category 2 candidate.

^b Listed by California Native Plant Society as rare, threatened, or endangered in California.

the county to consider all 29 species listed on the HCP Incidental Take Permit as endangered, even though many are California Species of Special Concern (U.S. Department of the Interior and U.S. Department of Commerce, 1996).

METHODS

Our study area was the valley portion of Yolo County, or the area below the 92 m elevational contour line along the foothills on the western side of the county. A grid of 2.56 km² resolution was digitized in the study area at the Agricultural Geographic Information System (AGIS) laboratory of the University of California–Davis. We used GIS overlays of land use, pesticide use, and natural vegetation maps, all at 1:24,000 scale, GIS buffer functions, and simple statistics. The land-use and natural vegetation maps represented conditions in 1989. We obtained the land-use map from the California Department of Water Resources, the pesticide-use data from the California Department of Pesticide Regulation, and the natural vegetation map from Yolo County.

We developed an ecosystem health indicator to represent the cumulative effects of residue concentrations of multiple pesticides. We indicated vulnerability, or exposure risks, of the special-status species to pesticides by adding all the amounts of pesticides used by each farmer in each

field for each 2.56 km² grid cell within Yolo County. To account for long-term pesticide use, we used data from 1990 through 1997. The ecosystem health index (EH) was estimated as follows:

$$EH = (100 - (\sum P_i/P_{hi} \times 100\%)),$$

where P_i was the amount (kg) of the i th pesticide used in a grid cell, and P_{hi} was the maximum amount of pesticides actually used in a grid cell ($P_{hi} \geq 11,363$ kg). Setting 11,363 kg as the ceiling for P_{hi} prevented the few extremely high reports of pesticide usage from rendering the majority of EH values as extremely small. It also allowed us to normalize the data for EH. Therefore, EH values ranged from 0 for grid cells using $P_i \geq 11,363$ kg of pesticides to 100 for grid cells using no pesticides.

The health indicator therefore measured 7 years of pesticide use, which bears on exposure of the special-status species, so long as these species were likely to occur in the same grid cell. Higher EH values represented higher health conditions in the ecosystem (lower pesticide application).

Ecological integrity (EI) was defined formally as the relative degree to which the functionally significant parts of the ecosystem are intact from the perspective of the 29 target species (Smallwood et al., 1998). More generally, ecological integrity measures the degree to which the endemic species assembly in the cell or region is intact and uninvaded by exotic species. The areas with higher values of ecological integrity should be given higher priority of restoration opportunities. Ecological integrity was an indicator composed of the area index (AI), connectivity index (CI), vegetation variety index (VI), vegetation occurrence index (VO), vegetation use (VU), restoration index (RI), and scarcity index (SI) (modified from Smallwood et al., 1998):

$$\text{Ecological Integrity (EI)} = \left(\frac{\text{AI} + \text{CI} + \text{VI} + \text{VO} + \text{VU}}{5} + \frac{\text{RI} + \text{SI}}{2} \right) \div 2 \times 100\%$$

AI indicates the size of the natural vegetation polygons overlapping the grid cell. AI ranges from 1 to 4, 4 indicating the largest polygon; CI measures the distance of the contiguous stretch of riparian vegetation polygon on the grid cell connected with non-riparian vegetation patch; VI is the number of vegetation species presented in each grid cell; VO is the percent of grid cell within the study area boundary consisting of natural vegetation species. The maximum value of VO (VO = 100%) is possible for some grid cells. VU is the sum of the species that are used for the targeted species in each grid cell. RI is a restoration index, which refers to the number of years estimated to restore the slowest growing vegetation species on the grid cell. For example, a grid cell containing valley oak riparian forest and vernal pools would be rated 100 because valley oak riparian forest would take about 100 years to restore to maturity, whereas vernal pools would take about 10 years. SI is a scarcity index which refers to the fraction of the study area covered by each vegetation species divided by the smallest fraction (most scarce type). Vegetation species were then ranked ordinally in ascending order from the most to least scarce and based on expert knowledge of the quality and magnitude of historical reductions in acreage of each species.

EI values ranged from 0 to 100. Higher EI values represented a higher likelihood that a larger subset of the 29 special-status species will be present in the grid cell. We assumed that a positive correlation between EI and EH would indicate a relatively healthy ecosystem, in which pesticide inputs are inversely proportional to ecological integrity.

We interpreted the spatial coincidence of health and integrity as relative levels of risk. The following exposure risk (ER) indicator expressed the coincidence of EH and EI as:

$$ER = (2EI/(EH + 1)).$$

This indicator expressed ER as a function of EH and EI. To emphasize the exposure risk for high-integrity areas, we designed this indicator in such a way that the range of EI values was

proportional to EI. There was no point in obtaining high ER values where there was low EI. ER ranges from 0 to 200.

Visual inspection of ecological integrity showed that high integrity areas were clustered around waterways. To adjust for this nonuniform distribution, a 1.6-km buffer zone was established around all major waterways within Yolo County, namely, Putah Creek, Cache Creek, the Sacramento River, the Colusa Drain, the Deep Water Channel, and Willow Slough. All subsequent calculations compared areas within the buffer zone to areas outside the buffer zone. A deviation index was established to quantify the deviation of both ecological integrity and ecosystem health from uniform spatial distributions. Several steps were involved in this process:

1. Integrity and health values were classified according to natural breaks in their respective frequency distributions, and a frequency distribution (F) for each was tabulated inside and outside the buffer zone.
2. A cumulative frequency (CF) for the study area was calculated for the i th of n classes as:

$$CF_i = F_{in,i} + F_{out,i}$$

3. The observed percent frequency (PF_o) for each class was calculated as:

$$\%PF_{o,i} = (F_{in,i}/CF_i) \times 100.$$

If the ecological integrity or ecosystem health distributions were uniform, then we would expect PF_o values to equal the proportion of the total study area which lies within the buffer zone. In other words, if 40% of the study area occurred within the buffer zone, we would have expected 40% of the high values to occur within the buffer zone. The expected percent frequency (PF_e) was therefore defined as:

$$PF_e = \sum F_{in,i} / (\sum F_{in,i} + \sum F_{out,i}).$$

4. The deviation index (DI) represented how much the observed integrity or health deviated from a uniform distribution and was calculated as:

$$DI_i = [(PF_{o,i} - PF_e)/PF_e] \times 100.$$

A DI value of 0 indicated a uniform distribution throughout the entire study area. A DI value > 0 indicated that a disproportionately high frequency was observed within the buffer zone, while a DI value < 0 indicated that a disproportionately high frequency was observed outside the buffer zone. DI values for ecological integrity ranged from -32 to 38 , while DI values for ecosystem health ranged from -12 to 12 .

Similarly, the deviation index for land use was calculated using the above steps. DI values for land use ranged from -0.3 to 1.25 . The positive DI values represented high concentrations of land use within the buffer zones while the negative values represented high concentrations of land use outside the buffer zone. Zero values indicated that the land use was uniformly distributed between the waterway buffer zone and the remainder of the study area.

The relative percentage of area (RPA) for each land use was defined as the area of the land use within the buffer zone (LUA) over the total area of the buffer zone (TAB). This index showed the percent allocation of land within, and outside, the buffer zone:

$$\%RPA = (LUA/TAB) \times 100.$$

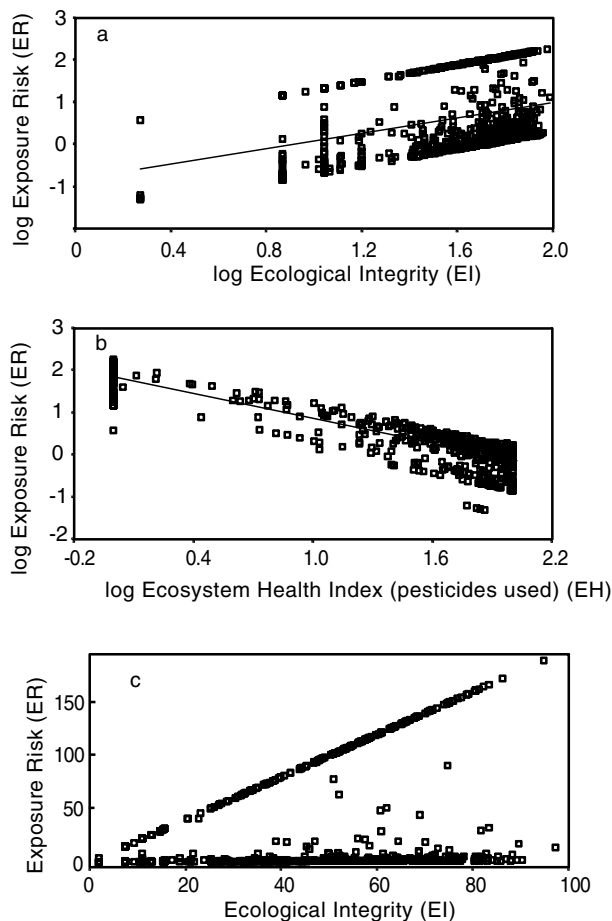

Figure 74.2 Log exposure risk increased linearly with increasing log ecological integrity (a) and decreased with increasing log ecosystem health (b). The value range of exposure risk increased as ecological integrity increased and was forced to 0 where ecological integrity was 0 (c).

RESULTS

As designed, ER values increased with increasing values of EI (Figure 74.2a) and decreased with increasing values of EH (Figure 74.2b). ER was forced to zero when EI = 0, and its maximum and range of values depended on the magnitude of EI (Figure 74.2c).

Higher ecological integrity (EI) values were concentrated within the 1.6-km waterway buffer zone and along the western edge of the study area (Figure 74.3). Patches of lower EI values were found in the northeast corner of Yolo County between the Sacramento River and the Colusa Drain, to the southwest of Willow Slough to the area between Cache Creek and the Colusa Drain, and to the southeast of Willow Slough.

Higher ecosystem health (EH) values were observed between the Colusa Drain and Cache Creek, and along the middle section of the Sacramento River, north of Sacramento (Figure 74.4). Patches of low EH values were found between Davis and West Sacramento (the Yolo County Bypass area), west of Woodland, and along Putah Creek.

According to the frequency deviation index, high EI values occurred at a disproportionately high frequency within the waterway buffer zones, where moderate values of ecosystem health also occurred at a disproportionately high frequency (Figure 74.5, left). High ecosystem health values

Figure 74.3 The spatial pattern of ecological health in the Yolo County study area.

Figure 74.4 The spatial pattern of ecosystem integrity in the Yolo County study area.

occurred outside the waterway buffer zones at a disproportionately high frequency, where low ecological integrity values occurred at a disproportionately high frequency (Figure 74.5, right).

The pesticide exposure risk map (Figure 74.6) depicts distinct bands of high-risk areas oriented from the northwest to the southeast and spanning our study area across Cache Creek, the lower reach of Willow Slough and across the Yolo Bypass to West Sacramento. Another area of high ER occurred along Putah Creek from Winters to Davis. Other high risk areas were the lower reach of

Figure 74.5 The frequency distributions were nonuniform for both ecological integrity (left) and ecosystem health (right) along waterways within 1.6-km buffer zones.

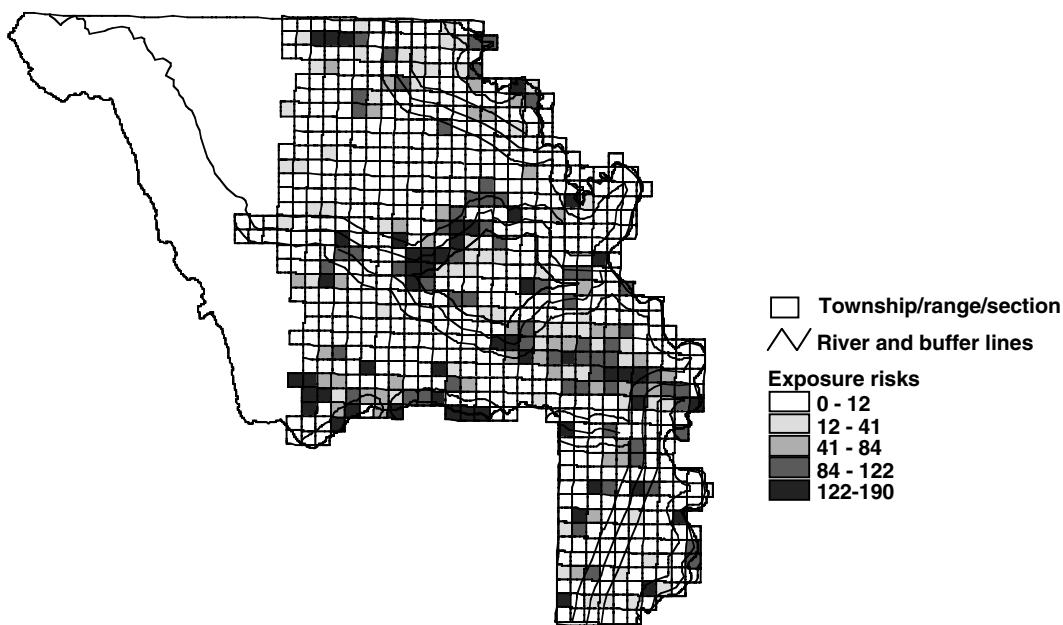

Figure 74.6 The spatial pattern of exposure risk in the Yolo County study area.

Oat Creek (northwest corner of the study area), and the southern portions of Yolo County in the vicinity of the Deep Water Channel. The low-risk areas for pesticide exposure included the upland areas between Putah and Cache Creeks and between Cache Creek and the Colusa Drain, where intensive farming and habitat loss have excluded most of the 29 special-status species used to assess ecological integrity.

Within the study area, EI and EH were not correlated, but the maps showed coincidence of high integrity and low health values that could be explained by considering other factors such as nearness to streams, land use, and possibly soils. The waterway buffer included streams that were artificial (e.g., Colusa Drain, Deep Water Channel) or that were degraded to the point where nearly no riparian vegetation remained (e.g., Willow Slough, segments of Cache Creek near areas of gravel mining, and segments of the Sacramento River).

Land uses associated with high pesticide applications occurred disproportionately within the waterway buffer zone (Figure 74.7). Higher percentages of citrus, orchards, field crops, rice, and

Figure 74.7 Land uses were disproportionately distributed within the buffers. Positive values refer to measures inside the 1.6-km riverine zone, while negative values refer to measures outside the zone.

Figure 74.8 Relative percentage of different types of crop acreage within and outside the waterway buffer.

vineyards were grown within 1.6 km of waterways. Figure 74.8 illustrates the relative percentage of crop acreage within and outside the waterway buffer. Orchards, field crops, grains, pastures, rice, and vegetables comprise the majority of agriculture within the buffer zone. Field crops, grains, pastures, rice, and vegetables comprise the majority of agriculture outside the buffer zone.

DISCUSSION

Due to the dominating influences of agriculture in Yolo County, the areas of high ecological integrity were concentrated along the waterways within the 1.6-km buffer zone. The special-status species were likely also concentrated along the waterways within this buffer zone. To better protect the biota along these waterways, exposures to pesticides should be reduced within the 1.6-km buffer zone.

The pesticide use is relatively uniform across the study area in Yolo County compared to the distribution of ecological integrity. Relating a uniform pattern to a clustered pattern forces any combined pattern to match the clustered pattern. The clustered pattern of EI depended on the vegetation cover, connectivity, scarcity, and landscape contiguity, all of which were determined

mostly by the spatial extent and practices of agriculture. It is likely that EI would be distributed differently in other counties. We also expect to find more uneven distributions of EH in counties with highly clustered cropping patterns.

Although the direct correlation between EI and EH was not statistically significant, a trend of negative correlation was displayed in Figure 74.5. Nevertheless, we were able to identify parts of Yolo County where exposure risk is likely the greatest, as well as the parts of the county where exposure risk is likely the least. The trends illustrated in Figure 74.5 may mean that the higher EI areas where the county's special-status species likely reside also had lower EH values. This indicated that the areas near waterways within the 1.6-km buffer zone may have received relatively high pesticide exposures.

The map of exposure risk provided us with well-defined patches of high vulnerability. Management efforts can be focused on these areas of high exposure risk to conserve the ecosystem upon which the special-status species depend and to sustain agriculture in Yolo County. This map also helps identify locations where the county can restore habitat that is less likely to be degraded by high exposures to agricultural pesticides.

The disproportionate distribution of land use within and outside the waterway buffer zone illustrated that there may be a soil-crop relationship leading to levels of pesticide use. The best soils for agricultural production tend to be nearby the streams, where sands have accumulated. On these soils, growers are more likely to grow higher-value crops and to protect them with chemical pesticides. Within the areas of high exposure risk, alternative cropping patterns could be considered in an effort to minimize the impact of pesticides on special-status species in these areas.

The concept developed in this study was rather simple, and our study was only a first step in comparing health and integrity indicators to estimate cumulative exposure risk. The environmental fates of many pesticides used need to be considered using pathway analysis, including portions of pesticides leaching into the groundwater, the rates and locations of pesticide residue reappearance at the ground surface, portions drifting with wind to nontarget areas, and portions removed from the environment by harvest or environmental degradation. Our approach is not intended to indicate species-specific or habitat-specific toxicological relationships, but rather cumulative relationships that are useful for top-down assessments in identifying where the greatest risks may occur, where management and conservation decisions may be prioritized, and where the focus of research efforts should be. Future applications of this approach could be improved by considering the toxicological sensitivities of each species to various pesticides, as well as their aggregative effects, and they could be improved by considering the behaviors of the species that modify exposures. Future applications of combining health and integrity indicators will also be improved by using sensitivity analysis and some validation based on sampling for impacts. As more explicit assumptions and exposure pathways are added to our model, we should be able to advance our modeling from one of hazards to risk of exposure dose (Rejesky, 1993; Beyea and Hatch, 1999).

Nature Policy Assessments: Strategic Surveying and Assessing Progress across Policy Levels

H.J. Verkaar, Hans A.M. de Kruijf, G.W. Lammers, and Rudo Reiling

INTRODUCTION

The need for sustainability in the use of natural and other resources has been widely accepted by decision makers and society as a whole. Following early warnings in Rachel Carson's classic *Silent Spring* (1963) and the Massachusetts Institute of Technology studies (Meadows, 1972), the Brundtland report (United Nations World Commission on Environment and Development, 1987) reflected a real turning point in public opinion. It later began to become clear, however, that it would not be easy to implement sustainability in complicated societal decisions. Apart from the acceptance of sustainability as a guiding principle, bridging the gap between the disciplinary borders of knowledge and political and governmental boundaries through integrated approaches was shown to be a vital prerequisite. In the past decade, an overwhelming number of integrated assessment studies have appeared for policy assessment — often in relation to sustainability — in technology, social welfare, monetary issues, agriculture, physical planning, fisheries, environmental issues, water management, and public health.

In Europe, integrated environmental and nature policy assessment studies are defined by the interdisciplinary process of identification, analysis, and appraisal of all relevant natural and human processes and their interactions that determine both the current and future state of environmental, natural, and landscape quality and resources on appropriate spatial and temporal scales, facilitating the framing and implementation of policies and strategies (European Environment Agency, 1995). In fact, they thereby analyze the degree of effectiveness and efficiency of actual and potential policies and strategies on nature quality and biological diversity for current and next generations. Here, we will demonstrate techniques developed in Europe, particularly in the Netherlands, to assess current nature and landscape policies. Furthermore, we will show the paramount importance of crossing knowledge and political boundaries if the implementation of objectives in nature and landscape policy is to be successful.

ECOSYSTEM HEALTH, CONDITIONING FACTORS, AND SOCIAL DOMAIN

In the Netherlands, values related to natural areas (e.g., forests, heathlands, dunes, and wetlands) have in the past century suffered from habitat destruction and fragmentation, environmental pollution, detrimental site and population management, and desiccation. Since 1900, active bogs, heathlands, and inland drifting sand dunes have decreased by 99, 91, and 86%, respectively. Most of the Dutch

Figure 75.1 Woodlands and natural sites in the Netherlands from 1800 onward. The broken lines indicate the current policy targets. (Adapted from Rijks Instituut voor Volksgezondheid en Milieu, 1997; and Van der Woud, 1998.)

landscape at the beginning of the 19th century was almost treeless (van der Woud, 1998). After 1850, however, many natural areas were reclaimed thanks to new fertilization techniques and other technology. Furthermore, dry and nutrient-poor drifting sands and heathlands were replaced with mainly pine forests, so that during the last two centuries the total area of natural sites has decreased to about 15%, whereas the area of forests, mainly plantations, has increased more than twofold (Figure 75.1). In the meantime, spatial scales in landscape have changed as well. In the western, Holocene, and the relatively open landscapes of reclaimed fenlands and marshes on clayish soil and in the much closer Pleistocene eastern landscapes on wind-borne sand deposits, fragmentation has occurred and is still occurring (Rijks Instituut voor Volksgezondheid en Milieu, 1997).

Apart from the loss of natural areas and landscape integrity, many native species have shown a decline or have even become extinct. A significant number of exotic species have also invaded the Netherlands (Hengeveld, 1989; RIVM, 1998a). These changes in species density and composition can largely be attributed to the habitat change, destruction and fragmentation, environmental pollution, and unsuitable water management. For instance, the decline in vascular plant species of wet and nutrient-poor habitats, and as a consequence, their sensitivity to eutrophication and desiccation was far larger than in species found in other habitats (Figure 75.2). Inappropriate site and population management (e.g., poaching, hunting, and inadequate mowing) has also contributed to the deterioration of natural areas.

There is no doubt that habitat deterioration and destruction and incorrect site management are not isolated factors within an environmental constraint but are embedded in a social and technological structure (i.e., in economic and technological, social and cultural, and institutional and environmental domains; De Kruijf and Van Vuuren, 1998; Van Ierland et al., 1998). Figure 75.3 shows schematically the relationships among these domains. Although the close relationship among them has long been widely accepted, clearly sustainable use of natural resources can be achieved only if the concept of sustainability is also incorporated in all the domains (United Nations World Commission on Environment and Development, 1987; Ul Hacq, 1996; De Kruijf and Van Vuuren, 1998). In this chapter we will confine our remarks to the issue of the relationship between the environmental and institutional domains.

THEORETICAL ASPECTS OF POLICY ASSESSMENT

Acceptance of a societal problem in the political life cycle (Figure 75.4) can cause government authorities to implement policy measures. In general, this acceptance is triggered by information

Figure 75.2 The change in distribution of vascular plant species in various habitats in the Netherlands between 1950 and 1990. (Adapted from Rijks Instituut voor Volksgezondheid en Milieu, *Natuurbalans 98*, Samsom, H.D., Willink, T., Alphen aan den Rijn, A., the Netherlands, 1998a.)

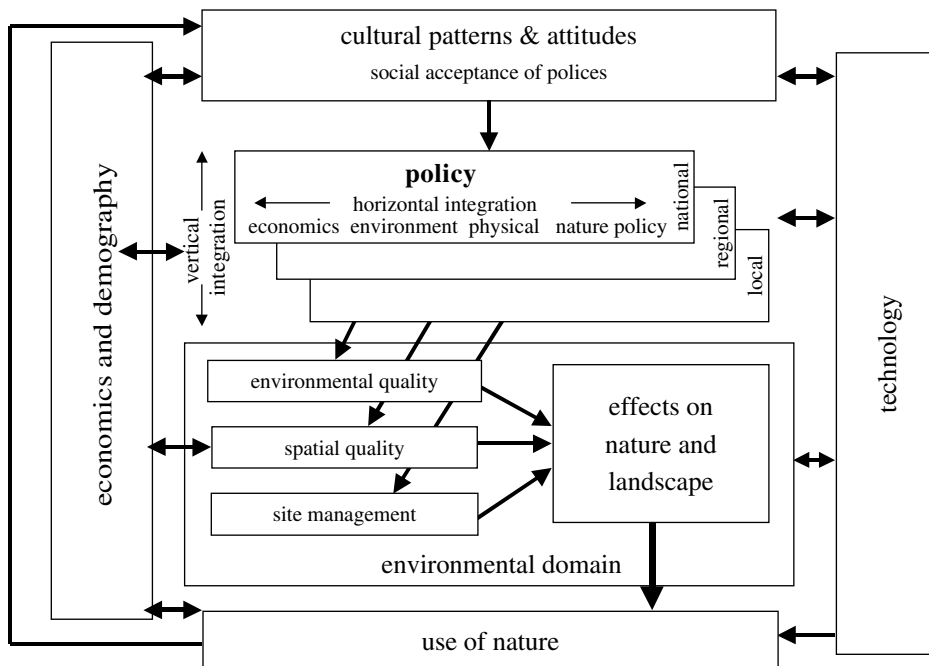

Figure 75.3 The schematic relationship among the economic and technological, social and cultural, and institutional and environmental domains.

on various indicators related to the so-called Driving Forces, Pressures, States, Impacts, and Responses (DPSIR) framework (De Kruijf and Van Vuuren, 1998; European Environment Agency, 1999). These indicators are summarized to four groups:

1. State quality of societally acknowledged values (e.g., nature and its biodiversity)
2. Pressures exerted on this
3. Policy responses to improve this quality aiming driving forces, pressures, and/ the quality directly
4. Impact of these measures on state quality

Figure 75.4 Simplified schematic representation of the policy life cycle and evaluation indicators.

All these indicators can be implemented into monitoring systems that judge the efficiency and effectiveness of the applied measures and such an evaluation can then lead to new societal problems. Thus, Figure 75.1 can be regarded as an example of a state indicator, whereas Figure 75.2 shows the impact of a pressure, nitrogen pollution, on natural vegetation. The impact of specific measures to improve natural quality is very difficult to monitor, as nature is generally influenced by a variety of environmental and biotic factors with very complicated dose–response relationships and very often a considerable relaxation time. Therefore, the effectiveness and efficiency of measures in terms of natural quality are very difficult to assess separately for each measure. Hereafter we will focus on indicators of the policy responses.

Within the framework of policy implementation several steps in the policy’s life cycle can be distinguished in greater detail:

1. The formulation of objectives
2. The definition of targets and policy tools, i.e., the concrete set of actions to be taken to attain these targets
3. The periodic assessment of achievements
4. The effects of these achievements

Without doubt, monitoring systems to assess the effectiveness and efficiency of policy measures can be successfully developed only if objectives, targets, and tools have been sufficiently defined.

POLICY ASSESSMENTS AND OBSTACLES TO INTEGRATION OF POLICIES

Authorities indeed have gradually come to acknowledge the decline of natural resources taking place since the 1970s as a societal problem. Initially, their efforts were focused mainly on human health and prosperity, as far as these were affected by environmental quality. Since 1950, there have been massive economic growth rates (e.g., an approximate sixfold increase of GNP in the Netherlands and an approximately 2.5-fold increase in Europe on the whole, with an annual expected increase in

the GNP for Europe of 2 to 2.5% in the next decade; European Environment Agency, 1999). Despite this, environmental quality has improved in some respects (e.g., water pollution and atmospheric SO₂- and NO_x-emissions), and eco-efficiency has increased by decoupling the resource use and pollutant release from economic activity (OECD, 1998). Conversely, the emissions of CO₂, waste, and other substances are not yet under sufficient control (RIVM, 1998b; European Environment Agency, 1999).

Besides taking measures to improve the quality of the conditioning factors, governmental policy makers see clearly that existing nature reserves should be preserved and new natural areas established to create and enhance ecological networks (Ministry of Agriculture, Nature Management and Fisheries, 1990; Bennett, 1991). In Europe, upwards of 10% of the territory is expected to be designated as nature conservation areas as part of the Natura 2000 Network (European Environment Agency, 1999). Furthermore, some 250,000 ha of new nature areas in the Netherlands will be connected to existing areas to create a National Ecological Network (NEN) in 2018. This has led us to conclude that policy makers will define objectives on a broad base so that we can assess the achievements of current policies on the improvement in the quality of nature areas and the landscape.

A number of policy tools in the European Union have univocal targets (e.g., the Habitat Directive in the framework of the Natura 2000 Network; European Environment Agency, 1999). The member states have defined and assessed such targets (Statistics Finland, 1997; RIVM, 1997, 1998a; Kuijken, 1999). For some policy fields, however, objectives cannot be assessed properly since verifiable targets and tools fail (e.g., in forestry and landscape policies in the Netherlands; RIVM, 1997; Table 75.1]).

Some policy tools are fairly successful (Figure 75.5). Indeed, the planned acreage of national parks, forests, and nature reserves, for instance, has increased; ecological corridors have been

Figure 75.5 An example showing the achievements as a percentage of the targeted figures in nature policy in the Netherlands between 1990 and 1997. (From Rijks Instituut voor Volksgezondheid en Milieu, *Natuurverkenning 97*, Samsom H.D. Willink, T., Alphen aan den Rijn, A., the Netherlands, 1997.)

established and agricultural site management has become popular (RIVM, 1997, 1998a). Without a doubt, natural values will be enhanced in the areas through the implementation of these measures compared to areas where measures are not implemented. It would be intriguing to know, however, why so many targets have not yet been reached. There are some marked examples: until 1997, the Netherlands had not succeeded in implementing international treaties of the European Union due to problems in establishing new forests near the large cities in the western part of the country (Randstad). Furthermore, targets for designating new natural areas and areas for habitat rehabilitation had not been realized. As an example of this problem in implementation we will discuss the creation of the Dutch NEN below in greater detail.

LACK OF INTEGRATION BETWEEN POLICY LEVELS

First of all, both national and regional water policies claim to aim at improving the quality of natural areas. An important feature of the NEN comprises the marshlands, and in particular seepage areas, in which many rare and vulnerable species occur. More than half of all designated marshlands in the NEN are, however, dried up and desiccated. The national water policy aims at the recovery of 150,000 ha desiccated areas before 2000. Unfortunately, the measures will focus on only some 60% of the desiccated areas and on a little more than half of the 115,000 ha desiccated wetlands in the NEN (RIVM, 1998a). This can be considered an example of how horizontal integration between policy levels is being hampered.

The national government has commissioned the regional authorities with the implementation, through land delimitation and acquisition, of the NEN concept by 1998. Although acquisition is on average still taking place on schedule, there are distinct differences among the provinces (Figure 75.6). Provinces state a number of reasons for the delays in implementation (summarized in Figure 75.7),

Figure 75.6 Regional achievements after the purchase of land of new nature areas as a percentage of the total targeted area per province. (From Rijks Instituut voor Volksgezondheid en Milieu, *Natuurbalans 99*, Samsom, H.D., Willink, T., Alphen aan den Rijn, A., the Netherlands, 1999.)

Figure 75.7 Frequency of claims for limitations in land acquisition for new nature areas according to Netherlands' regional authorities. (From Rijks Instituut voor Volksgezondheid en Milieu, *Natuurbalans 99*, Samson, H.D., Willink, T., Alphen aan den Rijn, A., the Netherlands, 1999.)

including financial problems, as confirmed by an analysis of land prices. Although the national government supplemented some of the major funds for land acquisition in 1998, prices are still increasing, and the current market price in eight provinces now exceeds the fixed standard price per hectare.

Apart from financial problems, there are evidently also communication and attitudinal problems hampering vertical integration of nature policy. These problems include a lack of acceptance of national policy targets by regional and local authorities, and the rural population and the regional authorities' criticism of the lack of a clear national policy (Figure 75.7).

Sustainable use of natural resources requires integrated policies, and the degree of integrating policies in all domains can be properly judged only by integrated assessments in which ecoefficiency and economic development are measured. Integrated assessments need integrated knowledge. We have shown a number of examples of integrated assessments in Europe and confined these to the Netherlands to the assessment of nature policy, which can be considerably upgraded if the ill-defined targets and some of the policy strategies are improved, and if obstacles to political boundaries are overcome.

ACKNOWLEDGMENTS

We thank the Environmental and Nature Policy Assessment Division at Rijks Instituut voor Volksgezondheid en Milieu (RIVM), in which the National Institute of Public Health and the Environment collaborates with the Department of Agricultural Research, for sponsoring the studies. We are also much indebted to N.D. van Egmond, F. Langeweg, R.J.M. Maas, R. van Oostenbrugge, and H.J.W. Oosterveld for the stimulating discussions and enthusiastic support given in carrying out this research. We are grateful to Dr. S. Carrizosa for his critical comments on an earlier draft of this chapter. Finally, we acknowledge the editing of Mrs. R.E. de Wijs.

Land-Use Change Due to Urbanization for the Middle Atlantic Integrated Assessment Region of the Eastern United States

Ronald W. Matheny and Keith Endres

INTRODUCTION

The U.S. Environmental Protection Agency (EPA) Regional Vulnerability Assessment Program (ReVA) is designed to develop and demonstrate approaches to identify the ecosystems at the greatest risk from regional population growth and economic activity (Smith, 1999). A region is a multistate area involving many metropolitan areas, drainage basins, associated ecosystems, and cultural infrastructures. The term *vulnerability* is a variable, ranging from no vulnerability to low and high vulnerability; without a qualifier, the term implies nothing. ReVA is particularly used to compare risks arising from all sources of potential harm, acting alone or in combination, over the entire region. ReVA is beginning with a pilot study conducted as part of the Middle Atlantic Integrated Assessment (MAIA). The study area includes all of Pennsylvania, Maryland, West Virginia, Virginia, the District of Columbia, and parts of North Carolina, Delaware, New York, and New Jersey. This area was selected because it has a wealth of ecological data collected by field surveys, remote sensing, and other ecological monitoring, modeling, and research activities.

The study reported herein addresses two key questions: (1) What will be the land conversion to urban use and nitrogen loading during the next 5 to 25 years? (2) Where are the most vulnerable ecosystems located? Immediate objectives are these:

1. Integrate multiple data sources and existing assessment technologies
2. Expand research to fill critical gaps in our ability to apply existing data at the regional scale
3. Incorporate socioeconomic research to better understand factors driving environmental change and to more accurately assess the true costs of environmental degradation

ReVA will test alternative approaches by applying the technology as it is developed to the MAIA and obtain feedback from decision makers at the regional and local levels and the public.

METHODOLOGY

The Community Growth Model (CGM) is a cellular-based model incorporating land-use categories, slope, roads, railroads, pipelines, transmission lines, streams, federal lands, and population

projections. Both the approach and data were selected to take into account the data determined to be significant in the literature. All data used are publicly available. Sewer lines were not used because a complete data set could not be located. Economic data, such as land value, developed through econometric methods will be used in the next version of the model. The model uses a base grid that integrates infrastructure and land use. It then calculates the area to be converted to the three urban uses (low-intensity residential, high-intensity residential, and commercial/industrial/transportation) from population projections. It then allocates new urban growth using a neighborhood function and modifies the base grid to prepare for the next iteration for each of the three urban classes. For this analysis, the model performed these functions at the county level, edge-matched (aligned) all counties together, and clipped the resulting grid to the MAIA region.

Base Grid

The 1992 Multi-Resolution Land Characteristics (MRLC) for the MAIA study area was used as an initial starting grid. This data set is a 30-m² grid coverage of the land use and land cover developed for the EPA MAIA project region. The coverage was produced using 1988, 1989, 1991, 1992, and 1993 Earth Resource Observation System (EROS) Landsat Thematic Mapper (TM) data. In addition, we used U.S. census data for population and housing density, U.S. Geological Survey land-use and land-cover data, and National Wetland Inventory (NWI) data as supplemental layers for data classification. The general procedure of the MAIA coverage was as follows:

1. Mosaic multiple summer TM scenes and classify them using an unsupervised classification algorithm (a computer-directed numerical process)
2. Interpret and label classes (land characteristics) into land-cover categories using aerial photographs as reference data
3. Resolve confused classes using the appropriate ancillary data sources
4. Incorporate land-cover information from leaves-off (without foliage) TM data and NWI data to refine and augment the *basic* classification from the National Land Cover Data Classification System. The classification number used in this study corresponds with the classification (see Table 76.1)

Modification of the Initial MRLC Grid

Since this analysis examines urban expansion and land use changes as the result of urbanization (see Table 76.2) the above classification detail was not needed. Eleven categories were examined, collapsed from the 23 categories listed above:

- Three urban classes (low-intensity residential, high-intensity residential, commercial/industrial/transportation)
- Bare rock/sand
- Transitional
- Deciduous forest
- Evergreen forest
- Mixed forest
- Pasture/hay
- Emergent herbaceous wetlands
- Woody wetlands

The urban/recreational grasses were collapsed into the low-intensity residential class, and gravel pits, quarries, and coal mines were merged into the commercial/industrial/transportation class. Digital line graphs (DLGs) were converted into grid cells. Class I roads, railroads, and pipelines were added to the commercial/industrial/transportation class. Class II roads were added to the low-intensity residential class. Assumptions built into the model are that open water, federal

lands, and land within 50 m of streams would not be developed. It was also assumed that land would not convert from the urban classes. Thus, any other land use could convert to any of the urban classes.

Calculations of Yearly Land Conversion Pixels

In order to calculate the number of cells that must be added to each year in the three urban uses the modified MRLC grid was used for each county. The grid was examined and the number of cells of each of the urban classes beginning in 1992 was placed into a file and merged with the Woods and Poole (1998) projection data. The merged data for each of the counties were based on the assumptions that the ratio number of households to the number of high-intensity cells, the ratio number of households to the number of low-intensity cells, and the ratio of total earnings (adjusted

Table 76.2 Change in Number of Households in the States within the MAIA Region^a Households (1000)

	1992	2000	2010	2020
District of Columbia	249	231 (-7.23%)	227 (-1.73%)	218 (-4.00)

^a The MAIA region contains portions of each of these states. The MAIA region was created by clipping grids at the county level for the MAIA region.

by subtracting out farm earnings and military earnings) to the number of commercial cells to be added each year will remain constant.

The Neighborhood Function

To determine which pixel would be *urbanized* a neighborhood function was used (see Figure 76.1). For each cell, we used a 7×7 area of 30 m² cells. Each cell in the grid was assigned a score based on the number of urban classes that were in the neighborhood. Each pixel then had a score for each of the urban classes for a total of three scores for each cell. The model then selected the cells with the highest scores as the most likely to be converted to urban uses and updated the modified MRLC grid for the next iteration. From these results, we calculated the number of cells that would be converted from nonurban uses to one of the three urban uses. This process was repeated for each county in the MAIA region to obtain a total number of cells that would be converted from nonurban to urban uses during the time span of 2000 to 2020.

In more technical terms, neighborhood functions require both a neighborhood (grid) and a combination rule (specifications of what to do to the grid) in order to work (Chrisman, 1997). For this analysis, the focal sum combination rule was used. The FOCALSUM command in ARC/INFO examines each cell location on an input grid, adds the values within a specified neighborhood, and sends the sum to the corresponding cell location on the output grid (ESRI, 1994). It passes a moving window over the input grid. For this model, a 7×7 grid moving window was used for each of the three urban classification. Each cell was assigned a value: urban = 1, nonurban = 0. The sum of the cells was placed in the center of the output grid. This process was repeated for each of the three urban classification 7×7 grids within each county grid.

Those cells with the largest number represent the areas most likely to have an increase in each of the three urban classes, as development will spread near areas that are already similarly developed. The number of cells determined in the calculations of yearly land conversion pixels were then divided between these cells to determine how many and which cells would change from nonurban to each of the three urban uses.

Nitrogen Loadings

Nitrogen loadings for the MAIA region for 1992, 2000, 2010, and 2020 were calculated using nutrient loading coefficients derived from the Chesapeake Bay study (Chesapeake Bay Program, 1995). The model yielded grids with 13 land-use categories. From these 13 categories, 5 categories were derived (see Table 76.3) and used to calculate the total nitrogen loading resulting from increased urbanization. Low-intensity residential, pasture/hay, and row crops remained the same as their output from the model. The high-intensity residential and commercial/industrial/transportation

Table 76.3 Nitrogen Loading Coefficients by Land Use Category

Land Use	Nitrogen Loading Coefficient
Low-intensity residential	11.9821
High-intensity residential/commercial/industrial/transportation	12.62119
Forest	2.62552
Pasture/hay	9.7399742
Row crops	19.74579

Note: It should be noted that the nitrogen loading coefficients for agricultural uses pasture/hay and row crops are very similar to the loading for low-intensity residential and high-intensity residential/and commercial/industrial/transportation classes.

were combined. Forest equaled the sum of deciduous, evergreen, and mixed forests. The area for each category was converted from the 30 m² output of the model to hectares. The total hectares for each of the five new categories were summed. The total area for each land-use category was then multiplied by their corresponding nitrogen loading coefficient.

RESULTS

Table 76.4 depicts the land use change in the entire MAIA region using the CGM methodology. The low-intensity residential area, high-intensity residential, and commercial/industrial/transportation area sectors increased by 5.11 and 16.21% in 2020, respectively. Forest area decreased by 0.73%, pasture/hay by 1.0%, and row crop by -1.00.2%. The decreases in the nonurban areas are very small, less than -1.19%, even though the increases in the urban classes seem high. This is because the urban classifications are a minor part of the total land use in the MAIA region, even though they may be close to sensitive ecological areas that might be degraded. The relatively minor decreases may also reflect that projections were made for only 28 years. Many other models have projection time periods of 50 to 100 years.

Also, urban growth occurred where there was already urban growth (sometimes called urban sprawl). There is strong concern over where this growth is occurring; if it is occurring near ecologically sensitive areas it could have severe impacts. This can be seen graphically by comparing the grids for each of the modeled years. Urban sprawl appears to be relatively minor (see Figure 76.1). When examining the growth in urban land use in the MAIA region it becomes clear that there is significant growth in land cover for all three urban sectors (see Figure 76.2).

Nitrogen Loadings Impacts

The significant growth in land cover for all three urban sectors may be applied to nitrogen loadings from 1992 to 2020 for the entire MAIA region. These results are not as insignificant as

Table 76.4 Land Use Change in Hectares (1000)

Year	Low-Intensity Residential Area	High-Intensity Residential/ Commercial/Industrial/ Transportation Area	Forest Area	Pasture/Hay Area	Row Crop Area
1992	13,243 (0.00%)	9780 (0.00%)	248,125 (0.00%)	71,049 (0.00%)	26,726 (0.00%)
2000	14,270 (7.76%)	11,319 (15.74%)	246,607 (-0.61%)	70,436 (-0.86%)	26,400 (-1.22%)

Year	Total Nitrogen	Percent Increase				
1992	215.33	—				
2000	216.87	0.712				
2010	218.76	0.872				
2020	220.64	0.863				

the land-use change. Table 76.5 presents the nitrogen loadings by land-use classification for the entire MAIA region. The urban classes are only 28.2% in 1992, 31.4% in 2000, 35.1% in 2010, and 38.7% in 2020 of the total nitrogen loadings in the region. Still, nitrogen loadings from all urban sources are proportionately small.

Table 76.5 also illustrates that increases in nitrogen loadings for the entire MAIA region for all land-use classes is less than 1%. On a regional scale, nitrogen does not seem to be a problem, but again, it must be cautioned that on a smaller scale, where urbanization is taking place near ecologically sensitive areas, there could be severe problems.

The changes occurring between the urban, forest, and agricultural land-use categories between 1992 and 2020 appear insignificant at the MAIA regional scale. The contribution of each land source to the total nitrogen loading in the MAIA region gives a more accurate assessment of where nitrogen problems could be originating. In relation to urbanization, all years show less than 1% increases over time (+0.712% from 1992 to 2000, +0.872% from 2000 to 2010, and +0.863% from 2010 to 2020).

Another way of showing the small change in nitrogen loadings is by comparing the urban uses with the nonurban uses and related nitrogen loadings (see Table 76.6 and Figure 76.3). Total nitrogen loadings are not increasing significantly. The source of nitrogen loading does change. Total nitrogen

from urban development increases 11.25% from 1992 to 2000, 11.87% from 2000 to 2010, and 10.4% from 2010 to 2020. Total nitrogen from nonurban areas decreases 1.89% from 1992 to 2000, 2.15% from 2000 to 2010, and 2.11% from 2010 to 2020.

SCENARIO COMPARISON

Besides the base case scenario described above, two other scenarios were analyzed. The *telecommuting* scenario varied the commercial/industrial/transportation category by 25% for each county and each year. It was assumed that now facilities would be smaller to allow for employees

to work either at home or at telecommuting centers in order to reduce land demand. The *smart growth* scenario varied household land demand by reducing land demand for the low-intensity residential and high-intensity residential categories by 25% for each county and each year. New households would require less land to be converted from each land-use classification. For both of these scenarios a geographic distribution of land-use change was made and compared with the base scenario. Table 76.7 compares the three scenarios by revised MRLC classification by year. Note that the nitrogen loading and hectare differences are relatively insignificant.

CONCLUSIONS

This approach to land-use change and associated nitrogen loadings has proven to be successful. We need to reconsider the assumption, however, that the land-use proportion in each urban category by county will remain the same since socioeconomic issues may change. To overcome this problem, the next version of CGM will be linked with an econometric model to include socioeconomic elements and to determine the amount of land that will be converted from one land-use category to another. The neighborhood function will be modified slightly to allow the CGM to take the resulting land-use change and allocate it geographically by county.

This version of the model used a single nitrogen loading for each land-use classification. Future model runs will use county or state level data to increase accuracy and, if available, modify the loadings by year to account for efficiencies in agriculture and forest management. Future model runs will also look at other loadings such as phosphorus.

The three scenario runs did not show great differences in nitrogen loadings for the urban categories. This may be a function of the allocation method of land change, poor assumptions on the part of the modeler, or possible poor quality control on the MRLC base grid and other geographic information system data sets. Comparisons with other model output is planned for the near future.

Anthropogenic pressures are often local in scale, and ecologically sensitive areas must be examined at the local scale. Fortunately, the data used in this model can be subdivided into smaller units, such as river basins, cities, or counties. Additional local data could then be added to conduct site-specific analysis. For example, monitoring emission factors on a highway system could produce a possible air quality analysis.

There is a need for integrated modeling of land-use and land-cover change. The methods to integrate the theoretical and simulation models of land use and land cover must be modeled through the interactions of the environment and society. At least two different approaches have been used. One approach is based on the theory of environmental and social interactions and the other approach attempts to join existing models. Neither one is sufficient. An integration of these approaches would provide the most promise for future models and is the direction the CGM is taking.

SECTION II.7

Agriculture and Human Health

Overview: Agriculture and Human Health

Marc Schenker

While the impact of ecosystem changes in agriculture on human health have not been accurately characterized, the occupational health hazards of agricultural work have been well described (Schenker, 1996). Agriculture ranks as one of the two or three most hazardous occupations based on fatality rates, with an injury mortality rate approximately three to five times that for all other occupations (Myers, 1990). More than 700 agricultural work-related deaths and 140,000 disabling injuries occur annually in the U.S. (Council, 1999).

Many illnesses (cardiovascular, respiratory, cancer, dermatitis, infection, neuropsychiatric disorders) occur more commonly among agricultural workers than in the general population, but the full burden of illness from acute and chronic occupational exposures in the agricultural workplace is unknown. However, consideration of illnesses from agricultural work illustrates the breadth of hazardous exposures in this environment, and provides some direction for future studies of ecosystem impact on health in the agricultural environment. Consideration of agricultural respiratory disease (Schenker, 1998) helps reveal the scope of the problem. The spectrum of agents causing respiratory disease from agricultural exposures ranges from simple irritant gases, to crystalline silica, to a variety of microorganisms (Table 77.1).

Documented agricultural respiratory diseases from these diverse exposures similarly cover a very broad spectrum. They include:

- Rhinitis (allergic and non-allergic)
- Asthma
- Asthma-like syndrome
- Tracheobronchitis
- Chronic obstructive lung disease
- Organic dust toxic syndrome
- Hypersensitivity pneumonitis
- Interstitial fibrosis
- Respiratory infections (bacterial, viral, mycobacterial, fungal, rickettsial)

While research is beginning to elucidate the risks of respiratory disease from occupational exposures in agriculture, very little is known about the effects of these exposures on agrosystem ecology and the health implications resulting from perturbations to the ecosystem from agriculture. For example, agricultural burning has been shown to increase ambient air pollution significantly, and some studies have shown an association of agricultural burning with acute respiratory disease among area residents (Jacobs et al., 1997). Interstitial fibrosis has been observed among rural

Table 77.1 Agricultural Exposures Affecting Respiratory Health

	Examples
Organic dusts	Pollens, cotton dust, fungal conidia
Microorganisms	Bacteria, fungi, viruses, mycobacterium
Mycotoxins	Aflatoxin, trichothecenes
Endotoxins	Heat-stable lipopolysaccharide protein complexes from Gram-negative bacteria
Decomposition and other gases	NH ₃ , H ₂ S, CO ₂ , CO, NO, NO ₂
Pesticides	Methyl bromide, metam-sodium
Fertilizers	Anhydrous ammonia
Feed additives	Vitamins, antibiotics
Inorganic dusts	Crystalline silica, silicates

residents with no history of agricultural work who reside in dry-climate farming regions (Sherwin et al., 1979). These harmful respiratory effects caused by agricultural practices are in contrast to the results of recent studies documenting a *decrease* in asthma prevalence among rural and agricultural residents, suggesting a benefit from environmental exposures while growing up in an agricultural environment (Ernst and Cormier, 2000).

Our knowledge about other health outcomes (e.g., neurologic disease, chronic immune disorders, cancer) is even less than for respiratory disease. For example, some studies have suggested that incidence of Parkinson's disease is elevated among residents in agricultural settings, but other studies have not observed such an association (Goldsmith et al., 1990; Semchuk et al., 1992).

Several agricultural exposures or environments are of particular concern with regard to their effects on the ecosystem and on human health. These include (1) agrochemicals, including pesticides and fertilizers; (2) agricultural wastes and wastewater, and specifically infectious diseases in this environment; (3) air pollutants from a variety of agricultural processes, including chemical spraying, soil preparation, and agricultural burning; and (4) genetic modifications of agricultural products.

Increased efforts at developing sustainable agriculture practices have begun to focus attention of the agricultural community on the broader ecosystem. In addition to managing agrosystems for long-term economic viability, efforts are developing to enhance environmental sustainability and human health. The social and political attention given to health effects of genetically modified foods has certainly increased concern about the social acceptability (and ecologic impacts) of agricultural practices (Longman, 1999).

In summary, scientists and others now increasingly recognize that agricultural policies must be developed with consideration of their ecologic and health implications, and similarly that environmental policies must consider their impact on agriculture. The result of this process will be systems that support both sustainable agriculture and ecologic health. To do less will result in unnecessary injuries, illnesses, and deaths.

The chapters in this section examine several different areas of the ecosystem and human health problems related to agriculture. Gunderson et al. provide an insightful overview of agricultural impacts on ecosystem health, including a historical perspective and a look into future practices that may affect this area. This seminal chapter covers a range of topics from economic and public policy factors to potential ecosystem and health effects of genetically modified foods. Three chapters raise different major issues involved with the potential effects of agriculture on human and ecosystem health — infectious diseases, air pollution, and pesticides.

The topics covered in this section are of profound importance to society. As noted by Gunderson et al., the future of society itself is dependent on preservation of sustainable agricultural production, which is in turn dependent on systems that maintain ecosystem and human health.

Effects of Agriculture on Ecosystem and Human Health

Paul D. Gunderson, Nancy B. Young, and Dean T. Stueland

INTRODUCTION

For most of the 20th century the American farm has performed at Herculean production levels. From time to time these production levels have been presumed to be at their limits; however, with new discoveries those limits were pushed well beyond what contemporaries thought achievable. En route the American farmer has been characterized as extraordinarily productive and resilient, as an early adapter of technological change, and a master at integrating signals from the world marketplace with individual agricultural enterprises. Described since the inception of our nation in heroic and generous terms (Jefferson, 1785), the American farmer pursues the objective of remaining competitively productive and capable of feeding the world (Pedraza, 1996).

DISCUSSION

Concurrent with the emergence of the American farmer as a key player in rural agricultural politics has been the recognition that sustainable agricultural production cannot remain a luxury. Once an agricultural resource base has been eroded, the larger society it sustains cannot remain viable (Runnel, 1995). Sustainability must be maintained in the face of projections that the world in the year 2060 will contain between 10 and 11.5 billion people and the discomfiting evidence that sustainable gains in the yield of agricultural commodities will be difficult to maintain (Faeth, 1993; Brummer, 1998; Mohapatra, 1999; Agnew, 1999; Mann, 1997).

The long-term capability to evaluate the ecological impact of agronomic practice on the larger ecosystem is essential. Fortunately, these evaluations have been under way for some time. The first was initiated in the mid-1800s with the establishment of the Rothamsted experimental station in England in 1843. Other sites in the English-speaking world include Morrow, IL (1876) and Sanborne, MO (1888) in the U.S.; Longerenong (1917) and Waite (1925) in Australia; and Lethbridge (1911) and Breton (1930) in Canada. More recently, a substantial number of long-term agroecosystem experiments have been established in other parts of the world. In general these initiatives have (1) identified management practices capable of either sustaining or foreshortening agricultural productivity across long time frames; and (2) assessed the differential impacts from natural and synthetic crop additives, fertilizers, and pesticides. In addition, these experiments

generated insight that has enabled scientists to model biological impact of overall change in global climates and the effect of increased atmospheric CO₂ on carbon sequestration (Houghton et al., 1999). As time passed, scientists involved in these initiatives called for less fragmentation in the agricultural research enterprise and more interaction with other disciplines, including the health sector (National Research Council, 1996; Wilson, 1998).

Unfortunately, these experiments were never designed to assess the human health impact of technological change occurring in agricultural production systems nor the evolutionary impact of these systems on human populations and adjacent forms of biology. Accordingly, we must turn elsewhere in order to marshal the evidence that exists relative to agricultural production on human health. It will be important to differentiate between health effects observable within the larger society vs. those experienced by human populations with the greatest exposure to agricultural practices. The most immediate exposures affect agricultural workers, resident households, and populations immediately adjacent to acreage devoted to agricultural production.

North American agriculture experienced several revolutions during the 20th century. The century began with mechanization of agricultural tasks and the widespread diffusion of information technologies; this was followed by the hybridization of plants, the technological transformation of whole sectors of the industry, and the recent emergence of *accelerated* genetically modified crops. Each revolution has changed the way in which agricultural workers react to these work environments. Wide variations in federal agricultural policy occurred simultaneously with these developments, including the emergence of environmental policy, public investment in agricultural research, response to global warming and other climatic forces, and consumer concern about the safety of food destined for human consumption. Each of these developments has or will have a significant impact upon the work tasks that agricultural populations pursue. Only a few of these impacts can be explored here.

Advances in agricultural technology have reduced the enormous levels of physical drudgery associated with many conventional agricultural tasks. Historically, from basic tillage of the soil, through the handling of agricultural inputs, to the harvesting and postharvest transfer of agricultural production, the human musculoskeletal system has absorbed the load. Now, much of that load is carried by technological invention in technologically advanced societies, resulting in substantially reduced levels of musculoskeletal disease or injury. Today's agricultural workers must concern themselves with the potential for mechanical entanglement; exposure to volatile organic chemicals resulting from use of the internal combustion engine; inhalation of silica, fungi, and spores that are disturbed and transported by mechanical cultivation and harvesting technologies; or exposure to agricultural pesticides. On balance, however, those who treat disease and injury associated with agricultural exposures believe that the incidence of those conditions resulting from the infusion of technology on the North American farm has stabilized.

On another front, until public policy began to encourage landowners, farmers, and ranchers to develop green ecological-filtering masses around fragile stream banks, ponds, and lakes, the potential for transmission of harmful protozoa that can survive in the bovine, human gut, and groundwater was intensifying. This is an important development given the dependence of agricultural populations and their urban neighbors on watersheds. As grazing livestock are moved away from fragile watersheds, the potential for disease among human populations should be substantially reduced.

As livestock operations increased their use of intensive confinement systems, the potential for increased virulence of bacteria and spread of zoonotic disease and the possible development of resistance to antibiotics in conventional human use have emerged (Borchardt et al., 1999; Diez-Gonzalez et al., 1998; New York Academy of Sciences, 1999). These new technologies were developed in an effort to reduce input resources, substantially increase labor efficiency, and improve the health status of livestock through management of wide thermal variances. However, these technologies can opportunistically induce human disease and thwart conventional public health containment measures. Unfortunately, the technologies to store and process the massive accumu-

lations of livestock waste lagged design and development of livestock confinement housing. The result is accelerated environmental risk when these systems do not work or malfunction in use.

Potentially, the most important revolution of the 20th century will result from the manipulation of the DNA of plants and livestock. In spite of current European and Asian objections, the world is likely to derive the majority of its food, natural fiber, renewable fuels, lubricants, cosmetic and pharmaceutical base components, and livestock feed from vegetation or forest preserves in which some genetic component has been changed (Abelson, 1998). Among the numerous impacts that are coupled to this revolution is its potential to reduce human exposure to agricultural pesticides currently in use. Alternative practices for the control of pests will change the nature, duration, and frequency of human exposures to both natural and synthetic crop and livestock pesticides. Genetically modified organisms that permit the use of more environmentally benign pesticides or agronomic practices and that provide alternative approaches to the control of pests (e.g., crop rotation, use of narrow spectrum natural pesticides or beneficial insect populations, or genetically different organisms that can be applied to plants themselves or the soil from which they draw their nutrients) could significantly reduce human exposure. When one couples these developments to technological change in application techniques, it is possible to envision a future where the agronomic tool kit will be radically different from that in use today (Lubchenco, 1998), virtually eliminating human exposure to conventional crop protection products.

The technological transformation of North American agriculture significantly reduced respiratory insult experienced by agricultural workers. New forage and grain-harvesting technologies permitted a concomitant reduction in airborne particulates that caused farmer's lung and other forms of hypersensitivity pneumonitis. Exposures remain, given that the structural integrity of protective work enclosures is often compromised in agricultural settings or workers may refuse to use personal protective equipment due to behavioral or thermal barriers. However, in the absence of major natural calamities, it is reasonable to expect that current levels of respiratory disease among working agricultural populations will continue to decline. Natural calamities, particularly in wet growing cycles, possess the potential of reversing the observed declines in respiratory disease, since microbial particulate found in many soil profiles is washed onto plant stems and grain surfaces, providing a route for aerosolization during harvesting activities. Wide fluctuations in growing climates across the world could dramatically impact on the incidence of respiratory disease of workers and populations adjacent to cultivated areas.

The ecological impact of North American agriculture can also be detected on wider community, regional, or national scales. For example, the change in agronomic practice that has transformed large areas of North America from forested verandas to legume cover has contributed substantially to the increase in the amount of fixed nitrogen that enters the global terrestrial nitrogen cycle (Malakoff, 1998). This development possesses potentially serious consequences for human populations far removed from agricultural production sites. Nitrogen loading is likely to have contributed to the observed declines in aquatic wildlife and the intensification of algal blossoming leading to significant human disease outbreaks (e.g., *Pfeisteria piscicida*). Additionally, since land now devoted to legume production must be productively maintained through the addition of organic and synthetic fertilizers, groundwater and surface water flowing out of these areas into holding ponds and reservoirs, estuaries, and coastal waters could impact human health on a wide scale. As watersheds become overwhelmed by agricultural runoff, public drinking water systems are likely to experience increased concentrations of nitrites and bacterial loading.

A second generalized population effect associated with current agronomic practice can be detected in the nontarget proliferation of selected agricultural pesticides. Although most products in current use such as organophosphates and carbamates are short-lived, they are acutely toxic, and some contain breakdown products that have been demonstrated in laboratory studies to suppress or alter basic immunology as well as mimic hormone activity (Matson et al., 1997). One key control strategy could be the adoption of new technologies which rely on spatial and temporal response to nutrient demand. Advanced farming systems that couple global positioning technologies to on-the-

go variable rate capability permit precise metering and response to the nutrient requirements of cereal and other feed grain crops (Moffat, 1996). With advancing biotechnology it is also possible to mate selected geographic or specie-specific characteristics such as perennial durability with maximized uptake of N, K, P, or heavy metals.

The emerging trend to house large numbers of livestock and poultry in concentrated settings holds various dangers. Alarms have been triggered fueled by the discovery that some bacteria that cause human disease have developed specialized resistance to selected antibiotics in common use in animal feeds. This development is particularly unsettling for hospitals where bacterial resistance has been a facet of clinical life for some time. Resistance to antimicrobial pharmaceuticals emerges either as the result of new mutations in the bacterial genome or through acquiring resistant new genes (Witte, 1998). While the empirical verdict is still out (Anon., 1999), prudence would suggest that a rigorous risk assessment must soon be undertaken relative to the use of antibiotic additives in livestock feed (Anon., 1999). This is imperative given that current animal husbandry practice typically calls for background use of these pharmaceuticals to promote disease-free growth of livestock.

Three related potential effects are associated with perpetuation of dominant agronomy practices in existence at the end of the 20th century. The first of these reflects the desire by many sectors of production agriculture, as well as numerous governments, to integrate fully the free enterprise model into most if not all of the world's agricultural sectors. Unfortunately, as Hardin so eloquently stated, "Freedom in a commons brings ruin to all," which from its original state has been extended to, "Individualism is cherished because it produces freedom, but the gift is conditional: the more the population exceeds the carrying capacity of the environment, the more freedoms must be given up" (Hardin, 1968, 1998). Should this postulate hold true, it would appear that unilateral adoption of the free enterprise system in which each productive agricultural entity is locked into a system that causes the entity to maximize production could result in a unsustainable worldwide environment.

Second, an inherent risk associated with manipulation of plant and animal genomic structures is the potential for restriction of biodiversity. While the world's scientists plead for public financing of plant and animal genomic banks, many of those pleas have fallen on deaf ears. Should diversity of genomic structures be reduced, the potential for future food scarcity, given the evolutionary nature of agronomic pests, looms as an ever-present threat.

Third, some evidence exists that migration of modified genetic structures to nontarget species can occur. While much public misunderstanding, indeed specific misinformation, has been transmitted by the popular press, justifiable scientific concern remains about the potential for such movement. Should that occur and the means to regulate and ultimately thwart such movement be restricted, the potential exists for future food shortages, since the ultimate impact could be unplanned retardation and removal of nontarget food species.

The ecological impact of these developments is obviously varied. However, the tools at the disposal of scientific establishments are likely to exist so that the embedded technologies can be harnessed toward the health and well-being of the world's human and animal populations. That we have yet some distance to travel should propel all of us to redouble our effort and focus our scientific zeal.

Infectious Disease Hazards to Agricultural Workers

Dean O. Cliver

The National Food Safety Initiative of May 1997 (Anonymous, 1997) refers repeatedly to manure management and implies that the use of animal manure in vegetable crop production constitutes a hazard to consumer health. Indeed, raw produce has been the vehicle in a considerable number of foodborne disease outbreaks in the U.S. (Beuchat, 1998), and most of the disease agents involved have been zoonotic infectious agents (agents that cause disease in humans but are usually of animal origin). If this is true, those who work in vegetable-growing fields to which manure is applied should be at greater risk, though little has been done to test this hypothesis (Coia et al., 1998). The zoonotic agents of greatest concern are *Escherichia coli* O157:H7, *Salmonella* spp., and *Cryptosporidium parvum*. These are shed, under certain circumstances, in the manure of food animals. The source animals are generally healthy, although mild diarrhea may sometimes be seen.

The effects of various treatments and storage of manure on the infectivity of zoonotic bacteria and protozoa are under study (Himathongkham et al., 1999); methods that destroy infectivity are known, but not widely used. The most rigorous treatment generally used is composting. It is important to note that composting is not defined in law or regulation, so that some manure handlers regard any stack that heats as undergoing the composting process. In fact, true composting, which entails turning a stack repeatedly to ensure aeration and efficient generation of heat by the microflora of the material, may not be necessary to reduce the named zoonotic pathogens to undetectable levels. The problem is that there are no guidelines or specifications that ensure that, given a certain treatment of manure, the pathogens will no longer be present and transmissible via the produce that may be fertilized with it. Dependence on events in soil to destroy pathogens from manure (California Certified Organic Farmers, 1996) is also inadequately supported by evidence.

People infected with such zoonotic agents may experience mild to severe intestinal illness, will shed the agents in their feces, and are able to transmit them to others (Benenson, 1995). In addition to causing diarrhea that may show frank, red blood in the stool, *E. coli* O157:H7 can cause life-threatening illnesses: hemolytic uremic syndrome (typically in children under 5 years of age) and thrombotic thrombocytopenic purpura (typically in older persons). *Salmonella* spp., after the gastroenteritis has resolved, may cause lifelong arthritis. *Cryptosporidium parvum* typically causes only severe diarrhea, but there is no accepted treatment for the infection, so persons who are immunologically impaired (e.g., AIDS patients) may remain infected for the rest of their lives, with intermittent recurrences of diarrhea.

Because infected persons shed these agents in their feces, surveys — using various methods of fecal sampling — are needed to determine the incidence of such infections among agricultural workers, as related to occupational exposure. For logistical and cultural reasons, sampling

arrangements have proven difficult. For example, in its efforts to protect worker health and the environment, the California Occupational Health and Safety Agency has regulations that require provision of portable toilets with effective disinfectants in their sumps and the use of these toilets by agricultural field workers. Our trials indicate that the disinfectants are typically quite effective, which makes the portable toilets of little value as noninvasive fecal sampling facilities. Another serious problem in the establishment of sampling programs is the perceived liability of the grower. If infected workers are identified in a food producing operation, there is a real probability that the product will be embargoed. Therefore, growers would rather trust the judgment of the field foreman as to the health of the workers than have fecal samples being tested in a laboratory. It is certainly true that not all infections with the agents discussed here result in disease, so more workers are likely to be infected than are overtly ill. *Silent infections* are unlikely to be detected other than in the laboratory, yet they could cause serious repercussions to the producer. In surveys of farm environments for infectious agents (outside the context of human feces), it has been necessary to have the sample taker code the samples in such a way that positive test results cannot be associated with the farm of origin. It may be necessary to adopt similar measures in studies of farmworker intestinal infections.

It is also important to recognize that treatments applied to manure to protect the consumer may not protect workers, in that at least some workers may be exposed to the manure before it is treated. This certainly holds true for those working in animal production, who will be in contact with freshly voided cow, chicken, or other animal manure. Therefore, control groups for studies of infections in workers growing produce should include people who work in fields to which no manure is applied and those who work directly with food animals and their manure.

In summary, some disease agents that may be transmitted to humans are shed in animal manure. It is known that these agents may contaminate produce via manure and thus lead to consumer illnesses. The degree to which agricultural workers, who are exposed to contaminated manure in the process of growing the vegetables, are infected needs to be determined. It seems reasonable to suppose that the field workers are more at risk than the consumer.

Size Distribution of PM₁₀ Soil Dust Emissions from Harvesting Crops

Robert T. Matsumura, Lowell Ashbaugh, Teresa James, Omar Carvacho,
and Robert Flocchini

INTRODUCTION

The majority of prior work on fugitive dust emissions in the U.S. has been related to wind erosion, paved and unpaved roads, agricultural practices, and source sampling of point or area sources such as construction and mining. Throughout this past work, the National Ambient Air Quality Standard for suspended particles has been based primarily on particle size:

- 1971 to 1987 — Total suspended particulate (TSP)
- 1987 to current — PM₁₀ or particulate matter less than or equal to 10 μm in aerodynamic diameter

The earlier TSP standard consisted simply of all particulate matter (PM) that could remain suspended in the atmosphere while the current PM₁₀ standard consists of suspended particles small enough to be inhaled and pose potential health effects. With the current reevaluation of the PM standard by the U.S. Environmental Protection Agency (EPA), another size cut at 2.5 μm has been recommended for compliance monitoring (Chow, 1995). The inhalation properties of the fine (<2.5 μm) particles are more relevant to health issues since they can be deposited deeper into the human respiratory system than coarse (2.5 to 10 μm) PM₁₀ particles. PM_{2.5} particles are also primarily secondary aerosols that form in the atmosphere and are more likely to contain hazardous chemical compounds.

Knowledge of fugitive dust size distributions may be important in determining which chemical compounds are associated with or adhere to suspended soil particles. Each particle size fraction has different inhalation properties that determine how far into the respiratory system the particles are deposited. For these reasons it is important that fugitive dust databases include species and size specific measurements. This is especially important because of the relatively wide particle size distribution of dust emissions.

HARVESTING

The San Joaquin Valley air basin, located in the southern portion of California's Central Valley, has been classified nonattainment for PM₁₀ primarily for exceedances that occur in the winter period. Fugitive dust is often the largest fraction of PM₁₀ in the summer and fall seasons (Chow

Table 80.1 Inventory of Top Ten Crops by Harvested Acreage in the San Joaquin Valley (SJV) Air Basin for Harvested Acreage and Cash Value in the SJV and California^a

Crop	Harvested Acreage in SJV ^b	Value (U.S. \$) in SJV ^b	Harvested Acreage in California ^c	Value (U.S. \$) in California ^c	California Share of U.S. ^c (%)
All cotton — lint	1,134,603	1,110,555,000	1,136,000	991,559,000	19.5
Hay — alfalfa and other	338,578	239,496,000	1,380,000	748,857,000	5.1
Grapes — raisin type	271,204	758,866,000	271,000	613,080,000	89.4
Almonds — all	208,093	577,805,000	402,000	911,430,000	99.9
Corn for silage	190,300	93,644,000	N/A	N/A	N/A
Grapes — wine type	149,340	354,949,000	307,000	854,485,000	89.4
Oranges — navel	107,543	424,250,000	114,000	277,008,000	26.7
Tomatoes — processing	106,900	179,862,000	274,000	529,038,000	92.7
Wheat	90,600	25,834,000	540,000	141,390,000	1.8
Walnuts	81,487	199,711,000	175,000	364,000,000	99

^a The California share of U.S. production is also included. Note that the dollar values in the SJV and in California are obtained from different sources, so they may not be consistent.

^c California Agricultural Statistics (1993).

et al., 1990). Many crops are harvested in the later part of this period. Table 80.1 shows the ten most widespread crops by harvested acreage in the San Joaquin Valley in 1993. Of these ten crops, the harvests of almonds, cotton, walnuts, and wheat were identified as possibly having high fugitive dust emissions. The purpose of this study was to evaluate the size of PM emitted during harvesting.

Beginning in 1994, the Air Quality Group of the University of California measured PM₁₀ fugitive dust emissions from the harvest of almonds, figs, walnuts, and cotton. The three orchard crops (almonds, figs, walnuts) are almost exclusively mechanically harvested using the same type of harvesting equipment. Their harvest entails three separate operations, although figs and walnuts combine sweeping and pickup into a single operation conducted simultaneously:

- *Shaking* of nuts from the tree onto the ground using a mechanical arm. (Figs naturally fall to the ground as they dry, so this operation does not apply to figs.) Almonds are allowed to dry on the ground for a few days.
- *Sweeping* of nuts or figs into windrows between tree rows using mechanical sweepers and blowers.
- *Pickup* of nuts or figs, using a harvester that gathers the nuts by sweeping, blows away dirt and debris, and unloads the nuts or figs into a trailer or bin container.

Cotton harvesting includes three basic operations. We examined only the first two in 1994.

- *Picking* of cotton from defoliated cotton stalks using revolving spindles to remove the cotton (with seed) from stalks. The cotton is then blown upward through tubes into a cage. Newer harvesters pick four or five rows of cotton during each pass, while older versions pick only two rows.
- *Stalk cutting* by flail shredders that cut and mulch the picked cotton stalks. Covered blades are spaced apart to cut several rows of cotton during each pass.
- *Stalk incorporation* using a disk to turn over the soil and incorporate the cut stalks into the ground.

METHODS

As part of our program to measure fugitive dust emissions from agricultural activities, we measured PM₁₀ and PM_{2.5} at locations upwind and downwind of various harvest operations. James et al. (1995), Flocchini et al. (1994), and Matsumura (1992) describe the sample collection and analytical techniques used. Table 80.2 summarizes the measurements. All aerosol samples discussed

^e Cahill et al. (1987).

here were collected at a height of 3 m above ground at distances ranging from about 3 to 100 m downwind of each harvested field.

Our PM₁₀ research focused on total gravimetric mass and geological material (soil dust). Through our suite of particulate measurements, we are often able to account for nearly all of the mass collected on Teflon filters. In this process, measured elemental species are converted to *composite variables* using some basic assumptions. For example, the majority of airborne soil is assumed to be composed of the geological material in their soil oxide forms plus a correction factor for other compounds, such as MgO, Na₂O, water, and carbonate. By measuring the soil elements and converting them to their soil oxide forms we are able to reconstruct the soil component of measured aerosols.

We refer to *reconstructed soil* as the sum of normal soil oxides calculated from our elemental measurements of particulate samples:

$$\text{SOIL} = (2.20 \times \text{Al}) + (2.49 \times \text{Si}) + (1.63 \times \text{Ca}) + (2.42 \times \text{Fe}) + (1.94 \times \text{Ti})$$

Table 80.3 shows how the conversion factors for each soil element were derived. Each conversion factor is divided by 0.86 to account for other nonmeasured compounds since the soil oxides account for 86% of average sediment (Lide, 1992). Potassium (K) is not directly used in the calculation of the soil composite because of a nonsoil fine potassium component from ambient

Table 80.3 Data Table Showing the Calculations Used in Deriving Reconstructed Soil from Elemental Values

Measured Element	Elemental Mass (g)	Soil Oxide	Soil Oxide Mass (g)	Soil Oxide/Element	Compositional Divisor	Conversion Factor
Al	26.98	Al ₂ O ₃	101.96	1.89	0.86	2.20
Si	28.09	SiO ₂	60.08	2.14	0.86	2.49
Ca	40.08	CaO	56.08	1.40	0.86	1.63
Fe	55.85	2*FeO+Fe ₂ O ₃	303.40	1.36	0.86	1.58
Fe (K)	39.08	K ₂ O * 0.6	56.50	0.72	0.86	0.84
Ti	47.90	TiO ₂	79.90	1.67	0.86	1.94

smoke. Instead, iron (Fe) is used as a surrogate for soil K assuming that the average K/Fe ratio for coarse particles is 0.6 ± 0.2 (Cahill et al., 1986). Iron is included as the sum of two iron oxides present in equal molar concentration and a potassium component that is derived from the measured Fe.

RESULTS

Table 80.4 compares $PM_{2.5}$ and PM_{10} for mass and reconstructed soil from filter measurements at the downwind field edges where harvesting operations occurred. *Close* sampler locations refer to downwind locations 3 to 10 m from the edge of the field while *far* represents locations 50 to 100 m downwind. To generalize the harvest emissions, all operations are included in the ratios. Upwind measurements were subtracted from the close and far measurements to isolate the harvest emissions.

On average, $18\% \pm 12\%$ of PM_{10} mass was less than $2.5 \mu\text{m}$, $74\% \pm 15\%$ PM_{10} mass was soil, and $46\% \pm 22\%$ of $PM_{2.5}$ mass was soil.

DRUM (Davis Rotating Drum Unit for Monitoring) impactor measurements provided reconstructed soil downwind of the operations in four size ranges less than $10 \mu\text{m}$: 0.07 to $1.15 \mu\text{m}$, 1.15 to $2.5 \mu\text{m}$, 2.5 to $5 \mu\text{m}$, and 5 to $10 \mu\text{m}$. We compared each size range of reconstructed soil against PM_{10} soil or the sum of soils from four DRUM stages (0.07 to $10 \mu\text{m}$). Figure 80.1 shows the average ratio of soil to PM_{10} soil in four size ranges for close and far sampling locations. This essentially provides the average size distribution of airborne soil, normalized to PM_{10} , for tested harvest emissions.

As expected, a majority of the PM_{10} soil was in the coarse size range (i.e., greater than $2.5 \mu\text{m}$). For the close sampling locations, the average ratio of the coarsest size range (5 to $10 \mu\text{m}$) was 0.49 ± 0.12 . The average ratio for the size range from 2.5 to $5.0 \mu\text{m}$ was 0.26 ± 0.08 , from 1.15 to $2.5 \mu\text{m}$ was 0.19 ± 0.09 , and from 0.07 to $1.15 \mu\text{m}$ was 0.08 ± 0.06 .

For both size ranges $< 2.5 \mu\text{m}$, the average ratios of far sampling locations were lower and within ± 0.03 of the close locations. In the coarsest particle size range, the far average ratio was also lower than the close, by 0.08 . Only between 2.5 and $5 \mu\text{m}$ was the far average ratio higher (0.40 ± 0.08) than the close (0.26 ± 0.08).

DISCUSSION

To simplify and generalize the results, our discussion of size distribution is restricted to relative size only and does not account for the actual concentration levels downwind of harvest emissions. For total PM_{10} crop harvest emissions, 80 to 85% were in the coarse size range between 2.5 and $10 \mu\text{m}$. Similarly for DRUM measurements, 75 to 81% of the PM_{10} soil emissions were in the coarse size range.

Table 80.4 Summary of Ratios for Mass and Reconstructed Soil by Size from Filter Measurements for Various Harvest Operations

Description	Sampler Location	Average Ratio	Standard Deviation	Variance	Number	Max.	Min.
$PM_{2.5}$ Mass/ PM_{10} Mass	Close and far	0.18	0.12	0.01	117	0.72	0.05
$PM_{2.5}$ Mass/ PM_{10} Mass	Close	0.15	0.07	0.01	62	0.41	0.05
$PM_{2.5}$ Mass/ PM_{10} Mass	Far	0.21	0.15	0.02	52	0.72	0.08
$PM_{2.5}$ Soil/ $PM_{2.5}$ Mass	Close and far	0.46	0.22	0.05	118	1.15	0.06
$PM_{2.5}$ Soil/ $PM_{2.5}$ Mass	Close	0.50	0.20	0.04	63	0.86	0.13
$PM_{2.5}$ Soil/ $PM_{2.5}$ Mass	Far	0.44	0.23	0.06	52	1.15	0.06
PM_{10} Soil/ PM_{10} Mass	Close and far	0.74	0.15	0.02	265	1.20	0.33
PM_{10} Soil/ PM_{10} Mass	Close	0.78	0.17	0.03	68	1.20	0.41
PM_{10} Soil/ PM_{10} Mass	Far	0.71	0.15	0.02	56	1.05	0.33

Figure 80.1 Average size distribution of reconstructed soil from harvest emissions, normalized to PM₁₀ soil. Soil size ranges include 0.07 to 1.15 µm, 1.15 to 2.5 µm, 2.5 to 5 µm, and 5 to 10 µm.

Our DRUM soil measurements showed an overall increase in soil quantity with increasing particle size. The far sampling locations suggest a natural maximum in soil mass between 2.5 and 10 µm aerodynamic diameter, while the maximum appears to be at 5 µm or greater for the close sampling locations. This difference between sampling locations can be attributed to the atmospheric deposition of coarse particles with transport of the dust plumes.

From filter measurements, soil accounted for 44 to 50% of PM_{2.5} harvest emissions and 71 to 80% of PM₁₀ emissions. The nongeological or unaccounted mass, such as organics, sulfates, nitrates, and volatiles, are significant, especially for PM_{2.5}. More site-specific composites for reconstructing soil based upon the soil source could increase the accuracy of our measurements.

CONCLUSIONS AND RECOMMENDATIONS

The data presented here provide general information on the size distribution of soil emissions generated by harvest operations. High variations of the calculated averages of PM₁₀ harvest emissions can be attributed to significant differences in the emission sources and to plume dispersion.

The concentration and composition of dust from harvest emissions are related to the agricultural practice (e.g., type of operation, implement speed, mechanical energy input, farm management) and the soil source (e.g., silt content, soil moisture, soil texture). On the other hand, the downwind impact of any dust source can be greatly affected by the environmental conditions (e.g., atmospheric stability, wind, humidity) that affect particle transport. Much additional work is needed to isolate these variables so that a generalized emission model can be constructed.

Evaluating Pesticide Effects on Ecosystems and Human Health: The Rotenone Application at Lake Davis

Marylou Verder-Carlos and Michael A. O'Malley

INTRODUCTION

Lake Davis is located in Plumas County (population 19,739), California, near the town of Portola (population, 2200; Rand, 2000). The lake and its tributaries are popular areas for boating and trout fishing, and also supply drinking water to Portola. In 1994, the California Department of Fish and Game (DFG) discovered illegally planted northern pike in the lake. DFG had successfully used rotenone to eliminate a 1991 infestation of Frenchman's reservoir, 15 miles to the east (Lee, 2001). DFG planned a similar treatment to eradicate the pike from Lake Davis, but quickly became involved in a community controversy that involved both legal challenges and a lengthy environmental assessment process (Roberts, 1996). Threats to DFG employees were even reported (Lee, 2001).

On October 15 and 16, 1997, a total of 49,000 acre-feet in the lake were treated. Deep water was treated with 15,785 gallons of a liquid formulation of rotenone (Nusyn-Noxfish™), containing 2.5% rotenone, 5% resin compounds, 2.5% piperonyl butoxide, and 90% naphthalene range petroleum distillate (a mixture of naphthalene, methyl naphthalene, alkyl benzene, toluene, xylene, and trichloroethylene [TCE]). Approximately 64,000 lb of a dust formulation (Pro-Noxfish™) was used near the shoreline.

The controversy over the eradication continued during the application itself: protesters gathered by the side of the lake and local officials chained themselves to a buoy in the middle of the lake. Other residents witnessed the application out of curiosity and some assisted DFG in the postapplication fish cleanup (Braxton Little, 1997a, b; Nacar, 1997a, b, c; Voet, 1997). After the application (La Ganga, 1998), local government representatives cited DFG officials for violating state water law, citing unexpected low level persistence of the adjuvant compound piperonyl butoxide (Braxton Little, 1997a,b; Martin, 1997).

TOXICOLOGY BACKGROUND

Rotenone is a pesticide of biological origin, extracted from the root, leaves, or seeds of various plants including cubé, derris, barbasco, haiari, nekoe, and timbo. The pure chemical is a colorless crystal with a melting point of 163°C, a vapor pressure of <1 mPa (<7.6 × 10⁻⁶ mmHg) at 20°C,

and molecular weight of 394.4. It is only slightly soluble in water, but readily soluble in acetone, carbon disulfide, ethyl acetate, and chloroform. It dissolves less readily in diethyl ether, alcohols, petroleum ether, and carbon tetrachloride. It decomposes on exposure to light and air, and is racemized to less insecticidal compounds by alkalis (EXTOXNET, 2000). Racemization occurs more rapidly in organic solvents and oils than in aqueous solutions (Ray, 1991).

Apart from the pike eradication project, reported use in California for 1997 included 386 lb (of active ingredient) in 9338 separate applications. Most of the use occurred on vegetable and nursery crops, with applications to lettuce accounting for slightly more than one third of the total (California Department of Pesticide Regulation, 1998).

Rotenone acts by poisoning electron transport in the mitochondria, a mechanism affecting a wide range of organisms. In the rat, the pure material has an LD₅₀ ranging from 25 to 132 mg/kg. Systemic poisoning, usually due to accidental ingestion, is associated with vomiting, respiratory depression or apnea, coma, and renal tubular necrosis.

Commercial rotenone products have presented very minimal hazard to humans (Ray, 1991). Some reports have noted numbness of oral mucous membranes in workers who got dust from the powered derris root in their mouths. Dermatitis and respiratory tract irritation have also been reported in some occupationally exposed individuals (Morgan, 1989).

California agricultural workers have experienced relatively few reported illnesses associated with the use of rotenone products. Between 1982 and 1995, 58 reported cases involved mixed exposure to rotenone and other pesticides, including organophosphates, carbamates, and pyrethroid compounds. These included 22 Ventura County lemon harvesters who reported dermatitis in 1988 after working in an orchard treated previously with rotenone and petroleum oil. The two cases of isolated exposure to rotenone involved both involved applicators, one with eye irritation and the other skin irritation.

Nonpesticidal Ingredients of Formulated Products

The aromatic hydrocarbons in the petroleum distillates contained in Nusyn-Noxfish have well-recognized irritant effects. The prototype compound, naphthalene, occurs commonly as white crystalline flakes, and has a vapor pressure of 0.054 mmHg (7199.4 mPa) at 20°C (American Conference of Governmental Industrial Hygienists, 1997). It also possesses a distinct coal tar, mothball, or menthol odor at concentrations above 40 to 84 ppb.

The threshold limit value (TLV) for naphthalene (10,000 ppb) was set in order to prevent ocular irritation (American Conference of Governmental Industrial Hygienists, 1997). The critical study was an industrial hygiene study reported by Robbins in 1951, who reported that indoor exposure to naphthalene over 15 ppm resulted in eye irritation. The number of subjects on which this observation was based is not described in the paper, but may have been the author's subjective experience of exposures he experienced while taking hygiene samples (Robbins, 1951).

Toluene is a colorless, highly flammable, and volatile liquid with an odor characteristic of aromatic hydrocarbons. Intentional solvent abuse or occupational exposures to 10 × 10 ppb can cause central nervous system depression and encephalopathy. Symptoms including headache and upper respiratory tract irritation may result from inhalation of 10,000, 75,000, or 100,000 ppb toluene for 4 to 6 h under controlled conditions. One should also note that ethanol has a potentiating effect to toluene. Xylene occurs in three isomeric forms and odor threshold ranges from 70 to 40,000 ppb. In general, various studies have concluded xylene is an irritant to the eyes, mucous membranes, and skin at levels above 200,000 ppb and the TLV has been set at 100,000 ppb. It can also cause narcosis at high concentrations.

TCE is a colorless, nonflammable liquid. It has a distinct sweetish odor similar to chloroform detectable at concentrations ranging from 180 to 5210 ppb. On topical application, it has typical primary irritant effect and pure TCE can cause localized pustular eruptions, pruritus, and erythema. Direct eye contact causes pain but not permanent corneal injury. Nonspecific systemic effects

include fatigue, irritability, headache, and gastric disturbances. Ethanol intolerance, known as degreaser's flush, may also occur. Exposure to caffeine and other drugs may also exacerbate the effect of TCE (American Conference of Governmental Industrial Hygienists, 1997).

Results of controlled studies with inhaled TCE in humans are the basis for the current TLV of 50,000 ppb. Although TCE is suspected as a carcinogen, extensive human epidemiological studies have failed to demonstrate development of excess numbers of cancers despite occupational exposure to high levels of TCE (American Conference of Governmental Industrial Hygienists, 1997).

METHODS

Follow-Up of Illness Reports

On October 16, 1997, residents around the lake and those who witnessed the application reported various upper respiratory and irritant symptoms. On October 20, 1997, the Department of Pesticide Regulation (DPR) received media reports of illnesses resulting from the Lake Davis treatment, and on October 23, 1997, DPR received the first Pesticide Illness Report from a physician's office in Portola and began receiving telephone complaints regarding the rotenone application. The illness registry staff initiated a telephone survey of those who consulted a physician, or who made a telephone complaint to DPR, DFG, Air Resources Board (ARB), or the Plumas County Department of Agriculture. The respondents were questioned about their exposure symptoms and medical history. Pesticide Illness Surveillance Program (PISP) staff developed a data file based on the results of the telephone interviews. The file included identifying information, exposure circumstances, and symptoms. Specific questions focused on eye and upper respiratory irritation, systemic complaints (headache, dizziness, nausea, diarrhea, vomiting, abdominal pain, etc.), and lower respiratory symptoms (bronchial pain, wheezing). Background medical history included allergies, cardiorespiratory, reproductive, and other problems of concern for each person interviewed. Similar information was recorded, where possible for subjects identified from illness reports but not available for interview. No medical records were available for review, and no resources were available to survey community members for unreported illnesses.

Air Monitoring

On October 18, 1997, the ARB emergency response team arrived at Lake Davis and established six air monitoring sites near and around the lake for rotenone, trichloroethylene, and aromatic hydrocarbons. Figure 81.1 shows the map of the air monitoring sites and the air monitoring results are displayed in Table 81.4 of the results section. The monitoring site closest to the Portola was the dam spillway, approximately 7 miles from the northern edge of the community.

RESULTS

A total of 71 individuals reportedly experienced symptoms between October 15 and October 29, 1997. Between October 24 and November 15, 1997, PISP staff conducted telephone interviews with 58 citizens of the Portola area who reported illness or injury possibly related to the DFG eradication program. Approximately nine proxy interviews were also conducted for nine children under age 16. Limited information was available for four individuals for whom pesticide illness reports were filed, but who could not be reached by telephone.

The 71 symptomatic residents included 29 males and 42 females (Table 81.1). Occupations varied, but most were retirees, homemakers, or students. The median age of the 66 individuals for whom an age was reported was 47 years, ranging from 2.4 months to 91 years. There were 8 children below 13 years of age (11%) and 11 adults between the ages of 61 and 91 (15%).

Figure 81.1 Map of air monitoring sites at the spillway below the dam for rotenone, TCE, aromatic heavy hydrocarbons, and other hydrocarbons.

Table 81.1 Summary of Age Distribution

Age Range (years)	Number of Subjects
< 1	1

^a Four adults and one student.

Table 81.2 Detection of Odor vs. Distance from the Lake

Distance	Noticed Odor	No Odor	No Information	Total
At lake/creek/dam	37	1	3	41
0.2–1 miles	18	1	2	21
>1 mile–8 miles	5	1	0	6
Not specified	0	2	1	3
Total	60	5	6	71

Circumstances of Exposure and Odor Complaints

Of the 71 subjects, 41 (57.7%) reported exposures at the lake, the dam spillway, or the creek immediately downstream during the application or in the week immediately afterward; 27 (38.0%) had exposures at distances ranging from 0.2 to 7 miles (in the town of Portola) but did not have direct contact with the lake, and 3 did not indicate their location at the time of exposure.

For 6 subjects, no information was available regarding the presence or absence of odor from the application. In the remaining 65 subjects, 60 (92.3%) reported smelling an odor after the rotenone application, at distances up to 8 miles from the lake (Table 81.2). Descriptions of the odor ranged from plain chemical smell, very strong odor, or extremely powerful odor, to more specific terms as creosote-like smell. Some described it as mothball-like odor, while others described it as insecticide or Raid-like odor.

Medical Evaluation, Medical History, and Medical Treatment Received

Of the 71 people reported sick (including the 4 subjects not available for interview), 20 were evaluated by either a physician or nurse practitioner, 27 were evaluated by a physician via telephone consultation, and 24 did not seek medical attention. Of the cases, 38 were reported to the illness registry from a single physician's office in the town of Portola, and 3 cases were reported from the community hospital emergency room. The remaining 30 cases were identified from telephone contacts only. These included 6 individuals who sought medical treatment at other primary care physician's offices, but were not reported by their providers to the registry.

The individuals interviewed reported symptoms that included ocular and upper respiratory irritation and nonspecific systemic symptoms. Irritant symptoms included sore throat, eye irritation, tearing, rash, coughing, and runny nose. Nonspecific systemic symptoms included wheezing, diarrhea, dizziness, headache, and nausea. There was no significant difference in the pattern of symptoms between those exposed at the lake and those farther from the site of the application (Table 81.3).

A few subjects reported unrelated, preexisting medical conditions, including six with a history of asthma, five with hypertension, two with a history of sensitivity to chemicals, and two with a history of recurring sinus infections. One individual stated she had bronchitis at the time of the application, and two individuals were recuperating from debilitating illnesses, one from a stroke and another from major surgery. Another individual experienced symptoms of diarrhea and abdominal pain before the treatment of Lake Davis. Other patients had fever in addition to nonspecific complaints of pharyngitis compatible with either chemical irritation or upper respiratory infection.

October 29	0.001	<1	3.07
October 30	<0.001	<1	1.78
October 31	<0.001	<1	1.13
November 1	<0.001	<1	1.61

Ten patients were prescribed antibiotics, and one child with gastrointestinal symptoms was sent for laboratory fecal analysis and culture. In one case a streptococcal infection was definitely diagnosed.

Air Monitoring Sites and Results

Among the six air monitoring sites ARB established, the site at the spillway below the dam was the location that generated the highest results and was also the closest to the town of Portola (approximately 7 miles to the south). At the five other sites, all samples confirmed significantly lower or nondetectable levels. Table 81.4 summarizes air monitoring results for the spillway below the dam.

According to the results reported by ARB, rotenone was detected at the spillway at very low levels (0.02 ppb) on October 18 and 19 and declined to nondetectable levels by October 30. TCE was detected only at the spillway on October 18. The levels after the 18 were less than 3 ppb until October 24, and less than 1 ppb on October 25 through November 1. Monitoring for aromatic heavy hydrocarbons showed the most significant levels with 281 ppb on October 18, 201 ppb on October 19 declining to 5.34 ppb on October 26, and dropping to 1.61 ppb on November 1. ARB terminated monitoring at the spillway on November 4 and at all other sites on October 29 because all samples were below the limit of detection.

DISCUSSION

On initial monitoring (October 18, 1997), air concentrations of naphthalene-range aromatics were markedly higher (201 to 281 ppb) around the lake than concentrations of rotenone (0.02 ppb), as would be predicted from the difference in their respective vapor pressures. Concentrations were highest at the dam spillway, with levels at or near the detection limit elsewhere. Although the measured concentrations at the spillway were below the reported 15,000 ppb TLV values, the occupational 8-h time-weighted-average standard (American Conference of Governmental Industrial Hygienists, 1997) is not based upon sufficient information (Robbins, 1951) to be used as an environmental exposure standard. Given the volume of liquid rotenone formulation used in the lake it is conceivable that local concentrations approached or exceeded the concentration necessary to cause eye and upper respiratory irritation and the nonspecific systemic symptoms reported by residents who were at the lake on October

15 to 17. As in previously investigated community environmental exposures to pesticides (Ames and Stratton, 1991; Scarborough et al., 1989) and waste-disposal by products (Shusterman et al., 1991), it is also possible that residents primarily reacted to the odor of naphthalene and related compounds present (Catanach, personal communication, 1997) in the liquid Nusyn-Noxfish formulation.

Given the 7-mile distance between the south end of the lake and the northern end of the community it seems less likely that levels of naphthalene present in Portola approached the existing occupational exposure thresholds. No air monitoring was conducted in the community, so it is not possible to ascertain whether community air concentrations approached the reported odor threshold for naphthalene (40 to 84 ppb). However, two individuals exposed at a distance of greater than 7 miles from the lake also reported noticing the odor from the rotenone application. The symptom complexes reported by those exposed at the lake were similar to those reported by persons exposed at distances of 0.25 to 1 mile, or those exposed at distances more than a mile. Both groups reported symptoms of eye and skin irritation and nonspecific systemic complaints (Table 81.4).

It was not possible, given available staff resources, to survey all 16,000 Plumas County residents or the 2000 residents of the community of Portola. It is therefore probable that symptoms possibly associated with the rotenone application occurred in some community members that were not reported to the illness registry. In this connection, no illness reports were received for six residents interviewed by telephone who stated that they had visited their own physician for symptoms they associated with the rotenone treatment. It could not be ascertained from the available information whether the treating physicians were unaware of the illness reporting requirement or simply considered the reported symptoms to be unrelated.

In addition to underreporting, it is possible that some symptoms actually unrelated to the application were captured in the mix of telephone complaints and physician-reported illnesses. In case 6, for example, a student who spent October 15 picking up dead fish at the lake was reported to have pharyngitis due to a streptococcus infection. It is ambiguous whether any of his symptoms (dyspnea, pharyngitis, abdominal pain) were actually due to petroleum distillate exposure at the lake. This example underscores the possibility that any hypothetical survey to determine the prevalence of eye and upper respiratory irritation and nonspecific systemic symptoms associated with the rotenone application would have been biased by the accompanying community controversy (see above).

Several illness episodes have been reported to the California pesticide illness registry that also involved off-site movement of a pesticide or its inert ingredients to adjacent areas. One 1994 episode involved 49 Pacific Gas and Electric employees who noticed an intense odor and developed symptoms following a chlorpyrifos insecticide formulated with naphthalene pesticide application to a cotton field about a quarter of a mile away. In 1995, the manufacturer changed the formulation to use a less odiferous carrier solvent. Nevertheless, a 1996 Kern County episode, involving chlorpyrifos formulated with the same naphthalene-range aromatic solvent, affected more than 500 workers. In these cases, the odor of the naphthalene solvent was probably mixed with the odor of mercaptan contaminants (O'Malley, 1997) present in the formulation.

Pike Reappear

A final controversy arose when pike were rediscovered in the lake in May 1999 (Lee, 2001). Did some pike survive the treatment or were they replanted in the lake (Lake Davis Steering Committee, 2001)? Was it possible to control the pike by electrofishing, nets, or would it be necessary to attempt retreatment with rotenone (Lassen County News, 2000)?

CONCLUSION

In the pike eradication program, some exposures occurred because of direct contact of community residents with the lake at the time it was treated. Symptoms included eye and respiratory

irritation, as well as nonspecific systemic symptoms. In nearly all cases, symptoms were associated with a perceived odor, described as being like menthol or like insecticide. Evaluation of cases was confounded by community controversy about the eradication program, the absence of monitoring data for the days the application took place, and the lack of an appropriate standard for environmental exposure to naphthalene-range aromatic compounds.

SECTION II.8

Mining Impacts

Overview: Mining Impacts

Jean Lebel

The models used for illustrating and conceptualizing the relationship between the environment and human health have advanced considerably over the past century. The modeling of human health from the perspective of interactions between humans and their surroundings was initially colored by the experience of the biomedical world and the spread of infectious diseases. Yet the world is subject to the influences of many complex factors that have the potential to undermine health and that cannot be controlled by a reductionist medical approach alone, no matter how sophisticated such an approach might be.

The ecosystem approach to human health constitutes a bridge between a strategy for integrated management of the environment (healthy ecosystems) and a global, ecological approach to promoting human health. The ecosystem approach to human health offers an unequaled opportunity to promote human health through an enlightened approach to management of the ecosystem. The creation of more sustainable ecosystems relates to the management of natural and environmental resources, of course, but it must also take account of all the many anthropogenic components, by integrating the social, economic, and cultural factors pertaining to the living environment. The ecosystem approach to human health is also dependent on a participatory and transdisciplinary research methodology that will remain sensitive to gender and other issues of social equity.

Within the context of mining, this ecosystem approach to human health represents a challenging and appealing way of trying to better understand the various effects on human health of this important economic activity. This approach also assists in developing intervention strategies that are effective and sustainable.

The chapters presented in this section are some of the keys that will open the door to a new world of knowledge. The particular focus given to the developing nations within this section reflects the importance of this sector in the economy of a growing number of countries. It also reflects the programming of Canada's International Development Research Centre (IDRC), an international aid agency that sponsored the participation of international scientists in the technical sessions related to mining at the 1999 International Congress on Ecosystem Health.

This section begins with a broad overview by Lebel and Burley of the effects of mining operations on the ecosystem, and on communities that are involved directly or indirectly in these activities. The authors point out that the complexity and dynamic nature of many of the relationships require an integrated framework in order to truly understand the damaging as well as the beneficial influences of mining. Following this introduction of the mining world, Shields and Šolar discuss some fundamental issues of scale related to selection and interpretation of mineral indicators. For time as well as space scales, the researchers are always selecting a certain perspective when studying

an ecosystem. The importance of knowing the limitations or the appropriateness of the scale in ecosystem approaches to human health research is fundamental.

As mentioned earlier, the human health concept has evolved significantly over the years. Maclean et al. present some of these concepts and make a good case for moving beyond the traditional ill-health conceptual framework, given the broad array of effects of mining activities that are linked not only to the development of diseases. In a related vein, Echavarría Usher invites us to pay particular attention to a population group often affected by mineral development: indigenous peoples. Through her work in Colombia, the meaning of health and well-being takes an entirely different aspect from the mainstream vision — a vision that needs to be included in intercultural research. Mergler integrates many of the previous points on human health in the conceptual frameworks she is presenting. With an overall goal of integrating in a sound manner human health within an ecosystem approach to mining, she demonstrates — through the use of a nested, hierarchal framework — the need to examine different effects of this activity, from the mine sites to distant populations. She also makes an eloquent case for the need to focus more on early changes in biological, psychological, and social parameters if one wants to take a preventive approach to human health.

Researchers are confronted by difficulties in the analyses and in understanding the complex and diverse links of the different issues related to human health that are raised through consultative process by a broad spectrum of stakeholders who are involved directly or indirectly with mining activities. Those complexities and difficulties in understanding can make researchers and policy makers reluctant to use an ecosystem approach to human health. This should not be the case. Noronha presents a brilliant case study in which the use of a multistakeholder consultation process for the identification of issues of the biophysical, economic, and sociopolitical-cultural domains served as the basis for development of tools to measure the contribution of mining over time toward the sustainable development of the iron mining region of Goa, India. The tools are indicators, quality of life instrument, and impact-adjusted income account. The last case study relates to the situation in the Langat Basin, a region of Malaysia. Through the use of different indicators, Pereira and Komoo demonstrate the possibility of evaluating the effects of the exploitation of mineral resources. Through careful use of information available from different sources, they show how measurement over time can reveal progression or failure to achieve a more sustainable use of mineral resources.

We hope that the views provided in this section will help the research community and policy makers to move toward the development of an integrated framework linking findings with actions.

The Ecosystem Approach to Human Health in the Context of Mining in the Developing World

Jean Lebel and Lisa Burley

IDRC AND THE ECOSYSTEM APPROACH TO HUMAN HEALTH: AN INTRODUCTION

The International Development Research Centre (IDRC) is a public corporation created by the Parliament of Canada to help researchers and communities in the developing world find solutions to their social, economic, and environmental problems. IDRC connects people, institutions, and ideas to ensure that the results of the research it supports and the knowledge that research generates are shared equitably among all its partners, north and south.

Program initiatives (PIs) are the IDRC's primary programming unit for funding research in developing countries. Managed by a multidisciplinary team from within the IDRC, PIs are working networks that link southern and northern researchers to address specific research problems and set a research agenda. By linking all the parties involved in the research process, IDRC hopes to add to the likelihood of success. Because of the interdisciplinary focus, PIs will often address issues that fall under several research themes.

The purpose of the PI Ecosystem Approaches to Human Health (ECOHEALTH) is to improve human health while simultaneously maintaining a healthy ecosystem.* We are referring to the concept of health as defined by the World Health Organization in its constitution, "Health is a state of complete physical, mental and social well-being, and not merely the absence of disease or infirmity." To this end, the PI supports research projects, all of which are carried out in developing nations, that explore the structure and function of stressed ecosystems on which people depend for their lives and livelihoods. Research projects have a mix of several characteristics, they are trans-disciplinary,** social and gender sensitive,** and participatory.****

The Ecosystem Approach at IDRC (1) begins with the ecosystem as the point of departure for understanding the nature of the stressor and for improving human health, (2) embraces a particular

* Broadly speaking, an ecosystem is a dynamic complex of plant and animal (including human) communities situated within a given environment. The boundaries of ecosystems often have more to do with the parameters that humans set arbitrarily according to the scientific, management, or policy question they wish to examine rather than with physical dimensions.

** *Multidisciplinary* research involves different disciplines that have parallel input without necessarily consulting one another. *Interdisciplinary* research implies some degree of integration between the different disciplines in relation to the problem at hand (IDRC, 1993). *Transdisciplinary* means transformation, going beyond disciplinary mind-sets into a re-conceptualization of phenomena, problems, goals, and approaches (Peden, unpublished 1999). The need for a transdisciplinary approach arises from developments in knowledge and culture that are characterized by complexity, hybridity, nonlinearity, and heterogeneity (Klein, 1994).

concept of human health, and (3) promotes research methodologies that are derived from a holistic vision and can effectively respond to the various dimensions of the human health concept.

The PI emphasizes improving health using ecosystem management as compared to relying only on health sector interventions. ECOHEALTH encourages and supports research activities intended to further develop methodology, to increase understanding of causal linkages between ecosystem management and human health, to test ecosystem-based interventions, and to disseminate the concept and research results to diverse stakeholders. The knowledge generated from research is applied to the development of effective and sustainable interventions and policies.

The PI focuses on several ecosystem stressors, one of which is mining. Like other stressors, this activity presents risks to human health and the environment. It also creates benefits for communities and individuals in these ecosystems. The PI recognizes that sustainable alternatives that promote the health of both humans and the ecosystem depend on the participation of all members of the community.

This chapter attempts to demonstrate that the sustainability challenges posed by the stress of mining on ecosystems affect the physical, mental, and social well-being of communities through various changes in mediums, such as the quality of air, water and food, and conditions, such as socioeconomics, culture, and politics. The chapter also attempts to illustrate that addressing these challenges requires methodologies that bring together various disciplines, that include and empower those people directly involved in and affected by mining activity, and that incorporate sensitivity to gender and sociocultural issues. In short, the purpose of this introductory chapter is to underline that an ecosystem approach to human health can provide stakeholders with a conceptual framework appropriate to tackling the many concerns and factors involved in mining in the context of developing nations.

MINING IN THE DEVELOPING COUNTRY CONTEXT: WHO ARE THE MAIN STAKEHOLDERS AND WHAT ARE THE MAIN ISSUES?

This section refers to generalities and broad categories in order to identify the principal stakeholders and some of the central challenges they face regarding the ideals of ecosystem and human health.

Governments

A recent change in exploration trends has been geography. With the dual (yet not necessarily causal) phenomena of democratization and the adoption of neoliberal policies for trade and foreign investment (Brown, 1994), many governments of developing nations have created conditions conducive to attracting foreign investment by revising mining law and policy. Walde (1992) points out, however, that the typically centralized structure of many developing nation governments means that authority over mining issues does not rest at the local level. In addition, formal mechanisms usually do not exist for involving local people in decisions made at the central or national government level (Clark, 1998). Many nations have made efforts to decentralize central government

*** Socially sensitive research is aware of the implications of age, gender, ethnicity, occupation, class, etc. on various social aspects such as power and decision making. Gender sensitive research recognizes that women and men have different interests, concerns, priorities, and needs. Research is therefore (1) aware of what men's and women's differences and needs are, and addresses the research issue accordingly, and (2) proposes to explore gender differences as part of the research (Kabeer and Subrahmanian, 1996; Singh, 1999).

**** Participatory research is broadly understood, and includes a plethora of tools and methodological approaches, including such commonly used methods as Participatory Rural Appraisal (PRA), Participatory Action Research (PAR), Rapid Rural Appraisal (RRA), and Farmer Participatory Research. Rooted in ideological and radical social movements which mobilized local people to challenge existing power regimes, participatory research has become increasingly popularized as a means of capturing local knowledge and perspectives and for involving local people in research and development activities which affect them (McAllister, 1999).

authority. Labonne (1999) points out that this decentralization has brought to the fore the necessity for good regional and local governance since these authorities will impact on the relationship between investors and the community. Labonne also points out that regional agencies often have weak capacities for management and regulation, and due to rural–urban migration, local governance structures are often in a constant state of change. Tyler (1999) explains that most government reforms involving natural resource management in many developing nations are almost always inadequately supported. Decentralization of authority from central to regional governments has not been accompanied by adequate funding, training, or capacity-building among the officials charged with implementing the policies. Further, Tyler reports that as a result, enlightened policies may either fail to be implemented or be implemented very differently at the local level than intended by policy makers.

Industry: Juniors and Majors

Lured by revised mining laws of many developing nations, and in the case of Canada, discouraged by high tax rates, stringent environmental regulations, expensive labor, and the excessive withdrawal of land from mineral exploration (Natural Resources Canada, 1993), junior* and major companies from this nation, Australia, and the U.S. began investing in exploration. For example, Canadian mining investment in Latin America began to increase in 1991. By 1993, the amount of investment created a veritable boom, which began to reshape the mining industry. Most of the junior firms leading this boom were Canadian and were funded through Canadian capital markets (Natural Resources Canada, 1997).

The studies of Pascó-Font (1998) have outlined that in the absence of proper environmental legislation, junior companies are more likely to behave irresponsibly. McMahon (1998) also observes that demands by communities for consultation are largely accepted by major companies, but less so by the juniors. McMahon also explains that juniors resist formal consultation processes as they wish to avoid a costly procedure given the small likelihood of actually finding an exploitable deposit. Moody (1998) outlines that this situation presents concerns since it is the junior mining companies, supported with venture capital raised on Canadian stock exchanges, that are conducting a large portion of exploration activity not only in Latin America, but also around the world.

The exploration budgets of the larger or major Canadian-based companies for Latin America and the Caribbean have grown at an average annual compound rate of over 50% between 1992 and 1997. In 1997, these companies held the largest share of the larger mining company market in all of Latin America (Canadian Intergovernmental Working Group of the Mineral Industry, 1998).

Although many mining companies now recognize the importance of community participation, many of them struggle with issues regarding *how* to involve communities. Prager (1997) explains that part of this problem is due to corporate culture. She points out that decision-making levels of company management do not often include social scientists, and rarely confront issues with an inter- or transdisciplinary approach. Indeed, the international Advisory Group made up of stakeholder representatives of the IDRC Mining Policy Research Initiative flagged the importance of research responding to corporate concerns of relationship building with civil society (MPRI, unpublished 2000).

* Broadly speaking, a junior firm is specialized in the exploration activities needed in order to detect a claim with a sufficient value to develop a mine. Juniors sell their concession rights to larger mining companies to continue with advanced exploration, feasibility studies, and, perhaps, exploitation.

Industry: Small-Scale and Artisan Mining*

This kind of mining is currently experiencing a resurgence around the world. In many cases, it is a response to poverty. It provides employment to unskilled workers and supports local economies. However, through contraband, taxes are evaded thereby precluding economic benefits to the national economy, although direct and collateral benefits are very important. Confrontations often arise with resident communities, and environmental impacts are severe. In addition, working conditions are very precarious. Developing nation governments experience many problems exercising control over small-scale and artisan mining (Wotruba et al., 1998).

Communities and Ecosystems

Another key stakeholder in the context of mining expansion in developing nations are people and ecosystems. Crane-Engel and Schanze (1988) point out that although some developing nations have a mining history, generally speaking, industrial large-scale, privatized mining has traditionally been an activity of wealthier nations of temperate climates. This geographical shift to more southern nations involves several different characteristics including pervasive poverty, considerable wealth disparities, large rural populations, and the conditions of a tropical climate where contaminants may infiltrate food chains more readily than in temperate or permafrost regions (Ripley et al., 1996). In many developing nations, ecosystems are already under stress from the many ways in which they are being used to provide subsistence needs and to support primary industries important to the export sector, such as foodstuffs, flowers, fish and sea products, timber, oil, etc.

In short, the developing nation context involves extremely vulnerable populations where the needs for economic development and the risk of falling to greater depths of poverty are acute. Since many subsistence livelihoods, some national industries and parts of the export sector are often linked to the natural resource base, ecosystems are equally vulnerable to overharvesting that may result from poverty increases and to contamination from misuse.

Clark (1998) observes that although many developing nation governments have emphasized mineral development and the creation of an attractive investment climate, they have not offered guidance to foreign mining companies regarding how to proceed with social and cultural issues. This skill set is precisely what industry is lacking; for junior companies, small-scale and artisan mining, problems also arise with the investment required to appropriately respond to socioenvironmental issues. The development of artisan and small-scale mining face several challenges and the costs and benefits of this activity continue to be the subject of considerable controversy (Wotruba et al., 1998).

Governments are also grappling with either centralized decision-making structures or the challenges posed by the transition to decentralized authority where regional and municipal agencies lack financial support and capacities to implement regulatory policy. Nonetheless, many aspects of revised mining laws have attracted and continue to attract investment in mineral development.

THE ECOSYSTEM AS THE POINT OF DEPARTURE: WHAT IS THE NATURE OF THE STRESSOR AND GENERAL IMPACTS ON THE ENVIRONMENT?

Mining is a complex and diverse activity. This section will speak more to broad categories, than of specific situations with a view to providing the reader with information in order to appreciate the complexity and diversity of the stressor under study.

* While there is no universal definition of small-scale and artisan mining, it may generally be characterized as being labor-intensive and utilizing low technology. Workers generally have little or no formal education and often have few options for making a living (Peiter et al., 2000).

The extent of mining impacts on ecosystems and human health are influenced by the several different ways mining can be done. Broadly speaking, four categories of mines can be described according to organizational structure, investment level, production level, and technological capacity: large, intermediate, small, and artisanal scale mines (IENIM, 1996). For the purposes of this chapter, large and intermediate mines will be grouped together, and small-scale and artisan mining will also be referred to as a single category.

The mining of each mineral commodity has its own distinctive set of environmental and health impacts. All of these effects are not equal in their significance, but at every level, there is the possibility of uptake and exchange of residuals by organisms (Ripley et al., 1996). In the case of small-scale and artisan mining, costs and benefits also vary according to the type of mining. For example, alluvial gold mining and the extraction of precious stones have far greater socioenvironmental costs, are more difficult for governments to control, and more likely to become contraband than coal and phosphate mining and quarrying (Wotruba et al., 1998).

Mining development in general involves three broad stages: (1) exploration and construction, (2) operation, and (3) closure and site rehabilitation (Ripley et al., 1996). While considerable randomness characterizes the length of the life cycle of these stages with small-scale and artisan mining, it is an extensive process with large and intermediate mines. Typically, exploration can go on for 5 to 10 years, with mine construction in the order of 1 to 3 years. Operation varies greatly, depending on market conditions but can easily exceed 50 years. Closure can take 2 years, and physical rehabilitation is highly variable, depending on the level of disruption and damage to the environment (Ripley et al., 1996), and the demands and lobbying influence of host communities.

Exploration and Construction

Typically, at the exploration stage of large and intermediate mines, the likelihood of significant biophysical damage to the environment is limited in extent and scope. Generally, exploration involves geochemical or geophysical techniques, followed by the drilling of promising targets and the delineation of orebodies. The early stages of exploration can be carried out using remote-sensing methods from satellites and aircraft. As promising areas are located, low-flying aircraft and ground-based exploration methods are used (Ripley et al., 1996).

In terms of environmental effects, exploration may affect more terrain than subsequent mining stages, but for a shorter duration and with less severity. Ripley et al. (1996) outline some environmental effects:

- Low-flying aircraft can affect people and wildlife.
- Exploration grids may leave visible scars that may also disturb wildlife and lead to considerable erosion.
- Trenching and stripping may have long-term effects on nearby waterways.
- Drilling may contribute to contamination of surface and groundwater.

Overall, however, road construction and transportation are frequently the main source of environmental impacts, depending on who uses them, and how much they are used after they are built (Ripley et al., 1996). Some sources claim that for each operational mine, up to a 1000 exploration programs have been conducted (EMCBC, 1998).

If artisan prospectors and explorers locate a significant deposit exploitable with low technology, often times considerable and immediate migration to the area occurs, resulting in an invasion of artisan miners. Since these areas are usually remote and because the invasion occurs quickly, enforcement of environmental laws is usually ineffective or nonexistent (Peiter et al., 2000). Indiscriminately, trails and roads are opened, timber is extracted from the forest, nearby water sources tapped, and *ad hoc* construction is undertaken. All of this is considerably damaging to the host ecosystem.

Operation

Many of the environmental impacts of small-scale and artisan miners are rooted in their lack of capital to invest in cleaner technologies, their own mentality and occupational culture, and their notorious ignorance of environmental issues and management. In the case of gold mining, host and surrounding ecosystems are seriously affected by (Wotruba et al., 1998):

- The removal of vegetal layers
- Poor air quality
- Dust
- Noise
- Water contamination
- Alteration of water courses
- Mercury contamination
- Effluent mixes of lubricants, oil, sulfur oxides, and heavy metals as part of water and ground contamination
- Erosion

Indeed, all mining is characterized by its awesome generation of gaseous, liquid, and solid waste material, a large portion of which can be classified as hazardous. Wastes are in the forms of overburden, tailings heaps, slag, sludge, mineralized toxic waters, smoke, and gas emissions (Pastizzi-Ferencic, 1992). For example, in the large-scale copper mining industry, the ratio of material handled to units of marketable copper metal is 420:1 with a typical ore grade of 0.6% (Dudka and Adriano, 1997).

Waste materials may be chemically reactive and, consequently, generate soluble acids or alkalis, soluble metal salts, and radionuclides. Liquid wastes can be produced by such reactions or directly by the processes themselves (Ripley et al., 1996). The potential for dispersion of the solid particulate of waste materials in many environments is also enhanced by climatic conditions (Ripley et al., 1996). Many of the mining sites in the developing world are in desertic or semidesertic regions where the eolian factor is important.

The most common and serious problem faced by large and intermediate mines in waste disposal derives from the mining and processing of sulfide ores, which can produce acid drainage. Essentially, this is the result of the chemical reaction that takes place when a metal sulfide combines with oxygen and water, yielding a metal hydroxide precipitate and sulfuric acid (Ripley et al., 1996; Dudka and Adriano, 1997). In Peru, numerous rivers have been declared biologically dead because of the leaching process of toxic materials (Ride, 1998).

Closure

Historically, mining operations were abandoned when they reached the end of their useful lives. Virtually all abandoned mines were operated during a time when environmental standards were less stringent than they are today; disturbed sites, waste dumps, and mine structures were seldom reclaimed. As a result, altered surface topography, surface and subsurface drainage, disturbed vegetation and soil, and abandoned roads and buildings were left behind after the operation ceased (Ripley et al., 1996). Abandoned mines present the risk of environmental problems that include acid drainage and metal contamination.

Most discussions of reclamation have centered on the damage done to land surfaces; however, mining also has environmental effects in other areas that include damage to water bodies, hazards to human health and property, and dangers to fish and other wildlife. An approach to the subject of amelioration requires a comprehensive view that emphasizes the interrelations between the various spheres of influence (Summers and Lewko, 1995).

It is important that developing nation governments often do not have sufficient resources to rehabilitate areas abandoned by large and intermediate mining companies. Small-scale and artisan operations are almost always left abandoned.

WHAT ARE THE IMPLICATIONS FOR HUMAN HEALTH?

McMahon (1998) states that social implications of large mine development have displaced the environmental concerns at the fore of the public debate on mining investment. This section will outline some issues of human health and mining. A full discussion of the topic covering the various types and stages of mining is beyond the scope of this chapter.

Physical Health

In terms of physical health in the occupational context, it has been recognized for a long time that working in a mine is a dirty job. Some of the most ancient cases of occupational disease were documented through the analysis of data coming from the population of miners. Dusty environments have been the basic cause for the development of different respiratory diseases of workers in mining operations (Reger and Morgan, 1993). For example, there is thorough documentation of coal mining and black lung disease (Weeks, 1993; Oxman et al., 1993), quarrying and silicosis (Wagner, 1997), asbestos mining and mesothelioma (McDonald and McDonald, 1996; Wagner, 1997), uranium mining and lung cancer (Samet, 1991). The Pan American Health Organization (PAHO) estimated in its 1994 *Work Illnesses* report that 8.5 million workers in Latin America from the mining, quarrying, ceramics, metallurgical, and construction sectors were at risk of developing silicosis (Joyce, 1998). Noise and vibration are also common problems encountered in the workplace, as are exposure to heat, mine gases, and to chemical vapors (Burgess, 1981).

Mining operations can also potentially affect the health of people who are living at a distance from the mine due to the effects of fallout gases and solids or dispersion of toxic materials to crops, farm animals, and food obtained from undomesticated sources such as fish or game.

For example, a major concern for the physical health of the greater community involves the contamination of groundwater, and thus of wells. Recent studies have shown in region II of Chile, an area of intense copper mining, that bladder and lung cancers were significantly associated to exposure to arsenic present in drinking water. Researchers estimated that arsenic might account for 7% of all deaths among those ages 30 and over (Smith et al., 1998). Similar evidence was found in other regions of Chile where copper is also mined (Ferrecio et al., 1998).

Castro-Larragoitia et al. (1997) provide another good example illustrating the complexity of health issues with the case study from the semiarid region of La Paz/Sao Luis Potosi in Mexico. Two hundred years of mining activities resulted in the significant accumulation of tailings, which had been dispersed by the wind over an area of 100 km². There was also leaching of toxic material in the surrounding river system that was used for irrigation purposes. Monitoring results have shown high concentrations of cadmium, lead, and arsenic in the leaves of corn used to feed cattle. The transfer of these contaminants to humans through the consumption of food have yet to be evaluated.

Another missing piece in the evaluation of the impact of mining on physical health involves a lack of clarity regarding the origin of the source of contaminants. To what extent is the source anthropogenic, resulting from mining activity, or naturally occurring? By identifying the origin of the different sources of the contamination, it is then possible to have a more global picture of the situation and to develop intervention measures that are more likely to be effective for the entire community. This information is crucial for the development of mitigation measures that will appropriately reduce human exposure.

For example, research in the Amazon has shown that exposure to low levels of methylmercury originating from the consumption of fish can adversely affect the nervous system of riparian

populations at levels lower than what had been reported in other studies (Lebel et al., 1996, 1998; Mergler et al., 1999). Although the original source of mercury was associated with the discharge of the substance from the artisanal mining, transdisciplinary research conducted with an ecosystem approach to human health revealed that agricultural slash-and-burn practices, in addition to artisanal mining, were also responsible for contamination of fish and deleterious human health effects. Erosion and lixiviation of mercury-loaded soils now appear to be the main contributors at the global level of the Amazonian Basin, while mining is the main source for areas surrounding mining sites (Roulet et al., 1999).

The above examples are only an infinitesimal illustration of the literature on physical health and mining. Indeed, there is much ground to cover when it comes to evaluating the health impacts of mining operations ranging from mental health and social well-being of communities as well as physical health.

Mental Health and Social Well-Being

There is a growing body of literature dedicated to the impacts of mining on culture and society; only a few highlights are mentioned here.

Social Well-Being

It cannot be denied that many people have benefited from the products derived from mining. The industry has favorably contributed to economic growth, particularly at the macro level. Yet, debate exists among researchers regarding the extent to which benefits are experienced by host and nearby communities. In the context of developing nations, recent research on large-scale mining questions the potential of this option for rural development. McMahan's (1998) conclusions from various studies state that large, technified mining requiring skilled workers creates little employment in rural areas in developing nations. He also adds that this kind of mining has tended to have a small multiplier effect since local, and sometimes national, economies of developing nations are not sophisticated enough to provide inputs to mining processes.

Pascó-Font (1998), a researcher from Peru, observed that whatever the macroeconomic benefits of a particular mining investment might be, most of the costs it generates, especially those involving the environment, are borne at the local level. In addition, the opening of new roads to rural areas often brings large numbers of migrants, many of whom remain in the area. The work of Sassoon (1998) shows that frequent conflicts arise between original residents and newcomers regarding territory, land use, and resource competition. Pascó-Font (1998) also cautions that his research results do not clarify whether the benefits of large-scale mining outweigh the costs at the community level.

The social impact of large-scale mining expansion also affects the lives of many women. In many Latin American countries, it is against the law for women to be employed in underground mines (Robinson, 1998). In addition, social and cultural values consider women in mines as taboo or bad luck (Robinson, 1998). This means that many new jobs created by mining expansion are not accessible to women. In addition, Robinson (1998) underlines that the low-cost labor of men from developing nations has been sustained and subsidized by unpaid female labor in the household, on farms and at markets.

Based on her work in Indonesia, Robinson (1998) examined several features of the place of women in a large-scale mining community. Some women become contract or second wives of mine workers while workers remain away from their original families. This literally multiplies the effects of migrant labor on family disruption, leaving women left with the burden of raising and providing for children alone. Robinson also points out that male-dominated mining towns create a thriving market for sexual services, in which women, and also some men and children, participate through prostitution. Robinson's observations also included growing incidences of alcoholism, sexual

assault, and other forms of violence against women, as well as teenage pregnancy. She concluded her work stating that, for many local people, mining expansion is changing attitudes toward sexuality and the role of women.

In terms of small-scale and artisan mining, the International Labour Organization (ILO) has flagged several important issues related to women. The current type and participation of women in this kind of mining means that they derive fewer benefits than men. Women need improved access to finance and law reforms, and discrimination needs to be removed which prevents women from holding assets and obtaining finance. Women often retain the primary responsibility for child and family care, so their participation in mining is accompanied by a search for balance with reproductive roles. Medical risks are also presented to women in the early stages of pregnancy (ILO, 1999).

Child labor is also found among small-scale and artisan mining operations, and in some countries, there is a gender component where boys are favored over girls. As a result of poverty, lack of education, and other opportunities, children are exposed to many occupational and health risks. Due to the financial crisis in Asia, there is evidence that child labor in small-scale mining is increasing. However, immediate removal of children from hazardous work and small-scale mining might result in further economic hardship through the denial of livelihood and income (ILO, 1999). The ILO also notes that in Ecuador, women and members of mining families were found to be key agents of change on questions of health and the environment.

In some cases, small-scale and artisan mining has become the mainstay of many rural economies (Labonne, 1994). It has created employment and provided workers with the potential to become economically self-sufficient (Davidson, 1993; Traore, 1994). It has also served to curb urban migration, which has been a serious socioenvironmental and health problem in many developing nations (Labonne, 1994).

Nonetheless, this type of mining has led to significant rural-rural migration, bringing instability to resident and indigenous communities. The isolated locations of small and artisan mining centers also gives rise to crime, and confrontations with settled communities who rarely benefit from the value of the extracted mineral. Invasions can bring changes to local systems of values and ethics, and in extreme cases, governments can lose control over the situation, as were the cases in Serra Pelada of Brazil, Muzo in Colombia, Nambija in Ecuador, and Mindanao in the Philippines (Wotruba et al., 1998). It has been pointed out that an extremely important externality of small-scale and artisan mining is the irreversible nature of cultural damage due to entry or invasion of sensitive tribal lands (McMahon et al., 1999).

Culture: Individual and Collective Mental Health

The impacts of mining on culture are better grasped by first defining parameters for the concept. While culture is the subject of intense study and debate within the field of anthropology, James Peacock (1989) provides an explanation useful as a point of reference to discuss impacts of mining. Peacock writes that culture is *partly* a manifestation of continuous negotiation among people regarding the role that established norms and values will play in dealing with routine and complex issues. Peacock argues that culture is dynamic, and can be seen as a subtext in everyday interactions requiring decisions and adaptation. This explanation draws attention to the linkages between culture — a system of beliefs and values as part of the identity of individuals and community — and dealing with practical issues. Peacock's work underscores two key issues to consider when looking at the impacts of mining on culture: (1) the pace of introduced change, and (2) the adaptability of individuals and their community.

Clark (1992, 1997) has argued that mining has its greatest impacts on rural, subsistence-based people. In these contexts the mode of production, often family-based agriculture and husbandry, plays a central role in individual, household, and community identity, and is inextricably linked to cultural values and beliefs. Gender relations, control of resources to nourish children and run

households, division of labor, degrees of reciprocity among community neighbors, socialization and nonformal education of children, the relationship to the environment, planting and harvest celebrations, and worship are interwoven to create cultural identity (Keesing, 1981).

Operating mines provide salaried employment to workers, most often male. This can have profound implications for gender relations, and control over resources required to nourish children and run households. In addition, movement away from direct control over one's interaction with natural resources through independent farming to laboring as a mine worker may affect the way in which the natural world is perceived (Simmons, 1993). This can affect the way in which workers, as fathers, socialize and educate their children, bringing another layer of implications for gender relations and control over household resources.

Operating mines in rural areas often result in mining communities made up of newcomers who have migrated to service the needs of the mine and its workers. These communities are typically characterized by high alcohol and drug consumption, prostitution, violence, and crime. These conditions present any community with challenges to maintaining cultural values and beliefs, particularly among youth.

Even the exploration stage of mining, which does not often cause significant environmental impact, can be the source of drastic sociocultural impacts. The presence of mining company personnel can create various expectations among community members, as well as opinions regarding what kinds of impacts might result and how they should be dealt with. These opinions can become set, and differences can affect community cohesion (Clark, 1992). Disruption to community cohesion can affect established reciprocity patterns and divisions of labor, both of which are strongly linked to productive activities. This web of reactions can ultimately influence not only subsistence levels, but also culture (Crehan, 1992).

In summary, the impacts of mineral development demand cultural change. Ideally, a parallel should exist between the pace of introduced change and the adaptive capacity of individuals and the community. In this case everyday interactions and decision making would continue to both draw upon and negotiate the role of the cultural subtext. Conversely, should the pace of change simply overwhelm the ability to adapt, the vital linkage between culture and dealing with practical issues suffers enormous damage.

CONCLUSIONS AND RECOMMENDATIONS

The stress of mining affects the health of ecosystems and, by corollary, the physical and mental health of humans and their social well-being. The exploration, operation, and closure stages of large-scale, small-scale, and artisan mining have deleterious impacts on ecosystem and human health, which are also conditioned by the various operational implications of the particular mineral under exploitation.

An intimate and intricate relationship exists between the environment and human beings. The pace of introduced change and the ability of communities to adapt both have repercussions on the resilience of human culture and ecological integrity. In many developing nations, people and environments are vulnerable to increased poverty and the implications of overharvesting and contamination of the resource base. The degree to which large-scale, small-scale, and artisan mining contribute to national and local economies through the generation of employment and multiplier effects needs to be considered along with various externalities. Some of these include environmental impacts, local and regional stability reflected in the extent of conflict over territory, land-use and resource competition, implications for women and children, and implications for physical health in the community and occupational contexts. In many ways, these externalities reflect many facets of ecosystem and human health.

Mining in developing nations presents challenges to various stakeholders whose concerns tend to be defined in terms of their position and interests. To be effective, research must engage stakeholders in a participatory process and draw on expertise from various disciplines in the social

and health sciences to work in an interdisciplinary fashion. Mining, in the context of developing nations, can be characterized by complexity and heterogeneity. Stakeholder needs and ecosystem and human health require transdisciplinary approaches capable of reconceptualizing problems and the goals to be attained. As mentioned earlier in this chapter, research needs to further develop methodology, to increase understanding of causal linkages between ecosystem management and human health, to test ecosystem-based interventions, and to apply results to the development of interventions and policies. The ecosystem approach to human health can provide stakeholders and researchers with a conceptual framework to respond to the many concerns and factors involved in mining in developing nations. This chapter puts forward the following recommendations for research.

Small-Scale Mining

The small-scale and artisan mining sector lacks organization and capacity to deal with the many problems generated by the activity. Participatory research and development on this sector is strongly recommended.

Mining Companies and Skills with Community Consultation and Participation

Community members are very familiar with a variety of conditions within and beyond a mining operation's area of influence, placing them in an excellent position to ensure development of a comprehensive health and socioenvironmental impact assessment. This assessment is one of the key tools for exploring alternatives and mitigation strategies, designing plans for socioenvironmental mine management, and implementing monitoring programs, which can also be led and involve community members (ICGPSIA, 1993).

There are several challenges to achieving community participation, particularly in the context of developing nations. Anderson's work (1998) draws attention to tendencies of community members to respond to companies with political and personal agendas, making it difficult for companies to understand the realities of host communities. Sassoon (1998) notes that many communities that have had a history of paternalistic relations with government are often not accustomed to assuming a central role in their own development. She also emphasizes the lack of information and expertise at the community level regarding the many issues related to how mining may impact upon their lives and environment. Sassoon (1998) underlines that this plays a role in the limited capabilities of communities to evaluate the risks they may be facing.

The importance, however, of community consultation and participation cannot be over emphasized. Consultation may take several forms. Whether an open meeting or among a select few, the consultation event can provoke informal preparation and debriefing among many community members, providing an opportunity to communicate opinions and react to expected change. This communication brings issues to the surface where they are handled within the dynamic parameters of community culture. Ideally, consultation can enable communities to assume elements of control over the pace of introduced change. If equipped and trained, companies can gauge the process of adaptation and avoid overwhelming their host communities. In many ways, community participation is a significant component of the company–community interface, and can play a large role in ensuring that mineral development results in positive sociocultural impacts (Gagnon et al., 1993; ICGPSIA, 1993). Research needs to respond to the needs of companies to develop methodologies for community interaction.

Community Participation and Empowerment

The probability that the results from research will translate into effective action can only be increased if the community is involved at every step of the research development and implementation process. The mining industry, governments, and the research community have encountered

difficulties in managing situations in which either their presence or their actions have been questioned and refused by communities. Dealing with the community is not a technique, it is an art. Without having the sensitivity for human relationships and the time required to build trust and confidence through prolonged presence and discussion, community participation will inevitably become a token process leading to dead-end solutions. Community empowerment can only be achieved if the visitors are transparent in their actions and are willing to walk into a field where ultimately they might not have the final word.

The constant in all mining operations is the presence of surrounding communities that also provide the workforce. These men, women, and children are impacted directly or indirectly by mining operations and are in many cases not receiving sufficient benefits. These communities need closer attention.

Government

Authorities of national, regional, and local government may have a significant impact on the relationship between investors and the community. Capacity building is a key issue.

Scaling-Up from the Specific to the Generic

The size of the mine and the type of ores and minerals extracted is also creating a very complex situation where the damage to the environment and to human health can be greatly varied. In this chapter only a few examples were raised in order to illustrate the diversity of the impacts on the environment and on human health. The fact is that basically all mines have their own particularities, and that generalizations, at this point, are difficult to make beyond some very broad and generic issues. One of the most challenging areas for the researcher will be to try to distinguish between what is generic and what is specific in order to extrapolate the results generated from a particular situation.

Long-Term Impacts of Prolonged, Low-Level Exposure

Another area that has received limited attention is the long-term impacts of prolonged exposure to low concentrations of contaminants at a distance from the source. In our view, it is critical to investigate and evaluate the long-term effects of this dynamic process, since it is a situation encountered across the board in all mining regions of the developing world. The situation should be looked at particularly from the point of view of the state of human health and also food resources.

Origins of Contaminants

Continued research aimed at clarifying anthropogenic and natural sources of contaminants will have significant impact on the design, implementation, and effectiveness of mitigation measures.

Issues of Scale in the Selection and Interpretation of Mineral Indicators

Deborah J. Shields and Slavko V. Šolar

INTRODUCTION

In 1992, the United Nations Conference on Environment and Development (UNCED) adopted Agenda 21. Subsequently, many countries embraced the concepts of sustainable development and, by extension, sustainable resource management. Agenda 21 (UNCED, 1992, Chapter 40.4) called for the creation of indicators of sustainable development that could provide a basis for decision making at all levels. In response, academics and governments, as well as nongovernmental and intergovernmental organizations, began the complex processes of first defining and then quantifying sustainability.

To date no single definition of sustainability has been agreed upon. Rather, a variety of different conceptual models have been proposed, including genuine wealth (World Bank, 1998), pressure-state-response (OECD, 1998), and ecological footprint (Wackernagel and Rees, 1997), each of which takes a different philosophical perspective. Whether or not agreement on a definition and modeling approach is reached, making the sustainable development paradigm operational will require research progress in many different areas, one of which is the development of indicators crucial to specific sectors (Billharz and Moldan, 1997).

One such sector is forestry. Several major international efforts, including the Helsinki and Montreal Processes, have developed sets of criteria and indicators (C & I) to assess the sustainability of forest ecosystems and the economic and social systems dependent upon them. The Helsinki Process started in 1990 in Strasbourg, France, with the First Ministerial Conference on the Protection of Forests in Europe. Pan-European C & I for sustainable management of temperate and boreal forests were subsequently developed within the Follow-up of the Second Ministerial Conference, held in Helsinki. Slovenia is a signatory to the Helsinki Process Resolutions (Shields and Šolar, 1999). The Montreal Process resulted in the Santiago Declaration, which contained a consensus list of C & I for sustainable forest management agreed to by the U.S. and nine other countries. Both sets of C & I represent ambitious attempts to provide both a context within which countries can engage in discussions about sustainability and a common framework within which to assess and evaluate progress toward sustainability at the national scale.

As noted above, the governments of both the U.S. and Slovenia have embraced sustainable development, including sustainable resource management. Slovenia has endorsed (or signed, in

the case of treaties) all the major international agreements on sustainable development (Agenda 21, Helsinki Resolutions). Sustainability principles are being incorporated into many national documents, such as the Environmental Protection Program (adopted by parliament in 1999) and Long Term Land Use Plan 2000–2020, which is currently being written. The content of the State Mineral Resource Management Programme, which was completed by mid-2001, also reflects sustainability principles. Selected indicators of sustainability, most of which were based on the Organization for Economic Cooperation and Development (OECD) approach, were presented in the 1998 government report, “Environment in Slovenia 1996”; however, no mineral indicators were included.

The U.S. Forest Service (USFS), which manages over 180 million acres of public lands, plans to utilize C & I of ecological, social, and economic sustainability as a major component of its comprehensive monitoring program. As a first step, the USFS has committed to implementing the seven criteria and 67 indicators developed through the Montreal Process on all National Forest System lands by 2003 (Dombeck, 1998).

The concepts of sustainable development and sustainable natural resource management are being extended beyond forests to other ecosystem types and resources, including rangelands and nonrenewable resources. Scientists are currently studying the applicability of the Montreal Process C & I to rangelands and grasslands, and although neither the Montreal nor the Helsinki Processes addressed the role of energy and mineral resources in sustainable development, these resources have not been ignored. The governments in several nations, including Australia, Canada, the U. S., and a number of European countries, have been studying the role of minerals in sustainability. Most of these efforts will result in generic, decontextualized C & I of mineral system sustainability (i.e., in measures defined so as to be applicable at many different locations, rather than being site specific and context dependent).

The Montreal and Helsinki C & I were intended to be applicable at the national scale, but the land management decisions that affect sustainability take place on the ground in specific locations. There is a need for local scale C & I and associated measures that can be used to assess how land management decisions influence ecosystem and social system sustainability. This is the case for all types of indicators, whether the sector of interest is forestry or minerals.

Many of the national and international groups investigating minerals in sustainability have taken a continental or national scale perspective, including the OECD (Australia and mineral/energy indicators) and the U.S. Sustainable Minerals Roundtable. Similarly, the work being done on material flows by the World Resources Institute is national in scope (World Resources Institute, 1997). Mineral indicators applicable at the local scale are also being developed. Berger and Iams (1996) have published a set of geoindicators that measure Earth system processes. Many of the indicators, such as groundwater level, shoreline position, and surface displacement can be used to address local sustainability issues. Scientists participating in the Mining & Energy Research Network (MERN) are studying sustainability as it relates to mine operations. They are designing indicators of process, such as capacity building, participation, and well-being, as well as more conventional input/output indicators of performance and social development (Warhurst, 1998).

The analysis and interpretation of complex phenomena at multiple scales is one of the central issues in the study of ecology. One part of the body of literature addressing these problems focuses on the conceptual structure of interrelationships across scales and methods for dealing with that structure. We apply a subset of that body of knowledge to the question of how mineral indicators of sustainability, which are currently being defined for use at different spatial scales, relate to one another. We begin by introducing concepts from hierarchy theory, applying those concepts to conceptual mineral indicators. We next present a framework within which mineral indicators can be organized and compared across scales, giving a series of examples. We close with a discussion of the policy implications of utilizing scale-specific indicators.

APPLYING CONCEPTS FROM HIERARCHY THEORY TO MINERAL INDICATORS OF SUSTAINABILITY

Every entity is both a part and a whole. It is a part of some larger entity and, at the same time, it is the sum of its own parts. This is the essence of hierarchies. Every level in the hierarchy relates in two directions, upward to the larger whole into which it is integrated, and downward to the parts of which it consists (Allen and Starr, 1982).

Hierarchies can be thought of as partially ordered sets with an asymmetry of relationship among the elements of the set (Sugihara, 1983). An element or entity in the set has a role that is defined by the upper level to which it belongs (i.e., the higher level constrains the context of lower levels). The broad-scale processes that take place at higher levels of the hierarchy constrain the finer-scale phenomena (Allen et al., 1984). Conversely, as fine-scale patterns propagate to larger scales, they can potentially constrain broad-scale patterns (Huston et al., 1988).

Although there is no single correct scale of analysis (Wiens, 1989), this does not mean that all scales serve equally well in all cases. Choice of scale should be an explicit function of the policy and management decisions that need to be made (Rykiel, 1998; Tainter, 1999). The information collected and analyses conducted should be consistent with the scale of the decision context. Moreover, scale must be an explicit function of our knowledge about and understanding of the systems in question rather than being an artifact of anthropogenic perception of phenomenon scale. This is because perception of pattern and process depends upon the scale at which variables are measured. Thus, the scale of investigation can have profound effects on what is found (see, for example, Weaver, 1995; Edmunds and Bruno, 1996).

Detection of pattern and process depends on the grain and extent of the investigation (O'Neill et al., 1986). Grain refers to the individual units of observation; extent refers to the overall area being observed. Grain constrains the inferences that can be drawn; below the grain size, there is no way to observe relevant information. Extent constrains the size of the entity we describe, because it is not possible to observe an entire entity unless the universe of observation is large enough to include all its parts.

A sieve provides a useful example of grain and extent. The size of the mesh in a sieve's screen determines the size of the particles that will be retained in the sieve as well as those that will pass through. Only particles larger than the mesh size can be sampled. It will not be possible to collect samples of particles so small they pass through the sieve. In this way the mesh size defines the grain of the experiment. The size of the sieve itself sets a limit on how much material can be passed through the screen within a specified time period, and hence the volume of material, or size of the universe, that will be examined. This defines the extent of the experiment.

We can apply the concept of grain to open pit mines, such as the one in Jersovec, Slovenia, where clayey to silty chert rubble is being extracted. Silty clay is a product of the weathering of carbonate rocks. Chert has very low Al_2O_3 and Fe_2O_3 content; the concentrations of these undesirable impurities are much higher in the silty clay portion of the sediment. The aluminum and iron oxides are removed by separating the silt/clay from the chert fragments through wet screening. By using a cutoff screen of 3 mm, the larger chert particles (>3 mm) can be separated from the silt/clay and smaller chert particles (<3 mm). Grain size is therefore 3 mm. The extent is volume of material screened within a specified time period.

The grain and extent set the limits of resolution for a study. It is not possible to generalize beyond the extent without making the assumption that pattern and process will not change (i.e., that they are scale-independent) (Wiens, 1989). Since system processes frequently differ across scales, scaling-up with existing information can be problematic. It may result in a biased understanding of broader-scale processes, with the process from the smaller scale being given more importance than is actually warranted in the larger system (MacNally and Quinn, 1998).

Viewed from the resource management perspective, the problem is one of practices that are appropriate for, and contribute to, sustainable resource management at the site level, but which

may not contribute to sustainability when applied to a larger geographic area (Fox, 1992). Multiple local optima do not necessarily result in a global optimum. This is why environmental impact statements typically include information on cumulative effects. Nor does it follow that the processes at work at broader scales are the same ones driving a system at smaller scales. Hierarchy theory suggests that using fine-scale data to make predictions about large-scale events is more likely to be accurate than the reverse (Fox, 1992). This is because the grain of the broad-scale data may be too coarse to detect the pattern and process occurring at finer scales. Great care must be taken when predicting from higher to lower levels.

For reasons of cost and tractability, expanding the extent of an experiment often entails collecting data at a coarser grain (i.e., as the study area is enlarged, fewer measurements are taken). In so doing, the observer gains information on the broad-scale pattern, but loses the fine-scale details. This can be a worthwhile trade-off when the policy issues of concern are broad-scale as well. Moreover, just as multivariate statistical methods can be used to summarize large amounts of fine-grain data to reveal broader relationships, moving up in scale can increase the scientist’s ability to generalize (Levin, 1992).

Mineral exploration displays this pattern, albeit in reverse. Exploration activities usually begin with studies of very large areas, perhaps as much as several thousand square kilometers. More detailed exploration activities are only undertaken in those areas with “good results,” so that as the extent of exploration target area shrinks gradually from the entire landscape to the mine site area (mineral deposit of a few hectares), the sampling grain becomes finer. However, the extent of the area over which sampling takes place must be at least the size of the ore body if the objective of exploration is to define the ore body’s boundaries.

Scientists in many fields utilize hierarchies to organize information (Figure 84.1). Those hierarchies may be either spatial (administrative or economic, for example) or temporal (historic, geological). Organizing into hierarchies clarifies information and facilitates the understanding of different aspects of complex systems. The hierarchies chosen for analysis are often interdependent and overlapping. This is because patterns and processes defined within one hierarchy affect the structure and functioning of entities within other hierarchies.

Consider, for example, the interrelationships among three hierarchies, geological (ore body limits within a geologic formation), administrative (mining property boundaries within politically defined boundaries), and economic (a mine within an industry sector). The extent of the ore body is defined within the geological settings hierarchy; however, the political units that make up the administrative hierarchy will define ownership of and access to the ore body. Mine profitability,

Figure 84.1 Hierarchies such as these are used to organize complex information according to scale.

which resides within the economic hierarchy, is dependent upon the property rights regime, as well as the nature of the ore body. The existence of the ore body can impact decisions made within the administrative hierarchy about access and ownership (i.e., administrative functioning). And these interactions between two hierarchies (geology and administrative) have implications for the way a process within the economic hierarchy, such as mine development, is handled.

The role an entity plays depends on the higher level system to which it is assigned. The higher level system to which it belongs is determined by the phenomenon in question (Allen et al., 1984; Allen and Hoekstra, 1990). This implies that entities can reside in more than one hierarchy, depending upon the phenomenon being investigated.

Returning to our mining example, an ore body can be thought of as an entity. The rock within that ore body could be pure limestone, clay, or a combination thereof (e.g., limestone [less than 5% clay], marly limestone, limy marl, marl, clayey marl, marly clay, or clay [less than 5% limestone]). If the phenomenon of interest is the genesis of the rock, then the hierarchy within which the entity resides is geologic. However, the composition of the rock also has implications for (pit) mine design because the ultimate angle of slope stability ranges from a few degrees in clays to a few tens of degrees in limestone. Thus, if the phenomenon of interest is mining or mine design, then the hierarchy within which the entity resides is economic, or perhaps engineering.

A FRAMEWORK FOR COMPARING INDICATORS AND PHENOMENA ACROSS SCALES

As the foregoing makes clear, inferring pattern and process at one scale based on information collected at another is fraught with potential difficulties. However, linkages can be made when a single phenomenon is significant at different levels of the same hierarchy (Allen et al., 1984). Some phenomena are applicable only at certain scales (e.g., global climate change is meaningful at the global, national, and industry levels, but not at the mine site level). Similarly, underground water balance is a meaningful concept at the mine site scale, but not at the industry-wide scale. Conversely, phenomena such as production and safety are relevant across many different levels of the hierarchies to which they belong (Figure 84.2). In cases where cross-scale linkages exist, it may be possible to predict the status of an entity at one scale in a hierarchy based on information about a shared phenomenon from another scale of the hierarchy.

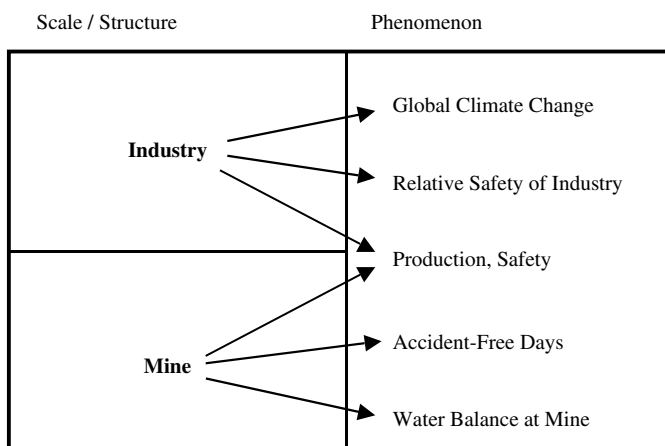

Figure 84.2 Unique and mutually occurring phenomena. Scales or levels within a hierarchy are connected to one another by mutually occurring phenomena.

		Indicator Type	
		Same Indicator	Different Indicator
Phenomenon	Same Phen.	I	III
	Different Phen.	II	IV

Figure 84.3 Two-by-two table of phenomena and indicators. Phenomena and the indicators that measure them may be the same or different across scales of a hierarchy.

Most entities and phenomena can be described by qualitative or quantitative measurements. This is the purpose of indicators: to provide information about the status of entities or functioning of phenomena. Although entities can be linked across scales by shared phenomena, it does not follow that an indicator of that phenomenon that is meaningful at one scale will be equally as informative at a different scale. An indicator can be used to describe a single phenomenon across scales (i.e., aggregated up or disaggregated down) only in those instances when its meaning does not change as grain and extent are changed.

The relationship among phenomena and indicators can be thought of as a 2-by-2 problem (Figure 84.3). A phenomenon may or may not be playing out at two different scales of a hierarchy. Similarly, an indicator that is applicable at one scale may or may not be applicable at a different scale. An additional complication is that an indicator may be useful at more than one scale, but indicative of different processes at the different scales. Each of the alternatives will be considered below.

Case I

Case I represents the straightforward situation in which both the phenomenon itself and the indicator that describes it are meaningful across two scales. Data on production of mineral resources is among the most convenient and understandable of examples. Production can be reported at many different spatial scales: quarry (company), quarrying area, county, state, country, region, continent, and global level. Typically, data are collected at the quarry level and then aggregated (summed) for reporting at broader scales. Aggregation of these data (scaling-up) is acceptable in this case because meaning does not change across the scales. Of course, as noted above, scaling-up results in a loss of detail that is available at the disaggregated lower level. There are also instances in which disaggregation is appropriate. Production data reported at the industry or firm level can be reported as average productivity per mine or per employee.

Case II

Case II represents the situation in which a phenomenon differs from one scale to the next, but the same indicator is descriptive of the phenomena playing out at each scale. This situation is much less common than is Case I, but sometimes does occur. One such situation concerns NO_x emissions. The local scale phenomenon is soil condition. Excess nitrogen makes the soil more fertile than it would normally be, which can lead to changes in ecosystem structure and functioning. Emission of NO_x could be used as a proxy indicator for nitrogen levels in the soil. At the continental or

global scale, NO_x has been identified as a greenhouse gas (a contributor to global warming). Thus emissions would act as an indicator of potential global climate change.

Case III

Case III represents the situation in which the phenomenon is the same at difference scales, but the appropriate indicators differ across the scales. Consider the phenomenon of the spread of exotic (nonnative) plant species. An indicator at the site level might be the presence of vehicles and equipment brought in from infected areas. At the landscape scale, an indicator could be fragmentation due to road building. Another example relates to the costs associated with the transport of mineral materials. At the mine site scale, an indicator might be transportation cost per unit of weight, whereas at the regional level, an indicator might be the dollar value of impacts on infrastructures (highways, bridges, etc.) caused by transport vehicles.

Case IV

Finally, Case IV pertains to situations in which the phenomena and related indicators are different across scales of a hierarchy. The concept of material flow, that is, the life cycle for a mineral, is relevant at the national and global scales, but is not meaningful for an individual mine. Conversely, as noted previously, water balance is an extremely important issue at the mine site scale and completely irrelevant at the national or global scale.

CONCLUSION

Commitment to sustainable development necessitates integration of environmental policies and development strategies to satisfy human needs and improve the quality of life today while protecting resources for the future. This will not be an easy task. Humans have developed complex cultural, institutional, and economic structures. The need to maintain these systems is of as great importance as is the need to maintain the health of biological systems. Exclusive focus on any single aspect is both inappropriate and impossible. Exclusive focus on sustainability at only one scale, be it local, national, or regional, is inappropriate as well.

Agenda 21 (UNCED, 1992, Chapter 40.4) calls for the development of indicators of sustainable development (SI) that can provide a basis for decision making at all levels. SI should:

- Be representative of the chosen system (social, economic, environmental, biophysical)
- Have a scientific basis
- Be quantifiable
- Include reference threshold values
- Be without social bias, represent manageable processes
- Have predictive meaning

Indicators of sustainable development may be transformations of underlying information or selected members of a larger set of data. As these indicators are developed, scale will need to be considered. There is no correct scale of analysis, only an appropriate scale for the issue at hand. Rather than trying to determine the correct scale, we must understand how the system description changes across scale (Levin, 1992). Then by moving up in scale we can abstract from unrepeatable and unpredictable individual cases to generalized behaviors. In the case of mineral resource management, site-specific information is needed for local decision making. However, an understanding of the broader phenomena should inform policy making. There is a need for both localized, site-specific indicators, and national-scale indicators of sustainability

for mineral resources. The framework presented here is intended as a tool for organizing phenomena and indicators across multiple scales.

Conceptual Approaches to Health and Well-Being in Minerals Development: Illustrations with the Case of HIV/AIDS in Southern Africa

Camilla Maclean, Alyson Warhurst, and Philip Milner

BACKGROUND

Introduction

This chapter focuses on conceptual approaches to human health and well-being in the context of the mining industry. It contributes to a multidisciplinary Mining and Environment Research Network (MERN) 3-year research project on environmental and social performance indicators detailed below.* The biomedical model of health and some of the implications that emerge from the predominant use of the biomedical model as a first step toward assessing the extent to which a minerals development project contributes to, or detracts from, the health of local communities is also examined. In addition, this chapter aims to build on, and contribute to, the work by the Tata Energy Research Institute (TERI) team in Goa, led by Dr. Ligia Noronha, and the Instituto de Estudios Regionales (INER) team, University of Antioquia in Colombia, led by Cristina Echavarría, on the effects of mineral development projects on human health and well-being.

Recent research concerning the broader determinants of health supports the supposition that the biomedical concept of health as the absence of disease is a partial and restrictive model. Emerging research consensus advocates a wider conceptualization of health that considers the critical determinants of health as those located within broader societal and environmental contexts, and which includes a subjective sense of well-being as a significant constituent of health. It also considers that the constituents of well-being are best located within a development rights framework (Echavarría, 1999; Warhurst, 1998).

While it is important for a mining company to undertake baseline health impact assessments (HIAs), it is not the intention of this chapter to offer an in-depth assessment of HIAs or community health strategies for mining development projects per se. Rather, we assert that further discussion is still required on the implications emerging from predominantly using the biomedical concept of health that *a priori* shapes the structure of health impact assessments, many health development policies and practices, and community development initiatives.

* This work was undertaken with the aid of a grant from the International Development Research Center (IDRC), Canada, and with the support of the Environmental Research Program of the Department for International Development (DfID), U.K.

Thus, the first section reviews several strands of the biomedical model of health. We suggest that the biomedical concept has been internalized by, and applied widely within, the mining industry, through both occupational health strategies and many community development strategies relating to health. Some of the adverse health effects traditionally associated with mining activities are listed to consider if or how they reflect the biomedical model.

The second section of the chapter reviews existing literature critiques of the biomedical model of health and subsequent health determinants and health measurements that are outcomes generated by the logic of this model. The implications of using such a biomedical model of health are considered for individuals and communities associated with mineral development projects. Initial evidence from MERN research in southern Africa suggests that the biomedical model is insufficient to evaluate the extent to which mining projects contribute to, or detract from, community health and well-being. Corollary evidence from an emerging research consensus also suggests that the biomedical model, if it is used in isolation and to the exclusion of community-level health definitions, is an incomplete foundation on which to base health assessments, policies, and strategies (Marmot and Wilkinson, 1999; Milner, 1999; Soskolne and Bertellini, 1998).

The final section sketches out a definition of a more integrated and holistic understanding of health that includes well-being. We conclude that a reconceptualization of health, negotiated and validated at the community level, and including, but not restricted to, the biomedical model, is needed in order to more accurately assess the health and well-being of those host communities affected by mineral development projects. Further, we suggest that new research is necessary to inform and frame the changes that mining companies will need to make in order to ensure that their activities contribute positively toward community health and well-being.

MERN Research Project: Environmental and Social Performance Indicators and Sustainability Markers in Minerals Development

MERN is an international collaborative research program involving centers of excellence in the major mineral-producing countries of the world. It was established in 1991 with the aim of generating analysis to facilitate the improvement of environmental and social performance and competitiveness of mining projects in the context of growing environmental regulation, societal concerns, and technological innovation.

MERN is currently working on a multidisciplinary 3-year research program principally aimed at developing environmental and social performance indicators (ESPIs) and sustainability markers for mining projects. The ESPIs project is core-sponsored by the U.K. Department for International Development (DFID) and Canada's International Development Research Center (IDRC). It includes collaborative support from principal MERN Industry Club members and research users, particularly for the fieldwork and research workshops phase. A key part of this research is collaboration with the INER team and with TERI. Phase two of this research will focus on the testing and verification of well-being indicators and quality of life tracking tools. Thus, one of the essential aims of this research is to provide policy input to enable mineral development projects to contribute positively toward human health and well-being.

MINING AND MEDICAL MODELS OF HEALTH

This section reviews the biomedical model of health and starts from the assumption that a biomedical model of health is a dominant paradigm. This means that the model has been widely internalized within the mining industry. Some of the adverse health effects traditionally associated with mining activities are reviewed to demonstrate how their typical classification as diseases or injuries illustrates this point. Some of the unintended consequences of operationalizing the biomedical model are considered in reflections on the case of HIV/AIDS in southern Africa below.

Models of Health and the Biomedical Paradigm

Debating concepts of health is not new; debates have occurred since the time of the early Greek Empire (Renaud, 1994). Larson (1991) supports this by suggesting that constructing an absolute conceptualization of health is problematic and “dependent upon the historical period in question and the culture in which it is defined.” In practice, among and across societies, health is conceptualized and measured in a variety of ways. However, a common thread running through many of the models is that health is understood as efficient human physiological functioning (brain and body). Few models challenge the fundamental principle that health is only the absence of disease or injury. It is this principle that characterizes and defines the biomedical model of health (Green, 1992; Larson, 1991). Within the biomedical model of health it is possible to identify several distinct strands. These are briefly outlined below.

One strand conceptualizes health as a measure of the state of the physical bodily organs. Implicit within this definition is the belief that ill health occurs when one or more parts of the body are malfunctioning. That is, an individual is unhealthy when the body’s functioning of one or more constituent parts and organs is impaired. In this view, health is the absence of disease or injury. Thus, the definition is based on an essentially negative concept: health exists when one is free from disease or injury (Bowling, 1991; Evans et al., 1994; Green, 1992).

The biomedical model of health is the dominant paradigm in conceptualizing and defining health status in most industrialized countries, and consequentially in most industries. The biomedical model shapes patterns of health care policy and may account for preoccupations with attention to the absence of disease and disability evident in all aspects of health care services. The biomedical model is established and embedded in industrialized countries, but its influence extends around the globe (Green, 1992).

The biomedical model has its foundation in the ascension of expert scientific medical research that relies upon knowledge gained from reductionist methods of inquiry and investigation. Of course, the benefits of medicine are immense and not to be minimized, as medical science has enabled the cure and prevention of many diseases (Evans and Stoddart, 1994). Indeed, this is a very powerful reason accounting for, in part, this model’s success as a dominant paradigm throughout the world. Although other social, political, economic, and cultural factors also contribute to the predominance of the biomedical paradigm, it is not within the scope of this chapter to address these factors. The chapter is more concerned with the implications.

In the biomedical model, the role of health care providers, hospitals, and medical treatments are seen as fundamental in alleviating symptoms, restoring capacity, eradicating disease, and reestablishing health. Disease, or illness, is seen as the result of physiological and/or organic deficiencies and resulting treatment and interventions are aimed at restoring function, usually centered on secondary and tertiary care.

A closely parallel strand found in the literature is a definition that conceptualizes health not just in terms of the mechanics of the different bodily functions, but in the ability of the body as a whole to function (i.e., how the disease or disorder is experienced by, or translated into an impairment or handicap for, the individual; Rapheal, 1996). This model incorporates the element of an individual’s subjective perception of their symptoms, but given that disease and injury are still paramount within the model, it nonetheless reflects a predominantly biomedical paradigm.

Last, the behavioral conceptualization of health falls within the biomedical paradigm as well. Here, health is considered to reside within the individual and is determined by individual behaviors. In addition to physiological functioning, health is conceptualized as “energy and physical-functional ability, wellness and the adoption and carrying out of appropriate disease-preventing lifestyles” (Rapheal, 1996). Central to this model is the focus on specific risk factors and the belief that a person’s behavior patterns are a critical determinant of health. However, the behavioral model is nested within the biomedical model of health insofar as the essential pattern is unchanged: an individual gets sick, is cared for by health care service providers, and is consequently treated or cured.

The biomedical model of health has been portrayed here as a discrete coherent entity. The reality is that individuals within companies and in other organizations are unlikely to subscribe to a simplistic view of health. Moreover, we are not proposing that there is a right or wrong definition of health, only to suggest that there are different implications associated with using different models. The implications of how the traditional classification of health problems associated with mining, reflecting the internalization of the biomedical conception of health as an absence of disease or injury, need to be explored more fully. These implications are evident in the description of health issues typically associated with mining reviewed in the section below.

Traditional Health Concerns in Mining

The list of adverse occupational health effects associated with mining is relatively well documented: injuries and accidents, respiratory conditions, i.e., tuberculosis or pneumoconiosis, chronic heavy metal exposure, and chemical exposure (Marcus, 1997; Williams and Campbell, 1998).^{*} These may be related to the mining life cycle, the wastes produced, and the hazards potentially generated, but all may be classified within the biomedical paradigm. If health is defined as the absence of disease or injury, then the converse must hold: that an individual is unhealthy if diseased or injured.

Figure 85.1 illustrates some of the possible hazards associated with the mining life cycle and the environmental, social, and, particularly, health effects that may ensue. The authors note that this mining life cycle is indicative of only some of the industrial processes now used to extract base metals. Different flowcharts can be formulated for different processes. Each chart may vary according to the extracted mineral, the processing method, environmental legislation, and degree of effective monitoring, as well as according to the preexisting biogeophysical conditions and social and cultural context of the host country and region.

Another way of looking at broader health effects associated with mining is through decommissioning and how the associated socioeconomic effects of unemployment, changing land-use patterns, and relocation link to health (Warhurst et al., 1999). Some of the socioeconomic effects, including health, of mining are summarized in Figure 85.2. Research by Warhurst et al. (1999) suggests that these relate to the failure of many mining projects to address key issues (e.g., ongoing social impact assessments through the life of the mining project, systematic closure planning, environmental management plans, etc.). Given that further in-depth analysis of these issues is detailed elsewhere, no further comment is offered here, except to note that many of the socioeconomic issues related to mine closure have significant direct and indirect intra- and intergenerational effects on community health and well-being.

The mining industry has historically relied on scientifically determined exposure limits with respect to toxic or heavy metal water pollution, air sulfur dioxide, fluoride, and particulate emission standards, and on technical solutions to mitigate against physical injuries or accidents. These acceptable limits and technocratic environmental solutions are crucial for the mining industry in terms of providing measurements for monitoring in order to provide assurances to their affected communities that mineral development projects are contributing to, and not detracting from, community health and well-being.

There are a number of significant problems with primarily using technocratic environmental solutions and exposure limits. There is the general population's growing inclination to distrust official data or reassurances commensurate with greater technical sophistication in scientific testing that raises doubts about what can be claimed to be known with reasonable certainty (Rodricks, 1994). Furthermore, the growing body of research under way that engenders a greater understanding

of the causal pathways between social and biological effects (Evans, 1994) needs to be considered within minerals development projects and its relevance for individual and community health and well-being. However, the fundamental problem is with how mining's traditional health concerns conflate disease with health (e.g., health concerns are framed within a biomedical model). This is explained further in the following section critiquing the biomedical model and its implications for health determinants and measurements.

PROBLEMS WITH HEALTH PARADIGMS

Following the outline of the biomedical model, this section will now turn to the literature critiquing the model, including its affiliated determinants and measurements of health. The implications of working from a biomedical model of health are considered for individuals and communities associated with mineral development projects. Implications of the biomedical model are detailed to show that, on its own, it is an incomplete model to evaluate the extent to which mining projects contribute to, or detract from, community health and well-being.

Critique of the Biomedical Model

The biomedical concept of health has been criticized as being inadequate for a number of reasons. The high cost of health care in industrialized countries and the persistence of ill health in all countries have prompted more detailed research into exploring health determinants. Noncommunicable diseases have replaced communicable diseases as the main causes of mortality and

morbidity in industrialized countries (Birley, 1995; Evans, 1994). Thus, while a specific disease may be eradicated, another disease or illness emerges as a cause of mortality. People in Europe and America now rarely die from tuberculosis. Instead, the World Health Organization reported in 1999 that depression is considered the second highest mortality cause (*The Guardian*, May 12, 1999). Therefore, if high levels of secondary and tertiary care exist in a specific country or location and people are *still* unhealthy, then there must be factors other than health care services, so central to the biomedical model, that impact on health.

While the absence of disease and injury may be a relevant consideration in determining an individual's status as healthy, many people with physiological conditions that can be classified as a disease still feel healthy (e.g., a diabetic whose symptoms are well managed). Individuals also may feel ill without being diagnosed by clinician as having a specific disease or being able to attribute symptoms to an identifiable cause.* If bad health can exist in the absence of disease or injury, and if disease or illness can exist without compromising self-perceived good health or quality of life, then the biomedical model is clearly an incomplete explanation. It is incomplete both for how people define health in its fullest sense, as well as for identifying critical health determinants. Further, an individual's functional capacity and perception of illness will be significant aspects, but not the sum of their health and well-being (Evans et al., 1994; Larson, 1991; Levine, 1987).

The biomedical model of health, defined by clinicians, often misses an important component: the individuals' perceptions of their own state of health. Individuals are ultimately concerned with the impact of illness on their lives, not necessarily with the disease itself. There is a growing awareness that physical health is not the sole purpose in life but more a resource in order to live fully.** This awareness has mobilized policy makers and regulators to consider how public and private activities impact on the elements of well-being or quality of life, as much as on people's physical health.***

With regard to the behavioral conceptualization of health in the biomedical model, it can be argued that insufficient consideration is given to the social and historical processes that shape individual behaviors and perceptions of risk. Research on individual perception of risk, particularly with respect to the nuclear industry (but not irrelevant to mining) suggests that people's own values and concerns represent coherent and reliable bases upon which to explain logical patterns of behavior and responses to potential health hazards (Wynne et al., 1993). Unfortunately, health promotion campaigns aimed at individual behavior may have the dual outcome of diverting attention from broader, perhaps more relevant, determinants of health and placing responsibility for ill health primarily on the shoulders of the individual, who thereby takes the blame for the ill health (Petersen and Lupton, 1996).

For example, with respect to HIV/AIDS health campaigns, in addition to the education and condom distribution programs, there is a movement within South Africa to have HIV/AIDS be classified as a reportable disease, which would in turn add to the risk of further stigmatization of sufferers. Moreover, while health promotion campaigns are often politically inoffensive, comparatively inexpensive, and highly visible, they are also relatively ineffective as the sole mechanism to bring about changes in health outcomes (Campbell and Williams, 1998; Evans, 1994). The Mozambican governmental HIV/AIDS prevention strategy is targeting individual behaviors, thus replicating health promotion campaigns designed in industrialized countries in efforts that seem not to take account of country-specific social and historical processes (Mozambican Deputy Director, personal communication, 1999). Some implications of this approach are discussed in further detail below in Consequences for Communities.

* A significant finding in the TERI case study survey is the high percentage of respondents who perceived themselves as being ill but were unable to attribute a reason or cause to their illness.

** World Health Organization definition quoted in The Gottenburg Consensus Paper (1999).

*** There are numerous examples of initiatives that reflect the growing awareness that a person's quality of life or well-being is based on many dimensions and many different aspects of living, such as the U.K. government's "Headline Indicators," (Department of Environment, Transport and the Regions, 1999).

If the biomedical paradigm is only a partial or incomplete conceptualization of health, then greater account needs to be taken of the multidimensional and dynamic aspects of health. This includes aspects of health that are more in accordance with individuals' and society's perceptions and interpretations of what constitutes their definition of health and well-being.

Determinants and Measurements

Part of ongoing MERN research effort is concerned with improving the understanding of the effects of mineral development projects on the determinants of health and well-being for individuals and communities. This is paralleled by medical and social science research's questioning causality of disease in a number of disparate but interrelated ways. Assumptions about genetic and biological determinism, how the social environment influence cellular responses along biological pathways, as well as cultural interpretations of who is considered ill and who is not have all been the theme of recent research (Evans et al., 1994).

It is not the purpose of this chapter to attempt to draw up a definitive list of determinants to health and well-being. Rather, the aim here is to illustrate that there are important health determinants for individuals and communities being missed by mining companies. These significant health determinants are not well understood and, yet, are still considered critical to a more comprehensive definition of health and need to be included in any future effort to measure the health and well-being of communities associated with mineral development projects.

Attempts to advance understanding of health determinants have generally been undertaken by the medical community, with the result that research has tended to focus attention on the narrower concept of health: absence of disease or injury. In part, this is due to the significant utility of being able to measure health through the easily quantifiable events of death (mortality) or the incidence and prevalence of diseases (morbidity).

However, this research has been enriched more recently with contributions from other disciplines (Evans et al., 1994) by including more general dimensions of health and well-being that many people would judge to be important in relation to their own goals and aspirations. For example, indigenous people in Colombia affected by the Cerrajón Norte Coal Project have indicated that well-functioning systems of reciprocity, complementarity, and social justice are critical to their sense of health and well-being (Echavarría, 1999).

The negative and positive impacts of a mineral development project on the physical health of individuals and communities have been the source of extensive MERN research.* However, the negative impacts on the social health of individuals and communities have been well documented across specific projects and regions (Carter, 1999; Macfarlane, 1998). The connections between the two are only now being established, reinforcing the need for improved knowledge and understanding about the significance of social, economic, and cultural factors in the etiology of disease.

According to Evans et al. (1994):

The factors that determine the health status of a population are not only multiple and complicated but they interact with each other in ways that are much more intricate than previously understood. The link between cause and effect is neither immediate nor direct. They show up in differential susceptibility to threats of illness; and the biological and social mechanisms underlying susceptibility are far from easy to understand, let alone to subject to clear and rigorous testing.

Indeed, the evidence for consideration of a broader set of determinants of health is emerging and accumulating from different disciplines to include not only health care, ecosystem health, nutritional security, and genetic patterns, but also includes identifying the supportiveness of the social environment, group cohesiveness, community resilience, and a sense of personal adequacy

* For example, refer to the 1997 World Bank Quito Mining and Community Conference papers.

or control as important determinants. Also increasingly apparent is that what is perceived as a well-being issue may be, or evolve into, a health issue in the narrow sense. New research is investigating the relationship between the two (Evans, 1994; Noronha, 2001). These social determinants affect health at all levels of its definition but also go well beyond traditional models of health care and ecosystem management.

Consequences for Communities: HIV/AIDS and Southern Africa

We argue for the need to use a broader conceptualization of health that evolves beyond the narrow biomedical model, that is, one that can be used as a framework for better evaluating the extent to which the activities and policies of mining projects contribute to, or detract from, community health and well-being *as defined by the community*. The consequences of using a biomedical concept of health for individuals and communities are explored through the following illustrations from the case of HIV/AIDS in southern Africa.

Each conceptualization of health used has critical implications, insofar as what is understood as health problems will differ within each approach. How one views health will affect how health problems are constituted, conceptualized, and solved. Decisions as to disease etiology will clearly structure the type of interventions and planning conceived as logical and possible.

In southern Africa many members of the medical community affiliated with the mining industry have identified one of their leading health problems as HIV/AIDS. While not denying the material dimensions of AIDS as a disease, and the fact that the pain and suffering experienced is very great, the dominant issue characterization has been in terms of the physiological condition of the individual, a reflection of the dominant biomedical model (Campbell and Williams, 1999). A more holistic conception of AIDS might include the social and psychological condition of individuals and those caring for them. The following explains how this can occur.

HIV/AIDS is imposing considerable pressure on those caring for ill or disabled miners, who are typically family members, in the southern African context. The household impacts being felt with HIV/AIDS are multifaceted and immense. As Whiteside and Michael (1998) point out, primary economic providers are dying with little or no provision for their families, a third of which will also be infected. Illness or death results in a household's spending scarce resources, as well as the loss of an adult income (i.e., spending "a full year's income meeting treatment and funeral costs"; Whiteside and Michael, 1998). Moreover, other family members may be left trying to support orphans, further burdening their own household resources. Generally, caring for the sick and dying is left to women in the household, reducing their opportunities to engage in other productive and income-generating activities.

Mining companies have adopted a dual approach to the problem of HIV/AIDS based on their conceptualization of it: first, to reduce the rate of transmission, and, second, to reduce the impact of the disease on the company. Interventions aimed at the former have been based on educational programs such as the Knowledge–Awareness–Prevention program, which is designed to promote changes in individual behavior patterns of condom use and multiple sexual partners (Senior mining industry physician, personal communication, 1999). This is clearly indicative of a behavioral approach within the biomedical paradigm that considers individual lifestyle and lack of personal information as a critical health determinant. This approach is based on the view that with the right information, individual behavior will change and, thus, incidence and prevalence rates will decrease. Interventions aimed at reducing the impact of the disease on the company have included changing employee health benefit packages for cost containment factors (Senior mining industry physician, personal communication, 1999).

However, as Renaud (1994) states:

One's capacity to modify potentially pathogenic behaviors and to "stick with it" is directly related to one's wealth, power and education — in short to the degree of control one has over one's future. The

higher up the social hierarchy, the more control one feels capable of exerting over life, the easier it is to change unhealthy habits. In other words, one's "will to change" is largely predetermined by one's social environment.* To be told by an education program or otherwise, that one's lifestyle should change is neither helpful nor effective.

Therefore, these health education campaigns, while laudable in their attempts to protect people's health, may serve to obscure the understanding that lifestyles are themselves determined by the social, economic, and cultural environment. The broader determinants of health are outside the sphere of influence for any one individual, and by focusing on individual risk factors, the status quo is maintained and more fundamental ways of thinking about health are left unchallenged and unchanged (Evans, 1994; Renaud, 1994).

While health promotion programs that focus on lifestyle changes have good intentions, they can also have uncertain or potentially negative outcomes. For example, there exists a twofold risk of failing to meet positive objectives (better health) and a greater risk of the unintended, and not so positive, consequences of individuals being held personally accountable for their ill health. Many health promotion programs take insufficient account of the larger social and cultural processes that are, in themselves, responsible for lifestyle patterns and for health and disease outcomes and health inequities.

The outcome of individuals being blamed for their ill health may arise from health promotion activities that typically, but not solely, target individual behaviors and lifestyles. If individuals are primarily responsible for their health, then the converse must also hold true: that they are also ultimately responsible for their ill health. This logic has important implications. First, it may encourage a disproportionate preoccupation with the physical self and with individual health risks and health hazards, privileging physical health above quality of life or pleasurable activities that contribute to a sense of enhanced well-being. Second, it diverts attention from the fact that people's actions are shaped by the surrounding social and economic context in which they live. As such, there needs to be a collective, rather than solely individual, responsibility for modifying that context if change is required to achieve greater health parity. Typically, health promotion campaigns do not convey the understanding that choice is largely determined by one's social and economic status, which can influence the degree of perceived personal control felt, and by dominant media or societal messages.

For example, while health campaigns in North America encourage people to exercise more and eat less, in reality people are subjected to endless and sophisticated media messages and product and service advertisements designed to encourage people to do the exact opposite. Health promotion campaigns can serve to absolve the larger collective entities, such as corporations and governance structures, of any responsibility for the individual health outcomes and divert attention away from increasing disparities in health, wealth, and power.

Third, and perhaps of most concern, is that health promotion campaigns that focus on individual behavior and chosen lifestyles as the prime determinants of health can create or encourage social and economic discrimination, disadvantage, and exclusion for certain groups and individuals. It allows for the maintenance of the status quo in existing power relations and puts those individuals or groups of people who fail to exhibit appropriate self-control or who fail to take steps to preserve their health in a medically established and accepted manner, at risk for stigmatization.

Health promotion activities in South Africa, with regards to high HIV/AIDS rates among predominantly black miners appear to be at risk for ignoring several factors. These factors include the historical path and logic of multiple partners in Africa and the disparity of economic and political power among different racial groupings in South Africa. Additionally, health promotion activities may ignore the diminished autonomy of women in many African societies. There is also a prevailing cultural belief that many miners articulated in a recent study (Campbell and

* Additionally, the authors would add that one's will to change is also predetermined or influenced by one's biogeophysical, as well as social, environment.

Williams, 1999) that flesh-to-flesh sex, (i.e., as opposed to using condoms) was imperative to maintain their physical health.

Further research would be required for verification, but we suggest that an unintended and unwelcome outcome of some health promotion campaigns in southern Africa might be that, inadvertently, they support paternalistic or, possibly, racist interpretations of patterns of behaviors. For example, one set of actions could be interpreted as being better than another for demonstrating self-control in preserving one's health. At best, such health promotion strategies have failed to stem the tide of HIV/AIDS in South Africa. At worst, they could reinforce the perception that citizens are irresponsible and ignorant through having failed to modify their behavior in light of scientific and rational knowledge (Petersen and Lupton, 1996).

Alternatively, it may be viewed that policy has failed to distinguish between the very different possibilities that men and women possess for exercising control over their own sexuality and the challenges women face. Challenges for women include trying to protect themselves and their children when the main means of control made available are principally in the power of men (i.e., use of condoms, multiple sexual partners, etc.). As Evans (1994) points out, well-intentioned efforts to maintain or improve the health of individuals and the populations they comprise may be wasted if there is poor understanding as to what actually contributes to their health and well-being in the first place. If the principal determinants of health lie elsewhere and are not to be found in individual behavior patterns and biomedical services, then interventions are missing important pieces of the puzzle.

In addition, the underlying reasons for selecting one health problem over another as worthy of attention and receiving targeted resources may obscure better understanding of the health and well-being concerns experienced by the individual. The mining community in southern Africa may be concerned with the alarming rise in HIV/AIDS statistics, and subsequent implications for workers' health, as well as the financial impact on company operations. However, female commercial sex workers working outdoors identified exposure to the flu and colds as their primary daily health concern (Commercial sex workers, personal communication, 1999). Likewise, in another study, mine workers identified concerns about death and injury as their main daily health concern (Campbell and Williams, 1998). In this context there appears to be a disjunction between the identified priorities of the mining and medical community and the priorities of the individuals whose behavior they are trying to influence.

Mining companies may not be optimizing efficient use of resources available for health interventions. Perhaps interventions will not be, in the long term, effectual or sustainable, if they are not cognizant of other, environmental, psychological, social, and spiritual health determinants that are more critical to individuals and communities than their current health and community policies acknowledge. The points outlined above underline some of the complexities and difficulties that need to be considered when assessing a mineral development project's contributions to, or detractions from, the health and well-being of individuals and communities.

National and international mining companies may consider their primary role in society to be wealth creators. However, this is changing. Increasingly, many companies are embracing a triple bottom-line approach, aiming for improved economic, social, and environmental performance. Companies may be making a mistake by focusing on increased individual income through direct employment or trickle-down effects, and contribution to the gross national product (GNP) as the primary benefits of minerals development for communities and countries. Increased income does not necessarily bring greater equity. It may also increase ecosystem disruptions and may disrupt or destroy the determinants of people's health and well-being, and the social fabric of families and communities. Moreover, quantitative goals, such as increased income, longer life expectancies, and higher GNPs, by definition, pay little account of the quality of people's lives.

We are not proposing that a focus on economic goals is exclusively limited to mining companies or mining activities. The effectiveness of a government's policy is measured primarily by that country's GNP growth and many public policy decisions are based on economic cost-benefit

analyses. Moreover, financial institutions assess credit ratings of municipalities, corporations, and governments alike on the basis of economic performance and potential rates of return. Although recent research suggests that, increasingly, those financial institutions are placing environmental and social conditions on the provision of finance to protect their returns against future liabilities (Warhurst and Hughes, 1998). However, the focus of our research remains on a mining industry that has been heavily criticized in recent decades over many aspects of their environmental and social performance in an effort to inform new corporate strategy about change and improvement.*

Therefore, we propose that it is within the realm, as well as the responsibility, of mining companies to enhance their social performance with respect to human health. These companies must not only encompass, but also surpass narrow occupational concerns, based on an understanding of health as negotiated with the communities likely to experience the impacts of the mine's operations (Milner, 1999). In turn, the negotiated community-based health definition should then be used in conjunction with mining company personnel and/or with specialist health expertise to develop health impact assessment methodologies and subsequent monitoring programs for community health during the operation of the mine and in planning for decommissioning and closure.

These community health investment activities can be considered to fall under the rubric of corporate social responsibility. Some of the drivers influencing mining companies to act in a socially responsible manner and expand the broader determinants to health are considered in the section below. A brief discussion about the implications for emerging strategies of corporate social responsibility is outlined in the chapter's final section.

Drivers

Over the last decade, multinational corporation (MNC) activity has expanded. In 1970, there were only 7000 MNCs and now there are around 40,000, with over 200,000 globally spread affiliates. In the minerals sector they are particularly active in developing countries and potentially major conduits for technology transfer and economic benefit.

Since 1989, over 75 countries have liberalized their investment regimes for mining to promote further investment and have privatized the large old state dinosaur mining companies, such as COMIBOL in Bolivia and CENTROMIN in Peru, leading to downsizing and drastic direct and indirect employment effects, which brings serious social and health consequences, as mentioned earlier. In turn, this has led to a reduction of the welfare-providing role of the state, which previously supplied a social wage to those large workforces and their families through the provision of subsidized food stuffs, health services, schools, and a salary. This constitutes a form of corporate social responsibility, a paternalistic one, as distinct from the proactive and more deeply embedded concept of corporate social responsibility being discussed now. These benefits were not sustained and were often taken away from one day to the next if metal prices fell, leading to increased poverty and inequity, particularly at old mining regions.

As a result, a growing voice of society is demanding that regardless of formal requirements MNCs, particularly those that have benefited from privatization, adopt a longer-term, forward-looking approach. This should be an approach that proactively anticipates these drivers and implications and takes responsibility for addressing some of the past inefficiencies and inequalities that have, in this new market context, provided them with their opportunities. In this context, it should not be a surprise to the industry that this voice of society is controversially demanding that MNCs apply their capabilities more broadly to address some of the more far-reaching and indirect effects of their activities on the health and quality of life of local communities affected by minerals development in general. This includes addressing the sins of the past (i.e., environmental damage and potential health liabilities resulting from past pollution, generated in the absence of regulation).

* The numerous criticisms and examples of poor performance have been well documented by MERN researchers and research associates. For example, see Echavarría (1999), Macfarlane (1998), Noronha (1999), Carter (1999), Warhurst and Mitchell (1998).

Societal concerns are increasingly expressed as demands for information, accountability, and, particularly, community participation. These concerns are also reflected in Agenda 21, the action plan resulting from the Rio Earth Summit in 1992, which, among other imperatives, obliges industry, morally not legally, to contribute to local capacity building in developing countries and to transfer clean technology.

At a sector level there are industry codes of conduct. For example, in mining there is the International Council of Metals and Environment Code of Practice, and within the quarry industry in the U.K. there is the Quarry Products Association Environmental Code of Practice. The Amnesty International Human Rights Principles for companies, in particular, urges companies to adopt an explicit commitment toward respecting and protecting human rights, including human health and well-being (Article 25 of the UN Declaration of Human Rights; Frankental and House, 2000).

Action groups, specifically nongovernmental organizations (NGOs), are increasingly important drivers of change. Friends of the Earth and Greenpeace have launched high profile exposé campaigns and, more recently, have sought to develop a solutions agenda with the business community as NGOs themselves have recognized the creative and shaping role that business can play in the global economy. The role of special interest NGOs has recently grown in importance, parallel with the retreat of government and the diminution of scientific authority, as seen with the scares surrounding bovine spongiform encephalitis, salmonella, and more recently, genetically modified foods. Those special interest groups that are especially active with respect to mining include Minewatch, Third World Network, and Survival International.

Regulation has always been considered a key driver of environmental and social performance. We are not underemphasizing the role that public policy has to play in framing the route toward the sustainable development goal. However, in a developing country context, environmental law is often weakly developed and poorly enforced; it plays its principal role in defining the conditions attached to the permitting of industrial activity (the license to operate) rather than the performance of an ongoing operation or its closure. Notwithstanding, it is important to note that there has been a fundamental shift from the regulation paradigm of command and control, single medium, pollution clean-up incrementally enforced through inspectorates, the courts, and penalties, to a paradigm of integrated pollution control and pollution prevention, promoted through market incentives and innovative rehabilitation bonds.

The environmental and social conditions attached to the provision of mine project finance (as noted above) are proving to be an even more significant driver of improved environmental and social performance on the part of business. In mining, the investment costs are so high (most projects are financed, as a rule of thumb, one third equity, two thirds debt) that equity investment or credit has environmental or, increasingly now, social conditions attached to it to promote environmental and social performance that reduces potential future liabilities.* A major bottom-line concern of financial institutions, as well as companies, is to protect themselves specifically against health damage compensation claims and class-action suits.

Finally, there are also growing internal pressures from shareholders and mining company employees to be more environmentally and socially responsible. Some NGO groups are even buying shares so as to be able to ask questions at company annual general meetings. These questions frequently concern the health and well-being of local communities.

PROACTIVE APPROACH

Mineral development projects have the capacity to contribute to and detract from the health and well-being of individuals and communities. We argue here that adopting a well-defined and

* For example, one senior mining physician in South Africa commented on the likelihood that in the future international, if not national, finance institutions would require a company HIV/AIDS prevention programs as part of their loan conditionality (personal communication, 1999).

monitored strategy of corporate social responsibility is key to ensuring that community health and well-being improves and does not decline. Public policy may provide the enabling framework, but detailed below is the argument that a proactive, anticipative strategy of corporate social responsibility can make the difference. For that reason, it is paramount that from the outset of mineral exploration, an integrated definition of health and well-being be employed. This definition will inform the constituents of that strategy of social responsibility, and show that there is consultation and agreement with regard to whose definition of health and well-being matters. This section briefly considers what might constitute an integrated definition of health and the implications of using a different model for assessing the effects of mineral development projects on community health and well-being.

Corporate Social Responsibility

The development of the concept of corporate social responsibility has fast expanded since the days when it was considered that, “the social responsibility of business is to increase profits” (Friedman, 1970). For example, as Andrews (1988) argues:

Corporate strategy is the pattern of decisions in a company that determines and reveals its objectives, purposes, or goals, produces the principal policies and plans for achieving those goals, and defines the range of business the company is to pursue, the kind of economic and human organization it is or intends to be, and the nature of the economic and non-economic contribution it intends to make to its shareholders, employees, customers and communities.

More recently, Drucker (1993) stated, “corporate citizenship means active commitment. It means responsibility. It means making a difference in one’s community, one’s society, and one’s country.”

Corporate social responsibility is defined here as the internalization by the company of the social and environmental effects of its operations through proactive pollution prevention and social impact assessment so that harm is anticipated and avoided and benefits are optimized (Warhurst, 2000). The concept is about companies seizing opportunities and targeting capabilities that they have built up for competitive advantage to contribute to sustainable development goals in ways that go beyond traditional responsibilities to shareholders, employees, and the law; they focus on sustained progress toward improvements in the health, well-being, and quality of life of mining projects’ host communities.

There is a need for consultation and agreement with regard to whose responsibility it is to protect and promote health and well-being on the part of individuals, community, government, and companies in different situations and at different times, particularly where political power is not equal. An evolving area of MERN research is, therefore, the concept of good governance and corporate social responsibility with respect to human health and well-being. We suggest that adopting an integrated view of health with regard to how the mining company’s activities directly and indirectly affect population health outcomes could usefully form one component of a company’s corporate social responsibility strategy.

Integrated Conception of Health

In 1946, the World Health Organization defined health as “a state of physical, mental and social well-being and not merely the absence of disease or infirmity” (Bowling, 1991). Putting this holistic and positive view of health into operation has been slow in developing. However, over the last few decades an emerging health consensus advocating a more integrated view of health has been gaining momentum. An integrated definition views health as a positive state with the ability to do things that are important or have meaning, and which result in a sense of enhanced well-being (Bowling, 1991).

This positive definition conceptualizes health as the integration of the body, mind, and spirit within the individual and the individual's integration within wider social and cultural spheres. In this view, the individual is understood as already embodying, and being embedded in, dynamic and interactive ecosystems and social systems. In contrast to other concepts of health outlined earlier, a key feature of this positive model is that constituents of health are determined by individuals in a dialectic relationship with their other psychological, social, spiritual, and biogeophysical environments.

This positive definition of health is reinforced by evidence of a strong correlation between mortality and social support networks (Evans, 1994; Levine, 1987). Social support networks provide integral mechanisms for coping with stress and adverse life circumstances. Recent research in Colombia suggests that the links between health and well-being and social support networks may be even more pronounced among indigenous peoples (Echavarría, 1999). This research, undertaken participatively with the Wayuu indigenous peoples of Colombia, demonstrates clearly the urgent need for those within the mining industry to understand the broader view of health and well-being and encourages respect for multicultural definitions.

Additionally, we argue that an understanding of a broader view of health should not be limited to health specialists hired by a mining company, given that many health specialists are themselves agents and proponents of the biomedical model, but should also reside within the company's human resources. This includes those responsible within the company for managing community development and environmental protection programs. The recognition that people are not only individuals, but also members of a family, community, and society* should have important implications for the way mining companies view and plan interventions to community health and well-being.

Analysis and Research Implications

We have argued in this chapter that a clearer definition of health is needed before progress can be made in measuring health. The emergent understanding within the medical community that health is more than the absence of disease or injury is reflected in the growth of health measurement scales that go beyond physical functioning. Efforts today are focused on measuring more than just physical aspects of health; they include efforts to measure subjective well-being or an individual's perception of their quality of life. The World Health Organization's research project to develop a quality of life measurement tool is one such example. Indeed, Bowling (1991) calls quality of life the missing measurement. This must be, therefore, taken into account in any attempt to "measure" a mineral development project's contribution to, or detraction from, community health and well-being.

One of the difficulties with most conceptualizations of health and well-being is that listing the constituents implicitly assumes equal importance of each constituent; however, not all people value these components similarly. Therefore, the question of weighting and explicitly clarifying whose values are determining the weighting toward one particular aspect over another becomes paramount in any attempt to measure mining's contributions to or detractions from community health and well-being. Individual and community-level values must also be factored in any measurement attempt.

An integrated health concept suggests that much broader interventions, including community empowerment and antipoverty measures, are necessary to promote health effectively. Evans, citing Wilkinson (1992), suggests that the health of a population depends on the *equality* within a group not the *average* income distribution. Averaging incomes may conceal the reality that the income is unevenly skewed or restricted to a small portion of the population and, therefore, rising incomes can still be

* "The protective sense of self-esteem or coping ability may well be a collective as well as an individual possession" (Evans and Stoddart, 1994, p. 52).

associated with declining health.* Evolving research on the full connections between socioeconomic standing and health status goes well beyond the initial analysis that higher incomes bring better health.

A mining company's efforts at being a good neighbor are often, like health promotion schemes, aimed at individual lifestyles. But they are likely to be ineffective if they are missing these several critical considerations listed above. Again, the conclusion is that greater regard must be given to the social and cultural weighting of what each society and its members consider to be important determinants for them and their health and well-being.

Moreover, the very act of beneficence could further undermine the very determinants that appear to be critical to our health, the degree of control people feel capable of exerting over their lives (Evans and Stoddart, 1994). Whereas a company may believe it is contributing to a community by building a school, unless this has been done in careful consultation and as a priority identified by the community itself, the company may undermine the community's sense of control and may foster dependency.

Additionally, the high incidence and prevalence of communicable diseases in developing countries should not obscure the reality that social support networks are also critical determinants to health and well-being. A mine-built health clinic may provide services that eradicate certain types of diseases and illnesses, but that does not automatically rule out the possible, equally negative, physical health impacts inadvertently caused or associated with the adverse social impacts associated with mineral development projects if they are poorly managed. The potential significance of social processes operating on health of group and population clearly needs greater attention and research. A mineral development project's impact on its community** health and well-being is wide-ranging and is not yet as well understood by those "coming in" to the community as it is experienced by those "already in" the community.

More work must be done to facilitate an integrated and multidisciplinary approach — within companies and between organizations — to ensure that health interventions are not tackled in isolation from their cultural and social contexts. Our research suggests that health information alone is not sufficient to change behavior, as exemplified by the growing HIV/AIDS epidemic in southern Africa.

Another line of research inquiry is to explore if differences in stakeholder perceptions as to what comprises their constituents of health and well-being, and determinants, are a source of conflict between stakeholders. Communities must be able "to determine priorities for improving the quality of their environment, and thus their own health and well-being" (U.K. Environmental Health Commission, 1997). Thus, to respond appropriately to the health needs of a particular community, those needs must be identified by, through, and with the people who live in that community, and priorities and targets set through a collaborative negotiation process.

In summary, as outlined above, preliminary research in southern Africa suggests that mining companies conceptualize health in the physical sense (disease and injury) based on the biomedical model. This model misses many health issues and may act as a conceptual, thus in turn, organizational, barrier to understanding the full impact of their activities on an individual's and a community's health and well-being. The links and interrelatedness between and among physical, social, spiritual, psychological, human, and ecosystem health are so far only being made in a very limited sense. This area needs a greater focus of research work.

* This is supported by resource-rent research undertaken by Markandya, A. and Warhurst, A., Analysis of the Distribution of Rents from Mining Operations, Mining and Environment, working paper, Corporate Citizenship Unit, Warwick Business School, University of Warwick, U.K. (1999). They have been advocating for greater distribution of economic benefits derived from mining.

** However the company chooses to define and understand the "community" associated with its mineral development projects. Most companies are likely to understand community spatially within a set geographical definition. However, due to the migrant labor system in South Africa several mining companies also define the communities associated with particular mineral development projects as those communities from which the migrant labor are drawn.

CONCLUSION

We have argued for the need of a broader, more integrated conceptualization of health beyond physiological functioning to include social, psychological, and spiritual aspects sometimes referred to as well-being or quality of life (Bowling, 1991; Bruton, 1997; Fallowfield, 1990; Nordenfelt, 1994). The inclusion of these terms in recent health literature and research efforts reflects a move toward the reconceptualization of health as being more than the absence of disease or illness. This argument is based on two interrelated lines of argument.

The first argument is that research into the determinants of health, even in the biomedical sense, suggests that they are still not well known. However, recent evidence indicates that social conditions are more critical determinants to our health than higher incomes alone and the existence of tertiary health services. Evidence is supporting the observation that social support networks and a personal sense of control have direct positive effects on human health in terms of physiological functioning (Evans et al., 1994).

The second line of thought is that any definition of health structures and limits our understanding of what health problems are and what the solutions might be. A biomedical definition of health typically characterizes problems as diseases or individual behaviors and as a result solutions are targeted at medical solutions or changing individual risk factors, behaviors, and hazards. This, therefore, has implications for the need to change business strategy in mining and policy mechanisms with regard to the implementation of strategies of corporate social responsibility, particularly in the areas of community health and well-being. Health policy based on the narrow biomedical model of health and health care will continue to have limited results. A narrow set of assumptions about what constitutes health will result in a limited view of which are the key health problems and lead to a limited view of what possible solutions exist.

It should be added that, although the implications of a broader conceptualization of health are daunting, we are not proposing that it is the sole responsibility of companies to address these socioeconomic and cultural contexts. Rather, we suggest that this very broadening of the concept of health broadens responsibilities too, and that the key lies in collaboratively addressing the problem and negotiating the solutions together across business, government, and community sectors.

While disease relating to the physical environment may in some instances be resolved, to a certain extent, with technical solutions, the structural causes of ill health associated with a mineral development project will be more difficult to act upon as solutions relate to social and spatial structures, as well as to intergenerational inequities. Although the links between mineral development projects and physical health of individuals have received some degree of attention and research, the understanding of mining's impact on the broader health and well-being of host communities, in its totality, is in its infancy and remains critically underresearched. It is the goal of the joint IDRC-funded research to advance knowledge in this key area of the sustainable development and development policy debates.

Mining and Indigenous Peoples: Contributions to an Intercultural and Ecosystem Understanding of Health and Well-Being*

Cristina Echavarría Usher

INTRODUCTION

Economic globalization and the concurrent liberalization of investment regimes have promoted the rapid expansion of mining activities to areas previously isolated from mainstream development processes in developing countries (Warhurst, 1999). Many of these areas coincide with territories traditionally occupied and used by indigenous peoples (IIPP), African Americans, and traditional *campesino* communities (IITC, 1996; World Bank, 1997).

Although demographic data on indigenous populations in many countries are often incomplete, it is estimated that there are some 300 million individuals who identify themselves as IIPP in the world today (Coordinadora de Organizaciones Indígenas de la Cuenca Amazónica, 1999). These IIPP inhabit 70 countries and are characterized by an enormous cultural diversity. In Colombia alone there are 81 ethnically and culturally distinct IIPP, although they total only some 600,000 individuals (Dirección General de Asuntos Indígenas, 1998).

On a global scale, indigenous peoples are increasing their levels of empowerment, while their issues of concern with regard to the manner in which large development projects in their territories affect their ethnic integrity,** their livelihoods, health, and well-being, all of which have reached greater visibility in both academic literature and mass media. Important international institutions such as the World Bank, the European Union, the International Labor Organization (ILO), and the United Nations (UN), as well as international nongovernment organizations (NGOs), are increasingly addressing these same concerns.

National legislation varies widely between countries in its degree of protection and recognition of the rights of IIPP. The general tendency is toward a growing recognition of IIPP rights, in a context characterized by cultural and territorial conflict resulting from the dominance of resource intensive development models and national fiscal objectives over local and regional social and economic development priorities.

* This chapter is based on the technical report, Social and Environmental Performance Indicators: Evaluating Progress Towards Improved Health and Well Being, Colombian Component: Indigenous Peoples, Vol. 1–3, Echavarría, C., Correa, H.D., and Puerta, C., Instituto de Estudios Regionales (INER), final phase 1 technical report to Mining and Energy Research Network, Warwick University (MERN), International Development Research Center (IDRC) (1999). This report is available from INER, University of Antioquia, Medellín, Colombia; and IDRC, Ottawa, Canada. The author made all the translations from Spanish.

** Ethnic integrity is understood as the maintenance of the essential factors of livelihood and of the recreation of the ethnic, economic, political, social, spiritual, and cultural systems of indigenous peoples (DGAI, 1998, p. 57).

The physical disruption that characterizes most mining activities often leads to conflict over natural resource use and development and to rapid changes in local livelihoods (Hoon et al., 1997). The pollution and degradation of the resource base (water, air, soil, flora, fauna, etc.) has a greater impact on the more vulnerable sectors of society that depend directly on the land for subsistence. Nevertheless, the problem goes beyond contamination to direct impacts on nutritional security through the destruction of livelihoods. This is often without proper compensation or implementation of livelihood alternatives that are culturally compatible or that respect cultural diversity.

The social impact caused by the immigration of foreign workers into marginal or remote regions also has multiple effects on the social fabric, health, and well-being of traditional communities. The construction of large infrastructure developments required by mining may fragment the traditional territories of these communities, disarticulating their use of space and disrupting food-gathering and herding circuits. Often land and resources required by miners constitute important assets of the typically diversified livelihoods of indigenous peoples, many of whom rely on a low-intensity, but extensive and diverse, use of natural resources. This itself may reduce the ability of IIPP to sustain their traditional ways of life and place severe stress on their ethnic integrity and well-being, generating intraethnic and interethnic conflict over both local natural resources and the economic benefits generated by mining activity.

In many of these regions and localities of the developing world, local communities still have high indices of unresolved basic needs, and great expectations are likely to be placed on mining companies to deliver tangible social benefits. In many cases, companies want to develop appropriate social policy, but local and regional state agencies are corrupt or inefficient. In addition, citizens do not have the capacity or the power to implement public auditing systems to ensure greater transparency and distributive justice in the management of royalties at the local level.

In this context of inefficient state institutions and poor governance, communities fear that pollution will go unreported and unnoticed until it is too late and the damage has been done. They are painfully aware that a diseased ecosystem will mean hunger and illness for them, and that political corruption is likely to exclude them from economic benefits that may be produced by the minerals development.

All these factors are fuel for social and political conflict. They increase the risk of operations being closed down, and in consequence, they tend to reduce opportunities for the attraction of the foreign direct investment that has become crucial for the sustainability of macroeconomic goals of many developing countries.

For many of the above reasons, and on the basis of their negative historical experience with development, it is common to find that indigenous peoples who oppose natural resource development projects (in their territories or close to them) are labeled by the press and governments as the obstacles of development* without sufficient analysis of the trade-offs involved. In countries like Colombia, this may easily lead to the physical extermination of indigenous leaders by extremist groups.

If improved well-being is a necessary outcome of minerals developments, then all of the above aspects need to be addressed by the main stakeholders, in particular, the mining companies and the national and local governments. This points to the need to develop conceptualizations and methodologies that incorporate intercultural criteria and decision-making mechanisms throughout the life cycle of a mineral's development. These should facilitate authentic indigenous participation, in both the planning and proper consultation of development projects that may affect them, and in the prediction, evaluation, compensation, and mitigation of the social and environmental impacts generated by mining activity.** Mining, in a multicultural world, and specifically in local contexts

* For instance, with regard to the negative of the U'wa peoples of Colombia to allow oil exploration and development in what they consider their traditional territory, the Minister of Mines in 1997 was reported as saying "one cannot compare the interests of 38 million Colombians with those of an indigenous community" (CCEU, 1997 cited by Project Underground 1998, available from project_underground@moles.org).

** It is not the object of this chapter to analyze present practice in environmental (EIA) and social impact assessment (SIA). For indigenous guidelines for use of traditional knowledge in EIA, see Emery et al. (1997).

characterized by the presence of several worldviews and cultures, calls for the development and application of intercultural forms of communication and understanding.

The object of this chapter is to report the advances in research to this end made by the University of Antioquia (Colombia) in the context of the Environmental Social Performance Indicator (ESPI) research program. It aims to contribute toward an integral understanding of health and well-being, to analyze some of the elements that have been identified as key issues for health and well-being by indigenous peoples, and to propose a working integration of these into the main ESPI framework.

KEY APPROACHES TO UNDERSTANDING HEALTH AND WELL-BEING

This section draws on key elements that have been produced by number of paradigms of health and well-being in order to develop an ecosystem and intercultural conceptual framework useful for developing tools for tracking health and well-being in multicultural mining regions. Not intending to make an in-depth analysis of each of these approaches, the aim is to make explicit the approaches that are being incorporated by the ESPI conceptual framework for indicators of health and well-being.

ESPIs: Beyond the Biomedical Model of Health

Due to the complexity of the social and environmental impacts involved, recent research supports the idea that the traditional biomedical concept of health (understood as the absence of disease or injury) is a limiting model for dealing with the impacts of mining on health and well-being (MacLean and Warhurst, 1999).

ESPI research team discussions and papers advocate that health concepts need to take into account the social, political, cultural, environmental, and economic conditions and processes that determine the well-being of communities and individuals. Evidence indicates “social conditions are more critical determinants of our health than higher incomes alone and tertiary health services” (MacLean and Warhurst, 1999).

Working definitions of health, well-being, and quality of life are used in ESPI research in an almost interchangeable manner, with subtle differences in emphasis. This results in the reconceptualization of health beyond that expounded by the predominant biomedical paradigm (MacLean and Warhurst, 1999), to a conception more akin to well-being (Max-Neef et al., 1996; Nussbaum and Sen, 1996) and quality of life. The World Health Organization’s (WHO) definition of health directly emphasizes the interdependency between health and well-being: “*Health* is a dynamic state of physical, mental, social and spiritual *well-being*, not merely the absence of disease or infirmity.”

The identification between well-being and quality of life, so evident in the writings of Nussbaum and Sen (1996), is also reflected in policy documents, such as the WHO definition of quality of life: “An individual’s perception of their positions in life in the context of the culture and value systems in which they live and in relation with their goals, expectations, standards and concerns” (WHO, 1993).

This definition recognizes another key characteristic: that conceptions of health, well-being, and quality of life are culturally determined and constructed. This is particularly important to understand in scenarios where macrodevelopment projects establish themselves in traditional indigenous and rural communities. Here, the values and cultures of various stakeholders may vary significantly with regard to what is meant by well-being and quality of life, as an expected result of the proposed development. In order for these projects to be sustainable in social and environmental terms, both the mining companies and governments need to ensure that they deliver culturally compatible community programs that generate improvements in well-being, health, and quality of life that are recognized as such by the local communities.

Well-Being and Quality of Life*

Despite cultural diversity, authors like Max-Neef et al. (1996) and Sen (1996), among others, have argued that some categories of well-being are universal.

According to Sen (1996), the core aspects of both well-being and quality of life are the capability and ability of individuals to achieve valuable functionings in terms of being and doing. “*Functionings* represent parts of the state of a person — in particular the various things that he or she manages to do or be in leading a life.” While “the capability of a person reflects the alternative combinations of functionings the person can achieve, and from which he or she can choose.” In this sense, “capability reflects the freedom of an individual to choose between different ways of living” (Sen, 1996).

Sen and others (Cohen, 1996; Corredor, 1998; Korsgaard, 1996; Max-Neef et al., 1996; Nussbaum and Sen, 1996) have offered extensive critiques of conventional measures of well-being and quality of life arguing that they overestimate the importance of primary goods. According to Sen (1985): “Although goods and services are valuable, they are not so by themselves. Their value is found in what they can do for people, or better, in what people can do with these goods and services.”

According to these authors, a theory of well-being must be based on a new approach that clearly incorporates ethical principles and rights. This would not give so much importance to the quantity of production of goods and services, as it would to the effectiveness of the economic and institutional systems to ensure the rights, valuable functionings, and capabilities of individuals.

What determines the absence of individual well-being is not only a budgetary restriction, but also the absence of capacity for freedom, in particular, the individual moral freedom of deciding and choosing between different options. Nevertheless, these options and the capacity and will to put them into action are directly dependent on the fulfillment of fundamental human needs. If basic needs, now recognized as social, cultural, economic, and developmental rights, are not resolved, there is little possibility that individuals and social groups will be able to develop the capabilities required to actually exercise these rights (Corredor, 1998).

For instance, if local indigenous communities in developing countries have not solved meeting their basic needs, such as in the case of the Wayúu peoples in Colombia, they are not free to exercise freedom of choice. When consulted by a mining company for their approval to have access to their territory in 1998, the Wayúu decision was heavily influenced by the fact that they did not have access to drinking water or sufficient territory for their livelihoods. They agreed to allow access for exploration on the part of mining companies in hope that these needs would be at least partially fulfilled, but with the risk of negatively affecting their ethnic integrity because the eventual development of the mine would inevitably change their way of life (Echavarría et al., 1999).

Most indigenous peoples want to improve their health and well-being without losing their identity, traditional territory, and autonomy. Often, they do not want to change their way of life or their own model of development or self-determination, but they do want to participate in the decisions that affect them. The promise of access to clean water, formal intercultural education and health care, more land, or compensation money is likely to put short-term trade-offs in the forefront, risking long-term ethnic integrity and well-being.

Freedom of choice in the absence of social, economic, cultural, and development rights is clearly difficult to exercise for many communities in developing countries. From this perspective, the insistence of indigenous peoples on the rights issues becomes clearly pertinent in understanding conceptions of well-being that give greater emphasis to freedom of choice as a crucial category.

Social Processes, Cultural Representations, Ecosystem Health, and Rights

The construction of an intercultural and ecosystem conceptual approach for tracking health and well-being in mining regions poses the challenge of articulating, in a meaningful manner, concepts

* The author acknowledges the contributions in this section of Betancur, O.L., *Enfoques sobre las Teorías del Bienestar* (Theoretical approaches to well being), Instituto de Estudios Regionales (INER) working paper, 2000.

from a number of other theoretical approaches, while at the same time responding to the actual diversity of conceptions of health and well-being. Abundant literature has been produced on these approaches and has been analyzed elsewhere (Puerta and Echavarría, 1999). The main contributions of these models to our approach are summarized below.

Social medicine proposes that health and disease need to be understood as social processes, both in terms of the historical relationships between human individuals and groups, and between people and the environment in specific contexts. In particular, the historical materialist view of social medicine gives importance to the relationship between type of work, living conditions, and health profiles (Laurell, 1982; Quevedo, 1992, 1993; Pinzón et al., 1993). The use of this last approach is particularly pertinent to occupational health in mining, and has produced important results in Colombia, such as in analyzing the health problems of the coal miners in the Guajira coal-mining region (CENSAT et al., 1995). More generally, the social medicine approach states that:

[D]iseases are of a historical and social character ... the social nature of disease is not verified in the clinical case but in the characteristic manner in which different human groups become ill and die ... it is not in the study of ill persons that we are going to better understand the social nature of disease, but in the pathological profiles of different social groups (Laurell, quoted by Quevedo, 1993).

The underlying assumption of this approach is that health promotion must link with the regulation of social processes — governance, participation, rights — and not only with the identification and management of specific vectors of disease or of particular biophysical pressures.

Researchers in medical anthropology such as Bibeau (1993), Chaumeil (1993), Langdon (1991), Pederssen (1993), Pinzón et al. (1993), and many others, especially in Canada and Latin America, emphasize, “the role of the social and personal life of the diseased in the genesis, configuration and meaning of illness” (Quevedo, 1992). Here the understanding of health–illness as a process also implies the need to recognize the existence of diverse cultural representations and interpretations, that is, the particular conceptions of health and disease that a cultural group has developed based on its historical experience and everyday living. “All illness is social illness ... it is the expression of the forms of social organization and symbolic representation of the group” (Quevedo, 1993).

Medical anthropology in ecological perspective is relevant in this case since it addresses precisely this problem:

Anthropology has usually emphasized that health and healing are best understood in terms of a given society’s system of ethno medicine, and that the “insider’s view” is necessary to understand how a society defines and diagnoses disease. Western medicine, on the other hand, usually considers disease as a clinical entity that can be diagnosed and treated while ignoring the cultural context (McElroy and Townsend, 1989).

The ecosystem approach to human health promoted by International Development Research Centre (IDRC) in its research initiative (1997) was initially based on the ecosystem health paradigm (Costanza, 1992; Holland, 1995; Interagency Ecosystem Management Task Force, 1995; Rapport, 1999). In complementing the ecosystem health paradigm with socially based approaches, this paradigm incorporates key elements that will make it more useful as a conceptual model for the purpose of developing intercultural and ecosystem tools that track health and well-being in mining regions, urban centers, and agroindustrial regions. As McElroy and Townsend (1989) state, “When the unit of analysis is a total ecosystem, rather than simply the individual or the society, health and disease become indicators of the group’s effectiveness in dealing with the environment.”

This recognizes the health implications of the interactions between human groups and their environment. The biophysical environment may in itself pose natural threats to health, for instance,

in environments with naturally occurring acid rock drainage of heavy metals or mangrove environments where malaria and yellow fever vectors have optimal breeding grounds. These naturally occurring risks, which we call restrictions or conditioning factors, are bound to become severe health problems for incoming human population attracted by large-scale development projects, such as mining. These risks and restrictions may be understood as vulnerabilities that need to be identified and managed from the outset of mineral development in order to prevent disease and conflict.

Our case study of the Cerrejón coal development serves to illustrate this issue.* The Guajira desert ecosystem in north Colombia has naturally occurring high levels of atmospheric particulate matter that increases during the dry season with the incoming northeastern trade winds. The opening of one of the largest open-cast coal mines in the world, El Cerrejón, in an environment with critical levels of dust, tends to exacerbate the incidence of respiratory illness in the rapidly growing local population. An ecosystem approach would indicate the need to implement an epidemiological monitoring system that takes into account this risk in order to monitor and evaluate the different types of respiratory illnesses reported at local medical centers and hospitals. The present system only identifies acute respiratory disease, which does not allow medical authorities to establish causal relationships between mining activities and respiratory health in the region and, as a result, fails to implement more stringent dust mitigation measures on the mining companies operating in the region.

World Health Organization and Pan American Health Organization Global Perspectives on Health and Well-Being

The WHO Health for All 2000 is a policy framework for health development adopted by all its member states. At a guideline level this policy has incorporated elements of many of these approaches (Ochoa, 1994). In particular, it has recognized the influence of factors, such as access to education, nutritional security, drinking water, basic sanitation, attention to mothers and infants, immunizations, prevention and attention to endemic diseases, adequate treatment of disease, and access to basic medicines, in the improvement of health. In practice, full implementation has not become a reality for many communities in the developing world. Nevertheless, it offers a framework that reinforces the political aspects of health and, as such, complements the ecosystem approach to human health paradigm (International Development Research Center [IDRC], 1997).

According to Alderslade (1998), "Health has multiple determinants, and is rooted in the political, economic, social and institutional circumstances of individual countries." Health for All 2000, aims at 38 targets that broadly encompass better health, lifestyles conducive to health, healthy environments, and appropriate health care services. It has also promoted the principles for sustainable development in health, as follows (Alderslade, 1998):

- Equity in health
- Solidarity
- Health as an essential component of quality of life
- Sustainability
- Human rights, dignity and integrity, and patient's rights
- Cost effectiveness
- Basic health care for all
- The systematic, rational application of current knowledge, using agreed health outcome measurements
- Clear, appropriately directed public information campaigns helping to promote healthy lifestyles
- A focus on health promotion, disease prevention, therapy, and rehabilitation
- Multisector health impact assessments
- The strengthening of primary health care, and family care
- An appropriate hospital system

* For further information on health in La Guajira, see Puerta and Echavarría (1999).

This understanding needs to be complemented if it is to be useful in the analysis of health–disease processes in many indigenous populations where illness is interpreted and addressed as an expression of conflict, disharmony, and imbalance of the different dimensions of individual and collective social and symbolic life.

Responding to these concerns, the Pan American Health Organization (PAHO) proposed at the Winnipeg Conference (1993) the SAPIA* initiative for addressing indigenous peoples' health programs in the Americas (Stout and Coloma, 1993; Pan American Health Organization, 1996; Rossi, 1996). Its principles incorporate key elements of indigenous conceptions of health and well-being:

- The need for an integral approach to health, “since for indigenous peoples the interrelations between health, environment, territory, work, nutrition, social relations, etc., constitute a holistic reality without the fragmentation characteristic of ‘modern’ societies” (Rossi, 1996).
- The right to self-determination of indigenous peoples in that they must have the possibility of benefiting from technologic and scientific advances, while maintaining control over decisions taken about their health.
- The right to participation and empowerment.
- Respect and revitalization of indigenous cultures.
- Reciprocity in relationships between medical personnel and indigenous patients and with traditional healers.

Clearly there are many coincidences and complementarities between these approaches. Figure 86.1 illustrates the models from which contributions are being taken to produce a working paradigm of well-being that is meaningful to indigenous peoples, as well as other local communities in different cultures. These approaches will be complemented in the following section with the analysis of those elements that are fundamental to most indigenous peoples.

INDIGENOUS PEOPLE'S CONCEPTIONS OF HEALTH AND WELL-BEING: KEY COMMON ELEMENTS

The general objective of international environmental and sustainable development law is the formation of a global partnership of all peoples and nations to ensure for present and future generations *the well-being of humanity and the larger community of life* [author's emphasis] by promoting equitable and sustainable development and by protecting and restoring the health and integrity of the Earth's biosphere, of which all life is a part and apart from which humanity cannot survive or realize its creative potential. This global alliance should be founded on commitment to an integrated framework of shared ethical principles and practical guidelines (World Council on Indigenous Peoples, 1993).

The pertinence and ongoing validity of core common elements in the interpretation of health and well-being on the part of indigenous peoples of very diverse origin is evidenced in their recurrence in numerous international agreements,** in the rights accorded to them by some national constitutions (such as, those of Colombia, Canada, Venezuela, Australia, among others) and in declarations and consultations*** made by IIPP in different fora and processes.

* SAPIA is Spanish for “Iniciativa de salud de los pueblos indígenas de América” (Health initiative for indigenous peoples of the Americas).

** See for example, UN Draft Declaration of the Rights of Indigenous and Tribal Peoples, World Bank O.D. 4.20, ILO Convention No. 169, The Biodiversity Convention, among others.

(1997); etc.

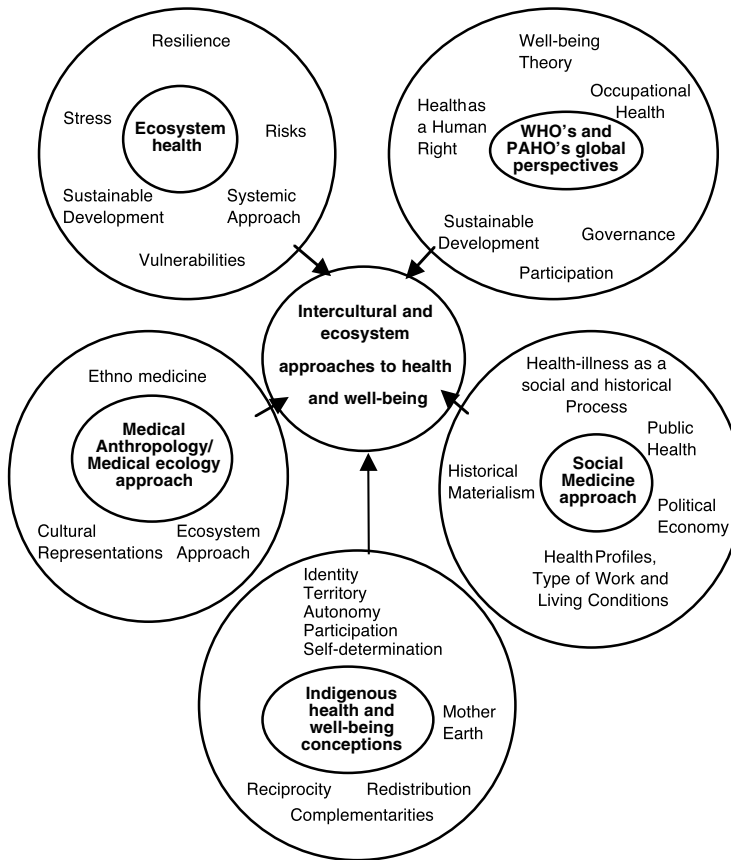

Figure 86.1 Conceptual sources for an intercultural and ecosystem approach to health and well-being.

The following common elements were systematically revised in our research and provide the basis for the identification of what we have described as fundamental elements of indigenous conceptions of health and well-being. It is important to indicate that these are not rigid and exclusive concepts and values that apply to *all* indigenous peoples, who are themselves very diverse, and have suffered different historical processes. They are true for many Latin American and Caribbean IIPP, and for some IIPP in the developed world (i.e., those who consider themselves as stewards of nature). The degree of present-day validity of these principles also varies depending on the ethnic integrity of each peoples, on their history of relationship with other regional and national social groups, and on their forms and degree of linkage to the market economy. Nevertheless, in the representations that IIPP make of themselves and of their understanding of health and well-being, the overall tendency is to emphasize the aspects proposed below.

Integral and Collective Conceptions of Well-Being

Although well-being is experienced on the individual level, many indigenous peoples conceptualize it as a collective state, where the individuals are usually seen in their relational dimension to other humans and to other beings of the world (nonhumans and superhumans).^{*} For indigenous peoples, disease and conflict are not usually individual issues. Their treatment involves both the

^{*} Understood as the humanization of natural phenomenon. For the Wayúu of Colombia and Venezuela, rain is the spirit of dead male ancestors.

immediate social network of the ill person, as well as other beings, all of which calls for a diversity of prophylactics.

Perhaps the most salient common characteristic of indigenous medicine is that both humans and animals, plants, rivers, mountains, stars participate in a totality. The elements that constitute this totality are all alive, they are closely related and interdependent. Therefore, the survival of the totality is a phenomenon which depends on the balance of the relationships between its various components (Arbeláez, 1990).

Well-being and health are seen to depend on the dynamic equilibrium* between humans and other beings in nature based on the ongoing validity and vitality of systems of reciprocity, redistribution, and complementarities (see below). This is not to ignore the processes of individuation that exist among IIPP. Many IIPP in the developing world emphasize the collective nature of well-being in the sense that due to historical disadvantage and the need to ensure ethnic integrity in the long term, it is necessary to elevate their collective rights as a people over the rights of their individual members. In Colombia, for example, IIPP have been recognized as collective social subjects by the Constitutional Court,** with five fundamental collective rights: identity, territory, autonomy, participation, and self-determination.*** If this position can be understood as a defensive strategy for maintaining ethnic integrity in a context of enormous external pressures, then the importance of maintaining the vitality of these systems reinforcing the collective nature of well-being becomes evident.

The integral nature of most indigenous worldviews also applies to their insistence on the integrity and interdependence of the five fundamental collective rights mentioned above. In Colombian jurisprudence, these rights, as components of the Constitution and its juridical system of human rights, are conceived of as an indivisible and integrated set.

Preventive and Participatory Health Management Systems

Elements such as wind, rain, thunder and other living beings of nature, like animals, plants, water ... are U'wa people of other times, with whom they still relate to, according to their own rigorous systems of reciprocity, redistribution and complementarities. [This is sustained by] a logic of harmony in the recreation of the totality of life and the survival of Mother Earth (Dirección General de Asuntos Indígenas de Colombia [DGAI], Letter to a Magistrate of the Constitutional Court of Colombia, 1997) (Perafán and Azcárate, 1995).

The values, beliefs, knowledge, traditions, and environment of a given social group are the source from which common law and ritual actions aimed at preventing illness and managing potential social or natural conflict are developed. In this way, the risk of becoming ill is controlled by actions framed within a specific social and cultural context (McElroy and Townsend, 1989).

An ideal state of well-being for many IIPP today may be represented in terms of dynamic stability in the context of a changing world. In other words, the ideal state of well-being depends on the ongoing capacity to regulate natural and social life through the exercise of conflict resolution mechanisms and health prevention measures, the essence of which is based on the principles of reciprocity, redistribution, and complementarities (see below).

This is not to imply that IIPP live in a permanent state of harmony. In many segmented indigenous societies, such as the Wayúu, conflict is the matrix that mobilizes alliances. It is

* Equilibrium (and harmony) is understood, not as absence of conflict, but as the existence of mechanisms for the effective regulation of social and environmental conflict. The Kaggaba peoples of Colombia use the word *yuluka*, which may be translated as "to be in agreement" (Reichel-Dolmatoff, 1985), to describe collective health.

** Colombian Constitutional Court Sentence T380/93 (DGAI, 1998, p. 70).

*** This does not mean that these are the only rights of IIPP in Colombia, but that under these fundamental collective rights can be grouped many other rights that they have acquired through historical resistance to integration, extensive lobbying, and organization.

important to understand that creating and recreating well-being in society is an ongoing process, the rules of which are established in reference to the particular worldviews and traditional laws of each IIPP. The challenge is to learn to understand these views and incorporate them into the actions and procedures of all public and private actors in their relations with IIPP.

Trust building between corporations, governments, and local communities around mining and other large-scale developments in IIPP territories is a key component for sustainable and equitable development. The real intercultural challenge lies in understanding how these traditional systems of reciprocity, redistribution, and complementarities work in each case, and how this understanding can be applied to the process of consultation and negotiation, impact evaluation, and compensation, mitigation, and management, in order to prevent and reduce conflict from the outset. This will improve the opportunities for delivering culturally compatible benefits when natural resource development is accepted as an option by indigenous peoples in a particular territory.

A Spiritual Dimension at the Base of an Ethic of Reciprocity

There will be cases where intensive natural resource development is not an option. This will be due to the lack of trust in the will and capabilities of the responsible stakeholders to deliver promised benefits, or because of ethical principles in relation to the nature of these resources.

Most IIPP consider that they belong to broad universes inhabited by interrelated beings of diverse nature. These usually include their ancestors, spirits of elements of the cosmos, and other nonhumans and superhumans. *Every element, event or phenomenon is provided with a spirit.* This knowledge alone has ethical and moral implications for human/other relationships, that make for all-encompassing conceptions of well-being and respect for the “diversity of spirits” (Achito, 1997).

Some indigenous peoples of Australia, Canada, the U.S., and Latin America see themselves as stewards of life on Earth, despite their present situations. Territorial reduction has forced many groups to overexploit the little they have left. Ethnic disintegration associated with natural resource development has been a common experience for many communities during the past century (CECOIN et al., 1995). The adaptation difficulties produced by rapid cultural change (such as that generated by mining projects in remote areas) has usually brought with it loss of traditional knowledge about the local territory-ecosystem (identity-territory); the generation or deepening of intraethnic conflict through the disruption of traditional systems of reciprocity, redistribution, and complementarities (participation and self-determination); and the breakdown or invisibilization of indigenous systems of common law (autonomy). Often changes in resource availability and access, caused by an activity such as mining, will directly affect livelihoods, while forced relocation will cause the breakdown of social networks built into the territory.

On the other hand, full economic and management participation of IIPP in mining development, even with the best of intentions, consultation, transparency, and equitable negotiations, has also been the cause of rapid cultural change bringing undesirable effects, as in the case of the Golden Bear Mine in Canada (Asp, J., personal communication). Unprecedented economic benefits rapidly transformed the values of the younger generation, many of whom adopted the consumer patterns of the dominant society. This was sometimes in excess of what would seem reasonable from the standpoint of indigenous cultural values (as understood by more traditional IIPP of Latin America and the Caribbean), especially because these changes have emphasized individual profit rather than collective well-being.

Yet, the past decades have seen the empowerment of indigenous organizations all over the world and a growing concern over indigenous issues, particularly in relation to natural resource development, such as mining, fossil fuel extraction and transport, and dam building. New realities are accentuating the political trend of indigenous peoples the world over to present themselves

as stewards of nature.* This reflects the *ethic of reciprocity* that opposes that of extraction and fragmentation of nature, based on the predominant instrumentalization of relationships between humans and nature driven by globalization and the expansion of the market economy to all corners of the planet.

DETERMINANTS OF WELL-BEING FOR INDIGENOUS PEOPLES

The ESPI conceptual framework for health and well-being proposes that satisfactory levels of well-being require that ecological, social, and economic systems function efficiently (Noronha et al., 1999). These “well-functioning systems” may be regarded as determinants of well-being (MERN et al., 1999), i.e., *What is instrumental to our flourishing?* (Dasgupta, 1993; O’Neill, 1997).

Building on the previous points, this last section explores the categories that constitute the determinants of well-being for indigenous peoples. In the case of indigenous peoples, the proper functioning these systems is equally pertinent, but the indigenous systems need to be further understood in terms of well-functioning systems of reciprocity, redistribution, and complementarities. These systems form the basis of traditional livelihoods, even though they increasingly include linkages to local, regional, national, and international economies and societies.

Our research indicates that these systems will only function adequately** in an international, national, and regional context where it is possible for indigenous peoples to exercise their five fundamental collective rights of identity, territory, autonomy, participation, and self-determination.

Exercise of the Five Fundamental Collective Rights of Indigenous Peoples as a Determinant of Well-Being

Five generic issues are of great concern to indigenous peoples in terms of their ethnic integrity, and especially in the context of resource development in or near their territories: identity, territory, autonomy, participation, and self-development. These core issues are at the heart of most declarations by indigenous peoples. They appear in international agreements, such as the International Labor Organization—ILO 169), in international charters (the United Nations Draft Declaration of the Rights of Indigenous and Tribal Peoples), and many other documents, and to a greater or lesser degree, as rights in the constitutions of some countries, such as Colombia, where:

These ... form the integral context of the fundamental collective rights that cannot be separated, isolated or negated without increasing the vulnerability of the ethnic and cultural integrity of these peoples (DGAI et al., 1998).***

In the Colombian Constitution these rights are generically defined as follows (DGAI, 1997):

- *The right to identity* as indigenous peoples is related with the right to be different and the right not to be discriminated against in their relations with the state and with society in general.
- *The right to a territory* is understood as habitat and as enough space and resources for the cultural reproduction as a peoples.

* Some people may not agree with this, but stewardship is a common representation that indigenous peoples and organizations make of themselves and their self-determination models.

** In terms of contributing to progress toward increased health and well-being, as they are locally understood.

*** In Spanish: “Estos ... forman un contexto integral de los derechos prioritarios y fundamentales colectivos que no pueden ser separados, aislados ni negados sin vulnerar la integridad étnica y cultural de estos pueblos.”

- *The right to autonomy* in the various spheres of their life as peoples: government, justice, education, health, and territorial management, social and economic reproduction.
- *The right to participation* in the different spheres of national life. Participation includes the right to *prior consultation** with regards to laws, plans, programs, and projects that may affect their ethnic integrity, their territories, or the resources found in them.
- *The right to self-determination*, meaning the ability to participate in determining the future evolution of the social groups and their culture. Also in the improvement of their own quality of life according to their conceptions of well-being, as well as in the life plans that they build as a peoples and in their intercultural relationships with other social groups.

Systems of Reciprocity, Redistribution, and Complementarities as Determinants of Well-Being

On another level, key determinants of well-being also need to incorporate the systems of reciprocity, redistribution, and complementarities that have been mentioned above. Insofar as these systems act as regulators of social conflict and, at the same time, as territorial resource management systems, their proper functioning and adaptation to changing circumstances facilitate improved well-being among indigenous peoples.

Systems of Reciprocity

“Systems of reciprocity” refers to the historical links woven by indigenous peoples among their members (kinship systems, work organization systems, authorities of different jurisdictions of same ethnic territory, etc.), with other human groups (members of government, private agencies, other indigenous peoples, and NGOs), and with other beings in nature (totemic kin, spirits, ancestors, etc.). This is the social fabric that sustains livelihood systems. The aim of livelihood systems may be understood as the maintenance of *stability* required for the prevention of disease and the proactive management of social and environmental conflict.

Systems of reciprocity with other beings of the world,** are usually managed through the religious sphere. Usually it is the responsibility of shamans,** spiritual leaders, or healers to monitor and control the fulfillment and maintenance of these reciprocities. This may be done through the interpretation of dreams, visions, or through divination and the use of diverse curing practices. It also may be done through established forms of payment or compensation by humans with objects of symbolic value to these other spirits, in reciprocity for the use of resources or the curing of disease. Illness and conflict are thus interpreted as early warning indicators of the breakdown of stability in existing systems of reciprocity. Prophylactics call for, among other actions, the reestablishment of the social and spiritual fabric with the reaffirmation of reciprocities through ritual symbolic interchange, usually associated with collective ceremonies.

Among humans, the system of reciprocity may be understood as:

[A] distribution system characterized by the transfer of goods and services from one person to another without immediate payment or exchange for other goods, but where it is expected that the receiver will repay the favor at some future date, when the giver needs it. Long term relationships between partners along social networks are thus established and maintained (Perafán and Azcárate, 1995).

Reciprocity is particularly important in relation to proper compensation in justice arrangements (also known as systems of social regulation and control), both for the prevention of conflict and as a mechanism for managing conflict once it has arisen. In segmented societies that have no unified,

* See ILO Convention 169.

** There are also superhumans (natural elements with human attributes) and dead ancestors, perceived as humans (Puerta and Echavarría, 1999).

*** Shamanism is the predominant religion among traditional indigenous peoples.

central representation, such as the Wayúu peoples of Colombia and Venezuela, the smooth functioning of traditional social control and regulation systems is crucial for the maintenance of social stability and harmony. Although conflict arises easily, its presence and the existence of conflict resolution mechanisms is a powerful driving force for alliance building in segmented societies, and a crucial aspect of well-being.

Likewise, in the context of compensations related to negative impacts of mining activity, the development of intercultural compensation systems needs to build on the traditional local legal practice (common law) of the particular indigenous peoples affected. This will facilitate improved well-being and ensure that agreements are both compatible and sustainable with the local culture.

Systems of Redistribution

Reciprocity is directly linked with the maintenance of systems of redistribution among humans. Although there are everyday reciprocities within the close family, the main collective instances of redistribution are rite of passage celebrations (birth, puberty, matrimony, and wakes) and other traditional gatherings related to religious and economic calendars. When a centralized authority exists, communal produce is usually managed by this authority and redistributed among the community during celebrations. Otherwise, it is the head of the family who is in charge of redistribution and who ensures its equity (understood in the sense that all give according to their capacity).

The determination of how economic or social benefits are distributed by a mining company requires proper consultation with the indigenous peoples in each case. The articulation of social policy through an understanding of how local redistribution systems flow may optimize social benefits in the short term, and prevent many conflicts between mining companies and local communities.

In addition, the integrity of the ceremonial cycle is crucial for the exercise of systems of redistribution, and its continued observance is an indicator of ethnic integrity and well-being. In this perspective, consultation processes and meetings related to mineral development and labor agreements need to take into account the ceremonial cycle, respecting the time they require and understanding their importance for social stability and ethnic integrity.

System of Complementarities: Territory, Identity, and Well-Being

La tierra para el indígena es como la salud. Un indígena sin tierra vive enfermo

— Jacanamijoy

quoted in: Cárdenas et al. (1998)*

The maintenance of complementarities in the use of territory and resources refers to the diversified and extensive subsistence strategies that characterize many indigenous peoples and many traditional *campesino* societies. This means that livelihoods based on combinations of agriculture, horticulture, herding, hunting, fishing and gathering, etc., often depend on the extensive use of resources either from niches at different altitudes (as in Andean societies) or from several, more or less adjacent ecosystems.

An extensive family may have different segments living in different niches, and would be then regarded as having a polyresidential settlement pattern.** In this way, specific social groups (such as extensive families) maintain permanent obligations of product interchange and resource use in different econiches, both as a strategy to diversify livelihoods and to strengthen interdependence between segments and as a strategy to prevent conflict. This strategy reflects both recent historical and long-term adaptation strategies aimed at the reduction of vulnerability through the development

* In English: "Land for IIPP is the same as health. An Indian without land lives in disease."

** We use polyresidential as opposed to nomadic since the second has the connotation of weak rooting to the land, while the first clearly emphasizes the complementary nature of subsistence strategies and settlement patterns.

of social systems and territorial management systems adapted to ensure availability and access to diverse and complementary resources, which today usually include paid labor and commerce.

By affecting one particular place, station, or resource, an industrial development may be affecting, not only the livelihood of the local family, but also that of other families that form part of a particular network as well as others who may only use it seasonally (or eventually through established cultural practices embedded in local common law).

The impact of territorial reduction due to mineral development would then need to be analyzed from the perspective of how livelihoods are affected in the light of complementarities in resource use on a particular territory. An indigenous territory must be regarded, not only as a particular parcel of land, but also as a network of resources located in different places, to be used in different seasons, on the basis of the existence of social networks that sustain complex livelihood systems.

CONCLUSION

Each social and biogeophysical context presents specific vulnerabilities and opportunities for mineral development. Different cultural groups interpret, represent, and cure illness in different ways. If mineral development is going to deliver improved well-being and health, all of these variables must be identified and managed from the outset.

We have argued that the construction of an intercultural and ecosystem approach, as a basis for developing tools for tracking health and well-being in multicultural mining regions, needs to incorporate concepts from a number of theoretical models and the key common elements and determinants of indigenous conceptions of health and well-being.

In addition to the proper functioning of natural and social systems in general, an intercultural approach to the identification of the determinants of well-being for indigenous peoples must incorporate two key elements: an understanding of the actual systems of reciprocity, redistribution, and complementarities that characterize each particular indigenous peoples and clarity in regard to how the five fundamental collective rights unfold in each context.

Although a global, generic, and broad definition of well-being is possible, further research is required to develop tools to aid in the understanding of how determinants of well-being unfold in each cultural context. To this end, the INER research team, within the ESPI program, has developed a cultural matrix that will aid researchers in identifying the constituents of well-being. This matrix is a descriptive tool that may orient companies and governments to the challenges of intercultural communication and management. It will allow the recognition of the message of “the other,” and an understanding the internal significance and implications of general and specific impacts of mining on the total ecosystem and the issues raised by indigenous peoples themselves, from the outset of mineral development.

The matrix in mineral development is structured on the basis of the five fundamental collective rights of IIPP, identified above as determinants of well-being. It does not intend to be a final and complete description of any particular culture. In other words, it cannot be taken as officializing or freezing a culture, but it can be an important aid in understanding its strengths and vulnerabilities in the face of specific pressures, such as mining activities.

The elements described above provide a new understanding of the ecosystem approach to human health. They bring intercultural perspectives and identify synergies and complementarities of a number of approaches that contribute new elements to the ecosystem health paradigm. Further research expects to put evaluation tools in operation that will respond to the actual cultural diversity in which mining develops in the world today.

Integrating Human Health into an Ecosystem Approach to Mining

Donna Mergler

INTRODUCTION

The ecosystem approach to human health is an innovative concept that incorporates human health into the dynamic interrelations of ecosystem analyses. In this approach, humans are not solely the drivers and disrupters of the ecosystem or the passive victims of environmental destruction, but are in continuous interaction with changing environmental, social, and economic conditions. In this dynamic process, ecosystem changes, resulting from human interventions (mining, agriculture, urbanization, etc.), driven by the need for subsistence or the forces of economic development, affect current and future well-being, not only of the present, but also for coming generations. Human health and well-being are, in turn, determinants of social, economic, and cultural development. Appropriately applied to environmental and health impact studies, the ecosystem approach can be a useful tool toward attaining sustainable and equitable development.

Human health deterioration and its consequences for the quality of life are most often omitted from environmental and cost–benefit impact studies. Here, we propose a means of integrating human health into the ecosystem analysis, using mining activities as an example. Four major issues, keys to the understanding of the relation between mining and human health, are examined: (1) miners' health; (2) a framework for focusing on the impact of mining development and activities on human health; (3) a model for examining human health deterioration; and (4) the notion of fragile ecosystem, using the example of gold mining in the Brazilian Amazon.

MINING ACTIVITIES

The extraction and transformation of minerals and quarrying are almost as old as civilization, and so are the accidents and diseases that have afflicted those who are engaged in these activities. In ancient Greece, in the 4th century B.C., Hippocrates described illness among lead miners (Lan-drigan et al., 1990). Five hundred years later, Pliny the Elder called lead poisoning “one of the diseases of slaves” and described a bladder-derived protective mask to be used by laborers subjected to large amounts of dust or lead fumes (Hamilton, 1943).

The lure of easy riches brought the Spanish and Portuguese to South America, in the search for gold- and silver-bearing ores, which native populations had been mining for centuries. Anxious for large and quick profits, the *conquistadores* set up mining operations in areas such as the mountain of Potosi in Bolivia, one of the first to be exploited; even today, the Spanish expression *vale un potosi* means that something has much worth. Indians were brought in as miners within a harsh system called *la mita*. In 1585, Fray Rodrigo de Laoyza, a predecessor of the modern Latin American activist priests, describing the conditions and lives in this silver mine, stated that the Indians were being consumed like sardines (Gumucio, 1988). The recent photographs by Sebastião Salgado of Brazilian gold mining (Salgado, 1997) evoke the sardines of Fray Rodrigo, and show that harsh working conditions and child labor are not things of the past.

Workers' health is most often completely ignored when considering the environmental impact of mining. The workforce is usually incorporated into the production process and considered in terms of labor and liability costs. Although increased income certainly contributes positively to the health of workers and their families, the history of mining is fraught with occupational diseases and accidents. In countries with mining activities, mining is almost always at the head of the list of sectors with the highest incidence of accidents and occupational diseases.

Although mining is not a major employer, accounting for about 1% of the world's workforce (some 30 million people), it is responsible for about 7% of fatal accidents at work, which is estimated by the International Labor Office (ILO) to be around 15,000 per year. No reliable data exist for accidental injuries, but they are significant, as is the number of workers affected by occupational diseases (such as pneumoconioses, hearing loss, vibration disease, metal poisoning, cancers), whose premature disability and even death can be directly attributed to their work (International Labor Office, 1998). Small-scale mining is expanding rapidly, and often uncontrollably, in many developing countries, employing large numbers of women and children in dangerous conditions and generating a workplace fatality rate up to 90 times higher than mines in industrialized countries (International Labor Office, 1999).

Mining takes its toll not only on humans, but also on the environment in its yearly production of approximately 23 billion tons of minerals, including coal. For high-value minerals, the quantity of waste produced is many times that of the final product. For example, each ounce of gold is the result of dealing with about 12 tons of ore, and each ton of copper comes from about 30 tons of ore. For lower value materials, such as sand, gravel, and clay — which account for the bulk of the material mined — the amount of waste material that can be tolerated is clearly minimal. According to a recent report of the ILO (1998), the world's mines must process at least twice the final amount of earth required (excluding the removal of surface overburden that is subsequently replaced and therefore handled twice); some 50 billion tons of ore are mined each year, which is the equivalent of digging a 1-m-deep hole the size of Switzerland.

SPHERES OF IMPACT: A FRAMEWORK FOR EXAMINING HUMAN HEALTH

This disruption of the ecosystem has effects not only on the workers, who are in direct contact with the mining process, but also on other sectors of the community. The framework presented in Figure 87.1 is generic and can be applied to many situations of environmental disturbance. Here, it is used as a framework analysis of the human health consequences of mining activities whereby the positive and negative effects of economics, social, and cultural reorganization, geophysical alterations, and chemical changes in the environment can be examined within a nested hierarchy of four spheres: workers, the local community, remote communities, and the general population. The arrows are bidirectional. For example, toward the center: the economic situation in a country can determine whether mining activities are permitted as well as the control on its environmental impact; workers' economic condition can bring them to mining and are an important determinant for their health. On the other hand, mining activities can provide wealth for the different sectors

Figure 87.1 A concentric framework for studying the positive and negative impacts of mining activities on human health in an ecosystem perspective.

of the population, which may or may not be equally distributed; this wealth can contribute to improving the health of the four levels of the population. The spheres are not completely closed since the activities of one can affect the others, influencing their respective health status.

Mine Workers

Mining activities are situated in the center of the sphere and the workers constitute the first group whose health and well-being is affected by the working conditions. The statistics from the ILO on accidents and illnesses constitute only the tip of the iceberg. Since reporting these events is dependent on the capacity and the will of different countries, they are often underreported for various reasons. Among these reasons is the question of liability and compensation. Moreover, illegal small mining operations are rarely included in official reports. In addition, there is the healthy worker effect, which occurs when workers' health deteriorates to the point where they are unable to continue and abandon the workplace, leaving behind only those who are physically and emotionally capable of carrying out the work. The workers in poor health leave the mines and their illnesses and disabilities are not attributed to mining, while those who are healthy enough to continue to work constitute the healthy workforce. A high turnover of workers in mining activities can be an indicator of poor health; the statistics on accidents and illnesses often do not reflect this reality.

Working conditions in mines have improved over the centuries, and these improvements have accelerated during the last century, with resulting improvement in miners' health. Much of this improvement has been the result of major battles waged by workers, their wives, and their unions to obtain better working conditions and health services for themselves and their families. In 1975, International Women's Year, Domitila Barrios de Chungara told the world of struggles of the tin miners and their families in Bolivia, high in the Andes (Viezzler, 1976). Films, such as *Harlan County USA*, *Miner's Daughter*, *The Salt of the Earth*, and *Germinal*, have brought vividly to our screens stories of mining families' battles to improve their working and living conditions.

Threatened with the possibility of losing their jobs if the mine closes down, miners may often oppose environmental measures. Their voice must be heard and included in all multistakeholder endeavors and research for good ecosystem management.

Local Communities

Mining activities have a major direct and indirect impact on the health of local communities. People from outside the region, looking for jobs in mining or associated areas, can upset the structure of the existing society. Gender relations are affected since mining jobs are mainly available to men, with women in satellite roles (Wasserman, 1999). Hierarchical relations are modified through the introduction of a new power structure in the community. The movement of populations, particularly in areas with a potential for dissemination of infectious diseases, creates a further health hazard. Sexually transmitted diseases are known to increase in such situations (Campbell and Williams, 1999), and, in the case of gold-mining in areas with endemic tropical diseases, miners also constitute a vector for the transmission of malaria and other infectious diseases into local communities (Rambajan, 1994; Carvalho et al., 1999). The well-being and health of the local community can also be affected by the increased burden to families of workers who have been injured in mining accidents or are suffering occupational diseases.

There are also economic benefits to the local communities, which can have a positive impact on health, the most important being job opportunities. Many communities, living near mines or proposed mining areas, in different Latin American countries have used organized protests to obtain the setting up of clinics, sewage systems, and other collective installations, which positively affect health. After undertaking a cost–benefit analysis, a Peruvian private mining company set up an integrated health care and family planning program, resulting in improved children's health and reduced cost for pharmaceuticals (Foreit et al., 1991).

The greatest biophysical environmental destruction is most often, but not always, in the direct vicinity of the mining activities. Deforestation can have devastating and long-lasting effects, changing ecosystem dynamics. Many mining activities require great quantities of water, affecting the aquifers that are essential to human health and well-being. Pollution from the particular metal being mined or the waste products of the production process enter the surrounding ecosystem, potentially affecting the health of plant, animal, and human populations.

Remote Communities

Even communities living far from mining activities may be affected through water and airborne pollution (Figure 87.2). Rivers can carry pollutants over hundreds of kilometers into the sea, affecting the wildlife, fish, and seafood, which are then unknowingly consumed by the communities living far from the source. Ores are often transported by trucks or rail over large distances, polluting the areas through which they pass, and thus affecting the health of people living near these routes. The effects of low-level, long-term exposure to environmental pollutants are a subject of current concern, particularly in relation to their effects on the reproductive, neurological, immune, and endocrine systems.

General Population

The general population within a country can benefit from the accrued income from mining activities if regulations and policies so permit. However, while different segments of the population may reap benefits, others may become more impoverished. In the 1999 Pan-Canadian Ecohealth Lecture Tour, in which the theme was mining, Labonne (1999) pointed out that the activities of the extractive industry are now increasingly located in developing countries. These are countries where, paradoxically, mineral resources endowment, including oil, has had a corruptive effect on many governments, causing both impoverishment and restlessness of the population living in the mineral and oil producing regions.

Finally, since to date there has been little effort to plan for closure on the part of mining companies, the social and economic costs of cleanup are often taken on by the country, particularly

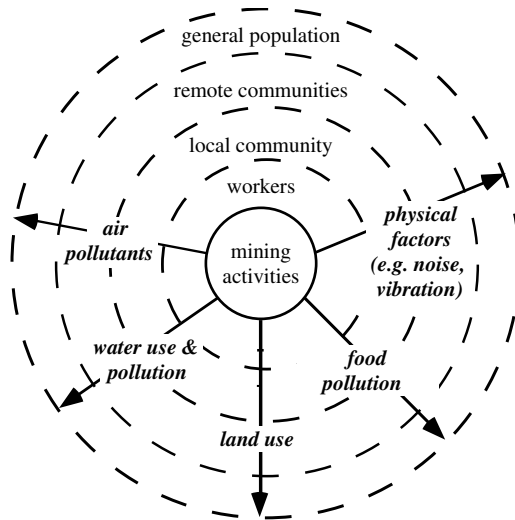

Figure 87.2 A concentric framework for studying the health of populations affected by geophysical and chemical environmental changes from mining activities.

when a mine has closed down, leaving behind waste and devastation and a population whose health has been affected by poor working and living conditions.

HUMAN HEALTH DETERIORATION ON A CONTINUUM

Human health is much more than the absence of disease. Ecosystem disruption associated with mining (with the exception of major disasters or spills) usually does not produce dramatic immediate effects on human health. Rather, there are slow, insidious changes in biological functions, reflecting diminishing well-being and affecting the quality of life and the collective capacity of the community to intervene and improve the situation. Schematically, the deterioration of human health can be represented on a continuum (Figure 87.3). The first stage corresponds to an increase in the prevalence of nonspecific symptoms of dysfunction that reflect early biological impacts among human populations resulting from ecosystem stress. The second stage includes early functional changes that are also not apparent in individuals, but can be measured, on a group basis, in exposed populations (Mergler, 1998). By the third stage, individuals are manifesting subclinical signs of

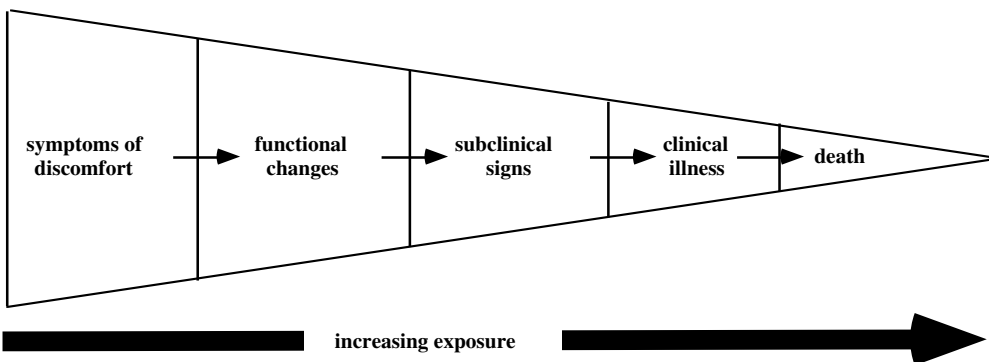

Figure 87.3 Stages of the health deterioration continuum. Exposure dose contributes to increasing deterioration. The areas within the triangle correspond to the relative frequency of the population at risk at different stages.

illness, while at the fourth stage frank illness is present. For the most part, environment-related disease processes are irreversible, or even relentlessly progressive. The final stage is death.

The rapidity with which persons progress along the continuum depicted in Figure 87.3 depends not only on the degree of ecosystem disruption, but also on individual factors (genetic makeup, age, lifestyle, other illness) and social factors (poverty, malnutrition, discrimination, lack of autonomy). These factors often interact with each other.

In the early stages of health deterioration, it is not possible to make diagnoses in individuals, but diagnosis of dysfunction within populations (community health) can be linked to ecosystem stressors. Early biological alterations constitute not only an early warning for increased risk of eventual illness, but, more importantly, reflect diminished well-being and impaired functional capacities. It is at this stage that intervention can be effective.

Diminished well-being, associated with an environmental pollutant, is well illustrated by the numerous studies on the relation between lead exposure from gasoline and children's IQ. While the levels of lead exposure from gasoline may not be sufficient to provoke clinical illness in the major cities where it is still used, the levels are sufficient to affect children's development, reducing the mean IQ of the exposed populations by about 4 to 10 points. Individually, this effect is not necessarily detectable; it is, however, measurable on a group basis, using sensitive, quantitative tests. A reduction of IQ of 5 points means that approximately twice as many children will have learning problems (<70 IQ points) and half as many children will have very high IQs (>130 IQ points) (Rice, 1998). Higher blood levels of lead are also associated with hyperactivity in children and reduced ability to concentrate. It is society that suffers, along with its capacity to develop fully. As a result, an increasing number of children become aggressive, have learning disabilities, drop out of school, and miss out on higher education (Needleman et al., 1996). Even very low levels of lead exposure can affect well-being and become dramatic when coupled to poverty, malnutrition, poor living conditions, inadequate health care, and poor schooling. From the perspective of an ecosystem approach to human health, these factors should be considered and included in analyses, rather than controlled or adjusted, when assessing the situation and working with communities to propose mitigating measures.

A Triangle of Risk

The proportion of the population at different stages along the continuum of health deterioration can be represented by a triangle with illness and death at the top. At similar levels of environmental destruction, those who are in poorest conditions and the most vulnerable may become very ill or die. At the base of the triangle, there are the many more persons who are, to some extent, capable of resisting and adapting to the loss of adequate life support systems and increasing toxic exposure, but who present the subtle, subclinical effects indicative of loss of well-being. As ecosystem stress increases, breaking down the human organism's adaptive capacity, more and more persons suffer from severe illness and die. Consequently, there is the need for more efforts in occupational and environmental health research to develop and apply quantitative and qualitative indicators of early health deterioration and loss of well-being, with a view to preventive intervention (Mergler, 1999).

Methodological considerations differ with respect to where one studies the impact of mining activities on population health along this continuum. Traditionally, we have examined the health impacts from mining at the tip of the triangle, where very large study populations are required, since fewer persons will be suffering from specific illness or die of specific causes. The outcomes are dichotomous (ill/not ill, dead/not dead). Moreover, the most vulnerable persons reach this level more quickly, making it difficult to distinguish between the health impact of ecosystem disruption resulting from mining and the effect of individual factors. As one goes farther down the continuum, more people are affected. Toward the base of the triangle, performance measurements can be made on everyone within the designated population, as was the case with studies of the effects of lead on IQ. With this approach, smaller populations can provide statistically relevant information.

An example of a study of early alterations associated with mining is provided by a study of 36 children in the Njamba gold-mining area of Ecuador, where mercury is used in the process of extracting gold (Counter et al., 1998). In this study, a significant relation was observed between blood mercury and hearing threshold. Although the children were not deaf, their hearing was increasingly impaired with increasing mercury exposure. In a comprehensive approach to health, the consequences of these changes are important in terms of learning capacity and future capabilities. Moreover, they should be further examined within the context of the other stresses on humans arising from the ecosystem disruption associated with these mining activities.

FRAGILE ECOSYSTEMS

Certain ecosystems are more fragile than others with respect to resistance to stress. The ecosystem approach requires a sound knowledge of the biophysical, chemical, and social parameters in management for ecosystem sustainability. For example, in a study of the mercury cycle in the soil, river sediment, and waters of the Amazonian Basin, my colleagues found that there were high levels of natural mercury in the soil. They also found that mercury used in gold mining was not the sole contributor to the high mercury levels observed in carnivorous fish and in the human populations who consumed these fish (Lebel et al., 1997; Roulet et al., 1998, 1999). Slash-and-burn agricultural practices throughout the Amazonian basin, resulting in soil erosion and lixiviation, were also responsible for releasing mercury into the extensive water system of this region.

The implication of this observation for ecosystem management of mining activities is that mercury released through mining activities cannot be isolated from the other activities that were likewise increasing the mercury burden in this ecosystem. The argument that mining activities are only adding a small proportion to the total mercury load is inappropriate. Because the fragile ecosystem already has high levels of naturally occurring mercury, the addition of even very small amounts from any source can have very important effects on ecosystem disruption and human health. Adequate mitigation measures depend on a comprehensive assessment of the ecosystem, as opposed to a random grab bag of measurements.

Because mines are established in areas where there are mineral ore deposits, in many cases the populations living on these deposits may already have relatively high levels of exposure to the substance through water, soil, and possibly food. For example, congenital disorders, identified in the Groote Eylandt population, that has been living since World War I in a manganese-bearing ecosystem, were subsequently exacerbated by manganese-mining activities (Kilburn, 1987).

The interaction among exposure to harmful metals, mining activities, ecosystem dynamics, and human health was recently demonstrated in studies of malaria in gold-mining areas. The inordinately high prevalence of malaria observed in gold-mining areas has been traditionally attributed solely to environmental destruction. In Brazil, the Evandro Chagas Institute, which specializes in tropical diseases, has traced most cases of malaria in Brazil to the gold-mining areas (Strickland et al., 1999). Recent studies suggest that exposure to mercury vapors, released during gold extraction processes that involve mercury amalgamation, can reduce resistance to malaria (Silbergeld et al., 1999). An ecosystem approach examining malaria in gold-mining areas should consider the many factors that potentially contribute to increased malaria: breeding conditions for mosquitoes, influx of miners from remote areas with minimal resistance to the disease, exposure to mercury vapors, poor health services, etc. Indeed, exposure to toxic substances may not only have direct effects, but also indirect effects, through modulation of different physiological functions. In regions where tropical diseases are endemic, the use of chemicals that possibly affect people's capacity to resist these diseases must be considered within a larger ecosystem context for adequate mitigation. Ecosystem management must strive to integrate rather than juxtapose information from various disciplines.

Within the context of ecosystem management, human health needs should be pursued in a holistic manner, by focusing on early changes in biological, psychological, and social parameters. In this way, emphasis is placed on characterizing the health and well-being of the population, disease prevention, and ecosystem equilibrium, rather than on treatment, disease, the assignment of respective responsibility and liability, and perhaps costly ecosystem remediation. Integrating human health considerations into environmental impact studies will help contribute to more equitable mining development.

A Conceptual Framework for the Development of Tools to Track Health and Well-Being in a Mining Region: Report from an Indian Study*

Ligia Noronha

INTRODUCTION

The purpose of this chapter is to present a framework for the development of a set of tools to track human health and well-being in a mining region.** More specifically, it will help identify, link, and guide the collection, organization, and analysis of data concerning the implications of mining activity to human health and well-being using a multi-stakeholder perspective. The chapter is divided into two main sections: In the first, existing frameworks are discussed that assess links between economic activity and human well-being, and in the second, the proposed framework is presented with illustrations from the case study in a mining region in Goa, India.

EXISTING FRAMEWORKS THAT ASSESS LINKS BETWEEN ECONOMIC ACTIVITY AND HUMAN WELFARE

The literature on frameworks that seek to assess the links between economic activity and human welfare can be classified as follows: (1) accounting, (2) reporting, and (3) sustainability frameworks. This classification is based on the type of function the frameworks serve.

Accounting frameworks are those that explicitly quantify and value economic activity and the use of resources in such activity, either through physical or monetary accounts. Earlier accounting frameworks only included economic activities. More recently, environmental and natural resources utilized in such activities are included in the accounting. The best known of these are natural and environmental resource accounting frameworks that require that gross domestic product (GDP), or net domestic product (NDP), be adjusted for the cost of using up natural resources and causing

* This chapter forms part of the project on Environmental/Social Performance Indicators (ESPIs) and Sustainability Markers in Minerals Development: Reporting Progress towards Improved Health and Human Wellbeing: Phase I sponsored by the International Development Research Centre (IDRC), Canada. A revised (modified) version of this chapter has appeared in *Natural Resources Forum*, 25, 53–65, 2001.

** The conceptual map that informs this framework only clearly emerged at the end of the empirical study of the mining region in Goa, India. This empirical study was initiated on the basis of certain preanalytical insights, which served to organize the data, obtained in part from the TERI 1997 study, and was, in turn, refined by the data. This process of formulating hypotheses and testing them has finally yielded the conceptual map mentioned earlier.

environmental degradation. Over the last few years, there has been a growing literature on natural resource accounting. Ahmad et al. (1989) provide a compilation of developments in this subject area. In 1993, the United Nations (UN) revised the system of national accounts (SNA) for the first time in 25 years, and recommended that member countries implement it. As part of this revision, integrated economic and environmental accounting was introduced. The concept and structure of such accounting are shown in the revised SNA manual, as well as in a separately published handbook for integrated environmental and economic accounting (UN, 1993). More recent developments in theory and practice include the work of Peskin (1996), Chopra and Kadekodi (1997), TERI (1997a), and Uno and Bartlemus (1998).

Reporting frameworks are those that report on environmental, economic, and socioeconomic conditions. The better-known economic indicators at the country level are the gross natural product (GNP) and the net natural product (NNP) or national income (see various World Development Reports). The Human Development Report (HDR) has improved upon these indicators by including a social component in its Human Development Index (HDI). This is the sum of normalized indices of life expectancy at birth, adult literacy, and per capita national income (UNDP, 1990). The conceptual framework that guides the construction of the HDI index sees development as an enlargement of the choices of people, indicators of which are the expansion of education, health, and employment opportunities. This framework's main shortcoming, from the point of view of our objective of assessing health and well-being in the mining region, is the lack of attention to the biophysical domain and its implications to health. There is a conceptual distance between longevity and good health, a distance that life expectancy at birth does not capture. In later versions of this index, separate HDIs for different population groups were constructed. The disaggregated HDI is said to be useful in detecting societal stress and potential conflicts (UNDP, 1994). The HDI offers an alternative to GNP for measuring the relative socioeconomic progress at national and subnational levels. Comparing HDI and per capita income ranks of countries, regions, or ethnic groups within countries highlights the relationship between their material wealth and income, on the one hand, and their human development, on the other. The HDR 1997 introduced a human poverty index (HPI) in an attempt to formulate in a composite index for the different features of deprivation in the quality of life to arrive at an aggregate judgment on the extent of poverty in a community. The HDR (1996) attempted this through a particular version of the capability measure (Doraïd, 1997).

Over the last decade, reporting on environmental issues has become the fashion led by organizations such as the UN Environmental Programme (UNEP), the Food and Agricultural Organization of the United Nations (FAO), the Organization for Economic Cooperation and Development (OECD), the World Bank, and the World Resources Institute (WRI) (UNEP, 1994; OECD, 1993; FAO, 1997; World Bank, 1996; Hammond, 1995). Environmental issues are discussed in terms of a stress–response framework (UNEP, 1994). The FAO has also been involved in building indicators for tracking state and trends of natural resources (FAO, 1997).

Frameworks to assess sustainable development seek to assess the long-term viability of systems, activities, or sectors. They include (FAO, 1996):

1. Ecosystem approaches that are based on assessing the performance of a sector according to ecological, economic, and social dimensions and use four criteria for sustainability: productivity, resilience, stability, and equity.
2. Total factor productivity where systems are deemed to be sustainable when total factor productivity (the ratio of the value of all outputs divided by all inputs, economic and environmental, normalized to remove change in prices) show a nondeclining trend.

Prescott-Allen (1996) developed the “sustainability barometer” in which one can have a static representation of sustainability. In this tool, human and ecological well-being are given equal status

and are taken to be the fundamental dimensions of sustainability. Rennings and Wiggering (1997) propose the use of ecological and economic sustainability indicators in a complementary fashion by targeting indicators, such as critical loads and levels, that should build the core of indicator sets for sustainable development. Socioecological indicators for sustainability are discussed in Azar et al. (1996).

THE PROPOSED CONCEPTUAL FRAMEWORK

The framework proposed in this chapter draws on these frameworks and has the following as its main features:

1. An ecosystem approach for assessing the impacts of minerals development to the economic, biophysical, social domains, and issues of relevance to stakeholders
2. Highlighting of the relations between mining and well-being
3. A determinants and constituents approach to understanding the concept of well-being
4. A multistakeholder perspective in the validation of issues of concern for indicator development
5. Tools for tracking well-being, which involve:
 - a. The development of environmental and social performance indicators based on these issues
 - b. The development of a quality of life tool to measure the satisfaction of individuals/communities with the conditions found in the region
 - c. An income accounting exercise to account more broadly for the environmental, economic, and social impacts of minerals development in the region

An Ecosystem Approach to Assessing the Impacts of Minerals Development

The approach used in this study to identify impacts is consistent with an emerging ecosystem approach, in which data are spatially referenced and organized on the basis of ecologically defined geographic units as well as administrative units. The point of entry for the study is mining activity, which is seen as the source of change in the ecosystem. Since mining is the driving force, the study area is defined with reference to clusters of mining villages. Using a cluster of mining villages as the ecosystem also allows the communication of what is involved in this definition because the context is known and clear.* We call these clusters of mining villages mining ecosystems, a man-made ecosystem created or developed due to mining activity, which has over the years developed certain specific characteristics. Thus, in the Indian study,** the clusters consist of villages under direct or indirect mining activity and as well as those under direct or indirect impacts of mining-related activities and those bounded by a natural activity; in this case, it is the river. In strict terms, these clusters are not geomorphic units, even though at places they are bounded by rivers.

* We follow Shugart (1998) here, and define ecosystems relative to the objectives of our study. This restricts the “definition to the important processes of the particular case of interest. The definition of which aspects of a system are important (or unimportant) to a particular problem is stated explicitly. The ecosystem, as an abstract term, is closer to systems concepts in other sciences” (p. 49).

** The Indian study was in the state of Goa, located on the west coast of India, bounded on the north by Maharashtra, on the east and south by Karnataka, and on the west by the Arabian Sea. It has a coastline 105 km long and a total area of about 3701 km². Goa can be perceived to have four main ecozones: the Sahaydrian watershed located in the Western Ghat region; the plateau area, which is in the midland region; and the alluvial flats and coastal zone in the coastal region (Alvares, 1993). Most of the mining activity is in the Western Ghat region and occurs amid dense settlements, agricultural fields, and forests. The state is drained by a number of rivers, namely, Mandovi, Zuari, Tiracol, and Chapora, flowing westward into the Arabian sea, of which the Mandovi has the largest drainage basin in Goa. The river basins of Mandovi and Zuari cover about 69% of the total area of the state and are together called the lifeline of Goa. These waterways are extensively used to transport the iron ore from the beneficiation plants to the main port from where they are exported. For details on the conditions in the mining belt in Goa, see TERI (1997b). This was a study to arrive an environmental management plan for the mining belt of Goa. It employed a multidisciplinary approach. The study combined spatial data obtained from aerial photographs and remotely sensed products, environmental data, and statistical data obtained from miner level and socio-economic surveys. The various data sets were integrated using geographical information systems tools.

Mining and Human Well-Being

Rees (1985) lists five major criteria that are commonly used to judge the impacts of resource development on human welfare. These impacts are (1) economic efficiency, (2) distributive justice, (3) economic growth and employment generation, (4) supply security, and (5) maintenance of environmental quality. This list indicates that mining has implications for human welfare mainly through three domains: economic, social, and environmental.

Goodwin (1997) discusses three world views on the relationship between economic growth (mining is a subset of this) and human well-being (HWB). These worldviews can be discussed in the context of minerals development as it directly contributes to economic growth. The dominant view in neoclassical economics, before the environmental and social imperative began to assume importance, was that growth would always lead to increased well-being. In developing countries, this is often the implicit view because it is generally believed that jobs are the bottom line for any improvement in well-being. Hence, any job-creating activity, such as minerals development, will, *ipso facto*, contribute to improved well-being. Since mining creates jobs, it is seen as contributing positively to HWB. The negative impacts are not recognized.

Another view holds that there are some aspects of well-being to which growth cannot contribute at all; growth cannot actually reduce well-being, but is neutral to it. In the context of mining, this translates to saying that the income, job, and revenue creation aspects of minerals development contribute to HWB, but that HWB involves many other aspects that minerals development has nothing to offer, positively or negatively.

More recently, there is a growing understanding that some aspects of minerals development do not contribute to well-being but are actually detrimental to well-being. This refers, for example, to the externalities from mining activity which are detrimental to well-being because of effects, such as disruption in community life, growth of alcoholism, destruction of indigenous communities and cultural values, growth of dust pollution, water quality deterioration, and land degradation. Excessive direct or indirect dependency on the mine in the absence of alternative opportunities can lead to considerable stress on a community when a mine closes down as well.

These perspectives on the relationship between minerals development and induced growth and human well-being suggest an investigation along two axes: (1) the different conceptions of well-being that are used, and (2) the different views of what minerals development actually involves in terms of contributions to society. Those who see human well-being in a materialistic sense of jobs and income, and who see minerals development essentially as contributing to these objectives, will subscribe to the first view of the relationship of well-being to minerals development. In contrast those who see human well-being as being more than just material prosperity and who have a wider definition of the good life will see minerals development as contributing to improved well-being, but only to an extent. Some aspects of minerals development do not, in fact, contribute to it, but remain neutral. A third view sees human well-being as including not only material prosperity, but something much wider.

Travers and Richardson (1993) discuss the concept of human well-being as having four components: material well-being, happiness, health, and social participation. They point to the argument made by some economists that because material well-being expands options and so contributes to well-being, it can adequately serve as a proxy indicator of individual and national welfare. However, they refer to evidence that suggests that while the association between subjective evaluation of happiness and wealth is positive, the relationship is weak. This is because the causes of unhappiness go beyond the realm of material well-being and the fact that there can be trade-offs between material well-being and overall human well-being. They further discuss the relation between material well-being and health, and suggest that the former is important at the national scale insofar as they determine the level of public investment in health services. At the individual level, health is far more related to the interaction between material and cultural inputs into health and of the social circumstances that make an egalitarian distribution of these inputs possible.

Some thinkers approach a definition of well-being by composing lists of the elements that go into it (Goodwin, 1997). Others discuss the concept with reference to two social goals: individual happiness and economic justice. These goals are then decomposed into lists of social values of which each is composed and the socioeconomic outputs required to achieve these values (Wilson, 1991).

This conception is similar to that discussed in Dasgupta (1993). He suggests two ways of assessing human well-being. One is to measure the constituents of well-being (e.g., indices of health), and the other is to value the commodity determinants of well-being that refer to the goods and services that are inputs in the production of well-being (e.g., real national income). The concept of well-being can be seen more broadly in terms of constituents (i.e., what constitutes our flourishing) and the determinants (i.e., what is instrumental to our flourishing) (O'Neil, 1993). This goes beyond commodity determinants.

Understanding Human Well-Being in the Context of This Study

From the literature, it is evident that there is no consensus on a single definition of well-being. However, since our objective is to track changes in well-being, we proposed to examine the concept of well-being in terms of constituents and determinants (O'Neil, 1993; Dasgupta, 1993). Nussbaum (1990) (quoted in Ackerman et al., 1997) suggests that what constitutes our flourishing can be approximated by a listing of various capabilities. These capabilities can be grouped under the following: activity* and health, freedom to make choices, and diversity.** While these constituents may not vary between cultures, the weight of each in the scale of well-being may vary.***

What is instrumental to our flourishing? The literature suggests that the ingredients of flourishing lie in well-functioning social, economic, political, and ecological systems. These systems contain the determinants of our flourishing. An ecosystem is considered to be well-functioning and healthy if it is active; maintains its organization, connectivity, and autonomy over time; and is resilient to stress (Costanza, 1992). Karr et al. (1986) state that a biological system can be considered healthy when its inherent potential is realized, its condition is stable, its capacity for self-repair when perturbed is preserved, and when minimal external support for management is needed (quoted in Rapport, 1995).

The physical and psychological relationships between individuals and the ecosystems and the social and political relationships they have with the rest of the community in terms of participation and civic engagement are central to well-being. It is important to recognize here that while the centrality of the individual as the repository of rights is accepted, some variations in the processes by which the individual is constituted has to be conceded. The social and cultural context through which an individual acquires a sense of the cognitive and the moral matrix (i.e., a sense of self and a sense of rights and duties) needs to be given due attention. By doing so, the framework will be achieving both the centrality of the individual and conceding that this individual can be embodied differently in different locations. These differences can vary from minor influences to more radical differentiation. This is important because the framework hopes to be relevant to countries in which the emphasis on community is different (e.g., U.S., India, Colombia), and it is different for an economic activity, such as mining, which generates communities of its own wherever the location. The framework needs to be read along two independent axes: (1) the region and the culture that goes with it, and (2) mining as an activity that shapes the individual and the community. Figure 88.1 illustrates our conception of well-being as being dependent and determined by well-functioning ecological and social systems.

* By activity, we mean that agents are in a position to engage in development, productivity, growth, and are in a position to recover from stress.

** The idea of diversity refers to the existence of many identities.

*** For example, health, as an end objective, may have a higher weight in an individual's welfare function in the U.S., whereas freedom may be more important in a country such as Colombia. For the latter, any improvements in levels of freedom may have a greater impact on the overall well-being than improvements in health.

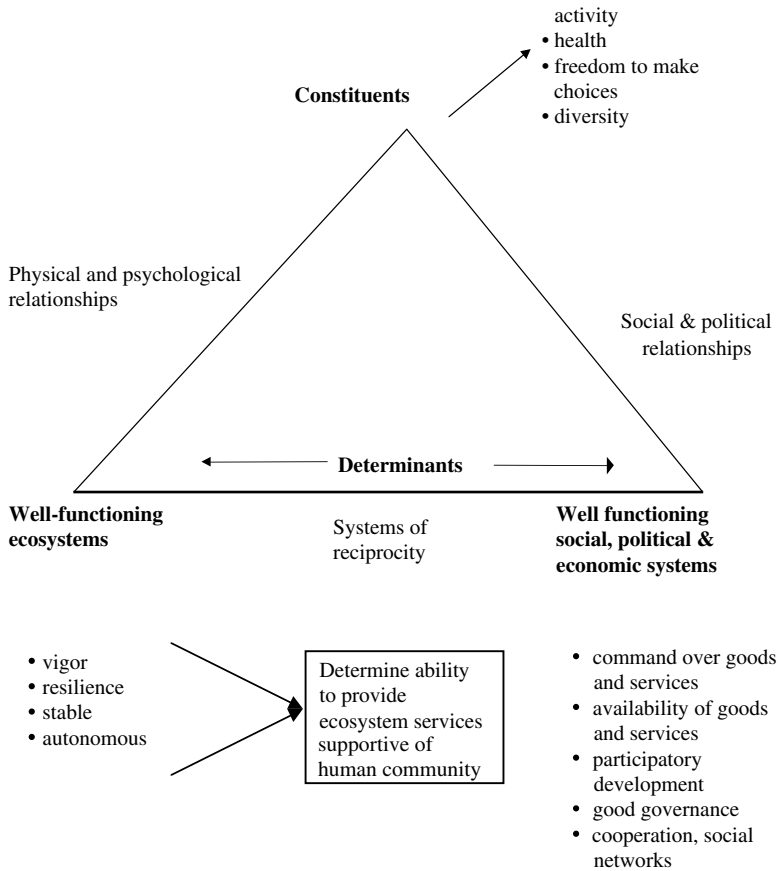

Figure 88.1 Constituents and determinants of well-being.

It can be argued that the following are important determinants of human health and well-being in a mining region context:

- *Command over goods and services* as made possible through increased employment and income. Purchasing power is crucial to a material well-being.
- *Availability of goods and services*, both natural and produced. This includes the availability of good quality and quantity air, land, and water as basic determinants of health, or the production of minerals and the ability to exchange these for other goods and services. Goods and services are important to support and maintain capabilities.
- *Participatory development*, a process by which stakeholders voluntarily come together to share, negotiate, and control decision-making in development issues. Stakeholders participate in development for two sets of benefits: development benefits and negative benefits. Participatory development in mining regions can enhance well-being through its impacts on the constituents as well as the other determinants of well-being.
- *Good governance* by which is meant the ability of governments and other institutions in civil society to create an enabling environment with which goals can be achieved. Three sets of rules are of relevance to good governance:
 - Rules of the game such as laws, rights (positive and negative), regulations, policies, customary laws, and court decisions.
 - Rules that constrain all law making at the level of the constitution.

- Rules of law and the standard of legality that informs the judiciary in any given society (IRIS, 1996).
- *Community and social cohesiveness and systems of reciprocity*, such as the building of networks, community relations, etc., which build up social capital are particularly valuable where the efficiency of legal rule enforcement is in short supply. Cooperation in terms of playing by unwritten rules and social norms then become important in progressing toward well-being goals.

Minerals development can affect all of these determinants and, through them, the constituents of human well-being. Such impacts can be positive or negative. In our case study in India, we identify how these determinants are impacted through an identification of issues of relevance: (1) from the social and environmental assessment and, (2) by stakeholders in minerals development. These issues are aspects of the determinants. For example, a concern with air quality is connected with the need for good quality natural goods and services that are important to our flourishing. A concern with poor rule enforcement reflects on governance and has implications for well-being. A concern with investment of a portion of mining income in developing nonmining skills reflects a concern with command over goods and services in a future period, after mine closure. Issues reflect various aspects of the determinants of our flourishing. In order for these issues to be representative, we need to adopt a multistakeholder perspective to issue development.

Multistakeholder Perspective to Issue Development

At least three sets of stakeholders and user groups are of importance here:

1. The mining company, both corporate management and plant level staff
2. The government, both in its capacity as regulator and as a development agent
3. The public, both local communities and therefore immediate stakeholders, and the wider public

The mapping of stakeholders and the identification of issues and their validation is illustrated with examples from the Indian case study below.

Stakeholder Mapping

In the Indian study, the following stakeholders have been mapped at the following levels:

1. Industry
2. Community and the public groups
3. Government

Mining companies in Goa are all in the private sector, and except for one large company are all family owned and managed. Five companies who represent 80% of all production and export of ore from the state dominate the group. Many of the companies are bound together by familial or kinship relationships. The companies do come together formally to present a joint front to the government and the public in the Goa Mineral Ore Exporters' Association, which is the main iron ore-exporting lobby group. The exporters operate in an international buyers' market that is mostly Japanese. There is no domestic market for Goan ore (Noronha, 1999).

The consumer's product needs and specifications rather than the price of iron ore are important factors in the supply responses of the mining companies. Decisions on how much to produce are based on contracts arrived at through negotiations with the buyers at international prices. The consumers have so far been unconcerned with the externalities created by the product. Their sole concern is that the end product come up to their specifications. In fact, the stringent specifications demanded by the consumers impose an additional burden on the environment since the ore needs to be beneficiated, giving rise to a large number of residuals. Because prices have not changed in

real terms since 1981, this has increased costs to the producer and, more importantly, increased indirect costs to the region through the degradation created by effluent discharges and improper tailings dams. Rising costs of production and inelastic prices faced by the industry are often used as an argument by the companies to justify not spending more on environmental protection.* This lack of spending protects the profit margins of producers, but degrades the environment. Except for one mining company that gets part of its capital through shares, the rest of the companies are all financed either through their own funds or bank funds. Investors and creditors are still not important drivers of environmental performance in India.

Transport operators and especially truck drivers are a very important feature of the mining industry in Goa. Ore is carried from the mine pits to the beneficiation plants by trucks and from there by trucks to loading points. From here the ore is loaded onto barges and then these carry ore through Goa's main rivers to the port where the ore is loaded on to the ships. The existence of the waterways is a key factor explaining the competitiveness of the Goan ore relative to ore from Brazil and Australia. Truck and barge operators and their associations are important factors in this cycle. These trucks and barges do not belong to the mining companies, but are contracted from outside the industry.

Informal public groups, such as environmental nongovernmental organizations (NGOs), and the local community provide the most important drivers for improved environmental performance in the mining areas. However, at the local community level, lack of organizational, technical, and financial resources prompt individuals affected by mining to approach companies directly. The solutions arrived at are short term, arbitrary, and *ad hoc*, and the problem surfaces again. The NGOs are better equipped to negotiate with the companies. They, however, prefer to approach the judicial courts for redress, since they find that the government agencies responsible for monitoring the activities of mining do not provide them with satisfactory answers.

Finally, the third category of stakeholders is the government with a dual stake: to promote the development of the industry and to protect the environment. Government has a positive stake in the industry because it creates jobs, income, foreign currency, and revenues for the economy and, hence, needs to ensure a climate that promotes the growth of the industry. But since it has the mandate to protect the environment, government has to constrain the options available to the industry through various rules and statutes. These rules are at three levels: the center, the state, and the village.** Because mining creates impacts on sectors other than itself, there is a need for action on the part of departments. For example, the irrigation department is needed for the pollution of waterways and canals, and the agriculture department is needed because mining reduces productivity and causes loss of farmlands. The transport department is needed because of the dust problem created by truck operations, while the town and country planning department is necessary because of the changes in land-use patterns that are occurring in the mining region due to creeping expropriation of present land uses. Figure 88.2 provides a map of the concerns of the main stakeholders as analyzed from the study.

The issues identified from the case study were then validated with the three major groups: the government, the community, and the companies. The predominant issues from individual and common stakeholder perspectives are organized using a Venn diagram (Figure 88.3.). This tool helps us to see which issues are common to all stakeholders and which to groups of two or just to individual stakeholders.

This multistakeholder perspective to issue identification and validation is a central methodological feature of this framework. It is favored here for many reasons.

* This is also the reasoning provided sometimes by government officials to explain the deteriorating environmental quality in the region.

** In Goa, there is on an average one panchayat for every two to three villages. A panchayat is made up of representatives elected from these villages.

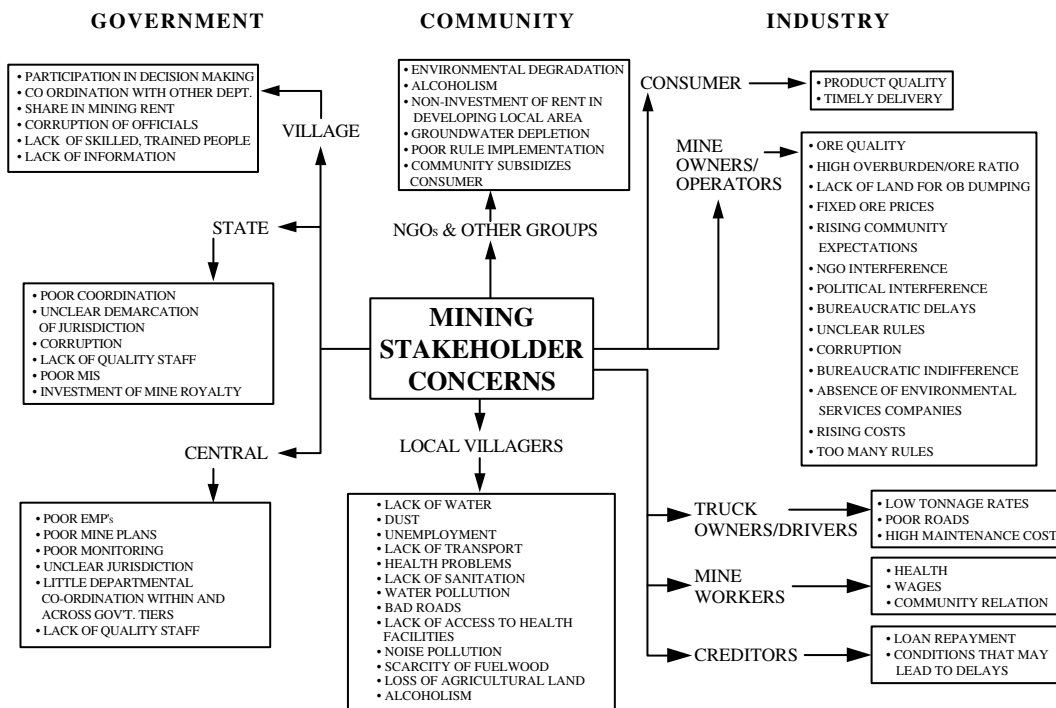

Figure 88.2 Stakeholder concern map. (From Noronha, L., *Nat. Res. Forum*, 25, 53–65, 2001. With permission.)

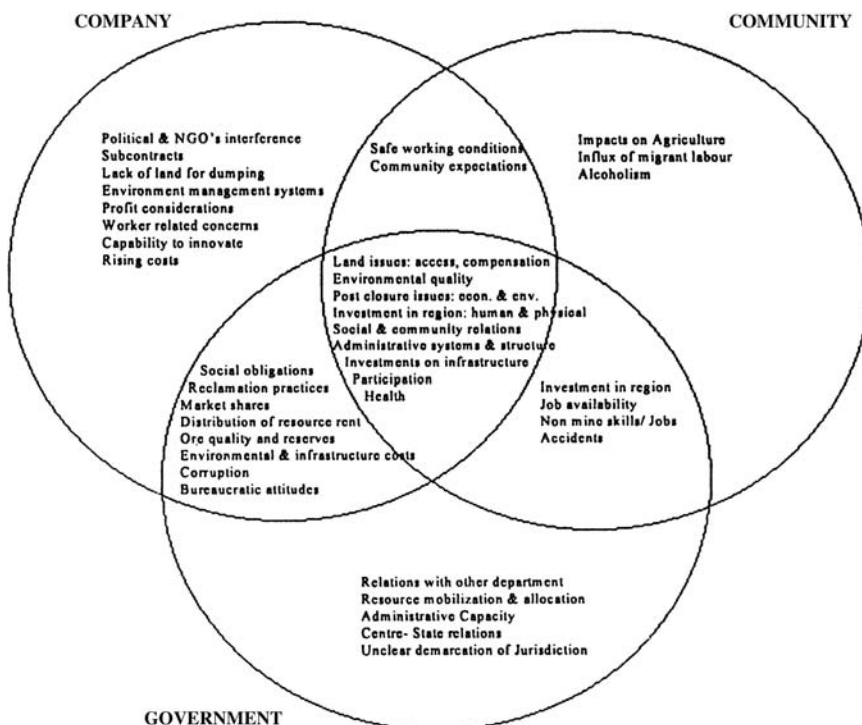

Figure 88.3 Issues of relevance arising from the Indian study. (From Noronha, L., *Nat. Res. Forum*, 25, 53–65, 2001. With permission.)

1. Tools that are based on a multistakeholder perspective will address the concerns and needs of the stakeholders. Such a perspective is more participative since the issues are those that have emerged from direct interaction with stakeholders.
2. A core set of issues common to all stakeholders can be identified from these lists. Tool development can then be based only on this smaller set of common issues. This makes the task more manageable.
3. Such a core common set, rather than an excessive focus on issues common to just one stakeholder, will also have acceptability from a wider audience. Indicators based on such issues will therefore have a wider appeal.

Tracking Well-Being

In order to be able to track how we are doing and to measure the movement toward improved health and human well-being, there is need to have a way of tracking well-being through measuring its constituents and determinants of well-being. Three sets of tools are suggested:

1. Determinants (using issues as aspects of determinants) can be measured using environmental, economic, and social performance indicators (ESPIs). Sets of environmental and social performance indicators are developed for the issues that have been identified by the various stakeholders. ESPIs provide a measure of the conditions that affect human health and well-being. Changes in these indicators represent improvement or deterioration of conditions in the mining region and provide relevant domain specific information to the main stakeholders.
2. A quality of life (QOL) instrument provides a measure of satisfaction with life of the individual and the community in a mining region. This instrument measures an individual’s responses with regard to his level of satisfaction with the conditions in the social, cultural, biological, economic, and political environment that he faces.* The QOL instrument tries to capture the relationship between conditions or determinants found in the mining regions, and the subjective responses of the individuals and the community living in the region.
3. An impact adjusted income account of the mining region. This tool seeks to assess the long-term viability of the activity and of the region in terms of the kind of impacts that the activity is creating. Such impacts may be consuming the very resources — natural, human, and social — that make the activity possible and may, over the long run, cause the region to go into a decline.

In Figure 88.4 the main elements of the framework are summarized.

How do these tools track well-being? This question is examined in the next section.

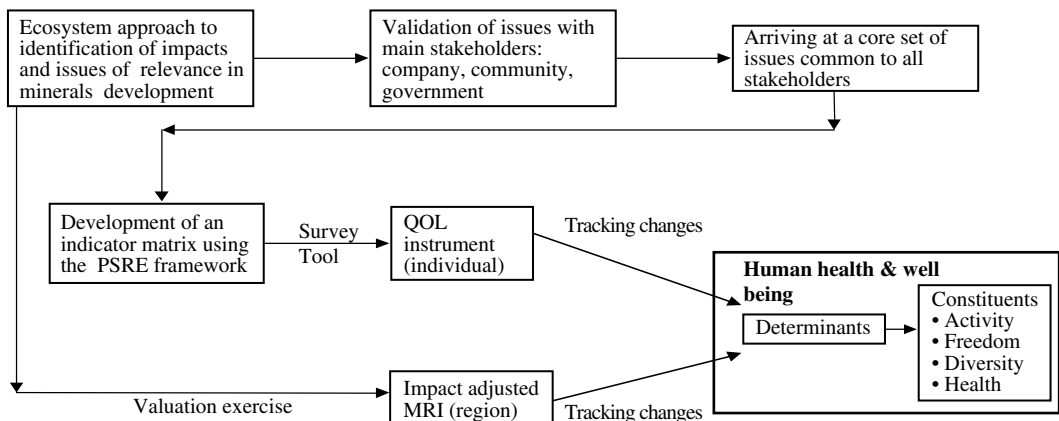

Figure 88.4 Main elements of this conceptual framework. (From Noronha, L., *Nat. Res. Forum*, 25, 53–65, 2001. With permission.)

* The literature on QOL is now vast. For a taste of the issues, see Nussbaum and Sen (1993).

Environmental and Social Performance Indicators (ESPIs)

An indicator has been defined as “a statistic or measure which facilitates interpretation and judgments about the condition or an element of the world or society in relation to a standard or goal.” Further, an indicator is a parameter (i.e., a measured or observed property), or some value derived from parameters (e.g., via an index or model), which provides managerially useful information about patterns or trends (changes) in the state of the environment, human activities that affect or are affected by the environment, or about relationships among such variables (EPA, 1995).

Indicators can be of use to various audiences. The type of audience in mind when working with developing indicators will influence the components of the framework that is developed. ESPIs are based on issues identified and validated by the stakeholders in minerals development. For purposes of this discussion, just the set common to all stakeholders is concentrated upon as this is the minimum set of issues that need to have indicators developed in order to be able to track well-being in the region.*

Quality of Life Instrument

The QOL instrument is connected to the indicator framework. Here the state indicators can be used as descriptors of the conditions faced by local communities. The survey instrument is then used to try to arrive at the sense of personal impact and satisfaction with these conditions. If it is desired that the two be related (i.e., that the indicator framework be related to the subjective well-being) this can be done by seeing one as related to the other (i.e., for each objective condition faced by respondents, what is their level of satisfaction with it).

For example, we have the following as suspended particulate matter standards for air quality: 200 µg/m³ to indicate good air quality and 500 µg/m³ to indicate poor air quality. These are then transformed to a normal scale varying from 0 to 1 (value function curve) in which 0 corresponds to poor air quality and 1 to good air quality. The level of satisfaction of individuals with this air quality is obtained through the use of this QOL instrument. The indicators track the conditions, and this instrument tracks the subjective dimension (e.g., the level of satisfaction with the conditions). The interconnections are illustrated in the matrix in Table 88.1

Issues in each domain can be given equal weights or an expert meeting can be had where weights are assigned for each issue area based on observations and data available. Alternatively, each country can have its own weighting since different cultures may have different relative

Table 88.1 Developing a Quality of Life Instrument

Domains	Multistakeholder Set of Issues Identified	Environmental and Social Performance Indicators	QOL Instrument
	Common	State indicators and exposure indicators	Level of individual/community satisfaction and perception of impacts on constituents of WB: health, freedom, diversity, and activity
Social			
Political			
Economic			
Biophysical			

* In practice, issues relevant to the community should be given added weight in the choice of issues that are used for indicator development, in order to concede the point that decisions are made within an asymmetric power matrix where state and company collude to disadvantage community.

priorities. These can then be combined into an overall index of quality of the biosphere, quality of the sociocultural political sphere, or quality of the economic sphere.

An Impact-Adjusted Income Account of the Mining Region

A tool to track sustainability in the mining region is one that accounts for impacts caused by mining activity, values these monetarily, and then adjusts the income obtained from mining to account for such impacts. For each unit of analysis, for example, a village or cluster, we estimate the net income using appropriate approaches. We then adjust this net income of the village or the cluster for the impacts created by the economic activities using the following formula:

$$IMRI_c = MRI_c \pm V_{MD/ME} \pm V_{ED/EI} \pm V_{SI}$$

where $IMRI_c$ = impact adjusted income of cluster/village, MRI_c = income of the cluster/village, $V_{MD/ME}$ = value of mineral resource depletion/enhancement, $V_{ED/EI}$ = value of environmental degradation/improvement attributed to mining, and V_{SI} = value of social impacts attributed to mining.

Different methodologies can be used to calculate resource change, environmental change (Markandya, 1998), and social impacts. In valuing social impacts of mining, care has to be taken to avoid double accounting. It is evident that jobs, income, and fiscal gains for example, are all accounted for in the traditional definition of income from the mining activity. The social impacts, such as those on health that are related to a declining environmental quality, are already captured when measuring environmental costs. Those aspects that are not reflected in those calculations need to be explicitly included. More difficult to estimate are sociocultural impacts such as change in traditional values, improved social mobility, etc.

The difference between the environmental and social impact adjusted income for the region and the MRI of the region is an indicator of the resource, social, and environmental changes in the region. The IMRI over time can serve as a sustainability marker. Accounting for impacts enables us to keep track of what minerals development is doing to mineral and environmental resources, to local communities, and provides information that is essential for corrective action.

CONCLUSION

In this chapter, a framework for the development of tools to track health and well-being in minerals development is presented. The main features of this framework are summarized below.

1. All domains that affect or are affected by mining activity need to be studied, such as the biophysical, the sociopolitical-cultural, and the economic domain.
2. Human well-being is understood as being made up of constituents and determinants, where the former refers to what contributes to our flourishing and the latter to what is instrumental to this flourishing.
3. A multistakeholder perspective consisting of the government, the mining company, and the community is adopted to identify issues of relevance in each domain.
4. Economic and social performance indicators for the issues are developed. These are sets of measures of the conditions found in a mining region of mining practices and activities that affect health and well-being, of responses to such conditions and pressures, and of the relationships among such variables.
5. An instrument can be developed to measure the satisfaction of the individuals and community in the mining region with their quality of life.
6. The use of an accounting framework helps develop an estimate of income from a mining region from which values of the impacts, both positive and negative, caused by mining are adjusted. This account, seen over time, will tell us if the mining region is able to continue functioning into the

indefinite future without being forced into a decline through the exhaustion and deterioration of its key natural, social, and human resources.

If these tools are used regularly, an information system will emerge that will provide markers of what mining is doing to the region and the communities. This set of tools, if taken together, provide the users with the following information:

1. Economic and social performance indicators that will provide trends of what companies are doing to prevent or mitigate the environmental and social impacts of mining
2. The QOL tool that will provide information and feedback on the levels of satisfaction among local communities with existing conditions
3. The adjusted income accounts that will provide a macroperspective of the impacts, both positive and negative

The trends revealed by these tools will enable appropriate and timely action by the users and the stakeholders to protect resources and human well-being.

ACKNOWLEDGMENT

The author would like to thank IDRC for this sponsorship and would like to acknowledge the considerable intellectual inputs provided by Professor Alyson Warhurst and her Mining Energy Research Network (MERN) colleagues at the University of Bath; Cristina Echavarría of Instituto de Estudios Regionales (INER) at the University of Antioquia, Medellín, Colombia; Professor Peter R. de Souza of Goa University; and several colleagues at TERI. This framework has benefited greatly from this interaction. Special thanks to Sudhir Khalwadekar of Tata Energy Research Institute (TERI) for help with figures and with formatting.

Addressing Gaps in Ecosystem Health Assessment: The Case of Mineral Resources

Joy Jacqueline Pereira and Ibrahim Komoo

INTRODUCTION

Mineral resources have been concentrated by a variety of geological processes, which operate so slowly by human standards that the rates of replenishment are infinitesimally small relative to its consumption. Once a mineral is extracted and used, it is gone forever. As mineral deposits are finite and exhaustible, they are considered a nonrenewable resource. Modern civilization is very dependent on mineral resources. Minerals are used in the construction industry, the electronics industry, the chemical industry, and many major manufacturing industries. Infrastructure development projects, in particular, require adequate supplies of minerals, especially aggregates, sand, and gravel. One of the most significant impacts of land development in certain parts of Malaysia is restriction on the availability of minerals to sustain the economic growth, due to lack of proper planning (Selangor State Government, 1999). The expansion of urban and industrial areas that encroach upon existing mines and quarries prevent the exploitation of and access to undeveloped mineral resources. If such resources become sterilized, minerals have to be transported into the area concerned, resulting in increased costs to the community.

The issue of ecosystem health is closely linked to sustainability. At the most basic level, a healthy ecosystem requires conditions that are sustainable. Sustainability has been described as a system's ability to maintain structure and function indefinitely (Costanza, 1992). This description is applicable to a variety of complex systems ranging from cells to ecosystems as well as economic systems. Indicators facilitate the assessment of ecosystem health. The selection of indicators is based on an integrated approach involving a combination of biophysical, socioeconomic, and human health parameters (Bertollo, 1998). The concept of ecosystem health is deeply rooted in the fields of biological and ecological sciences. The parameters at present utilized to assess ecosystem health are predominantly based on ecology and biology (Table 89.1).

Parameters developed to assess ecosystem health in the context of minerals are limited. One parameter that has been proposed as an indicator of the threat to ecosystem integrity is the depletion rate of mineral reserves (Munn, 1993, cited in Bertollo, 1998). Indicators of reduced threats to ecosystem integrity include increasing output of production per unit of nonrenewable resources, increasing recycling efforts, as well as decreasing economic and energy subsidies provided for the natural resource sectors. Several indicators have been proposed for minerals as part of the efforts to monitor the consumption of nonrenewable resources (Table 89.2). These indicators are not specifically designed to

Table 89.1 Types of Indicators to Assess Ecosystem Health

Ecosystem process rates and storage	Abiotic zones
Community structure	Biotic composition
Population structure	Disease prevalence
Diversity	Bioaccumulation of contaminants
Fish abundance and condition	Grazing and decomposer food chains
Exotic rare species	Lake size
Plant biomass	Stream/river width
Nutrient cycling	Contaminant levels in fish
Productivity	Algae bloom in water bodies

Table 89.2 Types of Indicators Proposed for Mineral Resources

Per capita consumption	Waste generation
Shortage	Reclamation expenses
Intensity of use	Soil quality
Available reserves	Groundwater quality
Price of commodity	Reduction/recycling
Mining activity	Waste management expenditure
Ex-mining land	Waste disposal charges
Erosion	Total material requirement
Recycling and substitution rates	Contribution to GDP and employment
Emission	Loss of biodiversity
Metal losses in waste	Consumption of energy and water

assess ecosystem health; however, they can be adapted to serve that purpose. One such example is the total material requirement (TMR) proposed by Adriaanse et al. (1997). The TMR is a summary indicator that integrates mineral resource utilization directly to economic activity at the national level (Adriaanse et al., 1997). The focus is on broad categories, such as metals, industrial minerals, construction minerals, infrastructure excavation, fossil fuels, and renewable resources. The TMR includes both renewable and nonrenewable resources, and its methodology can also be applied to assess nonrenewable resource flows within the ecosystem framework. The Canadian government has also embarked on an initiative to develop sustainable development indicators for minerals and metals (Natural Resources Canada, 1998). A preliminary menu has been compiled, based on the Organization for Economic Cooperation and Development pressure–state–response framework for national reporting purposes. The parameters proposed are the most comprehensive selection for the minerals sector to date.

This chapter provides an overview of mineral utilization trends in the Langat Basin, which is located in Peninsular Malaysia. All the minerals exploited in the basin to support economic activities are accounted for, including nonmineral materials removed during extraction and processing. The issues of mineral sterilization and information gaps that threaten the management of mineral resources within the basin are also highlighted. Finally, potential indicators are proposed for assessing the health of the Langat Basin, within the context of the minerals sector.

METHODOLOGY

The main sources of data for mineral production in Malaysia are the minerals and geoscience department and the statistics department of the Institute for Environment and Development (LES-TARI). Data on mineral production at the state level is estimated based on surveys conducted by these two departments. The mineral production data for the Langat Basin are based on that of the state production.

One method to chart material movement supporting economic activities has been developed by Adriaanse et al. (1997). The method accounts for the major flows of both renewable and nonrenewable resources in an industrialized nation's economic activities. The boundary between nature and the economy is defined at the point when humans first extract or move materials from natural sites.

The method developed to chart material movement in the Langat Basin is loosely based on the methodology of Adriaanse et al. (1997). However, the flow is calculated only for nonrenewable resources that are extracted in the Langat Basin. Due to lack of data, it has been difficult to estimate the amount of minerals imported into the basin. The total amount of minerals consumed in the Langat Basin has not been quantified.

The extraction of mineral resources is often accompanied by the removal of material that is associated with it. Aggregate extraction requires the removal of large quantities of overburden that can modify or damage the environment even though they are not of economic value. The washing of tin mine tailings to obtain sand results in the removal of fine material, which is eventually disposed along the waterways. All such flows are part of the economic activity in the Langat Basin, but never enter the monetary economy as commodities. The flows that do not enter the monetary economy are referred to as hidden flows. Hidden flows are estimates of overburden or gangue removed during mineral extraction. These estimates are obtained from the literature and modified based on field visits to extraction sites in the Langat Basin. In charting the mineral movement within the Langat Basin, hidden flows are separated from those that enter the economy.

MINERAL EXTRACTION IN THE LANGAT BASIN

The minerals produced in the Langat Basin include both metallic and industrial minerals. The industrial minerals extracted are aggregates, kaolin, clay, and earth materials, as well as sand and gravel. The main metallic mineral is tin. At present, there are 21 granite quarries, 3 clay pit sites, and 1 kaolin extraction site reported to be operating in the Langat Basin (Figure 89.1). In addition, 43 earth material extraction sites and 86 sand mining permits have been approved in the Langat Basin since 1997 (GSD-IM, 1997, 1998). In terms of tonnage, over 95% of the minerals extracted are consumed within the Langat Basin. Additional minerals required for the manufacturing industries located within the basin are imported from other Malaysian and foreign sources.

Aggregates

Aggregates refer to crushed rock materials obtained from quarries that are produced in various sizes. The main rock type exploited as aggregates in the Langat Basin is granite. The aggregates are utilized in the construction industry. Between 1980 and 1989, the annual production rate of aggregates in the Langat Basin increased by about 5% (Table 89.3). Between 1990 and 1996, the annual rate of aggregate production increased by nearly 30%. This increase coincides with the opening of the southern corridor for development, which includes part of the Langat Basin. In 1997, aggregate production dropped by about 60% compared to the previous year. This is due to the economic slowdown that has affected Malaysia and other Southeast Asian economies.

Kaolin

Kaolin, or china clay, is a special kind of high quality clay material suitable for a variety of industrial applications. Premium grade kaolin is used as paper coating and the manufacture of fine tableware, porcelain bone china, and electric insulators. Normal grade kaolin is best suited as fillers and extenders in the ceramic, paper, paint, and rubber industries. The production of kaolin in the Langat Basin has increased significantly (about 50 times) since 1980 (Table 89.3). The fourfold

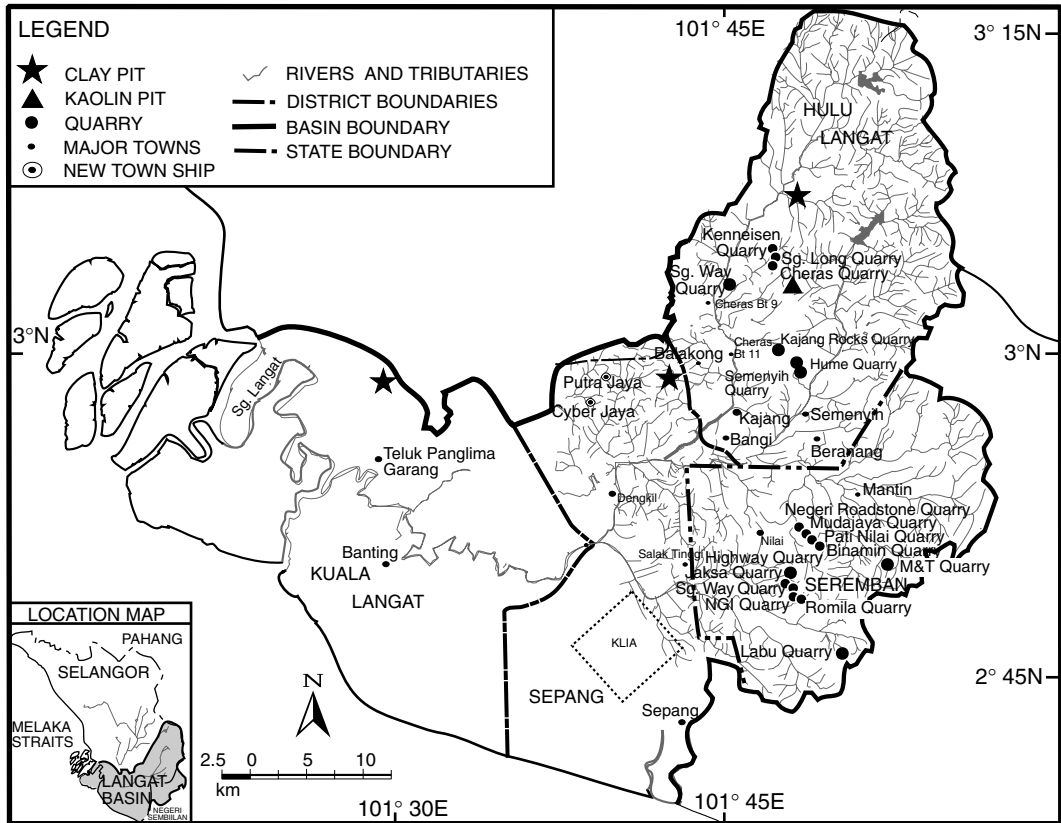

Figure 89.1 Location of selected extraction sites in the Langat Basin.

increase of kaolin production in the 1995–1996 period is attributed to the upgrading of facilities in the processing plants to make them integrated and capable of producing kaolin suitable for export to Taiwan and Korea (GSD-IM, 1996).

Clay and Earth Materials

Clay and earth materials include material used for landfill, common clay, brick clay, plastic clay, and fire clay. It excludes special clays such as kaolin described earlier. The various types of clay are used for different purposes depending on their properties and the extent to which they can withstand high temperatures (GSD-IM, 1996a,b). Ball clay and plastic clay are used in the manufacture of high-quality whiteware, pottery, clay pipes and tiles, ceramics, and other structural clay products. Common and brick clays are suitable for making building bricks while fireclay is essential for the manufacture of refractory products such as firebricks, refractory mortars and mixes, crucibles, and castable materials. Since 1980, the production of clay and earth materials in the Langat Basin has been stable, ranging from between 0.5 million and 1.6 million tons annually (Table 89.3).

Sand and Gravel

The basic materials used in the construction industry are sand and gravel. About 40% of the mines in the Langat Basin exploit sand from mine tailings while the rest extract sand from rivers. In line with the development of the Langat Basin, the production of sand has increased steadily since 1980. The highest production of sand and gravel in the Langat Basin was in the 1993–1994

Table 89.3 Mineral Production in the Langat Basin^a

^a Units are in metric tons.

^b C&E Material = clay and earth material.

^c S & G = sand and gravel.

^d Tin Conc. = tin concentrates.

— Data not available.

Extrapolated from state production data.

period (Table 89.5). Subsequent to this, sand and gravel production dropped slightly. In 1997, production of sand and gravel increased by about 38% compared to the previous year. There were 86 extraction sites for sand and gravel within the Langat Basin in 1997, compared to 115 the year before.

Tin Concentrates

The production of tin concentrates has declined substantially since 1980 (Table 89.5). The tin-mining industry used to be the major economic activity in the Langat Basin prior to the 1980s. The tin industry is now insignificant, with fewer than three mines operating at any one time, reworking tailings from dredges and old mines. The by-product of such operations includes gold, ilmenite, monazite, zircon, pyrite, and silica. Tin concentrate is at present being imported into Malaysia from Australia, China, and Bolivia for smelting. The refined tin is then exported to countries, including the Netherlands, Japan, the U.S., and South Korea. Since 1996, the consumption of tin metal in the country has been higher than the country's tin production. The metal is being consumed in the solder, tinplate, and pewter industries in Malaysia (GSD, 1996).

MINERAL UTILIZATION TRENDS AND ECOSYSTEM INTEGRITY

Total Mineral Extraction

Total mineral extraction (TME) is the sum of locally extracted minerals per capita that supports economic activity within the basin. The contributors to the TME for the Langat Basin for the period of 1980–1997 are aggregates, kaolin, clay and earth materials, sand and gravel, and tin concentrates.

Table 89.4 The TME per Capita in the Langat Basin, 1980–1997^a

Year	TME/ Capita	Aggregates	C & E Material ^b	Kaolin	S & G ^c	Tin Conc. ^d	Population
1980	11.0	7.7	2.8	0.0023	0.35	0.070	411,495
1981	12.5	8.7	3.3	0.0020	0.42	0.065	431,247
1982	14.0	10.5	2.7	0.0020	0.70	0.054	451,947
1983	13.2	9.6	2.8	0.0024	0.71	0.041	473,640
1984	14.1	10.1	2.7	0.0029	1.19	0.039	496,375

1995	37.0	35.2	0.9	0.0112	0.95	0.003	803,533
1996	35.2	32.9	1.3	0.0121	1.01	0.002	842,102
1997	13.9	11.5	1.1	—	1.3	—	882,523

^a Units are in metric tons/capita. An annual average growth of 5% was used for the population estimate.

^b C & E Material = clay and earth material.

^c S & G = sand and gravel.

^d Tin Conc. = tin concentrates.

— Data not available.

The TME per capita rose steadily in the Langat Basin by about 6% annually, from 1980 up to 1984 (Table 89.4). Between 1985 and 1988, the TME registered a drop of about 10%. This drop coincides with the economic recession in the mid-1980s, where the building and extractive industries were affected. From 1989, the TME per capita of the Langat Basin increased by about 20% annually up to 1996. In 1997, the TME dropped by about 60% due to the economic slowdown.

Aggregate is the largest contributor to the TME in the Langat Basin (Table 89.4). In the early 1980s, aggregates contributed to about 70% of the TME. This increased to about 90 to 95% in the mid-1990s. The national aggregate consumption for 1995 is 4.7 tons/capita, while in the Langat Basin the consumption for that year was nearly eight times higher, at about 37 tons/capita. This high level of aggregate production reflects the intense physical development in the Langat Basin, with the opening of the southern development corridor in Selangor. Aggregate is a basic resource that is required to support physical development to ensure societal well-being. However, the levels of aggregate consumption in the Langat Basin are unhealthy for the ecosystem. The aggregate depletion rates could not be established due to lack of data on the reserves. Based on the available data for 1980 to 1997, it is proposed that aggregate consumption be maintained between 11 and 14 tons/capita.

In contrast, the contribution of tin to the TME/capita has declined significantly since 1980 (Table 89.4). Tin extraction was one of the main economic activities in the Langat Basin where it contributed nearly 1% of the TME. In recent years, the contribution of tin to the TME is negligible. The contribution of clay and earth materials to the TME has reduced by about 5% annually between 1980 and 1996, while that of kaolin by 10% annually during the same period. On the other hand, the contribution of sand and gravel does not show any particular trend, ranging from 3 to 5% of the TME/capita.

Hidden Flows

Hidden flows (HFs) are associated with the extraction and processing of minerals. Hidden flows in the Langat Basin are associated with overburden and gangue (unused material) (Table 89.5). The

Table 89.5 Hidden Flows Associated with the Production of 1 Metric Tonne of Mineral

Aggregate Overburden: 5% Gangue: Minimal	Modified from Adriaanse et al. (1997); the high level of weathering in tropical climate generally results in very thick overburden; there is very little gangue associated with quarrying of rock aggregates
Sand and Gravel Overburden: Minimal Gangue: 2%	Modified from Adriaanse et al. (1997); there is very little overburden associated with the extraction of sand and gravel from ex-mining land; the washing of sand releases clay (gangue) into the drainage system
Clay and Earth Material Overburden: 1 tons/ton Gangue: Minimal	Modified from Adriaanse et al. (1997); the existence of rich residual soil enables the direct excavation of earth material; the amount of overburden removed is less than that recommended for clay in Adriaanse et al. (1997).
Kaolin Overburden: 3 tons/ton Gangue: 25%	Obtained from Adriaanse et al. (1997)
Tin Concentrate Overburden: 2 tons/per ton ore Gangue: 10%	Obtained from Adriaanse et al. (1997)

Adapted from Adriaanse, A. et al., in *Resource Flows: The Material Basis of Industrial Economies*, World Resources Institute, Washington, D.C., 1997; and field observation in the Langat Basin.

material removed is transported by stormwaters and cause siltation of river waters. In most long-term extraction sites, such as aggregate quarries and kaolin mines, silt traps are installed to mitigate this problem. Sand and gravel mines, which are generally small, short-term operations, normally do not install silt traps.

An examination of trends since 1980 shows that HFs associated with aggregate production are generally between 0.3 and 0.6 ton/capita except for the period between 1992 and 1996 where this number was almost doubled (Table 89.6). HFs associated with the extraction of clay and earth materials as well as tin has declined, while the reverse is observed for kaolin and sand and gravel. HFs associated with the total extraction of minerals in the Langat Basin have declined from about

30% of the TME in 1980, to about 20% in 1990, and less than 10% since 1995, while production has increased in proportion (Table 89.6). It appears that the overall efficiency of mineral resource extraction in the Langat Basin has improved.

STERILIZATION OF MINERAL RESOURCES

Aggregate Resources

In terms of area, about 35% of the Langat Basin has high potential for aggregate resources. The major high potential area is located in the upper eastern section of the Langat Basin (Figure 89.2). Four other high potential areas of limited extent have also been identified within the basin. In terms of land cover, it was revealed that 15% of the high potential area has been built-up, and its aggregate resources are effectively sterilized. About 54% of the high potential area is under water bodies and covered by forests, such as the Langat, Semenyih, and Galla Forest Reserves, and the resources therein are inaccessible. Only 31% of the high potential area in the Langat Basin is available for future exploration and exploitation. All the other areas with high potential within the basin are either sterilized or unavailable for exploration and exploitation.

Prior to 1981, the annual rate of aggregate sterilization by built-up areas in the Langat Basin was not significant (Table 89.7). The annual rate of aggregate sterilization between 1981 and 1998 was about 10%. Assuming that the forest cover and water bodies are retained, and that the focus of development remains on the high potential areas, it is estimated that total sterilization of aggregate

resources within the Langat Basin would occur within the next 15 years. As a result of this sterilization, the pressure to exploit high potential areas that are currently overlain by forest reserves will increase to support development in other parts of the basin. The removal of forest reserves in the Langat Basin for quarrying, particularly in the highlands, will adversely impact the overall health of the ecosystem.

Compounding the sterilization of potential aggregate resources, existing quarries are increasingly being encroached upon by housing development and industrial parks. This limits the expansion of such quarries to meet future demand in the Langat Basin. In addition, fly-rocks, dust pollution, vibrations, and sound pollution from quarry operations endanger humans when new development projects are located near existing quarry operations.

There is a pressing need to establish mineral land banks for aggregate resources. Mineral land banks refer to sites with substantial reserves of specific minerals or rock materials that can be extracted for future use. With the expected urbanization and development in the Langat Basin, the requirement for aggregates is expected to increase to meet the demand of the building industry. Mineral land banks should be delineated for aggregates to ensure that their supply is not threatened in the future. These land banks should be maintained for mineral development to sustain future physical development in the Langat Basin. In addition, buffer zones should also be identified around existing quarries. This is to prevent the encroachment of development that would limit the expansion of existing quarries.

Other Resources

About 12% of the national reserves of clay and earth materials (72 Mt), as well as 0.1% of kaolin (0.1 Mt), have been identified in the state of Selangor, where a major part of the Langat Basin is located (Loh and Hamadi, 1997). There are three areas containing kaolin resources in the Langat Basin (Figure 89.2). However, the reserves in the Langat Basin have not been inventoried. The availability of kaolin and clay and earth material resources is necessary to meet the demands of the expanding ceramics, advanced ceramics, and composite products industries in Selangor. Long-term planning should be considered to prevent the sterilization of existing kaolin and clay and earth material reserves in the Langat Basin.

A total of 60% of the sand and gravel in the Langat Basin is derived from rivers and about 40% are from ex-mining areas. There are no available data on the sand and gravel reserves in the Langat Basin. No study has been conducted on the requirement and availability of sand and gravel to support development within the basin.

Exploration for new tin deposits has declined substantially in the Langat Basin. The Kuala Langat area, located near the coast, is believed to contain significant tin resources. Unfortunately, with the depressed tin prices and the increasing competition for land, the area is under increasing pressure to be developed. Permanent nonmineral development in such areas will sterilize the existing tin resources and prevent its future extraction. The trade-off between using the land for the present

population and denying the next generation an opportunity for wealth creation should be carefully studied and understood before the area is developed.

Potential Indicators to Assess Ecosystem Health

The health of an ecosystem is assessed using indicators, and a healthy ecosystem requires conditions that are sustainable. In the context of minerals, a healthy ecosystem would have sufficiently accessible basic resource stocks to support economic growth and societal well-being in an effective and equitable manner, and would experience minimal adverse environmental impacts from its extraction. In the case of the Langat Basin, aggregate and other building materials (e.g., sand and gravel and clay and earth materials) are considered basic minerals. These are essential to support physical development within the basin and to meet the needs of society. The lack of these minerals may threaten future infrastructure development or make it more costly if these minerals have to be imported into the Langat Basin. Minerals such as kaolin and tin are also important, but more so for the creation of wealth. Indicators that are useful for the assessment of ecosystem health in the context of minerals can be divided into three major categories: mineral availability and consumption, mineral extraction, and minerals management.

Availability and Consumption of Minerals

Indicators that are useful to gauge the availability of minerals in the Langat Basin are the amount of reserves. Currently, data are not available for all the minerals extracted in the Langat Basin. Kaolin is important for the resource-based sector and the advanced materials sector under the Second Industrial Master Plan for Malaysia. The Langat Basin has been delineated to host small- and medium-sized industries that will form the backbone of economic development over the next two decades. The availability of data on kaolin reserves will encourage investment in the advanced materials sector. Data on mineral reserves will facilitate long-term planning, with respect to the economic sustainability of the Langat Basin. In the case of aggregates, data will assist in determining the amount of mineral landbanks that should be established.

Another useful indicator related to the availability of mineral resources is rates of sterilization. The problem of mineral sterilization is not being seriously addressed in the Langat Basin, particularly for aggregates and other building materials. The high rate of mineral sterilization of high potential aggregate areas threatens the health of the ecosystem as the high potential areas currently locked under forest reserves may be exploited to meet the demand for aggregates in about 15 years into the future.

The Langat Basin is a net importer of minerals, but levels of actual mineral consumption could not be established. Only the minerals that have been extracted from the basin have been examined, with respect to their consumption in the various economic sectors. The consumption level of aggregates within the basin has been extremely high between 1992 and 1996, at levels between 22 and 37 tons/capita. This indicator on aggregate consumption reflects the intense physical development within the basin due to rapid economic growth during that period. Reasonable levels of aggregate consumption for the basin would be between 11 and 14 tons/capita.

There are other indicators useful in relation to ecosystem health but these have not been examined in detail. These include recycling and substitution rates. At the ecosystem level, the only way to estimate the quantity of the minerals that are recycled is by extrapolating its use from industries already existing in the basin.

Extraction of Minerals

Indicators relating to the extraction of minerals serve to assess environmental impacts that are associated with the extraction of minerals and the direct effect of extraction on the health of the ecosystem. The indicator identified from this study is the amount of hidden flows associated with

the overburden and gangue during the extraction and processing of the minerals. Other hidden flows not considered in this study include:

- Loss of biodiversity
- Emissions into the air
- Discharge into waterways
- Accidental spillage during transfer of substances (e.g., explosives and diesel during mineral extraction)

Indicators directly related to the well-being of humans are the number of quarry-related occupational accidents, the number of and types of complaints related to quarrying activities, such as fly rock and subsidence from residents, and the number of violations of conditions set in operating licenses, as well as environmental infractions.

Management of Minerals

The maintenance of ecosystem health requires effective management of minerals with respect to their availability, consumption, and extraction. The indicators required for this purpose should measure the effectiveness of actions taken rather than the number of or type of action taken. For instance, reduced frequency of encroachment of housing and industrial development onto areas adjacent to quarries would indicate the effectiveness of the planning process within the basin. Other indicators of increased effectiveness in the planning process would be mineral sterilization rates, increased area for mineral land banks and buffer zones, and reduced number and amount of ex-mining areas. Examples of indicators showing improved management on the part of the industry would include:

- Reduced number of violations of conditions set in operating licenses, as well as environmental infractions
- Reduced consumption of energy and water
- Reduced emissions
- Occupational accidents and land used for waste disposal
- Increased tendency to self-regulate through certification to ISO 14000 and other standards

CONCLUSION

In terms of the balance of mineral flows, the Langat Basin is a net importer of nonrenewable resources. The minerals extracted from the Langat Basin for the period of 1980 to 1997 are aggregates, kaolin, clay and earth materials, sand and gravel, and tin concentrates. Aggregate is the largest contributor to TME/capita, reflecting the intense physical development in the Langat Basin. The high rate of aggregate sterilization threatens the health of the ecosystem, as the high potential areas now locked under forest reserves may be exploited in the near future. An examination of trends since 1980 shows that hidden flows in the Langat Basin have reduced from about 30% of the TME to less than 10%. It appears that the overall efficiency of mineral resource use in the Langat Basin has improved. Parameters such as estimates of reserves, rates of sterilization, rates of mineral consumption, TME, HFs, as well as total areas of mineral land bank, buffer zones, and ex-mining land were found to be useful indicators for ecosystem health assessment in the Langat Basin.

ACKNOWLEDGMENTS

SECTION II.9

Forest Health Monitoring and Restoration

Overview: Forest Health Monitoring and Restoration

Bruce A. Wilcox

Among all ecosystems, forests are simultaneously the most globally extensive, studied, historically exploited, and the most subject to management. It follows that forest health monitoring should be the most advanced of any ecosystem health monitoring efforts. Generally speaking, that is the case. As described elsewhere in this volume (see Wilcox et al., Chapter 32) more than 150 counties are involved in initiatives to define national-level criteria and indicators for forest management, including forest health and vitality. However, as also suggested, monitoring programs actually employing these indicators generally have not yet been widely implemented. Further, as the reader will discover from the chapters in this section, forest health monitoring is a highly complex specialty requiring not only a transdisciplinary approach, but one that crosses ecological and institutional scales, ranging from the local management unit or forest patch to an entire forest biome. Of the four chapters in this section, two based on work in Australia and Switzerland provide restoration and management policy perspectives bearing on monitoring at the forest or stand level. The other two describe national forest monitoring programs at the country (Canada) and regional levels (West Coast of the U.S.). As a group, these chapters provide a wide breadth of coverage on the science and policy issues bearing on forest health monitoring.

Brang, in his chapter, gets to the heart of the concept of forest health from a forest stand perspective, drawing on current understanding of forest dynamics in Swiss coniferous forestland. The chapter argues that determining the components, structures, and processes necessary for ecological stability essential to the long-term delivery of products and services lies at the core of the challenge of forest health monitoring. In the context of Switzerland's forests, whose intensive utilization for centuries has diminished the flow of human benefits, forest monitoring necessarily focuses on restoration of health. This situation forces Switzerland to explicitly confront questions such as which products and services are desired of a given forest, thus defining health according to social values, and, in turn, what ecosystem characteristics are required for their long-term delivery.

Calver picks up where Brang leaves off by dealing with how to determine whether forest health is significantly impaired once stakeholders agree on these characteristics. Focusing on management issues within jarrah forest in western Australia, Calver demonstrates how the Precautionary Principle can be used to establish quantitative standards for determining impairment of health, given a particular level of impacting activity (e.g., logging). The approach, along with others under development, represents an important area of progress in the field. It demonstrates that, despite the subjectivity inherent in deciding when an ecosystem is healthy and despite the imperfect state of ecological knowledge, establishing objective standards of measurement is nonetheless possible.

Hirvonen describes Canada's national program for forest ecosystem health indicators. Given Canada's immense size and extent of forested land, and its historic role in leading international ecosystem health and sustainability initiatives, the experience of Canada in developing a monitoring framework provides valuable lessons about the scientific and policy challenges of monitoring forest health. Paramount among the challenges is how to design a system for gathering data that can be meaningfully aggregated, accounting for both spatial and temporal scale differences, workable at the country level, as well as meeting international reporting requirements.

And finally, Campbell et al. focus on the U.S. Forest Service's present monitoring efforts on the West Coast. By contrast to Hirvonen's panoramic discussion of Canada's program and the monitoring system design challenges in general, Campbell et al. bring the focus of section back down to the forest or stand level. They describe the U.S. West Coast program in terms of the specific indicators being measured to indicate ecosystem change and stress, for example, as well as those pertinent to societal values.

Overall, the chapters in this section reflect how far we have come toward incorporating the concept of ecosystem health in forest management science and policy. They also show that, perhaps more so than in other areas dealing with the conservation of global biodiversity, the attempt to distinguish and reconcile natural attributes and social values of ecosystems has been carried further for forests. Yet we also see from these chapters that forest health monitoring is still in its infancy.

Resistance and Elasticity: A Conceptual Framework for Managing Secondary Forest Ecosystems in Switzerland

Peter Brang

INTRODUCTION

The purpose of this chapter is to propose a novel approach to the design of **human disturbance*** regimes in forests. Human^s disturbances are sudden changes in forest composition and structure caused by forest management, while **natural disturbances** are those caused by natural agents such as storm, snow load, and bark beetles. The dynamics of managed forest ecosystems need to be restricted to those system states where desired products and services are continuously provided. These restrictions need to be both sufficiently narrow to ensure that human demands are met, and sufficiently large to allow for **ecosystem dynamics** to occur. Implementing a strict regime to control ecosystem dynamics has led, in some examples, to long-term management failures (Holling, 1987). To what extent such failures generally occur is an open question.

In order to ensure the supply of products and services, managers should strive to create forests that are both resistant to changes that lead to unacceptable states and resilient (Grimm and Wissel, 1997) (i.e., able to return from unacceptable to acceptable states after disturbances). The speed of this return has been termed “**elasticity**” (Grimm and Wissel, 1997).

In this chapter, I will show that in Switzerland and elsewhere in Europe the **resistance** and elasticity of forest ecosystems have been degraded by inadequate management practices. I will demonstrate this by comparing these man-made forests with remnants of **old-growth forests** on similar sites, most of which are located in Slovakia (Korpel, 1995, 1997). These comparisons reveal important differences in **ecosystem composition, ecosystem structure, and processes**, which are causing management problems today. Solutions to these problems may lie in partially restoring old-growth composition and structure to **secondary forests**. I explore how the concepts of resistance and elasticity can be used to evaluate the extent of such restoration.

* Terms in bold type are defined in the glossary at the end of the chapter.

CURRENT USES OF FORESTS IN SWITZERLAND

In Switzerland, 68% of the forest is publicly owned (Brassel and Brändli, 1999), and most forests are managed for multiple products and services. The main forest product is timber, and the main services are protection against natural hazards (e.g., snow avalanches, rockfall, torrents, and soil erosion), recreation, and conservation. Although most forests serve multiple purposes, providing protection against natural hazards is often the most important. It is the main service in 8 to 45% of the forest area in the Swiss mountains, depending on the region and the definition of a protection forest (Brassel and Brändli, 1999).

HUMAN IMPACT HAS SHAPED SWISS FOREST ECOSYSTEMS

For centuries, human activities have strongly shaped almost all forests in Switzerland. People have used the forests for timber harvesting (including clear-cutting and permanent deforestation), grazing, litter-raking, and hunting. Only 20 ha of old-growth forest remain. Air pollution and anthropogenic climate change have emerged as new influences during the past few decades. As a result, Swiss forests are secondary forests. Their compositions, structures, and processes differ markedly from those of old-growth forests (Figure 91.1).

Important examples of changes in ecosystem composition are reductions in forest area, growing stock, and volume of coarse woody debris, and an altered species composition, which has shifted toward *Picea abies* (L.) Karst. The average growing stock of all Swiss forests is currently around 366.5 ± 3.5 m³/ha (mean \pm SE; Brassel and Brändli, 1999). This is much less than the 500+ m³/ha reported for Slovakian old-growth forests (Korpel, 1997) on the majority of those sites that are similar to those found in Switzerland. The low-growing stock in Swiss forests is due to the underrepresentation of late seral stages in managed forests (Burschel and Huss, 1987).

The volume of coarse woody debris in Swiss forests amounted to 11.9 ± 0.5 m³/ha (mean \pm SE; Brassel and Brändli, 1999) around 1994. It has certainly increased since, especially as a result of Hurricane Lothar in 1999, but is still much smaller than the volumes of 50 to 280 m³/ha reported for Slovakian old-growth forests (Korpel, 1997), boreal old-growth forests (27 to 201 m³/ha; Linder et al., 1997), and for temperate old-growth forests (60 to 1189 m³/ha; Harmon et al., 1986).

Figure 91.1 Qualitative evaluation of the magnitude of human-mediated disturbances and their effect on Swiss forest ecosystems during the past 1000 years, and projected through the year 2040.

In comparison with what is assumed to be the species composition in old-growth forests, *P. abies* is overrepresented in Swiss forests. Using a site-classification model, Kienast et al. (1994) classified 6793 forest inventory plots out of a total of 10,400 plots as sites where deciduous trees should be dominant. However, inventory data showed that one fifth of these plots had more than 75% basal area of *P. abies*, and two fifths had more than 75% basal area of *P. abies* or other coniferous species. In contrast, *Abies alba* Mill. is underrepresented. This shade-tolerant species is not competitive in large open areas and is much more heavily browsed by ungulates than most other tree species (Liss, 1988). Its distribution was greatly reduced by large clear-cuts and grazing in the 19th century, and by the intense browsing pressure of recent decades. In eastern Bavaria, a region more heavily impacted than most parts of Switzerland, the proportion of *A. alba* was reduced by 75% over 200 years (Eichenseer, 1997). The two examples of *P. abies* and *A. alba* show that the current species composition deviates considerably from the species composition of old-growth forests.

The stand structures are much more uniform in the current man-made forests than in old-growth forests. On most sites, the remaining old-growth stands in central Europe are structurally diverse, with patch sizes rarely exceeding 1 ha (Zukrigl, 1991). In the Swiss Forest Inventory, 68% of the plots were classified as having uniform stand structure (Brassel and Brändli, 1999). There are no representative data from old-growth forests on similar sites. However, many case studies in Slovakian old-growth forests are available (Korpel, 1995). Given those studies, I conclude that without human interference, over three quarters of Switzerland's forests would be structurally diverse. This structural diversity would be found in *Fagus sylvatica* L. forests, mixed *A. alba*-*F. sylvatica* and *P. abies*-*A. alba* forests, and subalpine *P. abies* forests (Brassel and Brändli, 1999). The increase in uniform stand structure is the result of clear-cutting, afforestation, and repeated thinning (Ott et al., 1997).

Ecosystem processes also differ between secondary and old-growth forests. Tree growth was probably adversely affected by centuries of litter-raking and other nutrient-exporting practices (Spiecker et al., 1996; Kuchli, 1997), which decreased site productivity. Recently, an increase in tree growth was reported for many parts of Europe (Spiecker et al., 1996). The abandonment of practices that depleted nutrient stocks coupled with increased nitrogen deposition, elevated CO₂ concentrations, and higher temperatures is likely to account for the increased tree growth (Spiecker et al., 1996), although definite proof is lacking. Other examples of ecosystem processes that have been interfered with include tree death and decay, which have been short-circuited by timber harvesting, and only partly been allowed to take place again in recent years. Even if no timber were harvested from now on, which is unacceptable, it would take many decades, perhaps centuries, to accumulate the amount of coarse woody debris characteristic of old-growth forests.

The lack of seedbeds created by decaying logs has also inhibited tree regeneration, another ecosystem process, on wet sites, particularly for those species that preferentially establish on nurse logs (Korpel, 1995). Grazing and browsing have also had a negative impact on regeneration. Although grazing pressure from domestic livestock has decreased in recent decades, browsing by wild ungulates has increased, mainly by *Cervus elaphus* L., *Capreolus capreolus* L., and *Rupicapra rupicapra* L. The absence of large predators, such as the wolf, lynx, and bear, and decreasing poaching have allowed ungulate populations to increase (e.g., Righetti and Huber, 1983; Brückner, 1993). Further exacerbating the situation, agricultural development has reduced the area of suitable ungulate habitat, thereby forcing animals into forested areas. These factors are serious obstacles to forest renewal.

Many of the reported changes in forest ecosystem composition, structure, and processes have been substantial. The current man-made forests clearly differ from old-growth forests, and must be considered secondary forests.

RELEVANT ECOSYSTEM CHARACTERISTICS HAVE BEEN IMPAIRED

Differences in the ability of old-growth and secondary forests to meet human demands cannot be inferred from differences in ecosystem characteristics. Indeed, many forests have been deliberately

and successfully altered to enhance their ability to provide specific products or services. This is the case with thinnings, for instance, that are aimed at enhancing wood quality and stand resistance to natural disturbances such as windfall and snow break (Slodiacák, 1995).

Nevertheless, many of the changes in Swiss forest ecosystems must be seen as the unintended side effects of other activities, which have impaired, rather than enhanced, the forests' ability to meet human needs in the long-term. A striking example of this is the reduction in *A. alba*. Previous loss of *A. alba*, and its continuing elimination by browsing, have greatly contributed to the current and future regeneration difficulties in many forests (Ott et al., 1997). This species has several silvicultural properties that facilitate its management, and make it an important component of forests managed for protection against natural hazards. It is rarely attacked by bark beetles, in contrast to the highly susceptible *P. abies*. Unlike most other tree species, *A. alba* is able to establish in dense shade (Mayer, 1984). It can avoid strong competition from herbs, grasses, and shrubs that need more light (Ott et al., 1997). It is also much less dependent on the availability of coarse woody debris as a seedbed than *P. abies* (Mayer-Wegelin and Schulz-Brüggemann, 1949; Hunziker, 1999; but see Mayer et al., 1972).

The regeneration problems for *P. abies*, the most important tree species in Switzerland, which have been caused by the loss of coarse woody debris, are another example of unintended side effects of past management practices. As a consequence, natural regeneration is often sparse, and costly investments in planting are necessary. Moreover, management has often promoted uniform stand structures, which are more susceptible to large-scale disturbances, such as windfall and bark beetle damage (Mayer, 1984), and therefore less able to protect against natural hazards and to produce timber. This has happened where pure stands of *P. abies* have been established on sites that, without human intervention, would have supported mixed stands of *P. abies*–*A. alba* or *A. alba*–*F. sylvatica*, which usually exhibit a small-scale natural disturbance regime (Korpel, 1995). The negative effect of the lack of old trees on species diversity (Perry, 1994; Samuelsson et al., 1994) is another unwanted side effect of past forest management. Reduced species diversity means that the forest is less valuable as a habitat.

RESTORATION — WHAT SHOULD BE RESTORED AND TO WHAT EXTENT?

As we have seen in the last section, some of the side effects of past forest management are undesirable. Restoration efforts are needed, and such efforts are about to be made in Switzerland and elsewhere in Europe. However, it remains unclear which ecosystem characteristics should be restored, and how far restoration should proceed toward a more natural condition. What is the goal of ecosystem restoration in this case?

I propose that, for the managed forests in Switzerland, the restored ecosystem characteristics should be components, structures, and processes that are crucial for the long-term delivery of products and services. I elaborate on these characteristics in the section, "Restoration Should Enhance the Resistance and Elasticity of Forest Ecosystems."

Full restoration of old-growth forest dynamics would entail undesirable fluctuations in the delivery of products and services (De Leo and Levin, 1997). Like some human disturbances (see above), some natural disturbances can impair management goals. Large insect outbreaks, for instance, cause considerable economic damage, and affected stands may provide ineffective protection against natural hazards. The same applies to disturbances, such as storms and fires, that have the potential to affect forest ecosystems on a large scale. Forest management aims to constrain forest dynamics within specific limits. These limits include only a portion of the possible states of a forest, as expressed by composition and structure. Forests should be kept in a stable condition — although the inherently dynamic nature of ecosystems (Holling, 1996) has to be taken into account. This means that the goal is not to restore old-growth forest dynamics entirely, but only to such an extent that human demands can be better met than they are today. In contrast to past

management, the long-term side effects of forest management on the ecosystem itself (De Leo and Levin, 1997) and on adjacent systems need to be considered. Such managed ecosystems can be called healthy, according to the utilitarian definition of ecosystem health (Kolb et al., 1994; Kimmins, 1996), or be said to have integrity (De Leo and Levin, 1997).

CURRENT APPROACHES TO DESCRIBING FOREST DYNAMICS FOR MANAGEMENT PURPOSES ARE OVERLY SIMPLISTIC

To cope with the dynamic nature of forest ecosystems, forest managers need to understand their dynamics. They also need to know which ecosystem characteristics are most important in influencing management goals, and the thresholds beyond which these goals could be impaired. This understanding takes as its starting point a description of the patterns at the stand and landscape scales and of the factors causing them (Brang et al., 2001). From this, the forest's future dynamics as a result of natural disturbances can be predicted. Finally, the management actions that are most likely to retain the system within the desired limits, or to bring it to such a state, can be designed.

Intuitively, forest managers have followed these steps for decades in Switzerland. However, there is still much guesswork involved. Long-term forest dynamics are often poorly understood so that predictions about future dynamics tend to be highly uncertain, and management tends to follow the lines of tradition and belief. Moreover, managers often delineate the system too narrowly, and fail to consider the side effects described above. In contrast, those limits where management goals are impaired seem to be better known. For instance, site- and hazard-specific target values for forest condition have been established for forests that provide protection against natural hazards (Wasser and Frehner, 1996).

A general framework for describing those aspects of long-term forest dynamics that are relevant for forest management has yet to be developed. Yield tables have been used to predict stand growth (Assmann, 1970). The coefficient of slenderness of the stem, crown length, stand age, species of tree, stem rot, and variables characterizing the site conditions have been used to explain and to predict a tree's susceptibility to windthrow and snow break (Rottmann, 1985; Schmid-Haas and Bachofen, 1991; Slodicák, 1995; Nykanen et al., 1997; Herold and Ulmer, 2001). Predictions from these studies have, however, usually been very rough, with the outcomes predicted in a few classes, such as high, intermediate, and low risk. Several ecologists have developed models to help understand and predict forest dynamics better (Shugart, 1984; Kräuchi and Kienast, 1993; Bugmann and Cramer, 1998), but most of these models have not been aimed at solving management questions (but see Erni and Lemm, 1995). Risk-based assessments (Mitchell, 1998; Pukkala, 1998) have come closer to getting to the root of the problem by providing predictions of how likely specific outcomes of *leaving* and *doing* are. *Leaving* means simply accepting natural disturbances as they occur, whereas *doing* means altering the natural disturbance regime by introducing human disturbances.

ECOLOGICAL STABILITY PROPERTIES: A USEFUL APPROACH FOR DESCRIBING FOREST DYNAMICS

The concept of *ecological stability* (e.g., Holling, 1973) has received great attention in ecology, and it may also be useful for describing forest dynamics. However, the term itself has caused so much confusion that Grimm and Wissel (1997) wrote a paper titled, "Babel, or the Ecological Stability Discussions: An Inventory and Analysis of Terminology and a Guide for Avoiding Confusion." They advocate avoiding the term ecological stability and referring to "ecological stability properties" instead, which include the basic concepts of (1) **constancy**, (2) **resilience**, and (3) **persistence**. Constancy includes the property resistance, and resilience the property elasticity.

Rather than deal with the broad properties of constancy, resilience, and persistence, I would like to focus on resistance and elasticity for the following reasons. Constancy occurs only on short timescales or for the most inactive system components such as the bedrock chemistry. Resilience as a general concept is also not very relevant in central Europe since the ability to return to predisturbance forest dynamics seems to be high for most disturbances (see below) and most forest ecosystems. Evidence for this is the fast recovery after the mid-19th century of many forests that had been heavily exploited prior to 1850. In contrast, resilience is important in ecosystems that are vulnerable to long-term degradation, such as many Mediterranean forests. In central Europe, however, only a specific aspect of resilience is relevant, namely, the *speed* of return to referential states or dynamics (i.e., elasticity). Persistence is a less important issue since the resilience of the forests seems to be high, and the existing forest area is protected by strict legislation.

High resistance means that the *probability* that the desired service or product of a forest will not be delivered is reduced, and vice versa. An estimation of how resistant a particular forest is to various disturbances is part of an assessment of the risk that products and services will be impaired. A resistance assessment contributes to an ecological risk assessment (Cairns, 1998). High elasticity, on the other hand, means that the *period* during which the desired service or product of a forest may be unavailable is short, and vice versa. An elasticity assessment is needed since disturbances will sometimes impair the delivery of the desired effects or products of a forest, and managers will want to know how long the gap in service will be.

RESISTANCE AND ELASTICITY APPLIED TO FOREST ECOSYSTEMS

A stability statement, such as “resistance and elasticity are important for forest management in central Europe,” is not helpful unless I specify the ecological situation or context (Grimm and Wissel, 1997). Do I mean the resistance of a landscape to changes in forest patch patterns? Am I addressing the resistance of an ant to a leaf falling to the ground? Grimm and Wissel stress the importance of defining the ecological situation to which a stability statement applies and provide a checklist with six characteristics (Table 91.1). In the context of forests managed to provide specific products and services, the answer to many of the questions about resistance and elasticity is given by the scale of these products and services.

To apply the concepts of resistance and elasticity usefully to the management of forest ecosystems in Switzerland, those disturbances that can affect management aims should be known, as should how and to what extent they affect these aims. The most important **disturbing agents**, the paths through which they disturb the tree layer, their occurrence and effect on the ecosystem, and their impact on two management aims (protection against natural hazards and timber production) are listed in Table 91.2. The disturbing agents are interconnected. The occurrence of the disturbances varies greatly in space and time and is species and site specific. Some impacts on the delivery of productions and services are immediate, while others become noticeable only after a time lag.

RESTORATION SHOULD ENHANCE THE RESISTANCE AND ELASTICITY OF FOREST ECOSYSTEMS

I proposed earlier that, for managed forests, the ecosystem characteristics to be restored are the components, structures, and processes that are crucial for the long-term delivery of products and services. Having seen the importance of resistance and elasticity, we can narrow our search for the ecosystem characteristics to be restored in central European forests to those that confer resistance and elasticity on a forest ecosystem. For the most widespread disturbing agents, a preliminary list of these characteristics is given in Table 91.3. Some of these characteristics can be altered by management and others not. The most important means of influencing resistance to disturbances

Table 91.1 Checklist for Ecological Stability Properties Applied to Forest Management

Characteristics of the Ecological Situation	Question to Be Answered	Possible Answers in the Context of Forest Management ^a
Level of description	On which hierarchical level of an ecosystem are we describing stability?	Individual to landscape, depending on the products and services to be delivered; for products and services that depend directly on trees, the population level is used to describe ecological stability properties
Variable of interest	Which (measurable) state variables are we referring to?	Indices of the spatial distribution of trees, dbh (diameter of breast height) distribution, distribution of gap sizes and orientations, volume increment, estimated nutrient cycling rates
Reference state or dynamics of the variable of interest	What is the state variables <i>acceptable</i> ^b behavior?	<i>Acceptable</i> values of state variables depend on management aims that are defined in order to maintain a permanent delivery of products and services
Disturbing agents and disturbances	Which disturbing agents are affecting the ecosystem's behavior, and to what extent? ^c	Disturbing agents that can cause the unwanted death of trees (storm, snow load, bark beetles), or that have the potential to alter tree species composition, and growth and mortality patterns (pathogenic fungi, extreme climatic events, bad management practices, browsing ungulates), frequency and magnitude of the disturbances
Spatial scale	To which spatial scale does the stability statement refer?	Tree to stand level (10–1000 m)
Temporal scale	To which temporal scale does the stability statement refer?	Years to several centuries

The table describes how the ecological situation can be defined to make valid ecological stability statements for managed forest ecosystems.

^a All answers depend on the goals of the particular forest management.

^b Grimm and Wissel (1997) focus on *normal* reference states or dynamics without external influences. This seems inappropriate in the context of an ecosystem managed for specific purposes. *Acceptable* behavior seems to be more precise.

^c Grimm and Wissel (1997) define disturbance as the result of dynamics exceeding reference dynamics. In the context of forest management, reference dynamics are dynamics where acceptable levels of disturbance are not exceeded. Management usually aims at replacing part of the highly variable natural disturbances by more predictable human disturbances.

Adapted from Grimm, V. and Wissel, C., *Oecologia*, 109, 323, 1997. With permission.

that directly affect the tree layer involves changing the composition of the tree species since the susceptibility of trees to disturbances varies among species. Another less influential option lies in changing the stand structure. Tree regeneration is the key to the elasticity of the tree layer. Resistance to soil acidification is a special case since it does not directly affect the above-ground part of the trees, but rather affects their roots through changes in soil chemistry.

Interestingly, the majority of the characteristics outlined in Table 91.3 are also characteristics of old-growth forests. This supports the hypothesis that, at least in central Europe, **natural disturbance** regimes lead to forests that have a fairly high resistance and elasticity to disturbances, and justifies restoring more **naturalness** in secondary forests. There is also some empirical evidence for this: old-growth forests are often less affected by disturbances, such as windfall, than adjacent secondary forests (Zukriegl, 1991). However, some old-growth forests show characteristics that make them less resistant and elastic than well-managed secondary forests. One example is the occurrence of pure *P. abies* old-growth forests on productive sites that are susceptible to large-scale disturbances (Korpel, 1995), in particular windfall and bark beetle mortality. This shows that even if our aim is to maximize resistance and elasticity, managed forests should not be made to resemble old-growth forests absolutely. Naturalness is not a goal in itself in managed forests. A certain naturalness, however, is a means of enhancing the probability that the long-term delivery of products and services is ensured.

Table 91.2 Most Important Disturbing Agents, Their Path of Effect, and the Effect of Disturbances Caused by These Agents, for a Forest Providing Protection against Natural Hazards, and a Forest Used for Timber Production (both in Switzerland)

Disturbing Agent	Path of Effect	Effect of Disturbance on Tree Layer	Impact on Management for Protection against Natural Hazards	Impact on Management for Timber Production
Storm	Direct impact on trees	From single treefalls to gaps > 10 ha; lower resistance to bark beetles	Protection impaired, often increased management costs	Lower wood quality, economic losses
Snow load	Direct impact on trees	From single treefalls to gaps < 1.0 ha; lower resistance to bark beetles	Protection impaired, increased management costs	Lower wood quality, economic losses
Bark beetles	Direct impact on trees, triggered by presence of weakened trees, often after storm or snow break	From single trees killed to gaps > 1.0 ha; lower resistance to other disturbances	Protection impaired, increased management costs	Lower wood quality, economic losses
Ungulates	Browsing and fraying on tree regeneration	Long-term changes in tree species composition, slower juvenile stand development; lower elasticity in the face of other disturbances	Protection impaired in the long term, increased management costs	Economic losses as a result of slower juvenile stand development
Pathogenic fungi	Root rot, stem rot	Mortality of single trees; lower resistance of single trees to storm, snow load, and bark beetles	In most cases no direct short-term consequence	Economic losses
Acid deposition	Decrease of ratio base cations/Al, soil nutrient leaching, in advanced stages damage to roots and mycorrhizae	Shallower roots, lower resistance to storm and snow load, nutrient deficiencies, growth reduction	No direct short-term consequences, in the long term increased management costs and impairment of protection	No direct short-term consequences, in the long term economic losses
Drought	Reduced tree vigor, making trees susceptible to bark beetle attack, seedling mortality	Lower resistance to storm, snow load, and bark beetles, growth reduction, lower elasticity in the face of other disturbances	No direct short-term consequences	Economic loss
Inappropriate harvesting practices	Damage to remaining stand, infection by wood-decaying fungi, root and stem rot, soil compaction	Lower resistance to storm and snow load, growth reduction	No direct short-term consequences, in the long term increased management costs and impairment of protection	Lower wood quality, economic losses

All disturbances vary highly in time and space and among sites and tree species.

Table 91.3 Characteristics of Swiss Forest Ecosystems and of Their Management That Make the Tree Layer More Resistant and More Elastic in the Face of Widespread Disturbing Agents

Disturbing Agent	Characteristics Increasing Resistance	Characteristics Increasing Elasticity
Storm and snow load	Highly structured stands with long internal edges, small-sized trees, tree species not susceptible to stem and root rot, low gravity point, low coefficient of slenderness of the stems, long crown, no silvicultural treatments creating edges exposed to storm, no thinnings that lower the individual or group stability of trees, <i>low site productivity (unless soils are waterlogged), aspect not exposed to prevailing winds (applies only to storm), deep soil</i>	Presence of tree seedlings waiting for release; if tree seedlings are absent, presence of seed-producing trees, presence of safe sites for seedling establishment, low competition from vegetation, low browsing pressure, <i>no drought during germination and early establishment, high genetic variability of the regeneration</i>
Bark beetles	Tree species not susceptible to bark beetles, mixed-species stands, low susceptibility to other disturbances (e.g., storm, snow load, and drought), high tree vigor (low defoliation, long crown, fast growth)	See storm and snow load
Ungulates	Tree species that are not or rarely browsed, low population density of ungulates, high forage value of habitat, defense measures (e.g., fencing)	Seedlings able to sprout, <i>large-scale disturbances that increase the forage value of the habitat, heavy winters reducing ungulate population density</i>
Fungi causing stem and root rot	Tree species not susceptible to stem and root rot, low damage to roots and to the bark by harvesting, tree fall, and rockfall	See storm and snow load
Acid deposition	Mycorrhizal fungi, <i>high buffering capacity of the soil</i> , tree species able to pump nutrients from deep soil layers, ground vegetation able to retain nutrients, liming, absence of nutrient-exporting treatments (e.g., whole-tree harvesting)	<i>High input of nutrients from weathering of the bedrock</i> , tree species able to pump nutrients from deep soil layers
Drought	Tree species able to cope with water stress (low evaporative demand, strong stomatal aperture control, extensive and deep-reaching root system)	Tree species able to grow a second set of leaves or to sprout
Inappropriate harvesting practices	Reward and punishment system depending on harvesting quality, high educational standards, low stand density	Tree species able to grow over bark damage fast

Italics indicate characteristics that cannot be altered by management, or only to a small extent, within <500 years, such as aspect, soil moisture conditions, and site productivity.

Note: A complete description of the ecological situation (Table 91.1) is not given since only relative stability statements are made.

OUTLINE OF A PROCEDURE FOR REACHING DECISIONS ABOUT RESTORATION

Most of the ecosystem characteristics given in Table 91.3 have already been considered by forest management so that experience and a body of scientific knowledge about how to influence these characteristics are available. However, resistance and elasticity with respect to acceptable ranges of ecosystem states have rarely been explicitly included in management decisions.

When deciding on the best management strategies for each particular forest, which often involves restoring impaired forest ecosystem characteristics, the following questions need to be answered:

1. Which products and services should a particular forest deliver continuously?
2. Which ecosystem characteristics are most important for the current and long-term delivery of specific products and services?

3. Which disturbances have the potential to cause ecosystem states that do not comply with management aims?
4. Which ecosystem characteristics are most relevant in enhancing resistance and elasticity in the face of disturbances?
5. Which variables and which assessment procedures should be considered in monitoring characteristics related to products and services, disturbances, resistance, and elasticity?
6. Which value ranges of the variables identified in question 5 are acceptable for specific sites and management aims?
7. How resistant and how elastic are the ecosystems in question at present, in relation to disturbances that have the potential to drive ecosystems to an unacceptable state?
8. Which ecosystem characteristics, if any, should be restored in order to make the ecosystems in question more resistant and more elastic?
9. Which management practices are most appropriate to achieve this restoration?
10. How much investment required for restoration is justified given the potential result?

CONCLUSION

It is commonly accepted among Swiss forest managers that many of the problems they are facing are due to failures of past management, and that more naturalness needs to be restored (Ott et al., 1997). For instance, the role of natural disturbances in shaping the forest has been underestimated, and the potential for replacing them with specific management practices overestimated. Ecosystem characteristics have often been considerably altered in order to enhance the forest's output of desired products and services, but without taking into account the long-term consequences for the resistance of the forest to disturbances and for its elasticity. Restoration measures in secondary forests in Switzerland to enhance their resistance and elasticity in the face of disturbances are therefore required.

The concepts of resistance and elasticity are not yet operational for use in describing forest dynamics, although a qualitative use of some of their aspects has been incorporated into management guidelines for forests that provide protection against natural hazards (Wasser and Frehner, 1996). Using a list of questions, I have developed a procedure that could make resistance and elasticity more generally applicable in forest management. I have tried to answer, in a preliminary way and for Swiss conditions, some of these questions for both forests providing protection against natural hazards and forests producing timber. The challenge is now to describe resistance and elasticity quantitatively, to develop suitable indicators for monitoring, and to apply these concepts to forests that serve primarily other purposes such as recreation and conservation. Achieving this will take us a step closer to designing forest management systems based on a rigorous assessment of the chances and risks that the forest will continue to provide the desired products and services.

ACKNOWLEDGMENTS

I would like to thank two reviewers for their helpful comments on the manuscript, and S. Dingwall for improving the English.

DEFINITIONS OF TERMS AS USED IN THIS CHAPTER*

Constancy “Staying essentially unchanged” (Grimm and Wissel, 1997).

Disturbance “Any relatively discrete event in time that disrupts ecosystem, community, or population structure and changes resources, substrate availability, or the physical environment” (White and Pickett, 1985). I would like to extend this definition of disturbance to include “events” caused by continuously acting agents, such as acid deposition, that lead to slow changes in the ecosystem.

Disturbance regime Type, frequency, spatial distribution, and magnitude of the disturbances acting on an ecosystem, which may interact with each other.

Disturbing agent Factor that has the potential to change ecosystem characteristics substantially.

Ecosystem composition Sum of the components in an ecosystem.

Ecosystem dynamics Temporal development of a whole ecosystem.

Ecosystem processes Temporal development of ecosystem components.

Ecosystem structure Spatial arrangement of ecosystem components

Elasticity “Speed of return to the reference state or dynamics after a disturbance” (Grimm and Wissel, 1997).

Human disturbance Disturbance caused by people.

Natural disturbance Disturbance caused by disturbing agents other than people.

Naturalness Degree to which an ecosystem, at a given site, resembles an old-growth forest in composition, structure, and processes.

Old-growth forest Forest that has been subject to natural disturbances only.

Persistence “Permanent existence of an ecosystem” (Grimm and Wissel, 1997).

Resilience The ability of an ecosystem to return to the referential state or dynamics after a disturbance.

Resistance The ability of an ecosystem to remain unchanged in spite of the presence of a disturbing agent.

Secondary forest Forest that has been subject to substantial human disturbances.

The Precautionary Principle and Ecosystem Health: A Case Study from the Jarrah Forest of Southwestern Australia

Michael C. Calver

INTRODUCTION

Forest health, sustainability, and ecosystem management are of interest to many people. The ambiguity of these terms encourages people to engage in forest policy discussions because their own ideas have not been predefined out of the debate. If foresters can't define forest health, or if their definition is unacceptably narrow, people will likely seek opinions about forest management elsewhere. Thus the forest health analogy is a powerful, but imperfect, metaphor for communicating with the public. (O'Laughlin, 1996).

[W]hat is a sufficient precautionary approach to forest use given the uncertainties and risks arising from imperfect knowledge, predicted climate change and unforeseen events? Norton (1996).

In January 1849, members of surveyor-general John Roe's expedition became the first Europeans to pass through the heart of the jarrah *Eucalyptus marginata* hardwood forests of southwestern Western Australia. In his journal, Roe commented with awe at the sight of "the splendid straight mahogany or jarrah trees, growing within 3 or 6 feet of each other, reaching to the height of 50 and 80 feet without a branch or blemish, and apparently quite sound" (Roe, 1852). However, he was a practical man and moved by considerations other than aesthetics. He further reflected:

It is also to be hoped that, as one of the most valuable and most readily available sources of wealth in this colony, the superb naval timber which I observed in such inexhaustible quantity in the forests behind Bunbury, will not much longer be suffered to remain there idle, but that, on the formation of practicable roads, the axe and saw will shortly resound amongst it, to the mutual advantage of the colony and of its parent country (Roe, 1852).

Roe's wish was soon fulfilled. By 1920, only 71 years after his expedition, "nearly one million acres of the jarrah forest were cut over for the removal of 750 million cubic feet of logs, causing a reduction of almost 50% in the forest canopy"* (Wallace, 1965). This period of almost unrestrained exploitation saw intense land-use conflicts between agricultural clearing and long-term forestry,

* One acre = ~0.404 hectares and one cubic foot = ~0.028 cubic meters. The original extent of the jarrah forest is estimated as 13,000,000 acres (Wallace, 1965).

bitter complaints of wastage in the timber industry, and large-scale government inquiries. Furthermore, in 1894 the Australasian Association for the Advancement of Science lobbied successfully to create a 65,000 ha conservation reserve in the heart of the jarrah forest, only to have it overturned in 1911 following pressure from the timber industry (Rundle, 1996). The timbers that Roe saw in “inexhaustible quantity” proved finite and, as always, people argued bitterly over a finite resource.

In 1918, the Western Australian state parliament passed a Forests Act, designating large areas of jarrah forest as State Forest for long-term sustainable timber production, and forest management has evolved since then. However, the basic land-use conflicts involving agriculture, forestry, and conservation in the jarrah forest persist today with unabated intensity (e.g., Abbott and Christensen, 1994, 1996; Calver and Dell, 1998a, b; Calver et al., 1999). In the late 1990s, the State Government of Western Australia and the Commonwealth Government of Australia attempted to resolve these issues through a Regional Forests Agreement (RFA), which balanced all competing interests for the next 20 years. However, both the process and its outcome have been criticized and disavowed so the RFA cannot claim to have achieved consensus (Horwitz and Calver, 1998).

Despite these difficulties, the debate over jarrah forest management during the 1990s highlighted strong community interests in the values inherent in the Precautionary Principle and in the concept of ecosystem health. The Precautionary Principle argues:

Where there are threats of serious or irreversible damage, lack of full scientific certainty should not be used as a reason for postponing measures to prevent environmental degradation. In the application of the precautionary principle, public and private decisions should be guided by: (i) careful evaluation to avoid, wherever practicable, serious or irreversible damage to the environment; and, (ii) an assessment of the risk-weighted consequences of various options (The Intergovernmental Agreement on the Environment, May 1992, quoted in Deville and Harding, 1997).

The ecosystem health concept argues that ecosystems may become dysfunctional under disturbance and that such dysfunction can be detected and corrected (Rapport, 1998a).

The Precautionary Principle is explicitly invoked in a ministerial condition governing the management of the jarrah forest (Calver et al., 1999). It was also the subject of an unsuccessful legal action against the Western Australian Department of Conservation and Land Management (CALM), which manages logging and associated practices in the region (Calver et al., 1999). The concept of ecosystem health was introduced into management issues in the jarrah forest by Calver and Dell (1998b) and Calver et al. (1998), after earlier authors had raised the related concept of ecological condition, a measure of the continuance of fundamental ecological processes (Abbott and Christensen, 1994; see also Rapport, 1998a). Ecosystem health caught the popular imagination recently when local physicians ran large advertisements in daily newspapers claiming that the consequences of some current forest management practices were unhealthy.

The widespread interest aroused by the Precautionary Principle and ecosystem health make these concepts ideal facilitators to bring together the diverse stakeholders involved in the forest debate to achieve consensus on management goals and practices. Preliminary frameworks for applying the Precautionary Principle are already available and there is a growing literature on forest ecosystem health. However, application of both concepts is vague and subjective unless measurable, quantitative standards are chosen for selected response variables that reflect possible changes in an ecosystem. In this chapter I illustrate the value of the Precautionary Principle in setting such quantitative standards for maintaining the health of the jarrah forest ecosystem in conjunction with a viable timber industry contributing to the economic well-being of local communities. Brief histories of the concept of forest ecosystem health and the Precautionary Principle follow, together with a background to management issues in the jarrah forest and an outline of a framework for applying both the concept of ecosystem health and the Precautionary Principle to forest management. The discussion reveals that ecosystem health and the Precautionary Principle can be used as quantitative bases for forest management in this case, but that this has not yet been achieved.

BACKGROUND

History of the Ecosystem Health Concept and the Precautionary Principle

Ecosystem health is a new concept scarcely a decade old (Rapport, 1998a,b). It centers on ecosystem resilience and sustainability, absence of significant environmental stresses, and the capacity of the ecosystem to sustain healthy human communities, making it ideally suited to forest management issues (e.g., O'Laughlin, 1994; Vora, 1997). Several authors have proposed quantitative criteria to assess forest ecosystem health (e.g., O'Laughlin, 1994, 1996; Yazvenko and Rapport, 1996), although value judgments are inherent in most measures (Kimmins, 1996). However, this is not necessarily a weakness if there is extensive consultation among all stakeholders in deciding the criteria for evaluation. Importantly, the concept of ecosystem health need not proscribe logging or other uses of natural resources, providing that such use does not compromise other ecosystem services, such as water catchments, erosion prevention, or wildlife conservation. Indeed, such resource use may be essential in sustaining local human communities. With regard to forest management, ecosystem health emphasizes reducing the risk of forest change undesirable to the wider community and, where forests are degraded, restoration of forest conditions that the community wishes (O'Laughlin, 1996). Criteria for ecosystem health include vigor (sustaining normal levels of energy throughput and primary productivity), resilience (capacity to recover from stress), and organization (maintenance of species diversity and a full spectrum of ecological interrelationships) (Rapport 1998a). The emphasis on risk reduction establishes a clear link with the Precautionary Principle.

The origins of the Precautionary Principle are unclear, but lie in politics rather than science. Most commentators accept that it was first explicitly included in an international agreement at the 1987 Second International North Sea Conference in London. The new approach focused on scientific uncertainty; required industry to demonstrate that its activities were low-risk; and gave priority to preventive management to avert possible, but not certain, damage (Gray and Bewers, 1996). Statements of the Precautionary Principle in national legislation and international declarations are widespread and no longer restricted to the marine environment (Deville and Harding, 1997). However, there is frustration in application, not least because there has been no consistent, widely held definition, and key terms within existing definitions may be undefined (Gray and Bewers, 1996). The formulation of legal and scientific definitions of the Precautionary Principle and guidelines for their application are important topics in the current literature (Gray and Bewers, 1996; Deville and Harding, 1997; Rogers et al., 1997). However, some authors take the view that the Precautionary Principle should remain a political or ethical issue distinct from science. It has been parodied as meaning "do nothing until you know everything" (Abbott and Christensen, 1996), or claimed to function best when understood clearly not to be a scientific concept (Santillo et al., 1998).

Ecosystem Health Issues in the Jarrah Forest

The jarrah forest bioregion of southwestern Australia is unique in existing on some of the most highly leached and impoverished forest soils in the world (Abbott and Christensen, 1996). It lies mainly within the Dale and Menzies subdistricts of the Darling Botanical District (Figure 92.1A) and has been fragmented greatly by agricultural clearing, leaving the main forest estate in State Forest managed by government agencies (Figure 92.1B). This discussion focuses on management issues within State Forest, which is managed for multiple uses including timber production, water catchments, and flora and fauna conservation and recreation.

There is considerable debate whether past management and, more particularly, the current multiple-use practices have impacted on values of the forests other than timber production such as tourism and species conservation (e.g., Abbott and Christensen, 1994, 1996; Calver et al., 1996,

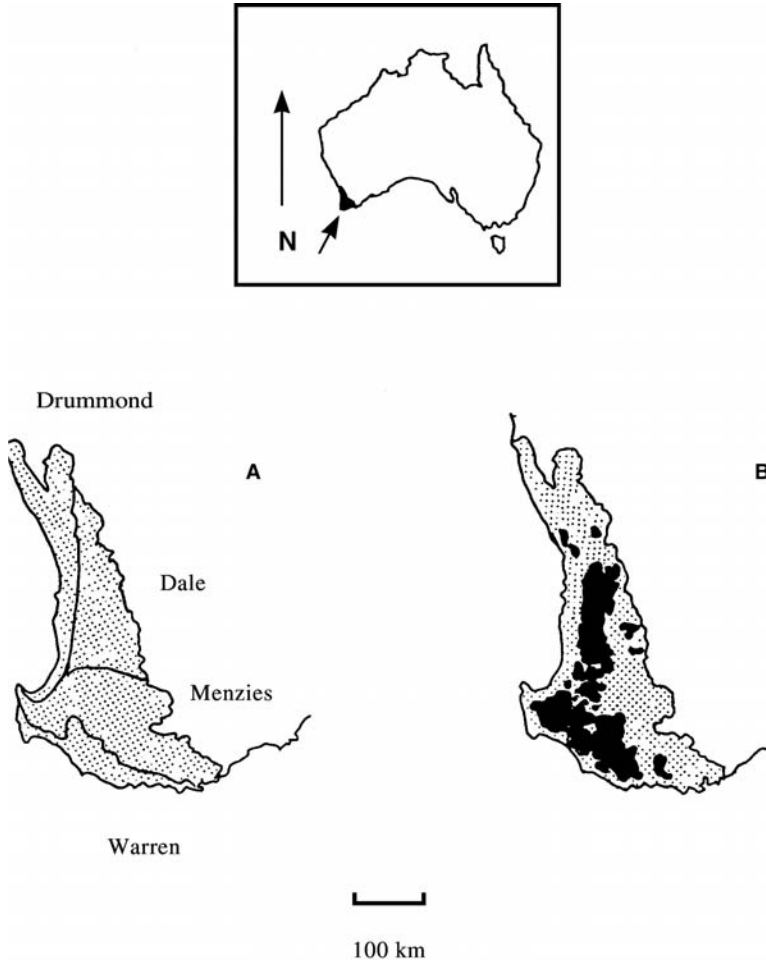

Figure 92.1 The location of the Darling Botanical District in southwestern Australia. (Adapted from Wardell-Johnson and Nichols, 1991). The jarrah forest lies predominantly within the Dale and Menzies subdistricts, with Drummond and Warren being dominated by other species (A). The boundaries of State Forest, which is managed by government agencies, are shown in B.

1998). The region is rich in endangered and threatened marsupials and relictual plant and invertebrate taxa (Abbott and Christensen, 1994). Therefore, the conservation value of the area is unquestionable, as is its value for tourism, recreation and protection of water catchments (RAC, 1993). This is recognized by CALM, which, until recently, had a dual role as principal conservation authority for State Forest as well as director of forestry operations (Stoneman et al., 1997; see Conservation Commission of Western Australia, http://www.conservation.wa.gov.au/forest_plan.html for recent reforms).

Perceived threats to ecosystem values include introduced predators, extensive agricultural clearing, and the spread of the exotic plant pathogen, *Phytophthora cinnamomi*, which infects plant roots, invades the vascular system, and ultimately kills susceptible hosts. Many plants in southwestern Australia are susceptible so *P. cinnamomi* may alter the structure and composition of plant communities and through this change hydrological regimes (Wardell-Johnson and Nichols, 1991). There is also debate on applying appropriate fire regimes to reduce the risk of wildfire while maintaining other ecosystem values (Russell and Rowley, 1998, and included references). Logging impacts on ecosystem values are controversial. Abbott and Christensen (1994, 1996) claim that adequate knowledge has been achieved and that the impact is negligible and not cumulative, while

Nichols and Muir (1989) admit that data are lacking but doubt that there are serious impacts. By contrast, Calver et al. (1996, 1998) and Calver and Dell (1998a, b) consider the question open for lack of evidence, while Mawson and Long (1994) believe that deleterious impacts are already occurring. In this chapter I focus on the logging issue, because it is the most contentious and the need for new approaches to resolve disputes is greatest.

APPLYING THE PRECAUTIONARY PRINCIPLE TO PROTECT ECOSYSTEM HEALTH

An important first step is to propose and defend criteria for ecosystem health and precaution. Procedures for applying the criteria can then be considered. The following outline is for illustration only and is intended to stimulate discussion, because final choice of criteria should involve all stakeholders. Such open, consultative processes are essential to the successful implementation of the approach proposed.

Setting Criteria for Ecosystem Health and Precaution

A useful starting point is the existing literature on assessing the ecological condition of forests. Definitions of ecological condition exclude the value judgments inherent in an assessment of "health" (Kimmins, 1996; O'Laughlin, 1996), so they are a less emotive beginning. Indices of condition have already been proposed for the jarrah forest (Abbott and Christensen, 1994). A valuable initiative was made in the 1995 Santiago Declaration on Sustainability of Boreal and Temperate Forests, in which Australia participated (Turner and Lambert, 1997). This declaration proposed criteria and indicators for quantifiable assessment of forest condition. Criteria included conservation of biological diversity, maintenance of the productive capacity of forest ecosystems, maintenance of forest ecosystem vitality, conservation and maintenance of soil and water resources, and maintenance of forest contribution to global carbon cycles. There was also reference to maintenance and enhancement of long-term multiple socioeconomic benefits to meet the needs of society and legal, institutional, and economic frameworks for forest conservation and sustainable management. However, these social and legal categories remained vague and poorly defined.

Extensive indicators accompanied each criterion. For example, in the case of the conservation of biological diversity, indicators included classification of ecosystem types and their conservation within reserves, determination of the conservation status of forest-dependent species, and estimates of the genetic diversity of species on the basis of any reduction in range they might have incurred. Updates on these criteria for implementation in Australia are given on the Australian Department of Primary Industries and Energy Web site, <http://www.dpie.gov.au/agfor/forests/montreal/international.html>. The combination of ecological processes and the needs of local human communities is an excellent basis from which to build locally applicable definitions of the health of the jarrah forest and to approach recent attempts to define forest ecosystem health (e.g., Kimmins, 1996; O'Laughlin, 1996; Yazvenko and Rapport, 1996).

Once criteria for forest ecosystem health have been agreed to the point where all participating stakeholders accept them as legitimate, the next step is to decide on a precautionary approach to activities that may compromise particular criteria of health. Several authors have considered the thorny problem of developing quantitative approaches to the Precautionary Principle for those cases where the principle is called for in legislation or a policy directive, but there is no agreed mechanism for its implementation. Suggested means for quantifying precaution include Bayesian statistics (Varis and Kuikka, 1997), risk analysis (Rogers et al., 1997), and statistical power analysis (Buhl-Mortensen and Welin, 1998; Calver et al., 1999, and included references). The following discussion considers only the power analysis approach because it is the dominant one in the literature, but this does not imply that the alternatives lack merit or might not prove superior.

Detailed accounts of the concept of statistical power can be found in basic biostatistics textbooks and specialist texts such as Cohen (1988). It is extremely relevant to environmental issues, since it deals with cases where an experimental test of a putative environmental impact is not significant. These cases are of special concern as they may arise either because there is no effect or because the experiment/monitoring lacked the sensitivity to detect an impact that actually occurred (Buhl-Mortensen and Welin, 1998). Power analysis helps in these situations by determining the probability that an impact of given magnitude would have been detected if it had actually occurred. This is known as the power of the test. If power is low (commonly defined as less than 0.85 or 0.9, Thomas and Juanes, 1996), then the test is insensitive and a possible impact has not been discounted. Power is directly related to sample size/replication in the study, the level of significance (α) chosen for the test, and the effect size (ES), which is the minimum difference/change that one wishes to detect. High power in a test can be achieved by increasing sample size, relaxing α above the traditional level of 0.05, or seeking to detect only a large ES. Given the likelihood of low power in many ecological studies and environmental monitoring, several authors have argued for a reversal of the burden of proof in impact studies (e.g., Underwood, 1997, and included references) or for explicit quantification of the power of studies (e.g., Di Stefano, 2001; see Craig, 2000, and Williams et al., 2001, for practical applications). This requires industry to demonstrate with high power that an unacceptable impact is unlikely, just as manufacturers of drugs must take reasonable steps to identify possible hazards or side effects (see reviews in Calver et al., 1999; Calver, 2000). Such a reversal is entirely consistent with the Precautionary Principle.

Applying the Criteria

Deville and Harding (1997) developed a four-step approach to applying the Precautionary Principle. Discussion of each step with reference to ecosystem health issues in the jarrah forest follows. The headings stated for each step are taken directly from Deville and Harding (1997).

Step 1. Are Precautionary Measures Needed?

Logging impacts on many proposed indices of ecosystem health in the Northern Hemisphere and in eucalypt forests in eastern Australia are confirmed or strongly suspected (e.g., see many detailed examples in the book edited by De Graaf and Miller, 1996). They are a sound scientific basis for believing that damage to fundamental ecosystem processes in jarrah forest might follow logging. Impacts could include local extinction of populations of endangered wildlife during logging operations, increased activity of introduced predators in disturbed areas, weed introductions, changes in hydrological regimes or soil properties, pest outbreaks, and possible spread of plant pathogens. These possible costs need to be balanced against the benefits of a timber industry to local communities, as well as the possibility that other industries such as tourism might provide the benefits with fewer environmental costs.

There is a long history of debate on such concerns with regard to the jarrah forest (see reviews in Calver and Dell, 1998a, b; Calver et al., 1999). Significant reduction in the forest canopy as a result of logging is documented (Wallace, 1965), introduced predators are widespread (Abbott and Christensen, 1994), and *Phytophthora cinnamomi* is altering vegetation patterns widely in the jarrah forest bioregion (Davison and Shearer, 1989). However, it has also been argued strongly that properly managed logging operations are not a threat to the long-term conservation of biodiversity or viability of ecosystem processes in the jarrah forest (Abbott and Christensen, 1994, 1996; Stoneman et al., 1997). On balance, I believe that most parties would agree that at present there is at least the potential of significant impact on ecosystem health values, but that disagreement arises on the question of whether these threats are ameliorated by current management practices.

Resolution is impeded by gaps in our knowledge of putative environmental impacts in the jarrah forest. The Australian Commonwealth Government's Resource Assessment Commission (RAC, 1993) completed the most recent detailed review of ecological impacts of forest use in Australia.

The RAC considered not only the number of impact studies (defined as work measuring impact of human activity on one or more ecological variables and reported in one or more publications) done in each Australian state, but also classified them according to other factors. These included:

- The major forest uses investigated
- The specific activities involved (of which 33 environmental variables were studied)
- The study design adopted
- The geographic scale of the studies

An analysis of the 51 Western Australian studies was summarized by Calver et al. (1998). This indicated a considerable emphasis on wood production and mining, which comprised 96% of the broad forest uses studied and 56% of the specific forest activity studies. By contrast, conservation management studies comprised only 2% of the forest uses studied, while recreation and tourism had not been studied as either a major forest use or a specific activity. Calver et al. (1998) also doubted the quality of the studies. Nearly half (49%) reported only a single post-disturbance observation, while just 16% used the powerful option of a before/after design. Finally, 92% of all studies were restricted in scale to a single site or local area, while 74% were short term, lasting only 2 years or less. This situation contrasts strongly to that in eastern Australia, where a larger number of more substantive studies have been completed (e.g., chapters in the edited volume by Lunney, 1991).

By the early 1990s many conservation or environmental impact issues in Western Australia's forests had not been researched intensively and there were limitations to some of the work completed. Although the research pace has accelerated and important work has been published recently, significant gaps remain and coverage is poor compared with eastern Australia (Calver et al., 1998). Overall, I believe that the important conservation values of the jarrah forest, the scientific plausibility of the hypothesis that deleterious impacts could occur, and the gaps in the relevant studies satisfy the criteria for a precautionary approach.

Step 2. How Precautious Should We Be?

According to Deville and Harding's (1997) framework, precaution should increase if either the threat or the uncertainty is great. If the threat is minor, little precaution is required, while if the likelihood of the risk is well known and grave, then the appropriate strategy is prevention, not precaution. The risk of significant declines in endemic organisms and decline of fundamental ecosystem services such as water catchments are substantial threats. When coupled with the gaps in published studies of putative impacts, these observations argue for very strong levels of precaution.

Step 3. What Precautionary Measures Can Be Applied?

The multiple-use policies for the jarrah forest appear to qualitatively follow the Precautionary Principle through their use of reserves, buffer zones, habitat tree requirements, and so on. However, quantitatively they may not detect serious environmental impacts before an irreversible consequence occurs. This is because the policies include no direct measurements of response variables, such as population trends of indicator species, which relate directly to chosen criteria of ecosystem health. It would be a daunting task to prepare monitoring plans or experimental tests for each component of ecosystem health, but priorities for evaluation could be set through the same consultation process proposed for setting the original ecosystem health criteria. If the power analysis approach to quantifying precaution were adopted, it would also be important to agree on the levels of power and effect size that would be required for precaution in the context of each criterion of ecosystem health. In turn, these would determine the sample sizes and level of α required in individual studies. Two examples from published studies of environmental impacts in the jarrah forest illustrate the

Table 92.1 Median Numbers of Counts of Individual Birds Noted per 100 m of Transect per Hour in Jarrah Forest

Species	Untreated Forest			Forest Logged between 1982 and 1983

Data are a subset of Appendix 1 from Abbott and van Heurck (1985), showing only those birds that occurred at some stage in the treated forest.

power analysis approach. They are both applicable to a criterion of maintenance of endemic species diversity, which could be used as an indicator of ecosystem health.

The first example is a study of logging impacts on bird counts in jarrah forest by Abbott and van Heurck (1985). The authors surveyed 32 bird species along set transects in two jarrah forest sites during 1981–1983. In early 1983, one of the sites was thinned, reducing the canopy by approximately 50%. Nonparametric Mann–Whitney tests were used to compare the median number of individual birds in each species/100 m of transect/h between sites and between years (see summary data in Table 92.1). At the logged site, no species was recorded as significantly less frequent after treatment and only two species were recorded as significantly more frequent after treatment. The authors were cautious in interpreting their results, concluding: “These findings suggest that most bird species in the jarrah forest may be adaptable to gross disturbance of the forest” (Abbott and van Heurck, 1985).

Power analysis can aid in interpreting the data by determining the probability of rejecting the null hypothesis of no significant impact of the thinning operation if it is truly false. The results of such an analysis for large, medium, and small effect sizes at α levels of 0.05, 0.1, and 0.2 are shown in Table 92.2. The effect sizes were based on the recommendations of Cohen (1988) and, assuming an approximately normal distribution, correspond to the difference between the means of samples divided by the common standard deviation $((\mu_1 - \mu_2)/\sigma)$ giving 0.8, 0.5, and 0.2, respectively. The analysis used the nonparametric test option in the nQuery Advisor software (Elashoff, 1997).

Under most conditions in this study, power is very low. At the conventional level of $\alpha = 0.05$ used in the original study, there was only a 6% chance of rejecting a false null hypothesis at a small effect size and this only improved to 44% at a large effect size. If α is relaxed to 0.2, power

Table 92.2 Results of a Power Analysis for the Mann–Whitney Tests Used by Abbott and van Heurck (1985) to Detect Differences in Bird Counts before and after Logging in Jarrah Forest (%)

	$\alpha = 0.05$	$\alpha = 0.10$	$\alpha = 0.20$
Small effect size $(\mu_1 - \mu_2)/\sigma = 0.2$	6	12	21
Medium effect size $(\mu_1 - \mu_2)/\sigma = 0.5$	21	31	45
Large effect size $(\mu_1 - \mu_2)/\sigma = 0.8$	44	56	70

Power is shown as a percentage for three different levels of α and large, medium, and small effect sizes (based on Cohen, 1988). μ_1 and μ_2 are the means of the two groups being compared in the test, and σ is the common standard deviation of the groups.

improves to only 21% for a small effect size and a more respectable 70% for a large effect size. Unfortunately, the exact probabilities for individual tests were not presented in Abbott and van Heurck (1985) so the number of significant results following relaxation of α cannot be determined. However, the authors’ original caution is vindicated, because the power analysis shows that their study had only a very low probability of detecting significant impacts. To follow a precautionary approach, quantitative standards would be agreed in advance to determine a standard of proof to be met before such logging operations could proceed on a wider scale. Stakeholders might also raise concerns about the cumulative impact of successive disturbance (see, for example, Recher, 1996). The results of the power analysis could be compared with the *a priori* criteria to determine objectively if permission should be granted.

A second example concerns a test of the hypothesis that fuel-reduction burning practiced in the jarrah forest could influence the fate of egg clutches of the rare frog, *Geocrinia lutea* (Driscoll and Roberts, 1997). As part of a larger study, the authors monitored the survival of 60 *G. lutea* egg clutches at six pairs of burned and unburned sites in mixed stands of jarrah and karri *Eucalyptus diversicolor* forest near the southern extremity of the jarrah forest. They found no significant association between burning and egg clutch survivorship ($\chi^2_1 = 1.72, p = 0.19$), with survivorship of clutches in the absence of fire being ~0.5 (18/32) and in the presence of fire being ~0.4 (11/28). Assuming a constant sample size of 60 clutches overall, half of them exposed to fire and half unexposed, with a survivorship of 0.5 in the clutches from unburned areas, the power of detecting a range of survivorships less than 0.5 in clutches in burned areas was determined using Elashoff (1997) (Table 92.3).

The power of detecting a survivorship of 0.4 at $\alpha = 0.05$ was only 11%. Relaxing α to 0.1 improved power to 19%, while at $\alpha = 0.2$ power rose to 30%. A power of greater than 80% at $\alpha = 0.05$ could be achieved by seeking to detect only a survivorship of 0.1 in clutches in burned areas, considerably less than the survivorship of 0.5 established in the unburned controls. Assuming that the overall sample size is a fixed constraint, the only option for testing for smaller changes in survivorship (assuming that this is desirable) with moderate power is to relax α above 0.05.

However, relaxing α to improve power increases the probability of concluding falsely that fire had an impact on egg clutch survival (a Type I error: Di Stefano, 2001). A recent review (Calver

Table 92.3 Results of a Power Analysis for the Egg Clutch Data of Driscoll and Roberts (1997) to Detect Differences in Survivorship in Burned and Unburned Forest

Significance Level (α)	Proportion Egg Clutches Surviving in Unburned/Proportion Egg Clutches Surviving in Unburned Areas (%)			
	0.5/0.4	0.5/0.3	0.5/0.2	0.5/0.1
0.05	11	34	69	94
0.10	19	47	79	97
0.20	30	62	88	99

Sample size is assumed fixed at 60 clutches and power is shown as a percentage for three different levels of α and four different combinations of survivorship in burned and unburned areas.

et al., 1999, and included references) argued that this is acceptable when the cost of a Type I error (falsely concluding an impact) is less than that of a Type II error (falsely concluding no impact). Ideally, these errors should be costed with, perhaps, some special monetary value built in for noneconomic costs, such as intergenerational equity or aesthetic values. Then it is possible to express the ratio of cost of Type II error/cost of Type I error. Cohen (1988) suggested using this ratio to judge the acceptable ratio of Type II/Type I errors in a study and the concept was applied specifically to forests by Di Stefano (2001). Ideally, the ratio of Type I/Type II errors acceptable to all parties would be decided as part of the initial consultative process preceding implementation of a quantitative, precautionary approach to monitoring forest ecosystem health. This approach would also lead to better assessment of research needs and justification of the necessary level of funding to meet them.

Step 4. What Precautionary Measures Should Be Applied?

The significant strength of a quantitative monitoring process is that it measures the direct response variables to putative impacts, rather than indirect variables, such as width of buffer zones which it is hoped will correlate with ecosystem health. However, it is also important to specify what steps should be taken if significant impacts are evident.

Most authors have concluded, albeit with important qualifications, that sustainable logging in eucalypt forests is possible without significant detriment to environmental values (see reviews in Calver and Dell, 1998a, b). Under this view, sustainable logging requires a correct balance of a range of management practices and incorporation of environmental values into projected timber yields (e.g., Calver et al., 1998). Dissenting views such as that proposed by Mawson and Long (1994) argue that a timber industry is incompatible with conservation interests in the jarrah forest, which by extension suggests that it would be incompatible with ecosystem health. Therefore, the options being argued range from different perspectives on multiple-use policies to a shift in timber production from native forest to plantations. Under the Deville and Harding (1997) framework and the Intergovernmental Agreement on the Environment (1992) that they cite, choice of precautionary measures would be sensitive to social and economic costs and integrated with other principles of ecologically sustainable development. It is appropriate to consider these factors at the stage of deciding the criteria to be used to monitor forest ecosystem health and to quantify the level of precaution required.

DISCUSSION

The Precautionary Principle and the concept of ecosystem health both share popular appeal with laypersons (Earll, 1992; O'Laughlin, 1996). When combined, they encourage a range of stakeholders to participate in drafting management guidelines for the jarrah forest. Several authors have already identified important, quantifiable components of forest ecosystem health (e.g., O'Laughlin, 1994, 1996). Others have provided quantitative definitions of precaution with a basis in statistical power analysis (e.g., Gray and Bewers, 1996; Buhl-Mortensen and Welin, 1998) and a framework for applying the Precautionary Principle (Deville and Harding, 1997). This application of the Precautionary Principle to assessing the ecosystem health of the jarrah forest is unoriginal in its components, but rather is a case study using tools that others have developed. Nevertheless, it demonstrates that despite much effort and good intentions, current management of the jarrah forest falls short of a quantitative, precautionary assessment of the possible significant impacts of forestry practices on ecosystem health because it does not set quantitative standards for response variables. As a result, this discussion provides little confidence in the ability of government regulatory agencies in Western Australia to regulate an economically viable timber industry, which does not compromise ecosystem health.

Two important weaknesses of the approach are that (1) decisions based on a small set of indicators would not anticipate or preclude deleterious impacts in other variables of ecosystem health, and (2) that the case study does not endorse one action over others when evaluating precautionary measures. The solution to both problems lies in full involvement of stakeholders in determining initial definitions and indicators and complete availability of relevant information for decision making. Many authors have called for these measures (e.g., Norton, 1996; Calver and Dell, 1998b; Calver et al., 1998) and they are implicit in mediation processes for forest management developed in eastern Australia (Pressey, 1998, and included references). The acknowledged popular acceptance of both ecosystem health (O’Laughlin, 1996) and the Precautionary Principle (Earll, 1992) should contribute to wide involvement of stakeholders. Criteria for monitoring ecosystem health can then be agreed on, and steps can be taken if any criterion is compromised.

Significant successes in applying the Precautionary Principle as a political process have occurred in an atmosphere of accord regarding goals (e.g., Kruger et al., 1997; Santillo et al., 1998). In other circumstances, such as the case discussed by Calver et al. (1999), applications of the Precautionary Principle have been contested politically or in the courts and judgment has been complicated by the lack of clear, quantitative definitions. This is a driving force in the development of both legal and scientific definitions of the principle (e.g., O’Riordan and Jordan 1995) and is a strong basis for attempting the participatory, quantitative approach proposed in this chapter.

Perhaps the true role of quantitative approaches will come in monitoring activities permitted under the Precautionary Principle, subject to the condition that they will be monitored and halted before any serious or irreversible damage occurs (Deville and Harding, 1997). Such a position gives primacy to the political process in initial applications of the Precautionary Principle and uses science and statistics effectively in placing unambiguous quantitative guidelines on the standards expected of any activity permitted. The jarrah forest case is a clear example of the value of developing such quantitative guidelines. If stakeholders can agree on quantitative criteria to maintain forest ecosystem health in the face of economic use and clear standards to ensure that each criterion is not violated, then progress will be made in resolving current disputes over forest management.

ACKNOWLEDGMENTS

The ideas presented in this chapter have benefited greatly from discussions with Stuart Bradley, Barbara Jones, Harry Recher, and Ian Wright and from a review by L.D. Ford. However, these colleagues do not necessarily endorse all the author’s opinions.

National Indicators of Forest Ecosystem Health: A Science Perspective on the Canadian Initiative

Harry Hirvonen

INTRODUCTION

In 1993, the Canadian Council of Forest Ministers (CCFM) embarked on an initiative to define, measure, and report on the forest values Canadians want to sustain and enhance. An extensive consultative process was carried out involving scientists and others from the federal, provincial, and territorial governments, as well as experts from the academic community, industry, and non-governmental organizations. Two years later, as an outcome of this initiative, the report “Defining Sustainable Forest Management: A Canadian Approach to Criteria and Indicators” was published (Canadian Council of Forest Ministers, 1995). This report represented the best-available scientific knowledge on indicators related to sustainable forest management in the Canadian context. Appendix 93.I lists the six criteria and elements associated with each criterion.

Soon after the release of the national framework for criteria and indicators for sustainable forest management in 1995, the CCFM created a task force to report on Canada’s ability to measure the various indicators. Those findings are the basis of the report “Criteria and Indicators of Sustainable Forest Management in Canada: Technical Report 1997” (Canadian Council of Forest Ministers, 1997), which provides information on Canada’s capacity to measure forest sustainability.

This CCFM report, in terms of the ecological criteria and indicators, was more of a status report on the various indicators than an analytical assessment. For example, in discussion of one of the indicators, “rates of pollutant deposition,” the amount of wet-sulfate deposition was depicted. However, discussion was minimal on the impact of this deposition on forest ecosystems. The report was good at describing what was happening, and sometimes on why it was happening, but not as good at describing its impact or significance. The report’s value lay in introducing the framework in a concrete sense and as a foundation upon which to build. The 2000 CCFM report aims to look more closely at this significance aspect. It strives to better address questions of sustainability. A specific objective is to discuss cause-and-effect relationships.

Ecosystem health is inherent in the determination of sustainable forest management. Several of the ecological indicators in the Canadian criteria and indicators framework relate directly to assessment of the status and change in forest ecosystem health. This chapter focuses on the practical considerations associated with reporting on progress toward sustainability, touching on aspects such as definition, scaling, targets, and cumulative effects. Although the CCFM criteria and indicators include economic and social components, concentration here is on the ecological criteria and

indicators pertinent to forest ecosystem health. Assessment of progress toward sustainability, however, must include the complete package of criteria and associated indicators.

THE POLICY CONNECTION

Reporting on progress toward sustainability is complicated for many reasons. One of the more complicated factors is the definition of sustainability itself. CCFM defines sustainable forest management as “the development of forests to meet current needs without prejudice to their future productivity, ecological diversity, or capacity to regenerate” (Canadian Council of Forest Ministers, 1997). The term *needs* encompasses ecological, social, and economic considerations. This definition leaves much latitude for interpretation. Some may view it as a way to limit development; others may see it as a means to ensure continued and enhanced development through minimal interference. These basic philosophical approaches to a common definition are hard to reconcile.

Nonetheless, these political spins on sustainability do not diminish or alter the task of the scientist who strives to understand and measure changes in ecosystem health. The objective is to provide the best science-based information as input to policy questions. Specifically, policy questions that guide forest health research and monitoring and reporting within the Canadian Forest Service (CFS) include:

How is the health of Canada’s forest ecosystems changing, and why?

What trends and changes can be predicted regarding the health of major forest regions in Canada?

How do conditions and predictions for Canada’s forests compare with the forest conditions reported or predicted in other countries?

What methods are required to improve the accuracy and effectiveness of forest health assessments and provide comprehensive data for the national initiative on criteria and indicators of sustainable forest management?

These questions drive the forest health program; still, answers to them are difficult. Several factors serve as obstacles to this national reporting: the current inability within Canada to measure ecological change over time, the limited understanding of cumulative impacts, and a myriad of perceptions of what a healthy forest really looks like. These science concerns are discussed in more detail later.

SUSTAINABILITY AND FOREST ECOSYSTEM HEALTH

Sustainable forest management and forest ecosystem health go hand in hand. A sustainably managed forest is a healthy forest. Inherent in sustainability is the obligation to think at regional scales of planning (Hirvonen, 1990; Marshall et al., 1993; King, 1993). Sustainable forest management must consider ecological dynamics over time, ecological cycles, and interactions with adjoining ecosystems. One cannot sustain a tree or even a stand; each is part of a bigger whole. If the regional landscape is not sustainable, certainly the components therein are not. More to the point, what impacts the regional landscape will inevitably impact the components within. This is not necessarily the case the other way around. For example, one may harvest a stand of trees and the sustainability of the regional landscape may not be affected.

An analogy, depicting the interdependence of the site and the regional ecosystem, may be of an individual farming operation. No matter how ecologically friendly and forward-thinking a farmer is with regard to his or her own operation, that farm will not be sustainable if the region within which it exists is characterized by unsustainable activities. Pollution may impact on the farm through the air, the waterways, or the ground. Regional activities may alter insect or disease cycles, climate, or wildlife habitat, all of which could be detrimental to the isolated farmer in one way or another.

Such ecological isolation from the surrounding area has been termed *islandization* in the context of national parks and other protected areas (Panel on the Ecological Integrity of Canada's National Parks, 2000; Loo and Hirvonen, 1999). Protected areas surrounded by incompatible land-use activities cannot maintain their ecological integrity, regardless of plausible efforts within the boundaries. Ecological islandization is not compatible with sustainability.

In this context of sustainability, ecosystem health must also be considered as a regional or landscape concept (Hirvonen, 1990; Forest Health Network, 1999). Certainly, identification of ecosystems is dependent on scale. A pond, wetland, or forest plantation may be considered an ecosystem, as may components of these ecosystems. Much depends on the perspective of the user and the scale of application (King, 1993). Regardless, in terms of health all these ecosystems, at whatever scale of conceptualization, are linked. An adverse impact on one ecosystem will certainly reflect on the health of adjacent ones. To understand ecosystem structure and function, one must understand the broad picture. This broad ecological picture can be encapsulated by the pressure, exposure, and response model of stressors on ecosystems (Hammond et al., 1995; Environment Canada, 1991; Hunsacker and Carpenter, 1990). Managers must understand the origin of the stress, its pathways, its impacts, and finally its significance to the health of desirable forest ecosystems. Such an analysis necessarily takes a regional and sometimes national, continental, or global view of ecological interactions and relationships.

SCIENCE ISSUES AND INDICATORS OF FOREST ECOSYSTEM HEALTH

As ecology is not a science with black-and-white answers, many factors come to play in understanding interrelationships between external pressures and ecological cycles. A brief discussion ensues on key scientific considerations for sustainability and indicators of forest ecosystem health.

Scale of Application

Scale, both spatial and temporal, defines the indicator. As mentioned earlier, sustainability is a regional concept and progress toward it must be measured by regional-scale indicators. It is important to understand the relationship between spatial scales and ecological processes and functions to develop indicators to track and report on ecosystem change. Each spatial scale is associated with natural and anthropogenic influences or stressors that impact ecosystem components. Broad-scale influences impact broad-scale ecological cycles. For example, at global or continental scales, stressors such as global change or long-range transport of toxic chemicals may be an issue. At regional scales, perhaps the issue becomes one associated with acid rain. At local levels, a myriad of factors including soils, vegetation, and aspect come into play to determine an appropriate indicator (Hirvonen, 1990; Marshall et al., 1993). Local indicators do not report on sustainability directly. They may serve to track specific forest management practices which, in total, may be looked at to determine progress toward sustainability.

The linking of indicators to appropriate scales of application is paramount. The ecological context of the influence must be understood. The mixing of broad-scale indicators with local conditions or site-specific indicators to track broad-scale influences is not good science. The Canadian framework of criteria and indicators for measuring progress toward sustainable forest management is for national reporting purposes. The intent is to report on changes to forest ecosystems at regional and national scales. The ecological indicators must reflect this. The current review process is looking at this question of scale among its list of issues. In part, the original 83 indicators have been pared to 49 for the CCFM 2000 report because of this consideration. For example, an original indicator, "water quality as measured by water chemistry, turbidity, etc.," is too specific to provide a regional context, much less a national one.

Monitoring Status and Change of Forest Ecosystems

A basic need for measuring progress toward sustainability is the ability to measure status and change over time in forest ecosystems. On a national basis in Canada, we can measure status but we are woefully inadequate in tracking change over time. The largest national ecological database for the country is Canada's Forest Inventory (CanFI), a compilation of individual provincial and territorial forest inventories for national reporting purposes (Lowe et al., 1996). A major weakness of this integrated database is that the information contained therein cannot be used to measure ecological change over time. The data are the most-recent available but they may be a few months old or over 30 years old, depending on the inventory cycles of the individual provinces (Lowe et al., 1996; Gray and Power, 1997).

In addition, the provincial inventories are not random, plot-based inventories. Data are not compiled from the same piece of land during the inventory cycles. Without permanent plots inventoried in comparable ways, measures of forest ecosystem change are not possible. CanFI has served its historical purpose very well: provision of information on the commercial forest useful for timber management purposes. In recent years, provinces and territories, along with the federal government, have recognized the need for forest inventories to provide information on biodiversity and other nontimber values, as well as timber values. These jurisdictions also recognize the need to measure ecological change over time in order to meet reporting obligations associated with the CCFM criteria and indicators of sustainable forest management. With this in mind, through the efforts of the Canadian Forest Inventory Committee, these jurisdictions are embarking jointly on a new random, plot-based National Forest Inventory (NFI) that will allow reporting on change over time in a statistically defensible manner. Recognizing the need to report on a regional basis, a minimum of 50 ground plots per ecological zone has been determined as necessary to provide minimal acceptable information for extrapolation to this ecozone level.

Initial reporting, based on NFI, is not expected until 2005. Until then, there does not exist a valid scientific basis for determination of changes in the health of Canada's forests. This lack of ecological monitoring data severely tests the interpretive application of the ecological indicators associated with the CCFM initiative.

Targets for Sustainability

Measurement of ecosystem change is one prerequisite in determining progress toward sustainability. Another prerequisite is the understanding in measurable terms of what the end points are for sustainability. There is a need for targets of sustainability. Ecological indicators are most useful if they can be compared with an acceptable target. A measure of change in itself is not helpful in answering the question of whether things are getting better or worse. The current problem is that no such generally acceptable targets exist for ecological indicators.

Targets are available for some pollution concerns. In Canada, for example, target loads of 8 to 20 kg/ha/year of acid rain have been suggested for receiving waters, depending on the sensitivity of these waters (Research and Monitoring Coordinating Committee, 1990; Federal/Provincial/Territorial Ministers of Energy and Environment, 1998). Levels at or below these loads are not considered harmful to these lakes. No such targets exist for air pollution or other stressors on forest ecosystems (Hall et al., 1998).

For acidic deposition, critical loads for forest ecosystems are being developed. Some preliminary results carried out through the University of New Brunswick in conjunction with CFS forest health data are available (Moayeri and Arp, 1996). The Eastern Premiers/New England Governors Secretariat is carrying out a major forest-mapping project for eastern Canada and the northeastern U.S. to establish critical loads for major forest ecosystems that characterize this part of the continent.

Ecological Baseline

In the CCFM process, there is mention of a historical baseline as a reference point for change, the inference being that such a baseline is a surrogate for a healthy forest. The term *historical*, in the Canadian context, is really a red herring. There is no argument that a baseline is needed for any determination of change. Otherwise, no reference exists for assessing whether forest health is improving, degrading, or remaining constant. However, all baselines are *de facto* historical, whether they are pre-European settlement, post-World War II, or present-day; the question is whether current forest ecosystems are considered healthy.

Holling (1986) states that ecosystems normally undergo both internal and external perturbations and have adjusted to these disturbances over long periods of time. These perturbations are in fact essential to the sustainability of the ecosystems. In other words, they are part and parcel of the ecological integrity of the ecosystem. Forests that maintain their ecological integrity can be considered healthy (Rowe, 1961; Holling, 1973; Woodley, 1993; Forest Health Network, 1999).

In Canada, large-scale forest harvesting and other intensive forest uses are barely 100 years old. For much of central, northern, and western Canada, current harvesting occurs within previously nonharvested areas. Second-rotation crops cover a relatively small portion of the commercial forest. With some regional exceptions, the present forest ecosystems have remained much the same since pre-European settlement. These forest ecosystems have evolved over time, having adjusted to natural perturbations such as ice storms, fire, and insect and disease attacks. Their ecological integrity has not been compromised and, as such, may serve as a baseline for change. This fact is reinforced through a recent national forest health report by CFS which states that Canada's forested ecozones are generally healthy. Some forested ecozones are under sustained stress from anthropogenic influences and continue to serve as priority cases for regional monitoring of forest health (Forest Health Network, 1999).

Inherent in the notion of an ecological baseline for healthy forests must be variability. Ecosystems are not static; they encompass spatial and temporal aspects. Succession, natural influences, and other ecological processes all come into play and must be recognized. Protected areas serve to illustrate this principle. The term *protected* is, in many ways, a misnomer. No one stage of ecosystem evolution can be protected in perpetuity. Ecosystems, by their nature, are dynamic. The key to conserving desirable ecosystems is to conserve the ecological functions and processes of these ecosystems. Succession, changing species composition and age classes, death and renewal, and associated nutrient, hydrological, and geochemical cycles must be included in the understanding of baseline.

Conservation of ecological function and process also has a spatial consideration. For example, protected areas have to be large enough to maintain ecological integrity. Size and fragmentation are key measures of this integrity. Also, ecosystems cannot be isolated from surrounding ecosystems. Some of Canada's highly prized national parks are threatened because of the islandization of these parks over the years. One national park within the Prairie Provinces has essentially turned into a forest refuge. Farming operations surround the park boundary. There are other examples in the mountain parks of British Columbia where clear-cutting operations abut the parks. These forested parks fall into the category of significant exceptions to healthy forests mentioned earlier. If they do not currently show signs of deterioration, the constant pressure from adjacent land-use activities certainly makes them prone to deterioration. To reiterate, sustainability is a regional concept. A bog, a stand of trees, or a national park cannot be sustained if not linked in a sound, ecological manner with surrounding ecosystems.

Human-Induced vs. Natural Variation

A recently released national forest health report for Canada states that a "healthy forest is one that maintains and sustains desirable ecosystem functions and processes" (Forest Health Network,

1999). Healthy forests are essential to sustainability. The determination of change from “desirable ecosystem functions and processes” is not straightforward. Certainly, *desirable* is a value judgment and can cause confusion. Yet, even if desirable is acceptable, the challenge to measure change is one thing; the challenge to measure unacceptable change is daunting. This challenge stems from the fact that both healthy and unhealthy ecosystems are characterized by temporal and inherent natural variability in their ecological cycles. The presence of dead and dying trees alone does not reflect a deteriorating ecosystem. To reiterate: life, death, and rejuvenation are all dynamic parts of healthy ecosystems. So are natural influences of ecological change such as insect and disease infestations and fire. In fact, without cyclical occurrence of these influences, our forested ecosystems will not sustain themselves. The absence of these influences, in fact, may be signs of ecological deterioration of desired ecosystems.

In essence, assessment of forest ecosystem health involves both an understanding of successional change and delineation of human-induced variation on ecological function and processes (Freedman, 1995). Certain anthropogenic influences are easy to quantify, such as air pollution. If levels of pollutants such as smog, heavy metals, and acidic deposition increase, the assumption is that this is undesirable and not sustainable. We are very good at tracking emission and deposition levels, and we can model trajectories for long-range transport of these pollutants; cause-and-effect relationships on receiving environments have had mixed results. As an example, good correlation exists regarding acidic deposition and aquatic impacts on fish populations (Jeffries, 1997). There is still uncertainty, however, concerning impacts of acidic deposition to forest productivity or site deterioration (Hall et al., 1998). Effects of land-use activities such as harvesting on cycles of insects and diseases, for example, are difficult to determine without long-term monitoring because the natural variability of cycles of infestation is great.

Ecological Reporting Framework

Canada is a huge country comprising close to 1 billion hectares. Its forest land comprises some 417 million hectares. A myriad of forest ecosystems characterize the country. These forests have both national and regional significance to the country’s health and well-being. Because of the diverse nature of the country’s forests, national averaging of the health of these forests is meaningless.

The use of Canada’s national ecological classification system as a reporting framework for the Canadian Forest Service allows for a consistent national reporting framework, while at the same time there is flexibility to focus on major regional forest ecosystems. This framework divides Canada into 15 broad terrestrial ecozones. These ecozones form the most general level of a nested hierarchical system that divides them into 214 ecoregions, which are further subdivided into over 1000 ecodistricts (Ecological Stratification Working Group, 1996). Nine of the ecozones have a substantial forestland component and form the basis for national reporting on the country’s forests (Forest Health Network, 1999). The CCFM ecological indicators are reported, to the extent possible, by ecozone.

The use of ecozones as reporting frameworks has advantages and disadvantages to reporting on forest ecosystem health. A major advantage lies in the fact that reporting boundaries are based on ecology rather than jurisdiction. Ecozones transcend provincial and other jurisdictional boundaries. They also have been linked with ecological units of the adjacent states of the U.S., allowing for a common international reporting framework. Ecozones and their subdivisions are used as the ecological reporting framework by several provinces and other federal departments. This fact aids in communicating information to the public, and in exchange of information.

Compilation of data is a concern. Historically, any ecological data gathered were normally aggregated by jurisdictional boundaries such as county, state, or provincial level. Conversion of these data to conform with ecological boundaries is difficult. Another characteristic of the ecological framework is its holistic nature. Ecological units were developed through consideration of major

ecological influences at the given scale of application. It is not a specific resource sector survey. Compromises had to be made by each resource sector to allow for development and use of a common ecological framework that most sectors can apply for reporting purposes. Naturally, a specific forest-based ecosystem classification would better delineate forest ecosystems at various scales. However, these kinds of specific resource classifications would have minimal use by other resource sectors. A result may be several maps covering the same region, a nightmare for the general public to understand, or to allow for spatial comparisons. A common acceptable spatial framework facilitates reporting and data exchange while at the same time facilitating communication with the general public (Carpenter et al., 1998).

Cumulative Effects

Cumulative impacts and complex interrelationships among ecosystem components serve to complicate the measurement of ecosystem health. To gain some understanding of cause-and-effect relationships, cumulative knowledge gained from several research and monitoring initiatives is needed more often than not. Such analyses must be carried out at the scientific level and then put into a format understandable by decision makers. Not only must data be translated to appropriately address the criteria and indicators of sustainable forest management, but the indicators themselves must be analyzed together to provide the desired scientific advice to the policy process. The CCFM criteria and indicators process emphasizes that all criteria and related indicators must be considered together in the assessment of sustainable forest management. Such an assessment is meaningless if based on some but not all criteria or indicators.

NATIONAL VS. INTERNATIONAL REPORTING REQUIREMENTS

Not only does Canada have a responsibility to report on progress toward sustainable forest management nationally, but it has international obligations as well. Canada has signed on to the Montreal Process Criteria and Indicators for Conservation and the Sustainable Management of Temperate and Boreal Forests. One country report has already been produced (Montreal Process Liaison Office, 1997). In terms of science, the choice between the two processes becomes one of compatibility. Are these two processes mutually compatible or are we comparing apples with oranges?

The Montreal Process is an international response to the call of the 1992 United Nations Conference on Environment and Development to improve the quality and management of the global forest estate (Canadian Forest Service, 1995). It is informally named after a seminar of experts held in Montreal, November 1993, looking at Sustainable Development of Temperate and Boreal Forests. The process brings together in common purpose 12 countries from the Northern and Southern Hemispheres. At its sixth meeting (Santiago, Chile, February 1995), the Montreal Process Working Group, which now includes Argentina, Australia, Canada, Chile, China, Japan, Republic of Korea, Mexico, New Zealand, the Russian Federation, the U.S., and Uruguay, endorsed the Santiago Declaration, a statement of political commitment with an associated, comprehensive set of criteria and indicators for the conservation and sustainable management of temperate and boreal forests outside Europe. European countries are part of a similar process to identify and measure indicators of sustainable forest management, known as the Helsinki Process. Canada serves as the Secretariat for the Montreal Process and has "Observer" status within the Helsinki Process.

Canada is an exporting nation as far as its forest sector is concerned. How customers in Europe and other international markets interact and react with the Canadian forest-sector forest practices can and does affect exports. More and more overseas customers are insisting that Canadian forest products and services be derived from sustainable forest management practices. Indicators of progress toward such sustainability are key in this process.

Table 93.1 Criteria of Sustainable Forest Management Frameworks: Comparison of the CCFM Initiative and the Montreal Process

CCFM Initiative	The Montreal Process
Conservation of biological diversity Ecosystem condition and productivity	Conservation of biological diversity Maintenance of productive capacity of forest ecosystems Maintenance of forest ecosystem health and vitality
Conservation of soil and water resources	Conservation and maintenance of soil and water resources
Global ecological cycles	Maintenance of forest contribution to global carbon cycles
Multiple benefits	Maintenance and enhancement of long-term, multiple socioeconomic benefits to meet the needs of societies
Society's responsibility	Legal, institutional, and economic framework for forest conservation and sustainable management

Thus, it is essential that the CCFM criteria and indicators initiative be compatible and in general agreement with the Montreal Process and other international processes. Domestic measures of progress toward sustainability must have international credibility, as well as serve to guide domestic forest management practices. The Montreal Process comprises seven criteria and 67 associated indicators; the CCFM process has six criteria and 83 indicators. Discrepancies do exist in the wording and context of some of the indicators (see Appendices 93.I and 93.II).

Still, there is substantial agreement at the criterion level (Table 93.1). The Montreal Process has an additional criterion not evident within the Canadian context. This is related to the legal and institutional framework in place to carry out the process, which may be an issue for certain countries that are part of the Montreal Process.

In terms of ecological criteria, the CCFM process has four such criteria and the Montreal Process has five. The latter essentially breaks down the CCFM criterion of “ecosystem condition and productivity” into the “productivity” and “condition” components. With this breakdown, the Montreal Process relates the criterion “maintenance of productive capacity of forest ecosystems” to the commercial forest. The CCFM indicators reflect a broader ecological interpretation.

All the science issues mentioned earlier apply to the international Montreal Process, as they do for the CCFM process. A close look at the ecological indicators of both processes reveals concerns in terms of appropriate scales of application. For example, the criterion relating to soil conservation and water resources, found in both processes, has indicators with doubtful application at national scales. Indicators relating to erosion, water chemistry, and aquatic biodiversity are local and watershed scale indicators within the Canadian context. The depiction of these indicators nationally would be inappropriate for a large and ecologically diverse country such as Canada.

Slight differences in the wording of indicators under a given criterion may cause concern when reporting is required under the national and international processes. The criterion related to conservation of biological diversity has consistent indicators for both processes and should not cause any interpretive concern in reporting on these indicators. Problems arise with some of the indicators associated with the criterion related to maintenance and enhancement of forest condition and productivity. For example, the CCFM process emphasizes area and severity of disturbances such as fire, insects, and diseases. The Montreal Process emphasizes area and percent of forest affected by disturbances beyond the range of historic variation. Undoubtedly, the same data, where available, would be used to address both processes but the spin would be very different. In this situation, the author would support modifying the CCFM process indicator to conform with the Montreal Process because annual area and severity of disturbances are meaningless in an ecological sense without understanding historical variation. Of course, data are not available to compile measures of severity or historical variation on a national basis. This lack of long-term monitoring data is prevalent for most ecological indicators.

The criterion “conservation and maintenance of soil and water resources” offers another example of similar yet different indicators that may provide confusing messages to a general audience. In this criterion, the CCFM Process emphasizes indicators related to soil erosion and loss of organic matter to harvested forestland. The Montreal Process applies these indicators to all forestland. The public concern in Canada is focused on forest management practices and impacts on the environment; thus the Canadian emphasis makes sense. There is a direct connection to cause and effect missing in the Montreal Process.

These are only two examples that illustrate the need to bring together these two processes on reporting progress toward sustainable forest management. In doing this, analyses and interpretations required by Canadian forest scientists to meet domestic and international reporting requirements in relation to criteria and indicators of forest ecosystem health and more broadly of sustainable forest management would be less onerous. Certainly, the perspectives and associated constraints of the two processes serve to justify, to some degree, the slight differences between the two processes: one national in scope and focused on Canadian views, the other international in scope and, by necessity, having to consider the views of many nations. Still, in the end, the objective of both processes is to communicate to a broad audience progress toward sustainability. For Canada, this objective may not be met because the differences due to nuances in definition may confuse rather than enlighten the intended audience.

Canadian Environmental Criteria and Indicators of Sustainable Forest Management

Six criteria define sustainable forest management in the Canadian context. Each of these six criteria has elements associated with it and progress within each element is measured through several indicators. In total, the six criteria comprise 22 elements and 83 indicators.

Elements and indicators are presented for the three criteria with direct relevance to forest ecosystem health.

Criterion 1: Conserving Biological Diversity

Element 1.1: Ecosystem diversity

Indicators:

Percent and extent in area of forest types relative to historical condition and total forest area

Percent and extent of area by forest type and age class

Area percent and representativeness of forest types in protected areas

Element 1.2: Species diversity

Indicators:

Number of known forest-dependent species classified as extinct, threatened, endangered, rare, or vulnerable relative to the total number of known forest-dependent species

Population levels and changes over time for selected species and species guilds

Number of known forest-dependent species that occupy only a small portion of their former range

Element 1.3: Genetic diversity

Indicators:

Implementation of an *in situ/ex situ* genetic conservation strategy for commercial and endangered forest vegetation species

Criterion 2: Ecosystem Condition and Productivity

Element 2.1: Disturbance and stress

Indicators:

Area and severity of insect attack

Area and severity of disease infestations

Area and severity of fire damage

Rates of pollutant deposition

Ozone concentration in forested regions

Crown transparency in percentage by class

Area and severity of occurrence of exotic species detrimental to forest condition

Climate change as measured by temperature sums

Element 2.2: Ecosystem resilience

Indicators:

- Percentage and extent of area by forest type and age class
- Percentage of area successfully naturally regenerated and artificially regenerated

Element 2.3: Extant biomass

Indicators:

- Mean annual increment by forest type and age class
- Frequency of occurrence within selected indicator species

Criterion 3: Conserving Soil and Water Resources

Element 3.1: Physical environmental factors

Indicators:

- Percentage of harvested area having significant soil compaction, displacement, erosion, puddling, loss of organic matter, etc.
- Area of forest converted to nonforest land use
- Water quality as measured by water chemistry, turbidity, etc.
- Trends and timing of events in stream flows from forest catchments
- Changes in the distribution and abundance of aquatic fauna

Element 3.2: Policy and protection

Indicators:

- Percentage of forest managed primarily for soil and water protection
- Percentage of forested area having road construction and stream crossing guidelines in place
- Area, percentage, and representativeness of forest types in protected areas

Criterion 4: Forest Ecosystem Contributions to Global Ecological Cycles

Criterion 5: Multiple Benefits of Forests to Society

Criterion 6: Accepting Society's Responsibility for Sustainable Development

Criteria and Indicators for the Conservation and Sustainable Management of Temperate and Boreal Forests: The Montreal Process

Only the indicators associated with the first four ecological criteria of the Montreal Process are outlined.

Criterion 1: Conservation of Biological Diversity

Indicators:

- Extent and area by forest type relative to total forest area
- Extent and area by forest type and by age class or successional stage
- Extent of area by forest type in protected area categories as defined by IUCN or other classification system
- Extent of area by forest type in protected area defined by age class or successional stage
- Fragmentation of forest types
- Number of forest-dependent species
- Status of forest-dependent species at risk of not maintaining viable breeding populations, as determined by legislation or scientific assessment
- Number of forest-dependent species that occupy a small portion of their former range
- Population levels of representative species from diverse habitats monitored across their range

Criterion 2: Maintenance of Productive Capacity of Forest Ecosystems

Indicators:

- Area of forestland and net area of forestland available for timber production
- Total growing stock of both merchantable and nonmerchantable tree species on forestland available for timber production
- Area and growing stock of plantations of native and exotic species
- Annual removal of wood products compared to the volume determined sustainable
- Annual removal of nontimber forest products compared to the level determined to be sustainable

Criterion 3: Maintenance of Forest Ecosystem Health and Vitality

Indicators:

- Area and percent of forest affected by processes or agents beyond the range of historic variation
- Area and percent of forestland subjected to levels of specific air pollutants
- Area and percent of forestland with diminished biological components indicative of changes in fundamental ecological processes and/or ecological continuity

Criterion 4: Conservation and Maintenance of Soil and Water Resources

Indicators:

- Area and percent of forestland with significant soil erosion
- Area and percent of forestland managed primarily for protective functions

Percent of stream kilometers in forested catchments in which stream flow and timing have significantly deviated from the historic range of variation

Area and percent of forestland with significantly diminished soil organic matter and/or changes in other soil chemical properties

Area and percent of forestland with significant compaction or change in soil physical properties resulting from human activities

Percent of water bodies in forest areas with significant variance of biological diversity from the historical range of variability

Percent of water bodies in forest areas with significant variation from the historic range of variability in pH, dissolved oxygen, levels of chemicals, sedimentation, or temperature change

Criterion 5: Maintenance of Forest Contribution to Global Carbon Cycles

Criterion 6: Maintenance and Enhancement of Long-Term Multiple Socioeconomic Benefits to Meet the Needs of Societies

Criterion 7: Legal, Institutional, and Economic Framework for Forest Conservation and Sustainable Management

Forest Health Monitoring in the U.S.: A West Coast Perspective

**Sally Campbell, Barbara Conkling, John Coulston, Peter Neitlich, Iral Ragenovich,
and William Smith**

INTRODUCTION*

Forest Health Monitoring (FHM) is a multiagency national program to monitor, assess, and report on the long-term status, changes, and trends in forest ecosystem health in the U.S. The program was initiated in 1990 in response to a legislative mandate and public concern over the nation's forests (Heggem et al., 1993). The Forest and Rangeland Renewable Resources Research Act of 1978 (92 Stat. 353, as amended; 16 U.S.C. 1600, 1641–1648), per the 1988 amendment, directed the Forest Service to establish a 10-year program to monitor long-term trends in the health and productivity of domestic forests (USDA [U.S. Department of Agriculture] Forest Service, 1997). The program initially was designed and implemented jointly with the U.S. Environmental Protection Agency (USEPA) as part of its Environmental Monitoring and Assessment Program (EMAP) (Palmer et al., 1991). FHM is managed by the USDA Forest Service in cooperation with other agencies and organizations. The primary partner is State Forestry or Agriculture in each state; other partners include the USDA Natural Resource Conservation Service; U.S. Department of the Interior Bureau of Land Management and the National Parks Service; the Department of Defense; the USEPA; and various universities. The National Association of State Foresters provides essential program support, guidance, and assistance.

PURPOSE AND GOALS OF FHM

Forest health information is available from a variety of sources, but frequently it has been for one particular geographic area or for addressing a single issue. FHM is designed to provide more complete, accurate, and unbiased information on which to base forestland-management action decisions. To achieve this, FHM has the following goals:

1. Developing environmental indicators and better ways for assessing forest health.
2. Developing national standards and guidelines for both plot and survey components of detection monitoring (discussed later).

* All general information about the FHM program is adapted from the Forest Health Monitoring Fact Sheet Series (USDA Forest Service, 1996–1999).

3. Integrating FHM, the Forest Service's Forest Inventory and Analysis (FIA), National Forest Inventories, and Forest Health Protection surveys to provide the basic data on forest health status and trends.
4. Bringing other key environmental information such as data on weather, soils, and air pollution into forest health analyses.
5. Increasing or reducing the base sampling grid intensity to answer national, regional, state, and local forest health questions.
6. Providing quality assured and quality controlled data.
7. Providing systematic follow-up via evaluation monitoring (discussed later) to forest health problems found in detection monitoring.
8. Providing a research link for understanding ecosystem processes in intensive site ecosystem monitoring (discussed later).

PROGRAM STRUCTURE

The FHM program is composed of the following four interrelated activities: detection monitoring, evaluation monitoring, intensive site ecosystem monitoring, and research on monitoring techniques.

Detection Monitoring

Detection monitoring is the most extensive of the FHM program's three monitoring activities. It is designed to provide data to determine baseline or current conditions of forest ecosystems, and to detect changes and trends over time. This information is analyzed to determine if detected changes are within normal bounds or indicate improving or deteriorating conditions. Detection monitoring covers all forested lands and has two components, which together describe forest condition: (1) the plot component, measurements made on the FHM network of permanent plots (in 2000, responsibility for these plots shifted to FIA); and (2) the survey component, forest surveys of insect, disease, and other stressor effects, conducted independently of the FHM plot network. Detection monitoring data are used to make national, regional, and state assessments of forest condition.

As of 2001, the survey component of the FHM program was funded in all 50 states; the plot component, now administered by FIA, was funded in 46 states. FHM is managed regionally by Forest Health Protection programs; FIA is managed regionally by Research Stations in the Northeast, North Central, South, Interior West, and the Pacific Northwest.

Evaluation Monitoring

Evaluation monitoring examines the extent, severity, and probable causes of undesirable changes or improvements in forest health beyond that provided in detection monitoring. Results of evaluation monitoring address likely cause-and-effect relationships; identify associations between forest health indicators and particular stressors such as insects, disease, or pollutants; identify management consequences; and identify follow-up research needs that can be met experimentally or by information from intensive site ecosystem monitoring.

Intensive Site Ecosystem Monitoring

Intensive site ecosystem monitoring (ISEM) occurs at selected sites throughout the U.S. At these sites, the FHM indicators are measured intensively along with other site attributes such as climate variables to obtain detailed information on key components and processes of that forest ecosystem. ISEM allows for a rigorous evaluation of cause-and-effect relationships, identifies indicators of key processes that shape forest ecosystems, and provides biological and abiotic databases that support monitoring and forest-health-related research at these sites.

Research on Monitoring Techniques

Monitoring techniques research is work specifically directed to improve all three of the previously discussed monitoring activities. Its purpose is to identify new indicators, improve current indicators, evaluate sampling designs and impacts from repeated sampling, and improve analytical and reporting approaches.

PLOT COMPONENT AND INDICATORS

The FHM plot sampling design is a spatially and temporally systematic sample on a national hexagonal base grid, with one plot per 38,364 ha; these FHM plots are now a subsample of the more intensive FIA plot network (one plot per 2428 ha). One fifth of the FHM plots is visited each year in each state, so that all plots are remeasured every 5 years. Analysis techniques allow for estimates of change from year to year.

FHM refers to the measurements associated with these plots as indicators. It defines an indicator as any biological or nonbiological component of the environment that quantitatively estimates the condition or change in condition of ecological resources, the magnitude of stress, or the exposure of a biological component to stress. The basic indicators used include:

- Lichen community diversity and abundance
- Ozone injury on bioindicator plants
- Tree crown condition
- Soil morphology, chemistry, and erosion
- Plant diversity
- Vegetative structure and diversity
- Down woody debris

Collection of data for the above indicators aids in the assessment of environmental or societal values (forest productivity, biodiversity and vitality, carbon cycles, soil and water conservation) identified in the Criteria and Indicators for the Conservation and Sustainable Management of Temperate and Boreal Forests, endorsed by 12 countries in 1995 in Santiago, Chile (known as the Santiago Agreement or Declaration) (Anon., 1995).

Selection of indicators in FHM follows a set process:

- Identify relevant environmental or societal values of concern
- Formulate key questions relating to those values
- Review the scientific literature and available databases
- Test indicators in pilot and demonstration studies
- Formulate plot-level indices
- Review indicators by partners and scientific peers

Part of the review process is the evaluation of indicators relative to six criteria to increase scientific objectivity, consistency, and depth of evaluation:

1. Low environmental impact
2. Simple field quantification
3. Unambiguous interpretation
4. Stable during sampling window
5. Meaningful when applied across various strata of interest (e.g., ecosections or forest types)
6. High signal-to-noise ratio regarding data error

Methods for measuring indicators on FHM plots are documented and updated yearly in field manuals (e.g., USDA Forest Service, 1999b). Some regional differences exist and regional manuals are published as well.

SURVEY COMPONENT

The purpose of the survey component of the FHM program is to detect broadscale disturbance events from forest insects, diseases, and other disturbance agents that the plot component may not be able to adequately detect. This information provides a context for interpreting plot data and for identifying likely factors that contribute to forest health changes. Both aerial and ground surveys are employed. The aerial surveys focus on tree mortality, defoliation, discoloration, dieback, tree uprooting, branch breakage, and branch mortality. Ground surveys focus on damage by specific insects, diseases, or other disturbance agents.

Implementation of the survey component differs widely from state to state. Unlike the plot component that was designed specifically for national consistency, survey programs were already established in most states prior to the FHM program. Some survey programs, such as the aerial survey program in Oregon and Washington, have been functioning for many decades. Each was initially established to provide for state and local needs such as locating dead timber for salvage or tracking defoliation to determine insecticide spray boundaries. By establishing reasonable survey standards, FHM aims to achieve survey conformance among previously existing programs, and thereby provide comparable data as a basis for regional and national analysis and reporting. Standards for aerial survey data collection, quality control, and data processing have been developed and are now being used by participating states and Forest Service Regions (USDA Forest Service, 1999a). General information and guidelines for aerial survey programs and associated geographic information systems (GIS) have also been written recently (McConnell et al., 2000; USDA Forest Service, 2001). In addition, standardized methods for particular ground surveys are available for the eastern U.S. (USDA Forest Service, 1995).

INTEGRATION WITH OTHER PROGRAMS

To achieve the goal of integrating FHM, FIA, and National Forest System Inventories, FIA began administering FHM plot data collection in 2000. In fact, FHM plots are now a subset of the FIA plot network and share the same plot design, core set of measurements, and data collection standards. In 2001, FIA also administered collection of plot data on national forests in Washington, Oregon, and California (previously, the national forest inventory was administered separately by Forest Service regions in these states rather than FIA). Progress is also under way to develop more uniform standards for surveys for damage by insects, diseases, and other disturbance agents conducted by Forest Health Protection programs in the Forest Service and the states.

ANALYSIS AND REPORTING

Results from plots and survey data have been reported in various publications, both nationally and regionally (Burkman et al., 1998; Campbell and Liegel, 1996; Dale, 1996; Stolte, 1997; Stoyenoff et al., 1998; USDA Forest Service, 1994; Wittwer, 1998). FHM data analysis methods, including procedures for estimating change, are presented by Smith and Conkling (2002).

WEST COAST PROGRAM

The West Coast Region in the FHM program consists of Alaska, California, Oregon, Washington, Hawaii, and other U.S.-affiliated Pacific islands. As of 2001, only California, Oregon, and Washington had both plot and survey components (detection monitoring) fully funded and operational. FHM plots are planned for Hawaii, the Pacific islands, and Alaska and are expected to be in place within a few years. Aerial surveys are being conducted in all four West Coast continental states. A variety of ground surveys or monitoring networks for insect populations or damage by insects, diseases, and other disturbance agents are also carried out as needed in all states.

Over the past 4 years (1998–2001), 22 West Coast evaluation monitoring projects have been funded by the FHM program. Projects have included investigating impacts from native and exotic insects or diseases, determining accuracy of aerial surveys, evaluating impacts of ozone on pine growth, determining fuel loads and fire risks from native and exotic vegetation, and conducting special aerial surveys.

EXAMPLES OF FHM FINDINGS

Changes in Carbon Sequestration

Maintaining forest contributions to global carbon cycles is Criterion 5 of the Santiago Agreement. It is widely suggested that the increased concentration of greenhouse gases, including carbon dioxide, will result in climate change in most regions of the world. There are many ways of mitigating this effect that relate to trees and forests. Among them is increasing forest growth, tree planting, minimizing loss of carbon to the atmosphere through catastrophic mortality, efficient use of harvested wood products, and salvage of mortality.

Carbon is removed from the atmosphere in the process of growth. Carbon is lost to the atmosphere when dead trees or wood products decay. Approximately one half of the carbon harvested as biomass is stored for long periods as durable wood products. FHM data (specifically tree growth, size, and density, and tree harvest) have been used to estimate carbon storage or loss for variable time periods between 1990 and 1996. Other published data and relationships were used to estimate carbon in belowground portions of trees and in down woody debris (Birdsey, 1996).

Carbon storage was estimated by determining the biomass of the living boles and roots of all trees and saplings, and subtracting the biomass of the trees that have died and approximately one half the biomass of the trees that were harvested over the same time period. This one half represents the proportion of harvested biomass utilized in a durable form, e.g., bound books, wooden structures, etc. (Birdsey, 1996). A net gain can result from an increased stand growth and the efficient utilization of harvest trees and salvage of mortality, or some combination thereof. The estimated net carbon loss or gain for FHM plots in 10 ecoregions in California is presented in Table 94.1. Most of the losses are in the Sierra Nevada ecoregion where there was substantial mortality due to drought and insect-caused mortality in the early 1990s (USDA Forest Service, 1994).

Lichen Monitoring on the West Coast

Lichens are a component of most temperate North American forest communities, contributing to nutrient cycling and providing food and habitat for other organisms (Pike, 1978; Rominger and Oldemeyer, 1989; Sharnoff and Rosentreter, 1998). They are also indicators of air quality (Nash and Wirth, 1988; Seaward, 1993). Although trees may respond to moderate, chronic levels of air pollution, all of the other influences on tree growth, such as variation in soils, make the responses of trees to pollutants difficult to measure in the field. Therefore, lichen communities provide not

Table 94.1 Tree Carbon (kg/ha) of Softwoods and Hardwoods by Ecosection in California

only a measure of air pollution impacts on lichens, but also suggest air pollution impacts on trees and other aspects of forest health that are difficult to measure directly. Some small-scale studies have also shown that lichen communities respond to certain forest management practices. These studies found that young managed stands host relatively few species compared with mature forest, and, likewise, densely stocked, dark stands host far fewer species than stands with open structure (Neitlich, 1993; Neitlich and McCune, 1997; Peck and McCune, 1997). The FHM program includes lichen community diversity and abundance as one of the indicators of forest health. The results of FHM lichen monitoring help address Santiago Criteria 1 (Conservation of biological diversity), 2 (Maintenance of productive capacity of forest ecosystems), and 3 (Maintenance of forest ecosystem health and vitality).

Lichen communities were first sampled in West Coast FHM plots in 1998. The conclusions drawn from the data gathered in 1998 and subsequent years are limited until gradient models that describe climatic and air quality gradients for West Coast regions are constructed (McCune et al., 1997a,b). At that time, the model can be applied to the data to make more accurate interpretations of the results. However, the results from the first year of sampling are still useful and are presented here briefly and in more detail by Neitlich and co-workers (1999).

Field sampling was designed to be carried out by nonlichenologist field crews according to the procedures described in the FHM Manual (USDA Forest Service, 1999b). Professional lichenologists conducted the lichen training, quality assurance, sample identification, and data analysis.

In Oregon and Washington, the mean lichen species richness (number of species) was 17 species per plot (Figure 94.1), approximately 75% higher than species richness in California and 85% higher than Idaho. The region west of the Cascades hosted approximately 60% higher total number of species than the region east of the Cascades, with species richness in western Washington approximately 13 species per plot and western Oregon with approximately 20 species per plot.

Western Oregon and Washington also had a larger number of factors depressing species richness, including air quality (although determination of the extent of the problem awaits the regional gradient model). Willamette Valley sites and those near or downwind of Seattle and Portland had fairly low to intermediate species richness for this zone and are probably hosting lower diversity than they would in a clean air regime. Forest management probably plays a role in the low diversity in some sites in the Oregon Cascades and on the immediate coast (especially in Washington). It is likely (though yet untested) that species richness, where poor in these areas, was negatively influenced by the current forest age or structure.

In California, lichen species richness was predictably low given the relatively dry climate, with a mean of 9.6 species per plot (Figure 94.2). The steep natural gradients in California lichen community composition combined with small sample size over a large area made inferences

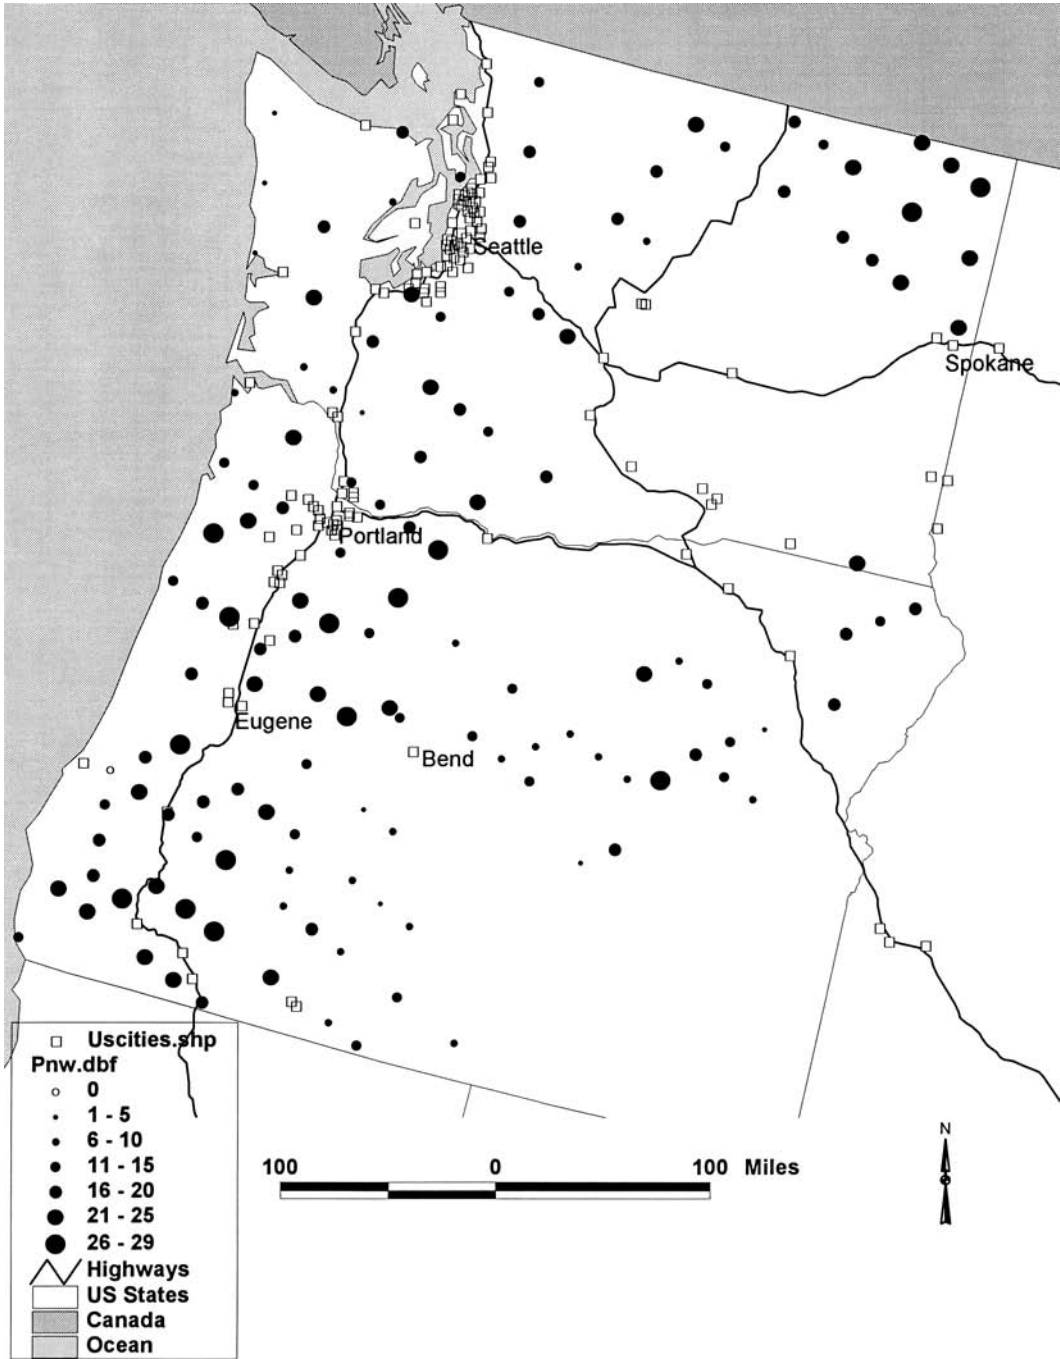

Figure 94.1 Lichen species richness on 170 Forest Health Monitoring plots in Oregon and Washington in 1998. Circular dot size is graded to indicate increasing species richness, with number of species per plot shown under "Pnw.dbf" in the legend.

about anthropogenic impacts difficult prior to developing regional gradient models. Pollution-related declines around large urban areas were expected, but the number of plots was not sufficient to address the question. However, anecdotal evidence is suggestive of air-quality concerns. First, observation and studies from other areas in the U.S. (e.g., McCune et al., 1997a) suggest that

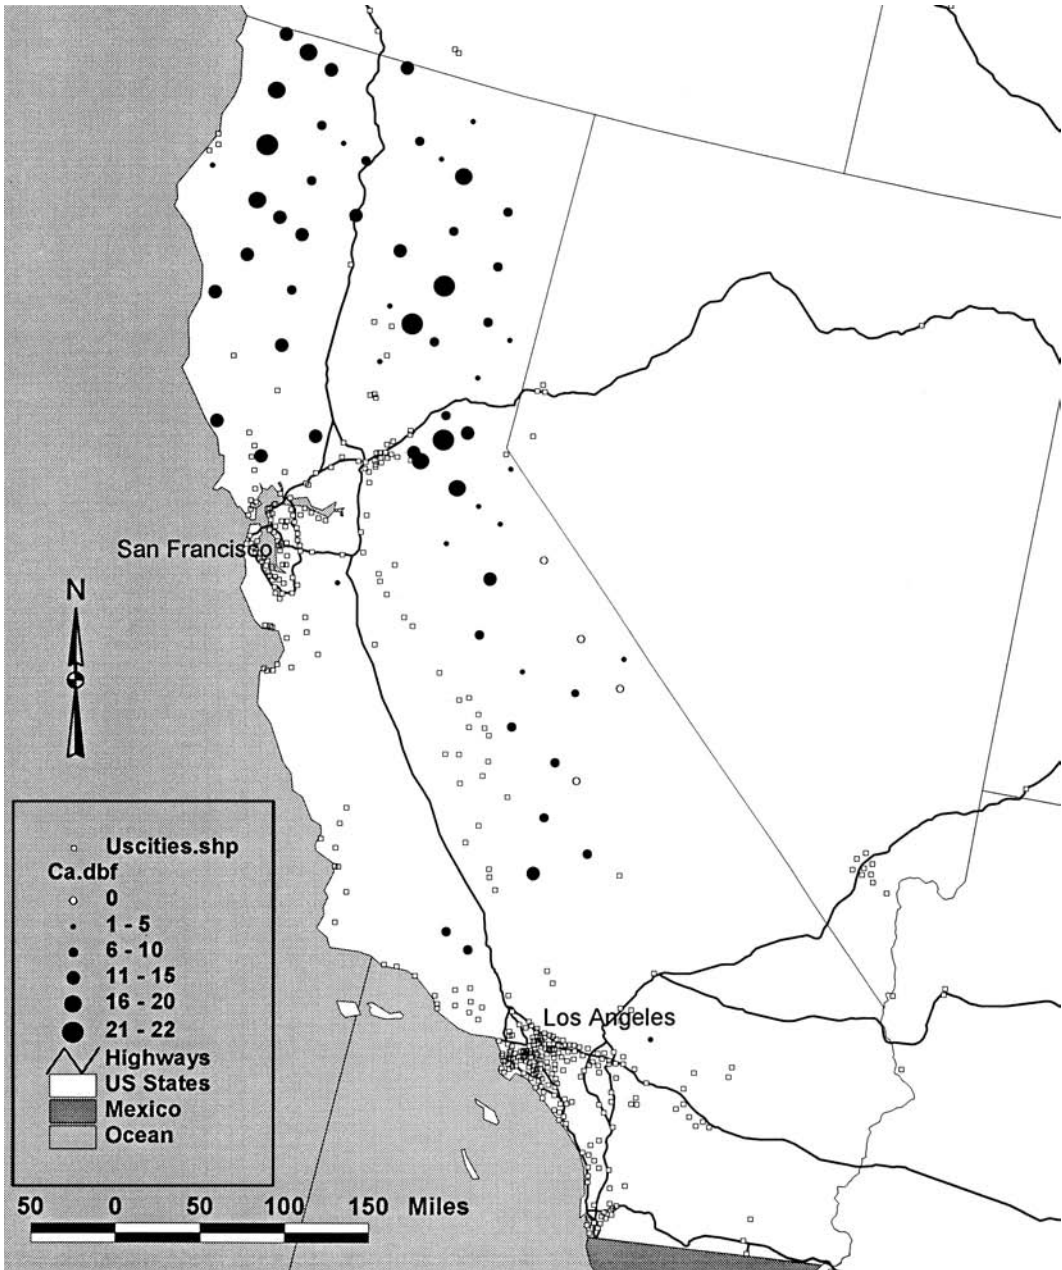

Figure 94.2 Lichen species richness on 76 Forest Health Monitoring plots in California in 1998. Circular dot size is graded to indicate increasing species richness, with number of species per plot shown under “Ca.dbf” in the legend.

the areas surrounding large- and medium-sized urban centers are likely to be most heavily impacted. Second, nitrification from agriculture in the Central Valley is likely to have fostered a bloom of nitrophilous species in areas adjacent to the Valley. Third, the air-pollution plumes from both Orange County (Los Angeles) and the Bay Area (San Francisco, Oakland) are likely to have an effect on downwind oak woodland (*Quercus* spp.) communities. In clean air conditions, these would normally host a high diversity of lichens, including some pollution-sensitive species that currently are not present.

The 1998 lichen data enhanced the base of knowledge of lichen flora in all three states. Many new point locations were found for several species, ranges of some species were expanded or changed, and knowledge was gained regarding ecological relationships.

Survey for Balsam Woolly Adelgid in Oregon and Washington

Balsam woolly adelgid (*Adelges piceae*) is an introduced insect that has had significant impact on true fir species (*Abies* spp.) in the Pacific Northwest. During the late 1950s and 1960s, balsam woolly adelgid caused extensive mortality in grand fir (*A. grandis*), subalpine fir (*A. lasiocarpa*), and Pacific silver fir (*A. amabilis*), primarily in the Cascade Mountains in Oregon and Washington. It also affects tree growth and reproduction, ultimately resulting in a significant decrease of the host species in many areas. In some cases, the host species may be the major tree species for that system.

The insect occurs in other states, such as Idaho, and in the eastern U.S. During the initial outbreak, a substantial amount of information was collected and outbreaks were characterized, based on the information at the time. Some permanent research plots were established to determine the effects of the insect on the host trees under various site conditions. Owing to suspected changes in balsam woolly adelgid distribution and impact on various hosts, a survey to gather up-to-date information was proposed and funded as a 3-year (1998–2000) FHM Evaluation Monitoring project. The objectives of the survey were to:

1. Conduct a ground survey of host type (subalpine fir, Pacific silver fir, grand fir) throughout Washington and Oregon to confirm occurrence and distribution of balsam woolly adelgid and supplement the forest health monitoring information collected during annual aerial surveys.
2. Determine effects of balsam woolly adelgid on the host species and changes in the local ecosystem.
3. Determine if the existing parameters for occurrence and risk described the situation at the time.
4. Explore opportunities for adapting this system for use in monitoring effects of other introduced species.

In order to accomplish the first objective, a map of risk and known occurrence was developed using historical aerial survey information and risk parameters of host type and elevation developed by Mitchell in the early 1960s (Mitchell, 1966). Also, areas were identified where balsam woolly adelgid was suspected to occur but had not been reported, or where there was personal but possibly undocumented on-the-ground knowledge. Ground surveys within those areas identified on the hazard/risk map would then be undertaken to verify and document the occurrence and impact of the balsam woolly adelgid.

From 1998 to 2000, approximately 1038 plots were visited, primarily in Oregon and Washington. At each plot, information was taken on location, elevation, tree species, tree size (seedling, sapling, or tree), balsam woolly adelgid symptoms (gouting, stem infection, crown abnormality, or adelgid-caused mortality), land use, tree structure, species contribution, and site description.

Also, seven permanent plots established in the early 1960s were revisited and data collected. Initial results from the permanent plots show that:

1. Tree damage was most severe in the first decade of the balsam woolly adelgid outbreak.
2. Environment played a significant role; higher mortality occurred on wet sites and at lower elevations.
3. Host species had unique responses. Shasta red fir (*A. magnifica*) and red fir (*A. procera*) showed considerable resistances at high elevations; subalpine fir was susceptible at all locations.
4. Grand fir was being eliminated from low-elevation landscapes and coastal streams in several western Oregon and Washington locations.
5. Subalpine fir was being removed as a pioneer species in important mountain environments such as alpine meadows, avalanche tracks, and old lava beds.

More detailed information can be found in Mitchell and Buffam (2001). Analysis of the ground survey plot data is currently under way.

Analytic Questions and Methods for Combining Aerial Survey Data and Plot Data

One of the goals of the FHM program is to develop methods for determining relationships between diverse data sets to create a clearer picture of insect and disease impacts on a landscape level. In particular, co-analysis of aerial survey and plot data presents some unique challenges. Aerial survey data are relatively inaccurate, owing to the method of collection (sketching areas of damage on a paper map from a small plane, 160 to 900 m aboveground, traveling at approximately 193 km/h). The data's inaccuracy, however, does not negate its usefulness in detecting overall trends in broadscale disturbance events or aiding local forest managers in locating or assessing damage. In contrast, plot data are more precise and geographically accurate but are a relatively small sample.

A method for analyzing aerial survey and plot data was tested by the FHM program. Washington was selected as the study area, using data from 1996–1998 aerial surveys and 1997–1998 plot data (Figure 94.3). Much of the state is fairly continuously forested, and has several national forests. Both FHM plot data and aerial survey data are available for the state, and aerial survey data show a relatively large area in south central Washington where defoliation damage increased over several years. Just a few insects and diseases account for 91% of the damage (mortality and defoliation) detected in aerial surveys in 1996–1998: western spruce budworm, balsam woolly adelgid, larch needlecast, fir engraver, western pine beetle, mountain pine beetle, and Douglas fir beetle.

The primary objective of this analysis was to predict damage or probability of damage at plot locations and unmeasured locations. Several questions must be answered to make these predictions:

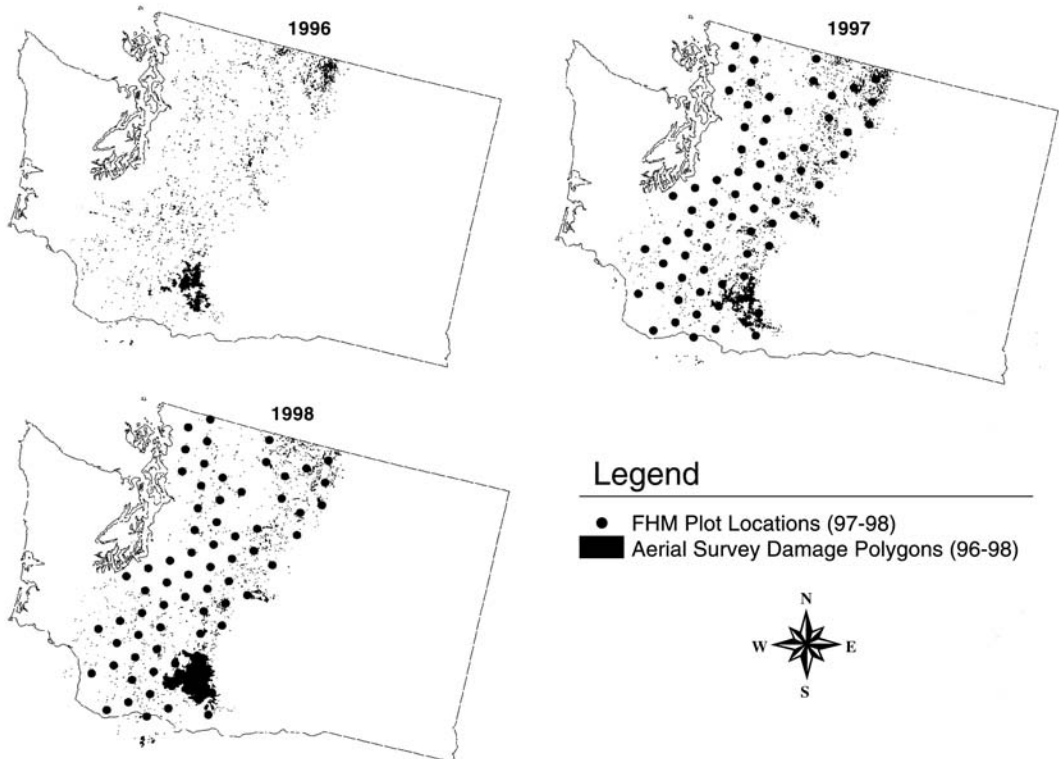

Figure 94.3 Maps of Washington state showing aerial survey damage polygons (irregular areas) and FHM plots (circles) for 1996, 1997, and 1998.

1. What is the relationship of damage polygons from one year to the next? Are they contiguous across years? Does damage expand from an epicenter or move linearly? Or is there no relationship across years?
2. Are there higher levels of crown damage (e.g., defoliation) or mortality on FHM plots when the plots are closer to aerial survey damage polygons?
3. What is the time lag between survey and plot data? What symptoms show up first on the plots and what symptoms show up first from the air? Is it dependent on the damaging agent?
4. What is the spatial relationship regarding damage between FHM plots, between aerial survey polygons, and between plots and polygons?

Cokriging and universal kriging are two predictive analytical tools that were used. Cokriging is spatial prediction based on covariables in space; universal kriging is a combination of regression and kriging where spatial predictions are based on one variable and spatial trend or drift from other variables (Cressie, 1993).

CONCLUSION

In less than a decade since it was initiated, FHM had made significant strides toward development of a national program to monitor, assess, and report on the long-term status, changes, and trends in the health of the nation's forested ecosystems. Each of its four interrelated activities, including detection, evaluation, intensive site ecosystem monitoring, and research on monitoring techniques, are being implemented at some level. The detection activity covers all forested lands. Its two components, a network of permanent plots on which measurements are made each year, and a survey component that includes monitoring the effects of insects, diseases, and other disturbance agents, are in place in most states. A set of forest health indicators, including tree crown condition, ozone injury to bioindicator plants, soil condition, plant diversity and structure, down woody debris, and lichen communities, continues to be measured on the permanent plots. In the West Coast region (Alaska, Washington, Oregon, California, and U.S.-affiliated Pacific islands), baseline FHM plot data were collected in the 1990s in California, Oregon, and Washington; remeasurement of one fifth of the plots is made annually. Plots are planned for the Pacific islands and Alaska. Examples of national and West Coast monitoring activities and analyses were described, including analyzing plot data to assess forest health issues such as species diversity or air quality (via lichen data) or carbon sequestration (via harvest, mortality, and tree measurement data); implementing FHM evaluation monitoring projects such as the balsam woolly adelgid survey in Oregon and Washington; and investigating methods to analyze diverse forest health data sets, such as the co-analysis of aerial survey data and FHM plot data.

SECTION II.10

Agroecosystems

Overview: Integrating Agricultural Production with Ecosystem Health

Terrell P. Salmon

In the 21st century, ecosystem health, regardless of scale, will depend almost entirely on how humans manage the environment. Many examples of negative land-use patterns and practices exist, including some for agricultural production. Despite cogent examples of agricultural practices that degrade the environment, agriculturists throughout the world are more concerned with ecosystem health than most realize. Clearly, without a healthy environment, agricultural production will decline.

The scale of agriculture amplifies its effects on the ecosystem because much of the environment is under agricultural production. In California's Central Valley, for example, more than 40% (6.2 million acres) of the ecosystem is devoted to agricultural production. The health of those agricultural acres and their influences on the remaining land affect the overall health of the Central Valley. While some people argue that agriculture should not dominate the landscape, most recognize it as a necessary part of managing the ecosystem. How we manage these lands is more important than the overall amount of land devoted to this resource use.

This section is devoted to understanding agriculture and how it relates to and alters the environment. This information is necessary to better define agricultural practices that are compatible with, and potentially supportive of, environmental health. The chapters cover four important aspects of agricultural production.

First, we deal with the overall impact of agricultural production on the ecosystem. Debates and discussions continue about large-scale agriculture and how it modifies the biodiversity of a region. John Hopkins' chapter, "Fallow Land Patches and Ecosystem Health in California's Central Valley Agroecosystem," examines habitat conservation and restoration programs and their potential for improving wildlife habitat. He also discusses the ways in which farming practices affect the ecosystem. He argues that greater availability and use of technical assistance and demonstration programs could significantly improve the overall health of the Central Valley ecosystem. By implication, his work has significance to other areas throughout the world.

While the spatial relationships of agricultural and other resources with the ecosystem are critically important, the specific agricultural practices used in producing food and fiber also compromise ecosystem health. One area of interest is soil disturbance resulting from normal farming practices. Mitchell et al. discuss their long-term research in "Reduced-Disturbance Agroecosystems in California." Conservation tillage is more widely accepted outside California, although the beneficial aspects of this farming practice on farm operations and the overall health

of the environment probably apply to California as well. They investigated soil health in relation to conservation tillage practices. Their studies are essential in demonstrating the importance of these techniques and in convincing farmers to adopt new farming methods. Often, adoption is the most difficult part of change because farmers resist uncertainty with its potential for devastating impact on a farming enterprise. Research on conservation tillage showing the long-term benefits to soil quality and productivity is essential to bring about necessary change that will lead to improved ecosystem health.

Pest management is another area of agricultural operations that can have huge impacts on ecosystem health. Pest management includes synthetic and natural inputs to the ecosystem, as well as techniques for altering the interactions of various organisms. Each of these has implications for environmental health. Altieri and Nicholls discuss pest management and ecosystem health in "Ecologically Based Pest Management: A Key Pathway to Achieving Agroecosystem Health." They argue that proper pest management techniques can restore and enhance the resiliency, sustainability, and health of agroecosystems. The key component to ecosystem health and sustainability is preservation of the cultural diversity of local agricultural ecosystems. They show how managing agricultural areas to improve diversity will lead to less reliance on artificial inputs such as pesticides. They also recognize that the biological system must exist in the context of social organization that encourages the harmonious interaction of humans, the agroecosystem, and the overall environment.

Farming practices have effects on the environment outside the agricultural system. Water is a vital resource for agriculture and is also a major transporter of nutrients and other materials through the environment. The impact of nutrients can have far-reaching implications on ecosystem health and must be understood for better management of agricultural operations to occur. Kaffka and co-workers have researched the effects of nutrients in northern California and southern Oregon. Their chapter, "Irrigation, Agricultural Drainage, and Nutrient Loading in the Upper Klamath Basin," evaluates nutrient loading related to irrigation practices. Understanding the effects of irrigation on water quality is important and will lead to improved ecosystem health.

Ecosystem health and agricultural production are inextricably linked. A clear and thorough understanding of the effects of agriculture on the ecosystem, and the changes that the ecosystem and all its components exert on agricultural systems, is key to maintaining the sustainability and health of agriculture and the environment.

Fallow Land Patches and Ecosystem Health in California's Central Valley Agroecosystem

John D. Hopkins

INTRODUCTION

California's Central Valley is 450 miles long and encompasses over 15 million acres (Great Valley Center, 1998). It includes the Sacramento Valley as the northern portion, the delta where the Sacramento and San Joaquin Rivers join, and the San Joaquin Valley as the southern portion.

The Central Valley was an extremely rich wildlife region prior to European settlement (Thelander and Crabtree, 1994). Estimates of presettlement vegetation suggest that there were over 800,000 acres of riparian forest along many of the rivers and streams, forming a band of trees up to several miles wide (Dawdy, 1989). There were additional groves of oaks scattered across grassy plains. Tule marsh encompassed 600,000 to 700,000 acres, much of it in the delta and around large lakes at the southern end of the San Joaquin Valley (Dawdy, 1989). Most of the remaining valley floor was a grassy plain, although there were large areas of alkali-tolerant scrub and alkali saltbush scrub in the southwest portion of the San Joaquin Valley. These different plant communities provided habitat for a rich array of animals, from huge flocks of wintering waterfowl; to large numbers of antelope, elk, and grizzly bears; to forest-dwelling song birds (Barry, 1972; Thelander and Crabtree, 1994).

The valley has been transformed into the most productive agricultural region on the planet (Platzek, 1995). With \$13.5 billion worth of agricultural products (U.S. Department of Agriculture, 1999), the industry produces about 25% of the U.S. supply of vegetables, fruits, etc. (Platzek, 1995), as well as major amounts of food and fiber for export to other countries. Natural areas are limited to small remnants for the most part (U.S. Fish and Wildlife Service, 1998). The only vertebrate groups that remain in large numbers are wintering waterfowl and shorebirds that benefit from wildlife refuges and duck clubs developed as waterfowl habitat and from winter flooding of rice fields (Heitmeyer et al., 1989; Shuford et al., 1998).

Farming is now very intensive, with economic pressures on individual farmers increasing that intensity. Big farmers, generally speaking, rely on large acreages, massive machines, and planting of every available acre to remain profitable. *Clean farming*, where field edges and stream banks are kept devoid of vegetation by disking and herbicide application, is common in the valley (Anderson, 1995). As of 1997, there were 6.2 million acres of harvested cropland in the Central Valley (field crops, orchards, and vineyards), forming the core of intensive agricultural production (Table 96.1) (U.S. Department of Agriculture, 1999). Also, since 1970, pasturelands and grain crops

Table 96.1 Changes in Acres of Harvested Cropland in Central Valley Counties, 1992–1997^a

County	Acres Harvested		Change, 1992–1997

^a Harvested croplands include field crops, orchards and vineyards but not pasture or rangeland.

Based on data from U.S. Department of Agriculture, 1997 Census of Agriculture, California State and County Data, Vol. I, Geographic Area series, Part 5, Washington, D.C., 1999.

have been giving way to increasing acreages of intensive vegetable fields, orchards, and vineyards (Kroll et al., 1991; U.S. Department of Agriculture, 1999), further depleting available wildlife-foraging habitat.

In contrast, less-intensive farming practices can provide a great deal of wildlife habitat through hedgerows, woodlots, strips of riparian woodland, vegetated field edges, and keeping areas of poor soils out of production (Biadi, 1998; Clark and Rollins, 1996; Yolo County Resource Conservation District, 1999). Studies by several authors highlight the tremendous loss of biodiversity in Europe and the central portion of the U.S. as this wildlife-friendly form of farming has given way to extremely intensive agriculture in recent decades (Biadi, 1998; Freemark and Boutin, 1995; Fuller et al., 1995; Ribic et al., 1998).

While the habitats that the wildlife-friendly practices could provide in the Central Valley are often different in composition and form from presettlement plant communities, they can provide habitat for a wide variety of native animals, including several that are imperiled or undergoing significant decline. This chapter examines some of the obstacles to creation of more wildlife habitats in Central Valley cropland areas, solutions to these obstacles, and the types of strategic thinking necessary to provide farmland habitat patches of maximum benefit to overall wildlife populations in the Central Valley.

CONSERVATION RESERVE PROGRAM DEMONSTRATES LACK OF HABITAT CONSERVATION ON CENTRAL VALLEY FARMLAND

The minimal enrollment of Central Valley farmland in the U.S. Department of Agriculture's Conservation Reserve Program (CRP) is one indicator of the lack of habitat conservation. Farmers enroll croplands in the CRP under 10-year contracts, agreeing to take them out of crop production and carry out one or more specified conservation practices. In return they receive an annual per-acre rent and 50% of the cost of establishing any long-term cover such as perennial grasses or trees.

Congress authorized the CRP under Title XII of the 1985 Food Security Act. The initial purpose was to reduce soil erosion by taking highly erodible land out of production. The vast majority of

acres enrolled were in midwestern and Plains states, and nearly all were converted to grasslands. Various studies have shown how the CRP has aided grassland birds (Dunn et al., 1993; Ryan et al., 1998), even though the original program did not target areas important for wildlife (Szentandrasei et al., 1995).

Subsequent legislation, most recently the 1996 Federal Agriculture Improvement and Reform Act (FAIR), expanded the CRP to include a strong wildlife habitat component (Farm Service Agency, 1997a). There is a special effort to enroll riparian areas. Enrolled lands must be planted with permanent vegetation, from grass to trees for the 10-year contract lifetime. Riparian acres should provide a vegetated buffer of 50 to 150 ft or more in width along the waterway.

Applications for annual CRP enrollments are analyzed with an Environmental Benefits Index (EBI), which awards points for land attributes and proposed practices. EBI includes a major wildlife component, with items such as establishment of wildlife habitat cover, provision of cover for endangered species, and proximity to protected areas. In addition, a water-quality component includes attributes met by planting riparian vegetation (Farm Service Agency, 1997b).

Furthermore, farmers may enroll lands in the CRP at any time (continuous sign-up) if they will carry out high-priority practices, most of which provide wildlife habitat on fallowed land. These practices include filter strips along waterways, riparian buffers, shelterbelts, and shallow water areas for wildlife.

Conservation Reserve Program Enrollment in the Central Valley

In October 1999, 31,261,014 acres were enrolled nationwide. Just 131,758 acres (4.2%) were in California, and only 25,994 acres (0.41%) were in the Central Valley. The 25,994 acres enrolled in the Central Valley contrasts to 6.2 million acres of harvested cropland in the region. Nearly all of the Central Valley acreage was located in Yolo and Merced Counties (Table 96.2). None of the Yolo County acreage (15,243 acres) was enrolled through the CRP continuous sign-up program (Weatherford, 1999).

Examination of the 18th sign-up (1998) shows how, nationwide, new CRP lands provided for wildlife almost as much as reduction in soil erosion, with 18.6% of the enrolled acres being permanent wildlife habitat, compared with 21.7% having highly erodible soils. None of the California acres enrolled in the 18th sign-up was wildlife habitat (Table 96.3). For the 10 new contracts in the Central Valley, 2070 out of the 2138 acres were existing grassland (Table 96.4).

The CRP is only one of a number of programs that provide funding for wildlife habitat, albeit the one with the broadest potential for habitat conservation. The U.S. Department of Agriculture's Wetlands Reserve Program has a larger number of enrolled farms in the Central Valley, but is

Table 96.2 Acres of Land in Central Valley Counties Enrolled in the U.S. Department of Agriculture's Conservation Reserve Program

County	1997 Acres Harvested Cropland ^a	1999 Conservation Reserve Program Acreage ^b
Colusa	287,630	876
Glenn	212,848	1231
Kern	893,221	1504
Kings	445,537	357

focused almost exclusively on seasonal wetlands for wildlife. Most other programs provide cost sharing for wildlife habitat enhancements but not direct funding for setting aside cropland.

OBSTACLES AND SOLUTIONS

Financial

Agriculture is a business and farmers are businesspeople, focused on making a profit under often-difficult circumstances. While Central Valley croplands have high-yield potential, there are many uncertainties that make farming a precarious venture. Many growers are just surviving (Rollins, 1999; Weatherford, 1999). Profit is determined by crop yield, selling price, production costs, and subsidies. Crop yield per acre is affected by weather, disease, and other factors. Furthermore, farmers in some places have to reduce the number of acres they plant when dry winters result in limited irrigation water. The purchase price for crops varies considerably from year to year but the trend has not kept up with inflation. Costs continue to climb each year.

While yields and income per acre for individual crops are available from individual counties, costs per acre are not. Thus, it is difficult to get an accurate figure of net profit or loss per acre for individual crops in different areas. The University of California Cooperative Extension Service developed very detailed cost estimates for growing a variety of crops on hypothetical farms in different counties (University of California Cooperative Extension, 1994–1999). They show that in many cases higher yields and higher purchase prices are needed to make better profits and that it is easy to realize a loss on individual crops.

These fiscal uncertainties focus farmers on maximizing their net income. Activities that seem superfluous to the business of farming and provide little or no economic return are unlikely to get attention. As a result, one of the biggest obstacles to habitat conservation on Central Valley farmland is the low payments from government programs such as the CRP. The CRP payments vary with county or conservation practice and average \$45.50 per acre across the U.S. (Table 96.3). For the 18th annual sign-up contracts in the Central Valley, the Colusa County contract had an annual rent of \$23.73 per acre; the seven Merced County contracts averaged \$19; and the Yolo County contracts averaged \$33.29 (Table 96.4).

Payment for land taken out of production is just one fiscal need. A second need is financial assistance with the often considerable costs of establishing native vegetation. The CRP pays half the cost for improvements such as permanent vegetation. Recent estimates for riparian enhancement along a slough amounted to \$8433.75 for a 20-ft strip along a quarter-mile stretch of slough, plus \$1722.12 for annual maintenance required over the first 3 years (Yolo County Resource Conservation District, 1999). A 50% cost sharing still leaves the farmer with significant out-of-pocket expenses. It is possible for a farmer to obtain additional cost sharing from a variety of other federal and state programs (Yolo County Resource Conservation District, 1999), but this will require development of grant applications.

The essential solution to this fundamental obstacle is to provide more significant funding for provision of wildlife habitat on farmland, and to make it as easy as possible to apply for and receive funds. A state-funded program providing annual rental payments should augment the CRP, for example. In addition, the different agencies and programs need a coordinated approach, focused on individual counties, watersheds, or other geographic regions, to make it simple for landowners to apply for additive funding from multiple sources.

Coupling of fallow land conservation practices with projects such as flood control that provide direct and obvious benefits to farmers is a helpful approach (Jones and Stokes Associates, 1996). Local flooding from creeks and streams occurs along the length of the Central Valley, making field croplands inaccessible for weeks at a time, often during planting season. Orchards can suffer from direct flooding impacts and to a lesser extent from damage by floating debris.

A focus on flood control can also provide additional sources of funding. In Fresno County, the California Department of Fish and Game and the Fresno Metropolitan Flood Control District are cooperating on a 20-year program to improve flood control, and to preserve and restore riparian habitat along 100 miles of streams on the east side of the Valley floor (Rush, 1998). This approach brings in funding sources not normally available for habitat projects.

Practices and Awareness

Farm practices in the Central Valley center around intensive agricultural production using modern equipment. In the San Joaquin Valley, in particular, land is laid out in large rectangular fields, often a half mile long. Cultivation with large tractors and farm equipment utilizes entire fields, with no patches of poor soils or field corners left fallow (Pinter, 1999). Areas with winding streams or sloughs, on the other hand, have fields with odd corners that cannot be cultivated as easily. Turning those areas into patches of native vegetation, such as perennial grasses, can solve the farmer's weed problem over time as well as provide wildlife cover.

Land ownership is another significant issue, as tenant farmers are less interested in conservation practices that, at best, provide long-term economic benefits (Soule et al., 1999). A growing share of U.S. farmland is rented out to operators, exceeding 40% by 1992.

In California's Central Valley, generally an area of rapid urban development, there is an aging farm-ownership population and nonfarming interests buying land for its speculative value. Anecdotal information suggests increasing rental acreage. Data are available to distinguish all rented and owner-operated acres in California. However, we can distinguish between farms operated by landowners who farm the land they own, and farms operated by tenant farmers. Comparison of 1992 and 1997 data for Central Valley counties (U.S. Department of Agriculture, 1999) suggests that there is not an overall shift from owner-operated to tenant-operated acres occurring in the Central Valley. Most counties show large increases in the owner-operated acres of harvested crop land between 1992 and 1997. One county, Sacramento, shows decreases in owner- and tenant-operated acres. Sacramento County has particularly severe pressure from spreading urbanization.

Some landowners who lease their property for agricultural operations still take an interest in providing wildlife habitat, e.g., one large corporate owner in Yolo County with over 16,000 acres. This farm provides significant acreage of wetland and saline soil upland habitat, and also provides

a great deal of vegetation along sloughs and ditches and in odd field corners. While this is often not native vegetation, it provides habitat for a variety of birds, including a number of nongame species, such as the rapidly declining northern harrier, and one species of concern, the tri-colored blackbird. In this instance, the public relations value of providing habitat is a major factor for the corporate landowner, and there are several tours each year for local residents (Hall, 1999).

Farmer and landowner awareness of the values of fallow land and techniques for providing wildlife habitat is another issue. For example, a farmer may spend considerable time and money keeping field and waterway edges bare of vegetation in order to control weed growth. He may not know that planting of perennial vegetation such as native grasses will solve this weed problem, as well as provide wildlife habitat. A strip of native perennial grasses requires minimal attention after 2 or 3 years and avoids repeated disking and spraying (Yolo County Resource Conservation District, 1999). Furthermore, the U.S. Department of Agriculture's Natural Resource Conservation Service (formerly Soil Conservation Service) promoted clean farming in earlier decades and successfully developed a culture that "only clean farming is good farming" (Saffel, 1998).

The Yolo County Resource Conservation District has promoted a variety of wildlife-friendly farming techniques for a number of years, many developed by local farmer John Anderson. It has enrolled a growing number of local farmers in conservation practices, held many workshops, and obtained cost-sharing grants to fund conservation practices (Pye, 1998). It is now taking a "whole watershed" approach, in a collaborative project with Audubon California (Anderson, 1999; Boshoven, 1999) (discussed later).

There are also individual farm showcases in other counties. For example, Glenn County farmer Allen Garcia has shown that rice farming on marginal land in the central Sacramento Valley can blend well with wildlife-friendly farming, using techniques that include providing vegetation along creeks and runoff channels and allowing some fields to lie fallow for a year (California State Coastal Conservancy, 1994).

An important valley-wide solution is to increase the education and outreach to local farmers. There are many resource conservation districts (RCDs) in the Central Valley, with varying degrees of activity but all with little money. RCD directors are all local farmers, so these organizations can effectively reach out to the agricultural community. Funding for a central or southern San Joaquin Valley RCD to develop a multiyear program that promotes wildlife-friendly farming techniques and tests the conservation practices in the more-arid climate of this southern valley is a great need. In addition, each RCD and the umbrella organization, the California Association of Resource Conservation Districts, needs funding to develop individual projects around the entire Central Valley to provide farmers with local success stories. Finally, more research is needed on the medium- and long-term economic benefits of wildlife habitat patches because a solid economic justification will provide the best approach to enroll more farmers.

Regulation

Endangered Species Act

Farmers and other landowners often fear Endangered Species Act restrictions on how they use their land if a listed species occurs on their property. As a result, they are unwilling to carry out habitat enhancements or leave land fallow in case these steps attract listed species (Environmental Defense Fund, 1999). The Central Valley, and especially the southern half of the San Joaquin Valley, is particularly rich in endangered species; therefore, this is a major issue.

The U.S. Fish and Wildlife Service has developed the Safe Harbor Policy to address some of these concerns (U.S. Fish and Wildlife Service, 1999). Under this policy, landowners can enter into an agreement with the service to carry out and maintain specific habitat enhancements on some of their property for a defined time period. If this habitat enhancement results in listed species moving on to the property, the landowner is not subject to any additional restrictions under the Federal

Endangered Species Act regarding species covered by the agreement. The landowner is free to remove the habitat enhancement after the agreement period. There is no equivalent policy for the California Endangered Species Act.

Establishment of Safe Harbor agreements covering regions within the Central Valley, and certain habitat enhancements such as establishment of riparian vegetation, would be a great help in promoting conservation practices. In addition, it must be simple for landowners to obtain permits or agreements. Currently, if a landowner obtains a Conservation Reserve Program or Wetlands Reserve Program contract with the U.S. Department of Agriculture, he or she does not have to deal directly with the U.S. Fish and Wildlife Service. However, there is still a review process for the individual contract (Lowrie, 1999). The Department of Agriculture's Natural Resources Conservation Service (NRCS) makes an initial determination whether the conservation practices that the landowner will use will have any effect on listed species. If NRCS determines that there will be no effect, it issues documentation that provides some assurance to landowners. If it determines that there will be some effect, it carries out a consultation with the U.S. Fish and Wildlife Service under Section 7 of the Federal Endangered Species Act. The result is a Biological Opinion that provides for the practices that the landowner will carry out. The landowner receives a letter from NRCS saying that it has obtained a Biological Opinion from the service. It does not appear that this procedure is as effective as a Safe Harbor agreement in alleviating concerns in the agricultural community.

Need for a One-Stop Permit Process

Many projects to provide fallow land wildlife habitat require various permits and a farmer will have to deal with a multitude of federal, state, and local agencies. Concern that obtaining these permits will be time-consuming and complex, and could result in restrictions of farm operations, limits landowners' interest in carrying out conservation projects. Cost is another consideration as there is a fee for each permit (Jones and Stokes Associates, 1996; Mountjoy, 1999).

A 2-year-old pilot project on the Elkhorn Slough watershed in coastal California's Monterey County provides an example of how one-stop-permitting aids conservation projects (Mountjoy, 1999). The local NRCS office can provide an overall permit to farmers carrying out any of ten conservation practices and using NRCS technical or cost-share assistance. This permit encompasses six separate permitting processes under federal and state Endangered Species Acts, the federal Clean Water Act, Monterey County ordinances, and other legal provisions. Because the conservation project serves a public purpose, reduction in the level of sediment and pollution entering the slough, there is no fee (Johnson, 1999).

Establishment of this one-stop permit had a major impact on local farmers' attitudes. In the first year, twice as many farms participated as were expected. Individuals that would normally refuse to participate in such a project participated because they obtained an easy way to deal with erosion and flooding on their land, without having to obtain their own permits from multiple agencies (Mountjoy, 1999). In addition, farmers accepted higher standards for the practices that they used.

Strategic Approaches

Provision of wildlife habitat in fallow patches and along waterways occurs in a random manner at present, driven by individual landowner decisions. Scattered patches of habitat, however, often have limited biological value for most wildlife, particularly sensitive and declining species. These small patches may provide for small populations of some vertebrates, but are unlikely to provide for long-term, viable populations. For example, small, very narrow riparian strips may attract a variety of riparian-dependent songbirds to breed. But these areas will provide for too few nesting pairs and are likely to have severe cowbird parasitism, as well as predation by additional birds or

small carnivores. Songbirds need at least a 20% nesting success for a population to survive (Robinson et al., 1995). The result is that small patches of trees could become population sinks, reducing the viability of overall populations (Donovan et al., 1995a,b). Unfortunately, research has not been done on this issue for Central Valley conditions and species.

For optimum effect, it is necessary to have strategic approaches at the regional scale. Following are some of the strategies that are pertinent to the Central Valley.

Focus on Watersheds Important for Declining Riparian Birds

There is a need for the creation of many, or more continuous, riparian strips in watersheds deemed important for particular riparian species, such as rare and declining birds (e.g., the yellow warbler, *Dendroica petechia*; the yellow-breasted chat, *Icteria virens*; and the song sparrow, *Melospiza melodia*), in a manner that is beneficial to those species. A Riparian Bird Conservation Plan (Riparian Habitat Joint Venture, 2000) provides guidance as to the most important locations for restoration of additional riparian habitat, and the types and extents of riparian vegetation required for different species. In addition, the CALFED project (see Chapter 14, this volume), while focused on restoration of delta waterways and aquatic species, also addresses needs in the larger Sacramento and San Joaquin River watersheds.

Focus on Entire Smaller Watersheds

Focusing on riparian vegetative strips and other habitat patches in small watersheds, with a long-term goal of involving many of the landowners, will provide for greater continuity of riparian vegetation and usefulness of upland habitat patches. The new Audubon California/Yolo RCD project for Union School Slough in Yolo County is taking this approach, reaching out to landowners, and developing a number of specific projects (Boshoven, 1999). Several years ago, the Napa County RCD in the San Francisco Bay area enrolled 63 Huichica Creek watershed landowners in a land stewardship project that involved a variety of conservation practices, including planting native vegetation along the creek. This project was so successful that landowners shifted from hostility toward the endangered freshwater shrimp in the creek to distress if it was absent from their stretch of creek, because the shrimp is an indicator of good water quality (Bowker, 1996).

Fallow Land Habitat Adjacent to or Near Permanently Protected Lands or Other Lands Managed for Wildlife

The Central Valley has a number of wildlife areas, most of which are managed by the U.S. Fish and Wildlife Service and the California Department of Fish and Game. In addition, there is the Grasslands Ecological Area, with over 100,000 acres of public land, duck clubs, and other lands. Most of these areas have waterfowl as their primary focus, in particular providing wintering habitat for Pacific Flyway birds. But they also provide for a variety of rare vertebrates, vernal pool invertebrates, and a number of rare plant species (Silveira, 1998). Additional and adjacent patches of fallow land, especially riparian and wetland habitat, will add to usable habitat for birds and other animals, and thus help increase population sizes. Winter flooding of rice fields now provides major wintering grounds for waterfowl, as well as nearly all the winter habitat for over 300,000 shorebirds (Shuford et al., 1998; Elphick and Oring, 1998).

In the future, there will be more protected areas, including lands managed for a variety of rare and endangered species. In addition, large blocks of land will be taken out of agricultural production to reduce groundwater and runoff water salinity on the west side of the San Joaquin Valley. Decades of cropland irrigation have raised the water table to just a few feet below ground level and have caused a buildup of salts and particularly toxic levels of selenium in that groundwater. The saline

groundwater causes significant crop damage and the area with shallow groundwater is expanding rapidly. For example, in the Westlands Water District in the west-central portion of the San Joaquin Valley, the area where the water table is within 5 ft of the surface increased from 38,000 to 328,000 acres between 1991 and 1997. The high levels of selenium cause major biological problems in the San Joaquin River system and associated wetlands, particularly birth defects in birds. Retiring sufficiently large blocks of land from irrigated agriculture will both lower the groundwater tables and reduce the transport of selenium into waterways (Land Retirement Technical Committee, 1999; U.S. Army Corps of Engineers, 1999).

Also, there is increased emphasis on protection of critical lands for endangered and rare species in the Central Valley. For example, several endangered vertebrates are now found only in limited patches of native habitat in the southern San Joaquin Valley (U.S. Fish and Wildlife Service, 1998). Fallow land providing wildlife habitat adjacent to one of these blocks would provide a temporary expansion of occupied habitat for key upland species and help build up their populations (Kelly, 1999). Additional patches of wildlife habitat on temporary fallow land adjacent or near to permanently protected habitat areas are likely to provide greater wildlife benefits (Kelly, 1999).

Creating Patches of Habitat in Lands Identified as Critical Wildlife Corridors

The recovery plan for upland species of the San Joaquin Valley identifies specific agricultural areas where wildlife corridors are necessary (U.S. Fish and Wildlife Service, 1998). These are mainly for the San Joaquin kit fox, an umbrella species that will travel significant distances and will make some use of agricultural lands. Kit foxes are subject to predation by coyotes and red foxes, and they construct numerous dens for year-round use in order to avoid predation. An agricultural kit fox corridor will need periodic dens on fallow land patches to provide for effective movement of the species and to avoid becoming a population sink.

Conservation of Habitat in Small Specialized Areas Such as Rare Plant Communities

There are small patches of natural habitat or poor-quality agricultural land scattered across the Central Valley that provide important biological values. For example, Yolo County has a small area of alkali soils supporting a population of the palmate-bracted bird's beak (*Cordylanthus palmatus*), an endangered plant (U.S. Fish and Wildlife Service, 1998). Patches such as this need to be permanently protected natural habitat.

CONCLUSION

Adoption of programs that overcome the obstacles to creation of fallow land wildlife habitat, and projects that focus on key areas such as those mentioned previously are essential for the long-term ecological health of California's Central Valley. With widespread implementation, they will provide for a tremendous increase in wildlife habitat and in the populations of declining and commoner species that can utilize agricultural lands or habitat patches located in a farmland matrix. Without these programs, most of the valley will continue to be biologically impoverished and society's ability to recover declining wildlife species will be severely diminished.

INTRODUCTION

Over the last several decades, growers in California's Central Valley, as in many other agricultural areas throughout the world, have become increasingly aware of the importance of soil organic matter (SOM) in relation to sustained soil quality or function (West Side On-Farm Demonstration Project Participant Survey, 1999; Romig et al., 1995; Magdoff, 1992). Soil carbon (C), which typically constitutes about one half of SOM, is closely linked to many desirable soil physical, chemical, and biological properties that are associated with enhanced soil productivity and quality (Reicosky, 1996b; Ismail et al., 1994). More recently, awareness has also increased concerning the negative impact that tillage has on SOM storage (Reicosky, 1995; Jackson, 1998). While moderate tillage may provide more favorable soil conditions for crop growth and development and weed control over the short term (Carter, 1998), intensive tillage of agricultural soils has historically led to substantial losses of soil C that range from 30 to 50%. Conventional tillage practices disrupt soil aggregates exposing more organic matter to microbial degradation and oxidation (Reicosky, 1996a), and are one of the primary causes of tilth deterioration over the long term (Karlen et al., 1990). Micro- and macrochannels within the soil, created by natural processes, such as decaying roots and worms, may also be destroyed by tillage (Carter, 1998). Deep tillage, as is customarily done as a routine soil preparation operation, is also costly and requires high energy and increased subsequent effort to prepare seedbeds. A recent survey by Jackson (1998), documenting a 40% decline in SOM since intensive tillage practices began in the Salinas Valley, confirms the conclusion drawn from other long-term crop rotation studies (e.g., the Morrow Plots at the University of Illinois; the Sanborn Field Plots in Columbia, MO; and the Columbia Plateau Plots near Pendleton, OR) that intensive tillage typically leads to decreased soil C via gaseous CO₂ emissions in virtually all crop production systems (reviewed by Reicosky, 1996b). There is mounting evidence as well as concern that this C source has been a significant component of the historic increase in atmospheric CO₂ (Wilson, 1978; Post et al., 1990), and the potentially associated greenhouse effect (Lal et al., 1998) that is attracting intense attention worldwide.

Recent pioneering studies by Reicosky and Lindstrom (1993), involving a variety of tillage methods, indicate major gaseous losses of C immediately following tillage but point to the potential for reducing soil C loss and enhancing soil C management through the use of conservation tillage (CT) crop production practices. Though these practices have been developed over several decades primarily for erosion control in other parts of the U.S., recent concerns have reemphasized the

Table 97.1 Typical Tillage/Land Preparation Practices before Planting Processing Tomatoes and Cotton in the San Joaquin Valley's West Side Region

importance of CT and how it might be implemented on a broader scale. These concerns include the need to sustain soil quality (Abdul-Baki, 1998) and profitability (Mitchell and Goodell, 1999) in areas such as California, where CT is virtually nonexistent, and potential global climate change. CT implementation will help reduce soil C losses (Carter, 1998) and thereby sustain soil quality and agricultural productivity.

Most current San Joaquin Valley (SJV) annual crop production systems are very tillage intensive. Typically 9 to 11 tillage operations are made in most fields following harvest in preparation for a succeeding crop at about 18 to 24% of a farmer's seasonal budget (West Side On-Farm Demonstration Project Participant Survey, 1999; Table 97.1). Tillage in these production systems is typically done in a "broadcast" manner throughout a field, without deliberate regard to preserving dedicated crop growth or traffic zones. Studies by Carter (1985, 1998) over the last several decades, however, have confirmed the potential to eliminate deep tillage, decrease the number of soil preparation operations by as much as 60%, reduce unit production costs, lower soil impedance, and maintain productivity in a number of SJV cropping contexts using reduced, precision, or zone tillage practices that limit traffic to permanent paths throughout a field. The result is the reduction of soil compaction and preservation of an optimum soil volume for root exploration and growth (Carter et al., 1991; Rechel et al., 1991). There have been relatively few other studies during the past several decades that have investigated aspects of CT (Table 97.2). Recent work by Herrero et al. (2001a,b), also in the SJV, evaluating a mulch-transplanted processing tomato production system has also demonstrated the potential to sustain productivity under certain mulches and increase soil C and earthworms using a CT approach. Given the successes of these component research studies and in anticipation of increasing energy (Carter, 1998) and production costs (Goodell, P., personal communication), and out of a growing desire among producers to improve soil quality via C sequestration, there is interest among many Central Valley farmers to develop CT practices that may be feasible in this region.

CURRENT CENTRAL VALLEY ANNUAL CROP PRODUCTION SYSTEMS

California's Central Valley is one of the world's most productive agricultural regions and leads the U.S. in the production of many crops (California Department of Food and Agriculture, 1998). A wide variety of annual crops is produced throughout the Central Valley. Corn, processing tomatoes, wheat, safflower, and edible dried beans are common annual rotation crops in the southern Sacramento Valley (Clark et al., 1998). Dominant cropping patterns of the central SJV include rotations of cotton, processing tomatoes, onions, garlic, cantaloupes, wheat, sugar beets, and lettuce (Mitchell et al., 2001). The productive capacity of these valleys is made possible in large part by intensive irrigation practices; agrichemical inputs, including fertilizers and pesticides; and frequent tillage of large, monoculture production fields that predominate throughout the area (Mitchell et al., 2001). While there are instances in which more than one crop is grown in a given field during one year, as in the case of wheat double-cropped with beans in the Sacramento Valley (Clark et al., 1998), or back-to-back spring and fall lettuce in the central SJV (Mitchell et al., 1999b), in general, most row crop acreage throughout the Central Valley produces one crop per year. It is not uncommon, therefore, for large acreages to be bare during periods between crops, particularly during the winter months from October through March.

Recently, there is evidence of growing interest in the use of cover crops to improve the productivity and sustainability in a number of agroecosystems in California (Ingels et al., 1994), including row crop regions in the central SJV (Mitchell and Goodell, 1999). Potential benefits as well as management issues associated with cover cropping in the Central Valley have been widely reported (Lanini et al., 1989; Groody, 1990; Stivers and Shennan, 1991). Growing off-season cover crops may also contribute to the goal of carbon sequestration, and may facilitate capture of winter precipitation if higher infiltration rates result from their use (Colla et al., 2000). Legume-based cover crop systems that have low carbon-to-nitrogen organic residue inputs have recently been shown to significantly increase soil carbon retention (Drinkwater et al., 1998). *In situ* production and retention of high levels of crop residues, part of which may derive from cover crops, in conjunction with no-till practices, may be the most cost- and time-efficient way to increase soil organic matter (Crovetto, 1996). Despite these potential benefits, adopting cover crops into many cropping systems has been slow, largely because innovative adjustments in traditional cropping practices have not been made.

CHANGES IN TRADITIONAL CENTRAL VALLEY AGROECOSYSTEM MANAGEMENT

To continue the Central Valley's phenomenal productive capacity, many farmers in the region are increasingly becoming interested in management approaches that reduce costs, increase grower revenues, and sustain the region's resource base (Mitchell et al., 2001). Recent on-farm demonstration work conducted through the Biologically Integrated Farming Systems (BIFS) Project in the West Side area of the SJV has resulted in 60% of farmer participants intending to increase their use of cover crops in this region during coming years, in contrast to the established practice of not using cover crops (Mitchell et al., 2001). The use of cover crops in such intensively managed ecosystems is not without potential costs, and ongoing research throughout Central Valley annual cropping systems is attempting to evaluate the long-term feasibility of this practice by answering such questions as whether cover cropping increases infiltration and reduces surface runoff enough to offset the soil moisture it depletes, and whether expected increases in infiltration that might result from cover cropping are high enough to increase groundwater recharge (Joyce et al., 2002).

There is also interest in evaluating and developing management systems that reduce tillage in the Central Valley, as evidenced by recent surveys and farmer-scientist focus sessions that have

Table 97.3 Central Valley Annual Crop Rotations in Which Conservation Tillage Practices Are Currently Being Evaluated

been conducted (Benefield, C., personal communication). Participant feedback from conferences in Five Points and Davis, CA in 1998 that focused on relationships between soil organic matter, tillage, and soil quality indicates that conservation tillage may become more widely adopted throughout the region if successful examples are demonstrated (Table 97.3). A variety of factors or motivations may drive the development of CT systems in this highly intensive agricultural region in which they have not been used widely before.

Unlike other regions of the U.S., where the need to reduce soil erosion has spawned the conversion of considerable farm acreage to CT practices over the last several decades (CTIC, 1999), erosion has not yet been identified as a research and management priority. There is, however, increasing attention being paid to potential benefits of reduced tillage production systems in terms of mitigating airborne respirable dusts that are known to result from heavily tilled agricultural production systems (Clausnitzer and Singer, 1997). Currently, however, reducing production costs and improving soil quality surface are primary drivers of the growing interest in developing CT or reduced disturbance production systems (Robertson, H., personal communication).

Many issues will need to be addressed and resolved, however, before CT practices are adopted in the intensive agricultural row crop regions of California's Central Valley. These issues include the complete array of decisions faced by producers throughout the area: profitability, weed and other pest management, irrigation systems that permit uniform water application in surface residue fields, appropriate CT equipment, crop rotation and bed configuration schemes that are compatible with CT, as well as the degree to which soil and water conservation is achieved through reduced disturbance systems. Several pilot studies have recently been initiated throughout the Central Valley (Table 97.4) and based on the interest that these have generated so far, there is a strong likelihood that more will be started in the near future.

Table 97.4 Response to Conference Evaluation Question by Participants of Emerging Soil Management Options for California (Soil Quality/Soil Organic Matter/Tillage) Conferences April 22 and 23, 1998, Five Points and Davis, CA

What do you think about the future adoption of the various conservation tillage (CT) practices in California that were presented at this Conference? (Number indicated is the number of respondents selecting a given option.)

- 0 CT practices will not be widely adopted in California.
- 11 Adoption of CT will likely be on a very limited scale.
- 34 CT may become more widely adopted if successful examples are demonstrated.
- 7 It is inevitable that CT will have a far wider role in California.

ACKNOWLEDGMENTS

The broad-based, ongoing research that is described here has been funded by the U.S. Department of Agriculture National Research Initiative, the University of California's Sustainable Agriculture Research and Education Program, the California Tomato Research Institute, the California Tomato Commission, the California Melon Board, the California Department of Pesticide Regulation, and the U.S. Environmental Protection Agency.

Ecologically Based Pest Management: A Key Pathway to Achieving Agroecosystem Health

Miguel A. Altieri and Clara Ines Nicholls

INTRODUCTION

The ultimate goal of all farmers should be to grow healthy and productive plants and animals, while maintaining the ecological integrity of the resource base of their farms. For agroecologists, such goals would translate into healthy agroecosystems exhibiting a high degree of integrity; a strong capacity to respond and adapt; and high levels of efficiency, productivity, stability, and self-dependence (Altieri and Nicholls, 1999).

Sustainable yield in the agroecosystem derives from the proper balance of crops, soils, nutrients, sunlight, moisture, and coexisting organisms. The agroecosystem is productive and healthy when this balance of rich growing conditions prevail, and when crop plants remain resilient to tolerate stress and adversity. Occasional disturbances can be overcome by vigorous agroecosystems, which are adaptable, and diverse enough to recover once the stress has passed (Altieri and Rosset, 1995). If the cause of disease, pests, soil degradation, etc. is understood as imbalance, then the goal of agroecological treatment is to recover balance, setting in motion the agroecosystem's natural tendency toward repairing itself. This tendency is known in ecology as homeostasis, the maintenance of the system's internal functions and defense mechanisms to compensate for external stress factors. But achieving and maintaining homeostasis requires a deep understanding of the nature of agroecosystems and the principles by which they function. Fortunately, there are new integrative scientific approaches that allow for such understanding. Among them is agroecology, which has emerged as a discipline that provides basic ecological principles on how to study, design, and manage agroecosystems that are productive and natural resource conserving (Altieri, 1995).

Agroecology goes beyond a one-dimensional view of agroecosystems — their genetics, agronomy, edaphology, etc. — to embrace an understanding of ecological and social levels of coevolution, structure, and function. Instead of focusing on one particular component of the agroecosystem, agroecology emphasizes the interrelatedness of all agroecosystem components and the complex dynamics of ecological processes such as nutrient cycling and pest regulation (Gliessman, 1998).

From a management perspective, the agroecological objective is to provide a balanced environment, sustained yields, biologically mediated soil fertility, and natural pest regulation through the design of diversified agroecosystems and the use of low-input technologies (Altieri, 1994). The strategy is based on ecological principles that lead management to optimal recycling of nutrients and organic matter turnover, closed energy flows, water and soil conservation, and balanced

pest–natural enemy populations. The strategy exploits the complementation that results from the various combinations of crops, trees, and animals in spatial and temporal arrangements (Altieri and Nicholls, 1999). These combinations determine the establishment of a planned and associated functional biodiversity that, when correctly assembled, delivers key ecological services that subsidize agroecosystem processes that underlie agroecosystem health.

In other words, ecological concepts are utilized to favor natural processes and biological interactions that optimize synergies so that diversified farms are able to sponsor their own soil fertility, crop protection, and productivity through the activation of soil biology, the recycling of nutrients, the enhancement of beneficial arthropods and antagonists, etc.

In this chapter, we provide an agroecological framework to achieve crop health through agroecosystem diversification and soil quality enhancement, key pillars of agroecosystem health. The main goal is to enhance the *immunity* of the agroecosystem (i.e., natural pest control mechanisms) and regulatory processes (i.e., nutrient cycling and population regulation) through management practices and agroecological designs that enhance plant species and genetic diversity in time and space, and the organic matter content and biological activity of the soil (Altieri, 1999).

MONOCULTURES AND THE FAILURE OF CONVENTIONAL PEST MANAGEMENT APPROACHES

Many scientists today agree that conventional modern agriculture faces an environmental crisis. Land degradation, salinization, pesticide pollution of soil, water and food chains, depletion of groundwater, genetic homogeneity, and associated vulnerability raise serious questions regarding the sustainability and health of modern agroecosystems. The loss of yields due to pests in many crops, despite the substantial increase in the use of pesticides, is a symptom of the environmental crisis affecting agriculture (Altieri and Rosset, 1995). It is well known that cultivated plants grown in genetically homogeneous monocultures do not possess the necessary ecological defense mechanisms to tolerate outbreaking pest populations. Modern agriculturalists have selected crops for high yields and high palatability, making them more susceptible to pests by sacrificing natural resistance for productivity (Robinson, 1996). On the other hand, modern agricultural practices negatively affect natural enemies (predators and parasites), which do not find the necessary environmental resources and opportunities in monocultures to effectively suppress pests (Altieri, 1994). While monocultures are maintained as the structural base of modern agricultural systems, pest problems will continue to be the result of a negative treadmill that reinforces itself, as vegetational simplification, nutrient imbalances caused by excess fertilizers and pesticide residues compound pest invasions (Figure 98.1). Thus the major challenge for those advocating ecologically based pest management (EBPM) is to find strategies to overcome the ecological limits imposed by monocultures.

Integrated Pest Management (IPM) approaches have not addressed the ecological causes of the environmental problems in modern agriculture. There still prevails a narrow view that specific causes affect productivity, and overcoming the limiting factor (i.e., insect pest) via new technologies continues to be the main goal. In many IPM projects, the main focus has been to substitute less-noxious inputs for the agrochemicals blamed for so many of the problems associated with conventional agriculture. Emphasis is now placed on purchased biological inputs such as *Bacillus thuringiensis*, a microbial pesticide that is now widely applied in place of chemical insecticides. This type of technology pertains to a dominant technical approach called *input substitution*. The thrust is highly technological, characterized by a limiting-factor mentality that has driven conventional agricultural research in the past. Agronomists and other agricultural scientists have for generations been taught the *law of minimum* as a central dogma. According to this dogma, at any given moment there is a single factor limiting yield increases, and that factor can be overcome with an appropriate external input. Once the hurdle of the first limiting factor has been surpassed — nitrogen deficiency,

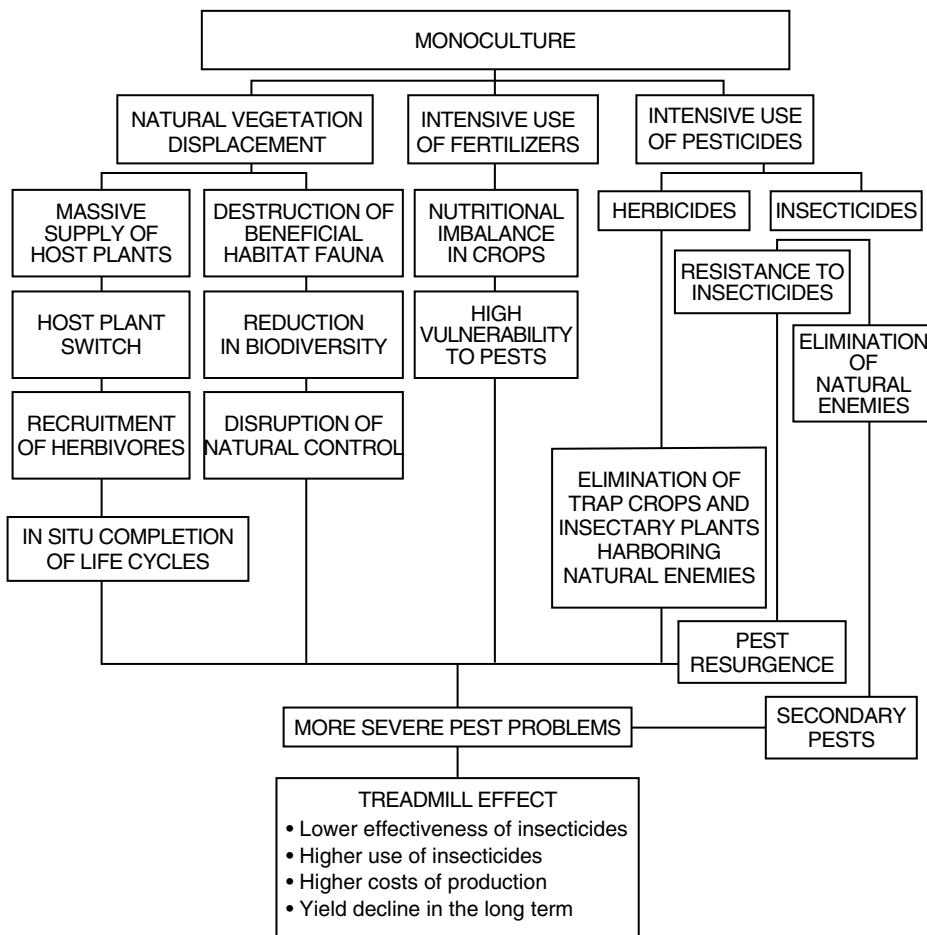

Figure 98.1 The ecological consequences of monoculture with special reference to pest problems and the agrochemical treadmill.

for example, with urea as the correct input — then yields may rise until another factor, e.g., insect pests, becomes limiting, in turn owing to increased levels of free nitrogen in the crop foliage. The factor then requires another input — insecticide in this case — and so on, perpetuating a process of treating symptoms rather than dealing with the real causes that evoked ecological imbalance (Altieri and Rosset, 1995).

Emerging biotechnological approaches do not differ as they are being pursued to patch up problems (e.g., pesticide resistance, pollution, soil degradation, etc.) caused by previous agrochemical technologies promoted by the same companies now leading the biorevolution. Transgenic crops developed for pest control closely follow the paradigm of using a single control mechanism (a pesticide) that has proven to fail over and over again with insects, pathogens, and weeds. Transgenic crops are likely to increase the use of pesticides and to accelerate the evolution of *super weeds* and resistant insect pests (Rissler and Mellon, 1996).

The *one-gene-one-pest* approach can be easily overcome by pests that are continuously adapting to new situations and evolving detoxification mechanisms. There are many unanswered ecological questions regarding the impact of the release of transgenic plants and microorganisms into the environment (Snow and Moran, 1997). Among the major environmental risks associated with genetically engineered plants are the unintended transfer to plant relatives of the *transgenes* and the unpredictable ecological effects on nontarget organisms. In fact, the effects of transgenic crops

are not as localized or as transient as advocated by biotechnology supporters. Rather, many studies suggest that the ecological effects of transgenic crops might spread via wind, move through food webs, and accumulate in the soil (Marvier, 2001).

Given the above considerations, agroecological theory predicts that biotechnology will exacerbate the problems of conventional agriculture (Altieri, 2000). By promoting monocultures, it will also undermine ecological methods of farming, such as rotations and polycultures, key strategies to break the homogeneous nature of monocultures. As currently conceived, biotechnology does not fit into the broad ideals of a truly sustainable agriculture.

ACHIEVING CROP HEALTH THROUGH ECOLOGICALLY BASED PEST MANAGEMENT (EBPM)

Nowhere are the consequences of biodiversity reduction more evident than in the realm of agricultural pest management. The instability of agroecosystems, which is manifested as the worsening of most insect pest problems, is increasingly linked to the expansion of crop monocultures at the expense of the natural vegetation, thereby decreasing local habitat diversity (Altieri and Letourneau, 1982). Plant communities that are modified to meet the special needs of humans become subject to heavy pest damage, and generally the more intensely such communities are modified, the more abundant and serious the pests (Andow, 1991). The inherent self-regulation characteristics of natural communities are lost when humans modify such communities through the shattering of the fragile thread of community interactions. Agroecologists maintain that this breakdown can be repaired by restoring the shattered elements of community homeostasis through the addition or enhancement of biodiversity (Altieri and Nicholls, 1999).

The key is to identify the type of biodiversity that is desirable to maintain, enhance, and carry out ecological services, and then to determine the best practices that will encourage the desired biodiversity components. Figure 98.2 shows that there are many agricultural practices and designs that have the potential to enhance functional biodiversity, and others that negatively affect it. The idea is to apply the best management practices to enhance or regenerate the kind of biodiversity that subsidizes the health and sustainability of agroecosystems by providing ecological services such as biological pest control, nutrient cycling, water and soil conservation, etc. (Gliessman, 1998). As depicted in Figure 98.3, crop health can be achieved by regulating insect pests through two routes: a healthy soil, and a rich natural-enemy biodiversity harbored by a diversified agroecosystem.

Healthy Soils, Healthy Plants

A key feature of modern cropping systems is the frequency of soil disturbance regimes, including periodic tillage and pesticide applications, which reduce soil biotic activity and species diversity in agroecosystems. Such soil biodiversity reductions are negative because the recycling of nutrients and proper balance between organic matter, soil organisms, and plant diversity are necessary components of a productive and ecologically balanced soil environment (Hendrix et al., 1990). The ability of a crop plant to resist or tolerate pests is tied to optimal physical, chemical, and biological properties of soils. Adequate moisture, good soil tilth, moderate pH, adequate amounts of organic matter and nutrients, and a diverse and active community of soil organisms all contribute to plant health. Organic-rich soils generally exhibit good soil fertility as well as complex food webs and beneficial organisms that prevent infection by disease-causing organisms such as *Pythium* and *Rhizoctonia* (Giller et al., 1997). On the other hand, farming practices that cause nutrition imbalances can lower crop resistance. High nitrogen fertilizer levels can enhance the incidence of diseases, such as *Phytophthora* and *Fusarium*, and stimulate outbreaks of homopteran insects, such as aphids and leafhoppers

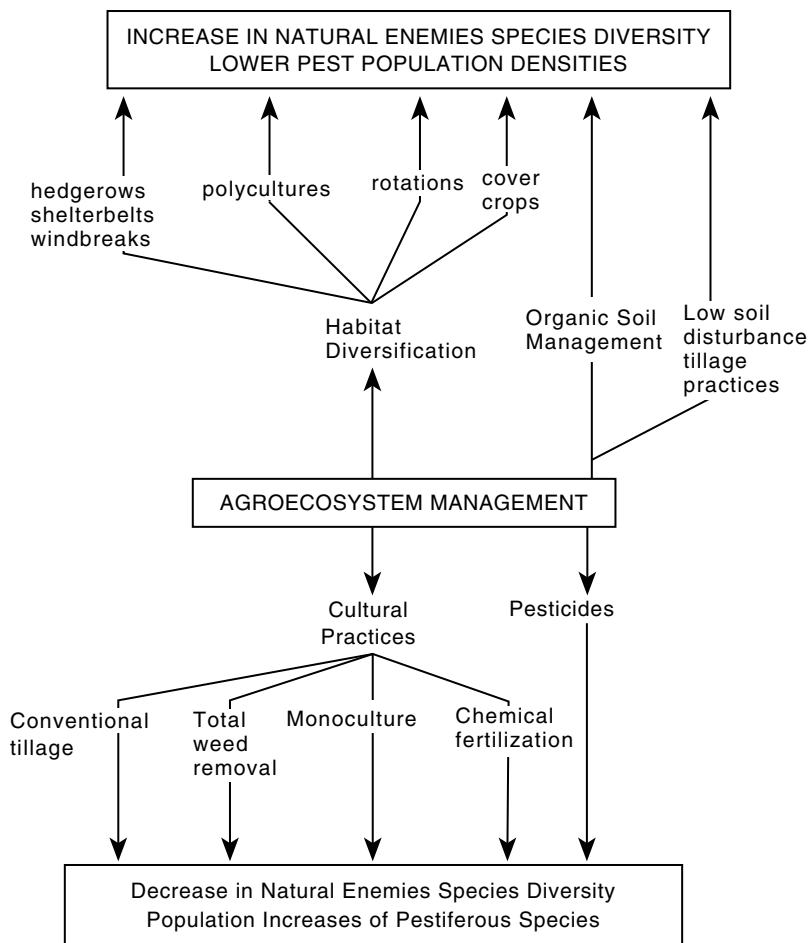

Figure 98.2 The effects of agroecosystem management and associated cultural practices on the biodiversity of natural enemies and the abundance of insect pests.

(Campbell, 1989). In fact, there is increasing evidence that crops grown in organic-rich and biologically active soils are less susceptible to pest attacks. Many studies suggest that the physiological susceptibility of crops and pathogens may be affected by the form of fertilizer used (organic vs. chemical fertilizer). Studies documenting lower diversity of several insect herbivores in low-input systems have partly attributed such reduction to a low nitrogen content in organically farmed crops (Magdoff, 1992). In California, a series of comparative experiments conducted on various growing seasons between 1989 and 1996 where broccoli was subjected to varying fertilization regimes (conventional vs. organic) showed that agroecological techniques can reduce the abundance of key insect pests, cabbage aphid (*Brevicoryne brassicae*) and flea beetle (*Phyllotreta cruciferae*), while sustaining yields. Lower herbivore numbers in organically managed plots were attributed to low foliage nitrogen content in compost-fed broccoli plants (Altieri, 1994).

In Japan, density of immigrants of the planthopper *Sogatella furcifera* was significantly lower while the settling rate of female adults and survival rate of immature stages of ensuing generations were lower in organic rice fields. The number of eggs laid by a female of the invading and following generations was smaller, and the percentage of brachypterous females in the next generation was also lower. Consequently, the density of nymphs and adults in the ensuing generations decreased in organically farmed fields (Kajimura, 1995).

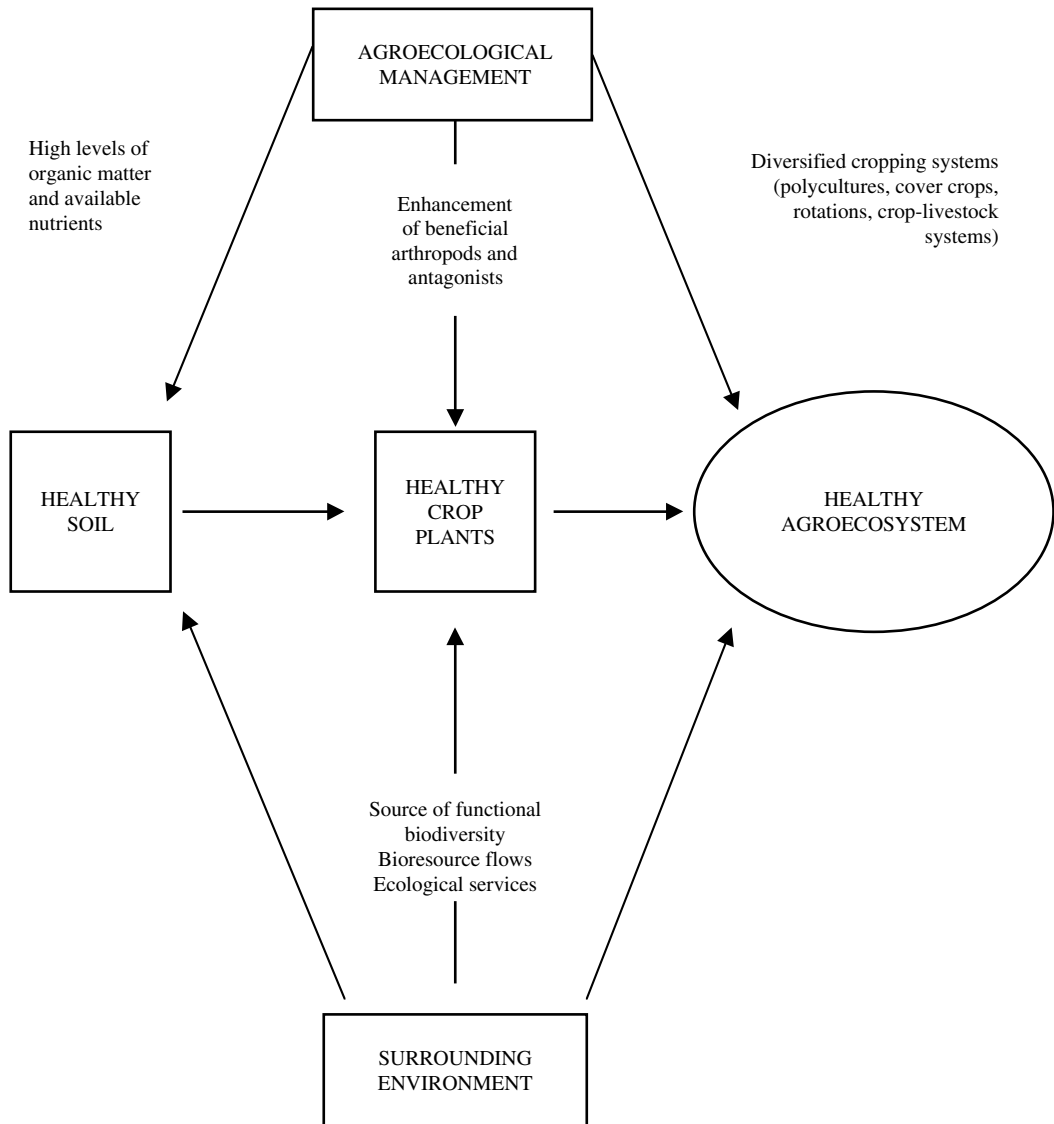

Figure 98.3 The pillars of agroecosystem health.

In England, conventional winter wheat fields developed a larger infestation of the aphid *Metopolophium dirhodum* than its organic counterpart. During June, this crop also had higher levels of free protein amino acids in its leaves, which were believed to have resulted from a nitrogen top dressing of the crop in early April. However, the difference in the aphid infestations between crops was attributed to the aphid's response to relative proportions of certain nonprotein to protein amino acids in the leaves at the time of aphid settling in the crops (Kowalski and Visser, 1979). In greenhouse experiments when given a choice of maize grown on organic vs. chemically fertilized soils, European corn borer females preferred to lay significantly more eggs in chemically fertilized plants (Phelan et al., 1995).

Nutrition is also important in determining susceptibility or resistance of plants to pathogens. Mineral nutrients are essential metabolic regulators of plant growth, and most studies indicate that nutrition affects pathogens and diseases indirectly. Biological activity in the soil becomes very intense in response to organic amendments and increases fungistasis as well as populations of existing microbial antagonists. Composts of diverse organic materials have proven effective in

controlling diseases. Many types of compost host beneficial organisms that feed directly on pathogens, compete with them for nutrients, or produce antibiotics (Tjamos et al., 1992)

Balanced soil nutrition helps plants stay more vigorous, increases the growth rate, makes better use of soil water, and improves anatomical or histological characteristics. These factors enable plants to produce greater numbers of roots, allowing more surface area for root absorption and nutrient uptake, and possibly shortening susceptible stages of plant growth. This allows plants to function more efficiently even when some roots are infected. Histological changes strengthen plants and possibly create barriers more difficult for pathogens to breach. A healthier plant may also increase quality of exudates, which can stimulate increases in populations of antagonistic microorganisms. These, in turn, may compete with pathogens for nutrients or possibly produce toxins that directly affect pathogen development and survival (Palti, 1981).

Application of nutrients (especially N) may increase competitive suppression of crops by weeds, as most weeds (especially C₄ species) are often more responsive to application of nitrogen than other crops. A study reported that application of chemical N fertilizer to wild oat–spring wheat mixtures increased wild oat growth and decreased wheat yields. On the other hand, other studies have shown that N fertilizer can improve the competitive status of crops. What seems critical in determining the outcome of competitive interactions is the timing of nutrient availability relative to crop and weed demands upon nutrient supplies (Liebman and Gallandt, 1997). Emerging research shows that the species composition and general ecology of weeds is radically different in organic vs. conventionally fertilized systems. Yield reductions of wheat due to interference from Italian ryegrass (*Lolium multiflorum*) were greater under conventionally fertilized conditions than under organic-fertilized conditions. In many cases, weed suppression is related to delayed N release from the organic N source compared to nitrate fertilizer. In other cases, soil-incorporated organic residues increase phytotoxicity or pathogen activity, which suppresses weed seed and seedlings (Liebman and Ohno, 1998).

Diversified Agroecosystems and Pest Management

Diversified cropping systems, such as those based on intercropping and agroforestry or cover cropping of orchards, have been the target of much research recently. This interest is largely based on the emerging evidence that these systems are more stable and more resource conserving (Vandermeer, 1995). Much of these attributes are connected to the higher levels of functional biodiversity associated with complex farming systems. In fact, an increasing amount of data reported in the literature documents the effects that plant diversity has on the regulation of insect herbivore populations by favoring the abundance and efficacy of associated natural enemies (Altieri and Letourneau, 1984). One of the key elements in diversified agroecosystems is the presence of flowering plants that provide pollen and nectar, which serve as alternative food for natural enemies. A number of studies have shown that many parasitoids require nectar for normal fecundity and longevity, and thus spectacular parasitism increases have been observed in annual crops and orchards with rich floral undergrowth (Leius, 1967).

Flowering plants can also increase populations of nonpestiferous herbivores (neutral insects) in crop fields. Such insects serve as alternative hosts or prey to entomophagous insects, thus improving the survival and reproduction of these beneficial insects in the agroecosystem. Many researchers have reported that the presence of neutral insects on flowering plants within or near crop fields increase predation and parasitism of specific crop pests (Altieri and Whitcomb, 1979).

Our research in northern California vineyards confirms the importance of maintaining full season floral diversity to enhance natural-enemy abundance and diversity in the grape agroecosystem. Growing summer cover crops of buckwheat and sunflower had a substantial impact on the abundance of western grape leafhoppers and associated natural enemies. During two consecutive years (1996–1997), vineyard systems with flowering summer cover crops were characterized by lower densities of leafhoppers (Figure 98.4). Such reduced pest numbers in diversified vineyards were due to the impacts of generalist predators. With increased plant diversity, insect pests remained at lower levels than in clean-cultivated vineyards, partly because the summer cover crop vegetation

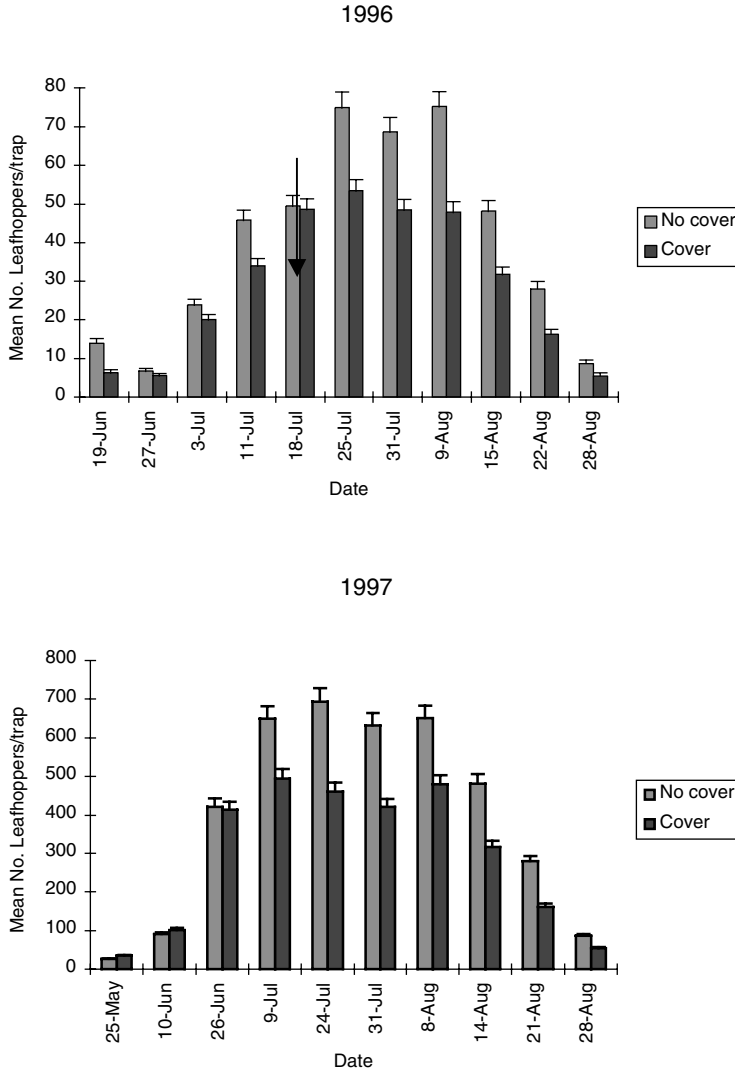

Figure 98.4 Densities of adult leafhoppers, *E. elegantula*, in cover-cropped and monoculture vineyards in Hopland, CA, in two growing seasons. Mean densities (number of adults per yellow sticky trap) and standard errors of two replicate means are indicated. In some cases, error bars were too small to appear in the figure.

harbored pollen, nectar, and neutral insects that served as alternative food and hosts for important predators, along with the parasitic wasp *Anagrus* (Nicholls et al., 2000).

Plant diversity around crop fields is also important in determining the diversity and abundance of natural enemies within agroecosystems. Emerging data demonstrate that there is enhancement of natural enemies and more effective biological control where wild vegetation remains at field edges in close association with crops (Altieri, 1994). These habitats are important as overwintering sites for predators, or they may provide increased resources such as pollen and nectar for parasitoids from flowering plants (Thies and Tschamntke, 1999). The presence of plant-rich habitats enhances predator colonization and abundance of adjacent crop fields but this influence is limited to the distance to which natural enemies disperse into the vineyard (Corbett and Plant, 1993). A corridor, however, could amplify this influence by allowing enhanced and timely circulation and dispersal movement of predators from edges into the center of crop fields.

In northern California, taking advantage of an existing 600-m corridor connected to a riparian forest that cut across a monoculture vineyard, we tested whether such a corridor served as a biological highway for the movement and dispersal of natural enemies from the forest into the center of the vineyard. The goal was to determine if the corridor acted as a consistent, abundant, and well-dispersed source of alternative food (pollen, nectar, and neutral insects) for a diverse community of generalist predators and parasitoids (Nicholls et al., 2001).

During 1996 and 1997, a 2.5-ha organic vineyard dissected by a corridor composed of 65 flowering plants species, which was connected to the surrounding riparian habitat, was monitored to assess the distributional and abundance patterns of the western grape leafhopper, its parasitoid *Anagrus* spp., and generalist predators. In both years, leafhopper adults and nymphs tended to be more numerous in middle rows of the vineyard and less abundant in border rows close to the forest and corridor where predators were more abundant (Figure 98.5). The complex of predators sup-

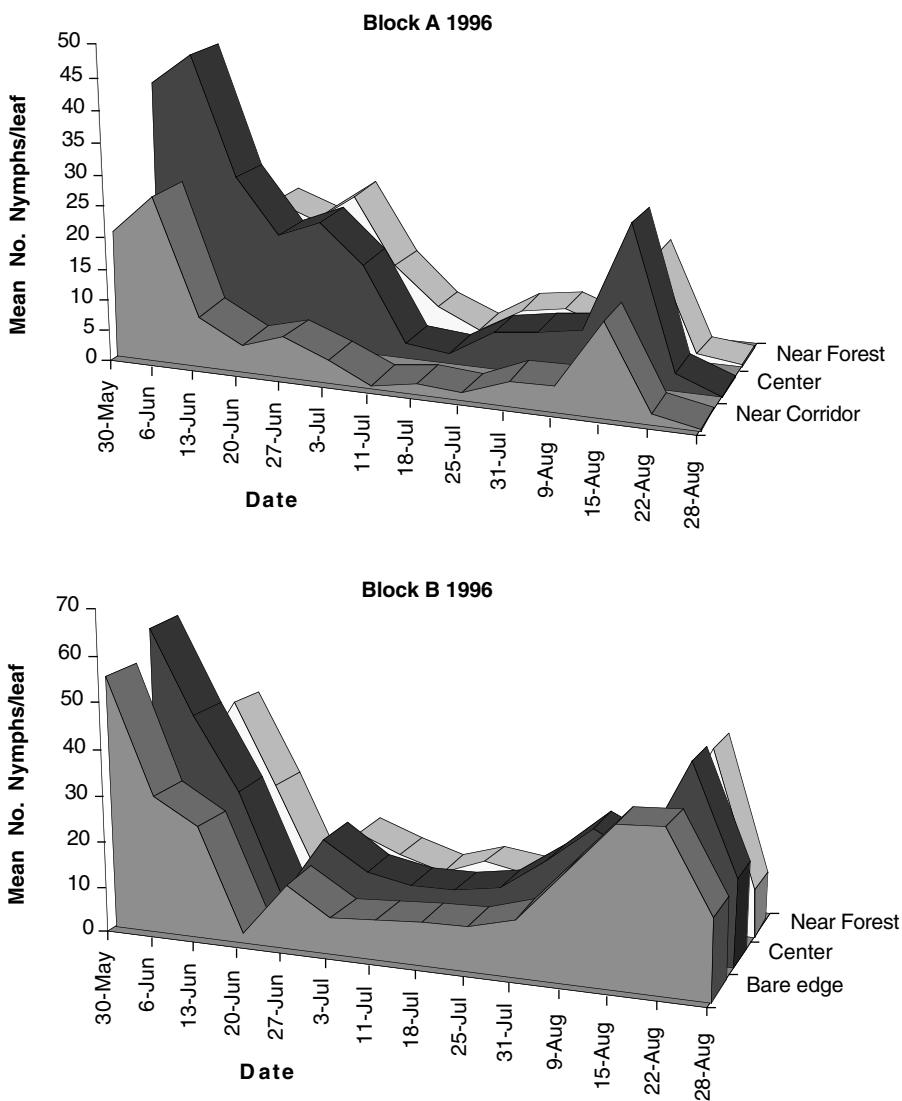

Figure 98.5 Seasonal patterns of leafhopper nymphs in both vineyard blocks, as influenced by the presence or absence of forest edges and the corridor (Hopland, CA, 1996).

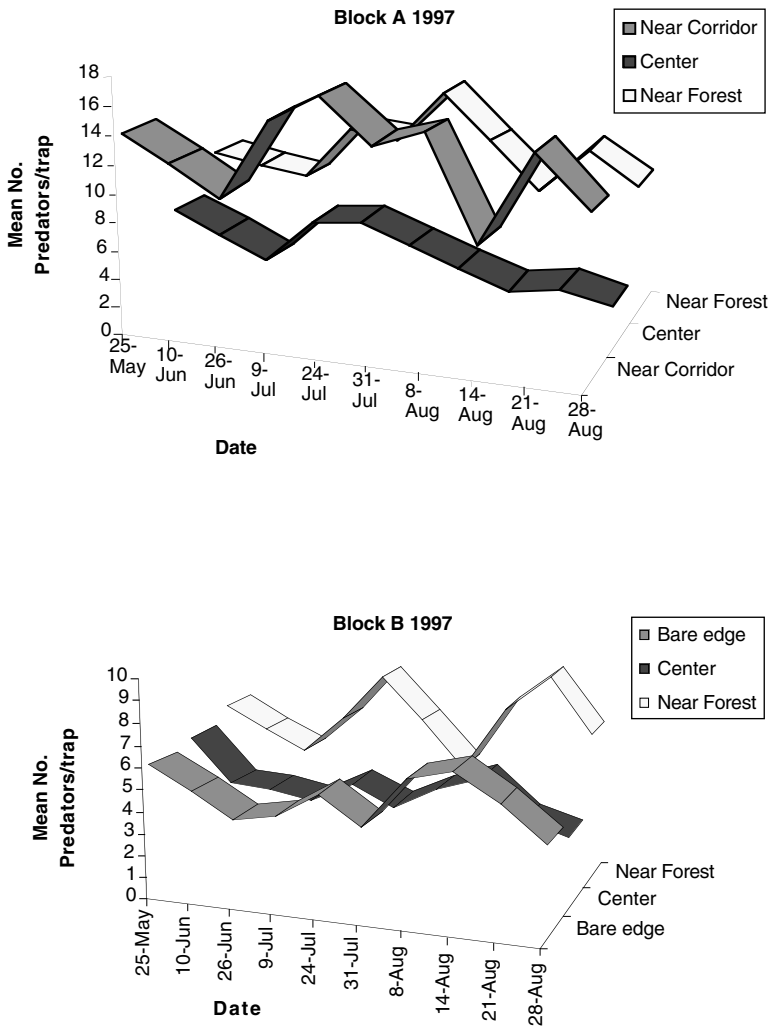

Figure 98.6 Seasonal patterns of predator catches (numbers per yellow sticky trap) in both vineyard blocks, as influenced by the presence or absence of forest edge and the corridor (Hopland, CA, 1997).

ported by the corridor moved to the adjacent vine rows and exerted a regulatory impact on herbivores present in such rows. Although it is suspected that the leafhopper parasitic wasp *Anagrus* depended on food resources of the corridor, it did not display a gradient from this rich flowering area into the middle of the field. Likewise, no differences in rates of egg parasitism of leafhoppers could be detected in vines near the corridor or in the vineyard center. The presence of riparian habitats enhanced predator colonization and abundance on adjacent vineyards, although this influence was limited by the distance (about 25 m) to which natural enemies dispersed into the vineyard (Figure 98.6). However, the corridor amplified this influence by enhancing timely circulation and dispersal movement of predators into the center of the field.

CONCLUSION

Achieving health in agroecosystems requires that management be directed at improving soil and plant quality, as the link between healthy soils and healthy plants is fundamental to EBPM.

Of key importance is also the realization that the level of internal regulation of function in agroecosystems is largely dependent on the level of plant and animal biodiversity present. In fact, there is overwhelming consensus that agroecosystem function may be significantly impaired by loss of biodiversity. In agroecosystems, biodiversity performs a variety of ecological services beyond the production of food, including recycling of nutrients and regulation of pest populations. For this reason, agroecologists promote multifunctional technologies that conserve or enhance biodiversity, as their adoption usually means favorable changes in various components of the farming systems at the same time. Many of these techniques do not demand a radical change in the farming system, but rather the establishment of the right type of ecological infrastructure that promotes key regulatory processes. An example is legume-based crop rotations, one of the simplest forms of biodiversification, that can simultaneously optimize soil fertility and pest regulation. It is well known that rotations improve yields by the known action of interrupting weed, disease, and insect life cycles. However, they can also have subtle effects, such as enhancing the growth and activity of soil biology, including vesicular arbuscular mycorrhizae, which allow crops to more efficiently use soil nutrients and water and thus better resist pest attack.

Many scientists are concerned that, with accelerating rates of habitat simplification through monoculture expansion, the contribution to pest suppression by biocontrol agents using these habitats will decline (Fry, 1995). This is why many researchers have proposed options to rectify this decline by increasing vegetational diversity within agroecosystems and throughout agricultural landscapes. Options include diversifying cropping systems with polycultural designs and maintaining wild vegetation adjacent to crop fields (Thomas et al., 1991).

The ultimate goal of agroecological design is to integrate components so that overall biological efficiency is improved, biodiversity is preserved, and the agroecosystem productivity and its self-sustaining capacity is maintained. The goal is to design a quilt of agroecosystems within a landscape unit, each mimicking the structure and function of natural ecosystems, i.e., systems that include:

Vegetative cover as an effective soil- and water-conserving measure, met through the use of no-till practices, mulch farming, and use of cover crops and other appropriate methods.

A regular supply of organic matter through the regular addition of organic matter (manure, compost, and promotion of soil biotic activity).

Nutrient recycling mechanisms through the use of crop rotations, crop livestock systems based on legumes, etc.

Pest regulation assured through enhanced activity of biological control agents achieved by introducing and conserving natural enemies and antagonists.

Irrigation, Agricultural Drainage, and Nutrient Loading in the Upper Klamath Basin

Stephen R. Kaffka, Ashk Dhawan, and Donald W. Kirby

INTRODUCTION

The Upper Klamath Basin (UKB) is a high desert region straddling the California–Oregon border east of the Cascade Range. Because precipitation averages approximately 25% of potential evapotranspiration, irrigation is necessary for crop production. Irrigated agriculture is the basis of the local economy. The UKB is the location of wildlife refuges that are critical for migrating waterfowl using the Pacific Flyway, and one of the sources of the Klamath River, which is important for its scenery, trout, and anadromous fisheries. Two native fish species in Upper Klamath Lake are listed as endangered, and steelhead trout and coho salmon also are listed or are likely to be listed as threatened or endangered in the Klamath River in the near future.

Irrigation and other agricultural practices in the U.S. Bureau of Reclamation (USBR) Klamath Project may result in impaired surface water quality, reducing its use for wildlife and fish in the Tule Lake National Wildlife Refuge (TLNWR), the Lower Klamath National Wildlife Refuge (LKNWR), and the Klamath River. Surface water within the basin can have high pH levels (> 9.0 in summer), high levels of nonionized ammonia (NH₃) (>1.0 mg l⁻¹), and low dissolved oxygen (DO) during warm months (MacCoy, 1994). These quality characteristics are related to the growth, death, and decomposition of algae and other aquatic organisms.

The relationship between agricultural drainage and surface water quality in the region is not well understood. Shallow waters in the UKB have always been eutrophic, but likely have been further enriched by human activity, particularly farming, grazing, and logging. Farming may enrich surface water with nitrogen and phosphorus from fertilizer applications or from the mineralization of the region's organic-matter-rich soils resulting from cultivation. Any effects on surface water quality resulting from agricultural drainage likely occur through stimulation of aquatic plant growth at higher than background levels by nutrients, especially phosphorus, lost from farm fields.

Nonpoint source (NPS) pollution of surface waters has been recognized as a significant problem nationwide for many years (Novotny and Chesters, 1981). The loss of nutrients from agricultural landscapes can lead to impairment of surface waters for other uses, including wildlife conservation. In the UKB, important conservation objectives for waterfowl and fish are linked directly to the use of land and water for irrigated agriculture because much of the water for the wildlife refuges is derived directly from agricultural drainage, and return flows from the project enter the Klamath River. To protect surface waters from NPS pollution, the current federal Clean Water Act provides

for the establishment of standards or limits, called total maximum daily loads (TMDL). By court order, TMDL standards must be set for the Klamath River by 2004.

In addition to water quality concerns, local farmers are faced with the loss of part or all of their irrigation supplies owing to restrictions related to the Endangered Species Act. The loss of irrigation water or narrow restrictions on the quality of drainage water will undermine the economic viability of the local community. The resolution of regulatory issues in the UKB provides a test of whether more ambitious conservation objectives related to species preservation or recovery can be adopted while maintaining the economic use of natural resources in rural, irrigation-dependent areas of the western U.S.

The USBR has measured surface water transfers since the project began in 1907, and water quality over a 60-year period, but sampling and analysis have not been consistent throughout this period. The U.S. Fish and Wildlife Service and the U.S. Geological Service (USFWS/USGS) carried out a multiyear sampling and analysis program for surface waters in the region (Sorenson and Schwarzbach, 1991; MacCoy, 1994). Snyder and Morace (1997) analyzed and modeled the rates of mineralization of organic soils surrounding Upper Klamath Lake in Oregon. Their model predicted large losses of N and P from mineralizing organic soils, but the concentrations they measured in agricultural drainage water were less than they predicted. Kaffka and co-workers (1995) reviewed all available historical data, and collected limited surface and subsurface tile drain data with the objective of formulating initial hypotheses about the relationship between agricultural nutrient losses and surface water quality. Their analyses included estimations of water and nutrient application rates by farmers and an assessment of long-term trends in surface water quality in the region. On the basis of USBR data, they reported a decline in the salinity of surface waters (measured as electrical conductivity) draining the Tule Lake Sumps and the Tule Lake Irrigation District (TID) from 1945 to 1990 (Figure 99.1). A salt balance calculated for the irrigated areas of the TID by USBR supports the hypothesis that by the 1980s, salt inputs and outputs were in approximate balance (Kaffka et al., 1995). Fewer data were available for determining trends for total P concentrations in surface waters. Sample collections and analyses made by the USBR and reported in Kaffka and co-workers (1995), revealed no apparent trend over the 10-year period from 1980 to 1990 (Figure 99.2). Salinity and P concentrations in water samples were not correlated during the period (Figure 99.3), suggesting that P concentrations in surface waters are not related linearly to the leaching and drainage processes resulting in the loss of salts from soils. They also collected a limited number of agricultural tile drain samples to estimate salt and nutrient losses but the number collected was insufficient to evaluate season-long nutrient concentrations and possible transfers from soils to surface waters.

Figure 99.1 EC_w ($\mu S\ cm^{-1}$) in the Tule Lake Sumps, measured at the D pump outlet. (From Kaffka, S.R. et al., Res. Prog. Rep. 108, University of California Intermountain Research and Extension Center, Tulelake, 1995.)

Figure 99.2 Total P measurements (mg l⁻¹) at the D pump outlet reported in Kaffka, S.R. et al., Res. Prog. Rep. 108, University of California Intermountain Research and Extension Center, Tulelake, 1995.

Figure 99.3 Total P and EC_w data over the 1980 to 1990 period. (From Kaffka, S.R. et al., Res. Prog. Rep. 108, University of California Intermountain Research and Extension Center, Tulelake, 1995.)

To investigate further the relationships between agricultural practices and surface water quality in the UKB, we have undertaken a multiyear reconnaissance survey of surface water and agricultural tile drain locations. The objectives of this effort are:

- To collect and analyze subsurface tile drain and surface water quality samples throughout the TID and surrounding locations.
- To integrate results with previous analyses into a hypothesis linking surface water quality with agricultural drainage.

This chapter presents results to date from the ongoing investigation.

MATERIALS AND METHODS

Starting in 1995, a reconnaissance sampling program for surface water and agricultural sub-surface tile drains was carried out in the southern portion of the USBR Klamath Project, focusing

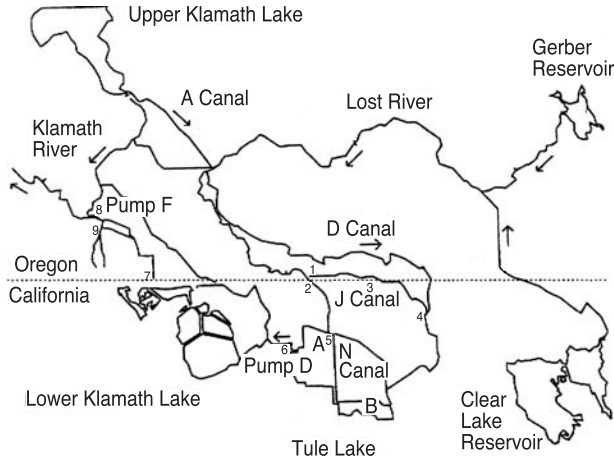

Figure 99.4 The Klamath Project in southern Oregon and northern California. The Tule Lake Irrigation District at the bottom of the map is the primary focus of monitoring and mass balance calculations. For an explanation of the numbers next to the sample points, see Table 99.1.

particularly on the TID (Figure 99.4; Table 99.1). Triplicate samples were collected at approximately 10-day intervals throughout the growing season (April through October) from tile drains and surface water sampling locations; in winter, surface water samples were collected twice a month or as often as possible. In 1995, five tile drain locations were sampled; in 1996, eight additional subsurface tile drains and additional surface sample sites were included. The 13 tile drain sample points are located throughout the irrigation district, with eight in the Lease Lands area, part of the TLNWR. Samples were collected directly from tile drain outlets, or if tile outlets were submerged, directly from tile lines near the drain outlets fitted with backflow check valves, using a small portable pump. Some samples were collected from drainage sumps fitted with lift pumps, integrating drainage water from several tile lines. Surface water samples were collected from inflow locations (J canal diversion [1], the Lost River as it enters California from Oregon [2], pump 7 [3], D canal

Table 99.1 Description of Surface Water Sample Locations

Location No.	Name	Description
1	J canal diversion	Anderson-Rose (A-R) Dam on the Lost River where water is diverted for irrigation use in the TID.
2	Lost River	The Lost River at the California–Oregon border. Quantities are estimated upstream at the A-R Dam, but there are additional, unaccounted return flows from farm fields added to the river before it reaches the state line.
3	Pump 7	Drainage canal from the Klamath Irrigation District to the north of TID. Water volume is poorly quantified.
4	D canal	Irrigation diversion–drainage canal from the KID adding to water supplies in the TID. Water volume is poorly quantified.
5	N canal	Irrigation return flow–Irrigation diversion canal.
6	D pump	Outlet for surplus water from the Tule Lake Sumps to the Lower Klamath Refuge and eventually the Klamath River.
7	Lower Klamath Refuge outlet (LKL)	Water leaving the Lower Klamath Refuge.
8	Klamath Straits Drain outlet (KSD)	Pumps F and FF at highway 97 in Oregon. Water leaving the straits drain enters marshlands and the Klamath River at this point.
9	ADY canal	Water is re-diverted from the Klamath River to the Lower Klamath Refuge and to provide irrigation water for the Klamath Drainage District (KDD).

[4], and selected distribution canals [5]) and outflows (D pump [6]; and the Klamath Straits Drain at its origin, leaving the LKNWR [7], and at its end by the lift pump intake near highway 97 [8]). These surface water locations trace water quality as it enters the TID, as it leaves, and as it returns to the Klamath River. They allow for an estimation of the amounts of nutrients transferred within and outside of the southern Klamath Project. One of the possible measures of ecosystem health, a subjective term, might be the retention or loss of ecologically important nutrients such N and P.

At collection, water temperature, pH, and electrical conductivity (EC_w : a measure of salinity) were determined. Samples were stabilized with toluene and refrigerated until analysis. Sample aliquots were filtered through 5- μ m filters and analyzed for filterable, reactive (largely inorganic) P by direct colorimetric analysis (AOCS 973.55; Watanabe and Olsen, 1965) and for soluble N (NO_3 -N) using HPLC methods (Thayer and Huffaker, 1980). Typically, 0.45- μ m filters are used for this procedure (Haygarth and Jarvis, 1999). In the UKB, most of the surface water samples are so laden with algae, aquatic plants, and other materials that filtration with smaller-diameter filters has proved impractical. A second aliquot was digested using a procedure modified from Johnes and Heathwaite (1992), using persulfate digestion. Digested samples were then analyzed for N and P using HPLC and colorimetric methods as above. Starting in 1999, filtered samples were redigested and analyzed for P as above. A schematic diagram of the analysis protocol is presented in Figure 99.5. Ammonia is collected separately in acidified sample bottles and refrigerated until analysis. HPLC and spectrophotometry methods are used for determination (Goyal et al., 1988).

Farmers were surveyed about fertilizer use, and fertilizer suppliers were interviewed about typical fertilizer application rates in the TID. Crop water use was estimated by Kaffka and co-workers (1995) based on data from California's statewide CIMIS weather data collection system combined with crop water use estimates developed over several years for a variety of crops in the region. A modified Penman–Montieth equation was used to predict ET_c (Snyder et al., 1987).

The proportion of irrigation water resulting in drainage was derived from Kaffka and co-workers' (1995) estimate of irrigation efficiency and TID data. Water use efficiency (WUE) was calculated as:

$$WUE (\%) = [\sum ET_c / (\sum ID \pm P)] * 100 \quad (99.1)$$

where ET_c is crop evapotranspiration; ID are net irrigation diversions derived from TID records; and P is yearly precipitation derived from weather station records (CIMIS) in Tulelake. Irrigation diversions include measurements at the J canal and net diversions from the Tule Lake Sumps. Water is transferred back and forth between the sumps and irrigation canals during the growing season.

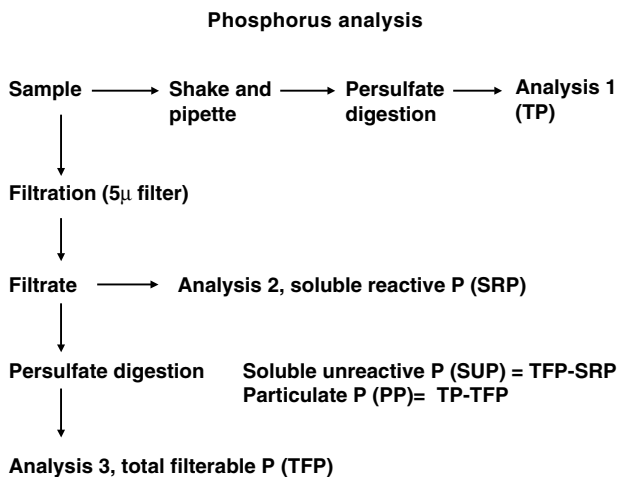

Figure 99.5 Protocol for the analysis of P in water samples.

Net transfers can be calculated from TID pump records (Kaffka et al., 1995). The water diverted but not used as ET_c is assumed to be agricultural drainage returned to the system. This value is 67% and corresponds to best estimates from agronomists working in the area. If precipitation is included in the equation, then the final value for crop water use is approximately 60%.

These assumptions about drainage water volume are conservative with respect to the potential contribution of agricultural drainage to surface water P and N levels. By conservative we mean that it is a maximum possible amount, and we may overestimate net drainage losses but are unlikely to underestimate them. This is because in practice less water is specifically diverted for irrigation than is applied to crops as irrigation in the TID. Diversions at the J canal roughly match ET_c estimates. Additional irrigation water is derived from other sources. During the irrigation season, water returning to the system as drainage is reused as an irrigation source by farmers downstream (roughly south) within the district. This water becomes enriched upon reuse with salts and possibly with nutrients. Also, there are poorly quantified drainage inflows, which serve as inputs into the TID from the irrigation district to its north, the Klamath Irrigation District (KID). Water is also diverted from the Tule Lake Sumps. Thus, the pathways and disposition of water within the district are extremely complex and poorly understood.

A recent study provided a higher estimate for WUE for the TID subregion of the Klamath Project. Davids Engineering (1998) estimated that water diverted for irrigation was used with very high efficiency by farmers in the project, with an estimate of 74% for WUE, and 93% for effective efficiency, a term attempting to account for reuse of drainage water by farmers on a project-wide basis, accounting for inputs and drainage among the sequentially related irrigation districts within the Klamath Project. The reuse process within the TID, however, is just now being modeled specifically and results are not yet available; thus the larger estimate for drainage is used instead.

Deep percolation below tile line depth is considered to be a small loss, and is discounted in this analysis because arable soils are underlain by deep, largely lucustrine clay deposits with extremely low rates of infiltration and hydraulic conductivity that are saturated most of the year (NRCS, 1994). Artificial drainage is required for farming. Additional justification for discounting deep soil drainage is indirect and is provided by the observation that overall water balances account for water inputs and outputs without large drainage losses to deeper soil profiles. Water balances for the area including the TID are calculated as:

$$I_p \pm I_J \pm I_{LR} \pm I_{KID} = O_D \pm O_{ET_c} \pm O_{ETL} \quad (99.2)$$

where I_p is a water input from precipitation; I_J is the water diversion at the J canal; I_{LR} is the water entering the Tule Lake Sumps from the Lost River; I_{KID} is water entering the TID as drainage from KID to the north. O_D is an output, water pumped from the Tule Lake Sumps at the D pump plant; O_{ET_c} is crop evapotranspiration; and O_{ETL} is evapotranspiration from the Tule Lake Sumps, considered to be equivalent to losses from an open water body. The water equation is balanced by adjusting I_{KID} , but the values determined this way are similar to those estimated by TID personnel and in the Davids Engineering study.

Data for the amount of water transferred from place to place within the Klamath Project are available from the USBR. Long-term data (1961 to 1995) were used to develop yearly and monthly averages using statistical software. For this report, an average year is evaluated using average total P and salinity concentrations and yearly water volumes. Using this approach, mass balances for salts (as TDS) and total P were calculated. P is emphasized because it is generally the limiting element for algal and aquatic plant growth in most freshwater systems and is the subject of heightened concern in the analysis of agricultural systems worldwide (Haygarth and Jarvis, 1999; Heckrath et al., 1995; Novotny and Chesters, 1981). Also, N is not thought to limit aquatic plant life in the surface waters of the UKB. Large amounts of blue-green algae are commonly present and some of the species are capable of N fixation, providing that sufficient P is available. Phosphorus transfers in aquatic systems can be complex and the form of P present can be important in regulating aquatic productivity

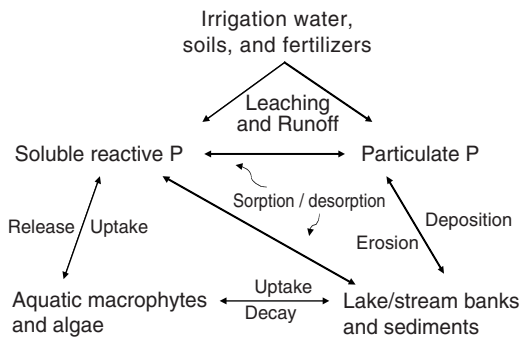

Figure 99.6 Phosphorus transformations during transfer from agricultural to aquatic systems. (Adapted from Sharpley, A.N. et al., in *Phosphorus in the Global Environment*, Tiessen, H., Ed., John Wiley & Sons, New York, 1995, pp. 171–199.)

(Figure 99.6; Sharpley et al., 1995). This analysis ignores unknown transfers within the aquatic portion of the ecosystem. There has been no study of these processes to our knowledge, and studying the mechanisms regulating them in the UKB is beyond the scope of our analysis.

RESULTS

Fertilizer Use and Crop Uptake

Responses to a questionnaire about fertilizer application rates from farmers ranged from less than 15% of all planted acres for sugar beets to greater than 25% of all planted acres for small grains. Nevertheless, average farmer responses agreed closely with estimates provided independently by the primary fertilizer supplier in the region for all the important crops. On average, crops take up and remove more N but less P than is applied as fertilizer. In particular, potato crops are heavily fertilized, thus most of the P surplus results from applications to potatoes (Table 99.2).

Table 99.2 Estimated Annual Average Fertilizer Application and Crop Nutrient Removal in the TID (mg yr⁻¹)

Crops and Land Area	N			P		
	Fertilizer N Application	Crop N Removal	Difference	Fertilizer P Application	Crop P Removal	Difference
Small grains (13,200 ha)	1300	1400	-100	170	330	-160
Potatoes and onions (4970 ha)	1110	780	330	530	210	320
Sugar beets (2390 ha)	240	530	-290	110	60	50
Alfalfa (4,660 ha)		(2200)		130	175	-45
Total (25,220 ha)	2640	2710	-60	940	775	165
Mg ha ⁻¹ yr ⁻¹			-0.0024			0.0065

Fertilizer inputs are based on recommended rates developed by the university, a survey of farmers and fertilizer dealers, supplemented by reports from individual farmers about their fertilizer use and the amount of land they cultivate. Crop removal is calculated based on literature values, or in the case of small grain crops, average crude protein values for the barley, wheat, and oats produced in the region. Crop yields and land areas are derived from annual reports by the TID, and are averages. All figures are rounded. Per unit area, potatoes and onions receive the most fertilizer, and for P, applications result in a district-wide surplus. N is in approximate balance if the assumption is made that all N removed by alfalfa is fixed from the atmosphere. If some N is recovered from soil by alfalfa, then N removed by crops is greater than N applied.

Water Balance and Use by Crops

Water transfers within the southern portion of the Klamath Project are presented in Figure 99.7 and Table 99.3. Approximately 40% of the water entering the TID from all sources including precipitation is diverted to the Lower Klamath National Wildlife Refuge. This water is supplemented and mixed with water from the Klamath River via the ADY and North Canals primarily and then returned to the Klamath River, acquiring additional agricultural drainage along the way as it passes through the Klamath Drainage District (Figure 99.4).

A water balance for the TID, the primary agricultural area in the southern Klamath Project is shown in Figure 99.8, and a water balance for irrigated cropland is shown in the TID in Figure 99.9. A quantity of water approximately equal to estimated ET_c in the TID is diverted into the J canal for irrigation. Other inputs include flows in the Lost River, and drainage from the KID to the north of TID or into the Lost River below the Anderson-Rose Dam but above the Tule Lake Sump. KID drainage and return flows to the Lost River are not well accounted for, and are assumed to be equal

Figure 99.7 Long-term average water flows in the Klamath Project at the most important surface water sample points (USBR data, 1962 to 1995).

Table 99.3 Water Balance Data

Location or Source	Amount (m ³ yr ⁻¹ × 10 ⁶)	Source of Data
J canal	154.5	TID and USBR records
Lost River (LR)	33.0	TID and USBR records
Precipitation	64.6	CIMIS data for Tule Lake
Klamath Irrigation District (KID)	48.1	Estimated (see text)
D pump	112.7	TID and USBR records
Crop evapotranspiration (ET_c)	148.0	Estimated based on crop acreage records from TID, CIMIS weather data, and the use of a modified Penman–Montieth equation (see text)
Sump evaporation (ET_{TL})	39.5	Estimated based on CIMIS data and corrected for the effects of open water bodies on lake evaporation
Cropland drainage	107.8	Estimated: Equal to average J canal diversions + precipitation + diversions from the Tule Lake Sumps to cropland during the growing season - ET_c - evaporation from irrigation canals; ^a data for diversions from the Tule Lake Sumps from Kaffka et al. (1995)

^a Losses from irrigation canals and drains are assumed to be equal to 80% of the year-long panevaporation amount derived from the CIMIS weather data system (880 mm) and a surface area of 4.86 km².

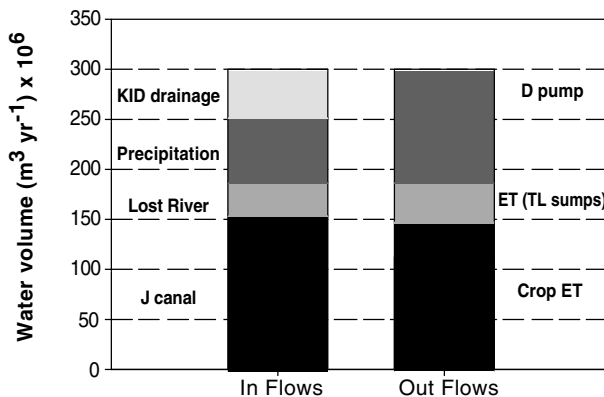

Figure 99.8 A water balance for the TID. All values are long-term averages and are based on USBR data for surface water flows, estimated crop evapotranspiration, calculated amounts of evaporation from the Tule Lake Sumps based on surface area and meteorological values. KID values are calculated by difference (see text).

Figure 99.9 A water balance for irrigated crop land in the TID (see Table 99.3 for details).

to the amount of water needed to balance water use and transfers among the regions within the study area. Unaccounted outputs (Figure 99.9, Other) are largely due to canal evaporation losses.

Mass Balances for Salts and P in the TID

The most common salts in surface waters in the UKB are calcium and sodium sulfates (Sorenson and Schwarzbach, 1991; Kaffka et al., 1995). The quantity of salt leaving the TID is approximately equal to the amount introduced in surface waters from all sources combined (Figure 99.10). This result supports the conclusions USBR project managers reported a decade ago (Kaffka et al., 1995). Salts also increase as water is reused, passing from the northeast to the southwest of the TID. Values for tile drains in the northeastern region of the TID average approximately 600 $\mu\text{S cm}^{-1}$, while in the southwest portion of the district they increase to 2000 $\mu\text{S cm}^{-1}$. This increase is a function of the reuse of water and higher levels of salinity in soils in some of the southwest areas of the district (Sorenson and Schwarzbach, 1991). The EC_w measured in surface waters over the 1995 to 1999 period also increase as water passes through the region. Water entering the district averages somewhat less than 300 $\mu\text{S cm}^{-1}$, water leaving the Tule Lake Sumps at the D pump increases to 600 $\mu\text{S cm}^{-1}$, and water reentering the Klamath River increases further to approximately 900 $\mu\text{S cm}^{-1}$.

Figure 99.10 Calculated mass balance for salt entering and leaving the TID, based on EC_w values for surface water samples. The amount of salt entering and leaving the TID (columns 1 and 2) is in approximate balance. EC_w was converted to TDS using the equation $TDS (mg l^{-1}) = EC_w (dS m^{-1}) \times 640$ (Mg = megagrams = metric ton).

Figure 99.11 Calculated mass balance for P entering and leaving the southern portion of the Klamath Project. Less P leaves the TID in surface water at the D pump, then enters with irrigation water.

Phosphorus behaves differently in soils and surface waters. At the scale of the watershed, the concentration of P increases as water travels from its entry into the TID to its return to the Klamath River. But the quantity of total P returned to the Klamath River is estimated to be lower than the amount of P entering the TID in surface waters because the amount of water returned is less than that diverted (Figure 99.11). The diversion of water through the southern portion of the Klamath Project, exclusive of use by the Klamath Drainage District north of LKNWR, including its use for agriculture and wetlands, results in an apparent storage or removal of P from the surface waters transferred through the system.

At the irrigation district scale, mean yearly total P concentrations in representative subsurface tile drains and drainage sumps from 1995 through mid-1999 are reported in Figure 99.12. These values on average do not reflect a large increase over the average total P concentration of waters diverted for irrigation at the J canal (Figure 99.13). If this increase (adjusted for drainage water volume) is assumed to equal the contribution to surface waters from agricultural soils, the net amount of P derived from agricultural tile drains is less than the amount of P imported in irrigation water, and is small with respect to the amount of P applied as fertilizer. This includes other types of drains in the district as well.

Figure 99.12 The average P concentrations (mg l⁻¹) observed in tile drain samples from 1995 to mid-1999. P losses in samples collected in the northeastern area of the TID are larger on average than those collected in the southwest portion of the district.

Figure 99.13 The average P concentrations (mg l⁻¹) observed in surface water samples collected from the J canal input location, compared with the D pump and Lower Klamath Refuge (LKL) outflows.

At the farming system scale, the amount of P introduced as fertilizer in the TID is approximately an order-of-magnitude greater than the amount of P entering the TID in surface waters. The amount of fertilizer P applied in excess of crop removal equals an amount approximately five times larger than the amount of P leaving as drainage water (Figure 99.14). Even if the highest average values for tile drainage concentrations are used instead of the district average, tile drainage losses remain small compared with other sources. If all inputs of P are added, and all outputs including crop removal and water transferred at the D pump are subtracted, then there appears to be a net accumulation of P of approximately 8 kg/ha per year. This P, derived both from imported water and from surplus fertilization, appears to be accumulating in soils and lake sediments in the region, but primarily in soils (Table 99.2).

DISCUSSION

Sources of Uncertainty in the Estimates

There are several sources of uncertainty associated with the estimates for salt and total P provided. The measurement of water volumes transferred within the basin is based on the field-

Figure 99.14 A phosphorus balance for the Tule Lake Irrigation District, including the TLNWR. All known inputs are included. Atmospheric deposition is unknown. Tile drain outflows are estimated using an irrigation efficiency of 67% and an average total P concentration of 0.34 mg l⁻¹.

rated capacity of pumps and measurements at weirs and gauging stations by USBR. All of these measurements are subject to error. In particular, Davids Engineering estimated recently that water balances for the southern- and westernmost portion of the project, comprising LKNWR and the farming areas of the Klamath Drainage District, were poorly accounted for. They suggested that pump ratings for the Klamath Straits Drain outlet (Figure 99.4, no. 8) may underreport the amount of water transferred at that location, while an apparently larger volume of water enters that part of the watershed than can be accounted for by the measured flows at the facilities maintained by USBR, particularly the ADY canal. If more water is being imported into this portion of the watershed than is accounted for, then the amount of nutrients imported also is underestimated. Alternatively, if export amounts are underreported, then the amount of nutrients leaving the Klamath Project and entering the Klamath River at this location also are underreported.

Agricultural fields are drained using three different types of systems. One is a combined series of collector tiles feeding a common sump and also usually intercepting water passing along one side of the field in an irrigation supply canal. Five of our sample locations are of this type. Another type of tile system consists of individual lines draining directly into surface drains at the ends of fields. Eight of our sample locations are of this type. The most common system is a deep ditch along one end of a field, emptied periodically into a master drain with a pump. Identifying the source of nutrients in the water derived from this last source is uncertain, because nutrients may originate from neighboring fields, from sediments, or from mobilization within the ditch or canal due to the biological and physical processes occurring in the ditches themselves, or from both. Because of this uncertainty, we believe that the water samples collected from simple tile drains best represent the subsurface soil water nutrient concentrations that have the potential to appear in surface waters. Nevertheless, we average all subsurface tile drain values together in estimating a value to use for drainage transfers.

The reuse of drainage water for irrigation throughout the Klamath Project further complicates the estimation of nutrient contributions from agriculture to tile drains. Each time water passes through the soil profile, it dissolves soluble salts and nutrients. Salt concentrations increase in the TID from north to south, reflecting increasing water reuse in that direction. The tile lines located in the southwestern portion of the district, however, average 0.24 mg total P l⁻¹, while those in the northeastern area average 0.42 mg total P l⁻¹. The latter are primarily drainage sumps. The data suggest that total P in tile drains declines as water is reused. There are several possible reasons for this trend. One reason is that more row crops are grown in the northeastern portion of the district on private lands than in the southwestern portion on public or refuge lands, where grains are more

common. Thus greater nutrient concentrations in these locations may reflect higher rates of fertilization, especially over time (Table 99.2). Another reason is a difference in the behavior of the drainage systems sampled. In the north portion of the district, sumps that integrate several field tile drains with water intercepted at field edges from agricultural drains are sampled. These values have been consistently higher than the simple tile line values. Differences between the two systems may reflect different hydrologic behaviors of the drainage system and the interception of P from other sources in the more-complex sump drainage systems. Additionally, N and P applied with irrigation water serve as inputs to the cropping system, contributing ultimately to the nutrient supply used by crops. In contrast, salts are not taken up except by sugar beets, and then only in small quantities. Thus, salt concentrations increase while N and P concentrations do not, suggesting that soils and crops act as nutrient sinks.

Our sampling of tile drainage is not linked directly to irrigation cycles. Upon initial soil saturation, drainage volumes increase, and concentrations of salts and some nutrients will be greater than later in the cycle. Over the period of sampling, tile drainage samples were collected at various times during the irrigation–drainage cycle and reflect the range in concentrations possible. Averaging them may underestimate the loading rates from waters derived from tile drains, particularly for salts. In any case, the behavior of soluble constituents in the soil water system of these unique organic soils is poorly understood. In particular, salt leaching is more complex in bicarbonate-dominated soil water systems such as those of the UKB than otherwise (Oster and Rhoades, 1975). Simple leaching ratios may not predict salt-loading rates because bicarbonate can increase salt solubility. Salt solubility may also be increased by oxidizing organic matter in the organic-matter-rich soils of the region. The behavior of N and P is more complex still because of their role in plant growth and microbiological activity and the complex solubility chemistry of P in soils.

We have adopted a simplified approach to determining mass balances in the region. By using an average year, we have simplified within-year variation. To date, we have detected no consistent pattern of variation in surface water nutrient concentrations, other than a tendency for concentrations to be higher during the early winter and spring periods when no water is being transferred from farm fields (data not shown). Fewer samples have been collected during this period of the year, however, and a seasonally adjusted mass balance will be attempted when sufficient data have been collected after the current cycle of sampling is completed.

Finally, we have not attempted to interpret the differences in the relative contribution of agricultural drainage to differences in bioavailable P or other types of P transferred from location to location in the UKB (see Figure 99.4). This may underestimate the importance of agriculturally derived P in nutrient cycles in the UKB. Sharpley et al. (1995) note that the form of P entering surface waters is important for its effects on productivity. However, in the UKB, surface waters are all shallow (typically less than 2 m), and subject to constant agitation from wind and from turbulent flow of water due to diversions and transfers. This suggests that sedimentary P is constantly resuspended in the shallow surface waters, and internal cycles between sediments and aquatic plants have the largest potential to influence levels of productivity (Figure 99.6). Phosphorus concentrations measured in the outflows of the two refuges (TLNWR/LKNWR) have been fairly consistent over the years (data not shown). This suggests that these values reflect the dynamics of the wetland systems rather than external loading rates.

Agriculture and Ecosystem Health in the Southern, Upper Klamath Basin

All older reports about water quality in the UKB, including simple observations by early explorers, report eutrophic and saline conditions (Kaffka et al., 1995). With the construction of the Klamath Project starting in 1905, the natural landscape was altered substantially, particularly by the draining of wetlands and the removal of surplus water as drainage. This alteration doubtless affected a number of native species of fish and waterfowl in the UKB, and may have caused some species extinctions in recent history that are not recognized. The hydrology of the UKB also was altered, particularly by

linking the Klamath and Lost River watersheds, which were previously separate, and by conserving more water in the upper basin late in the season than would have been conserved naturally. Organic soils developed in the region's shallow wetlands under anaerobic conditions may have released large amounts of organically bound nutrients when first exposed to air and cultivation (Snyder and Morace, 1997), enriching sediments in the region's lakes and streams. These sediments currently support abundant populations of algae and other aquatic plant species.

Total P concentrations are somewhat higher in the Tule Lake Sumps and in the surface waters draining LKNWR than they are in water in the Lost River used for irrigation. But waters tend to increase in nutrient content in all watersheds as they pass from headwater sources to the rivers delivering them to the sea. It is not likely that the small amount of nutrients derived from agricultural drainage, estimated we believe as a maximum, is ecologically significant when transferred to the already nutrient-rich surface waters of the UKB.

On a mass-balance basis, fertilizer is the primary source of accumulating P in the soils and sediments of the TID. Irrigation district or watershed scale calculations have only recently begun to be made and there are few references to provide perspective. A recent summary reported seven different calculated rates of P accumulation in arable farming systems, from largely temperate areas ranging from 2 to 94 kg/ha/yr⁻¹ (Haygarth and Jarvis, 1999). Five of the estimates were greater than 11 kg/ha/yr⁻¹, placing the TID loading rate in the lower end of the range reported. Nevertheless, accumulating P in soils above crop needs has the potential to result in P release to the environment over time. Heckrath et al. (1995) found in an analysis of the long-running Broadbalk experiment at Rothamsted, England, that P losses in drain tiles increased to undesirable levels only after soil P analyses rose to >60 mg kg⁻¹ Olsen P (NaHCO₃ extraction; see Olsen et al., 1954). There has been no systematic survey of soil P levels in the TID. Kaffka and co-workers (1998) reported Olsen P levels from a sugarbeet irrigation cutoff experiment that ranged between 10 and 20 mg kg⁻¹ on average over the soil profile to tile drain depth (1.1 m). It is not known if these values are typical for the region, nor can it be surmised that lower values in the soils in the UKB result in low values of P loss. Additional systematic surveys are required. In any event, reduction of P fertilization rates to potato crops would reduce loading rates, should be agronomically achievable over time, and would lessen further the potential for agricultural contributions of P to surface waters in the region. Improved fertilization practices for the region's potato crops, where possible, would reduce the amount of surplus P applied as fertilizer, and reduce this rate of accumulation to low or background levels. This strategy would be a positive step for agricultural producers in further reducing any possible contribution of P by farming to the surface waters (Sharpley et al., 1995).

Health is a subjective term, so it has no rightful place in science. The health of the UKB is a function of the observer's preferred reference point, and hence, more a matter of politics than science. The UKB's landscape was substantially altered early in the 20th century by the creation of USBR's Klamath Project. Conditions for many species of waterfowl, fish, and other wildlife were changed. If, for example, the health of the ecosystem is judged from the point of view of waterfowl use and the benchmark is presettlement conditions, then the health of the ecosystem has undoubtedly declined. A more reasonable reference point may be whether the current mixed landscape use results in ongoing or increasing impairment of surface waters for other purposes, particularly wildlife conservation. The capacity to retain or lose ecologically active nutrients like N and P is one possible measurement of ecosystem function that might be useful to decision makers in evaluating the health of the UKB ecosystem. By this standard, P losses do not appear to be quantitatively significant, and the system as a whole appears to conserve P on a mass basis.

Since the alteration of the landscape starting at the turn of the 20th century, there appears to be no compelling evidence that farming in the southern portion of the project, including TID, has significantly increased the rate at which nutrients are transferred to surface waters, or worsened ecosystem function. This conclusion may not be true for the northern portion of the UKB basin, however (Snyder and Morace, 1997). The use of the refuges by waterfowl has remained steady or increased in recent years, as waterfowl populations in the Pacific Flyway overall have recovered

from low numbers in previous decades, though this increase has not been uniform in both refuges (Mauser, D., USFWS, personal communication). The USFWS carries out its own farming operations on the refuges to increase waterfowl-carrying capacity by producing grain crops, and there is abundant evidence that residues from agricultural production elsewhere in the region also increase waterfowl-carrying capacity.

SUMMARY

The salt and nutrient content of surface waters increases as water moves through the watershed from the Lost River and J canal diversion to the Klamath Straits Drain. EC_w levels in input waters at the J canal diversion were approximately $300 \mu\text{S cm}^{-1}$, while water sampled at the D pump increased to $600 \mu\text{S cm}^{-1}$ on average over the sample period, and by the time water reenters the Klamath River, salt concentrations have increased further to approximately $900 \mu\text{S cm}^{-1}$. The salt content of surface waters increased approximately threefold as water moved through the watershed.

The EC_w values observed in tile drains were higher on average than in input waters and surface waters elsewhere in the region. EC_w values averaged approximately $2000 \mu\text{S cm}^{-1}$. Recycling irrigation water through soils in the TID increases the salinity of the water, especially by the time it reaches and is reused in the lease lands area in the southern portion of the district.

For total P, input waters averaged approximately 0.29 mg l^{-1} . Water leaving the Tule Lake Sumps at the D pump increases to 0.34 mg l^{-1} . Water leaving the LKNWR, sampled at the start of the Klamath Straits Drain, averaged 0.34 mg l^{-1} , similar to those at the D pump. The overall increase in P concentration in surface waters was much less than for salt, suggesting that processes other than simple enrichment are occurring, particularly those associated with the exchange of sedimentary P and aquatic plant species.

The average seasonal total P value in tile drains beneath farm fields calculated to date is approximately 0.34 mg l^{-1} . While average total P values in subsurface tile drains were not different from those found at the D pump and the LKNWR outlet, the range in values was great (0.1 to 0.8 mg l^{-1}). Similarly, high $\text{NO}_3\text{-N}$ values were observed at times in tile drains (data not reported). Very high values in tile drains lead to the inference that some fertilizer N and P is lost in drainage water. The amount estimated as lost, however, is much less than the amount of surplus fertilizer P applied and the amount of P surmised to be mineralized from decaying soil organic matter. Snyder and Morace (1997) reported lower tile drain N and P concentrations than their estimated organic matter decay rates would suggest. P from fertilizer and decaying organic matter appears to be accumulating in soils and lake sediments in the region.

Some leaching of soluble soil nutrients is unavoidable when crops are irrigated. Improved irrigation efficiency and reduced fertilizer used together can help bring P inputs and outputs into balance and may reduce further any avoidable losses of nutrients. These objectives should be the subject of an agronomic research program in the region.

Surface waters entering the TID, the TLNWR, and the LKNWR are already enriched with P. It is not clear that further reducing avoidable P losses from farming in the TID can reduce the amount of P present in surface waters sufficiently to make them significantly less eutrophic. The threshold for algae growth in fresh waters is variously reported as between 0.05 and 0.01 mg l^{-1} (Grobelaar and House, 1995), far below the values of waters entering the TID.

SECTION II.11

Grazing Animals and Rangelands

Overview: Grazing Animals and Rangelands

Albert C. Medvitz

California is known for the diversity and importance of its environmental resources. It is a large state with a landmass of about 100 million acres, about the same as that of Japan. California also has a current population of approximately 30 million people, which is growing rapidly and which will double in size in about 30 years. The state also has an important agricultural sector that includes substantial livestock production.

Roughly 40% of the state's land is used for grazing domestic animals. These grazing lands are composed of forest, desert, grasslands, and oak woodlands. Of these grazing lands, about 18 million acres of mostly grasslands and oak woodlands are in private ownership. Somewhat more than 20 million acres of mostly forestlands and desert are in public ownership.

Rangelands in California serve important environmental functions. They maintain the quality and quantity of the state's water supply, support diverse wildlife and native plants, and provide a valuable aesthetic resource for the state's growing urban population. But rangelands are also an important part of California's agricultural production. The animals they support contribute well over \$1 billion per year to the California economy. As a result, conflicts erupt over the use of grazing animals, creating problems in the management of both public and private rangelands. Grazing animals and the ranchers who maintain them are often seen by urban environmentalists as purveyors of ill health to range ecosystems.

Overall, however, properly managed grazing animals have constituted an important mechanism for maintaining the health of California rangelands. This series of chapters describes the extent, diversity, and importance of California's grazing land, summarizes available information on the beneficial impacts of grazing on ecosystem health, describes problems in the protection and beneficial management of range ecosystems, discusses federal and state policy about these lands, and presents the perspectives of scientific managers and sheep and cattle ranchers on the cooperation necessary to achieve scientific management of grazing lands in California.

Changing Public Perceptions of the Ranch: A Preliminary Review of Ancient and Contemporary Claims and Processes

Sally K. Fairfax

INTRODUCTION

The American people in general, and specifically those with environmental/conservation interests, have long had a love/hate relationship with ranching. On the one hand, ranches and ranchers are frequently discussed among our unique contributions to world popular culture. The cowboy image evokes a yearning, if not precisely for cows and sheep, for wide open spaces, simple virtues, masculine self-sufficiency, and healthy living. This image, though widely at variance with the actual working conditions of the real “cowboy,” nevertheless drives movie stars and Los Angeles dentists to purchase Montana ranches. The less well-heeled among us are inspired by the marketing of the ranch mystique to buy all sorts of products including some that are not good for our health, such as high-heeled, pointy-toed shoes and cigarettes. On the other hand, followers of John Muir* have also reviled ranching, ranchers, and livestock as land grabbers, cattle barons, hooved locusts, and whatever else the rhetoric of the day required.

In this chapter, I will discuss these conflicted and — I will suggest, rapidly changing — configurations of the ranch in terms of changing claims on ranch land. Different groups in society have different expectations about ranches, what academics frequently call different claims to ranch land. The claims are manifest in expectations about how the land ought to be managed and the goods and services that the lands ought to provide. These general public claims exist on land that ranchers typically consider their own, and frequently own outright. And, claimants have some pretty effective tools and processes for making their priorities felt. Not surprisingly, therefore, accompanying what I will describe as changing claims and claimants, and their expectations about ranch management, are changing processes for making decisions about how the land will be manipulated to meet the changing expectations.

The claims and processes discussed here present different challenges to the rancher and ranching community. These challenges include theft and trespass. If I think cows are inherently

* John Muir (1838–1914) is widely acknowledged as the dominant figure in American preservationism. He wrote numerous books and magazine articles that are fundamental to the canon of American nature writing. One of his best, *My First Summer in the Sierra* (1911), talks about his adventures and observations working as a shepherd in the Sierra in 1869. He grew to despise the sheep he tended, coining the now famous epithet, “hooved locusts.”

evil, following the familiar rhetoric of Edward Abbey,* “I might feel justified in shooting one. If I think your ranch is my open space, I might feel free to trespass. If I think that your cows are negatively impacting my drinking water or fishing stream, I might lobby for the adoption of federal, state, or local regulation of stream use, on either public or private land. But on the other hand, if I think ranching is a healthy antidote to city life, I might seek a way to come to a ranch and “help out,” so to speak, and I might even be willing to pay for the privilege. So, in and among these challenges are also many opportunities if the rancher — as an individual or as a group — is willing and able to capture them.”

These claims and processes have a long history, one that for many decades focused primarily on the challenges and opportunities inherent in national-level political activity, and on regulatory activity more generally. More recently, the process has become increasingly responsive to individual and market-based decision making.

In this chapter, I am going to do two things. First, I am going to run through a brief history of claims and processes. I am not going to dwell overly on current events. Once I get to the present — the new claims, claimants, and so on — I think things start to look pretty familiar. I will conclude with my opinion of the changing claims, claimants, and processes.

CHANGING CLAIMS AND CLAIMANTS

Ranching’s long history of wearing a black hat, in spite of its rarefied place as a cultural icon, emanates initially, I believe, from the view of ranchers as stealers of land — not just any land, but land belonging to the public and appropriately destined, had it not been stolen, for settlement by hardy yeomen, the “little guy” or “actual settler” who would build a home and become a part of a western community.

Cattle kings is a term of art — it goes along with timber barons — and it arose in a period of our history when “little guys” were increasingly frozen out of settlement and homesteading by the huge holdings which ranchers and timber interests assembled — claimed I should say — in rather flagrant violation or fraudulent manipulation of the 19th century settlement laws.

The legal structure of the disposition era was not inspired. As Robert Nelson has argued in *Public Lands and Private Rights* (1995), almost everything that Congress tried to do failed. Policies pertaining to the arid intermountain west were a particular flop, based as they were on the assumption that family farms would settle the arid lands even as they had succeeded in the Shenandoah Valley or the “old North West.” There was, in fact, no *legal* way for ranchers to take title to the amount of land needed to support a family ranch, as opposed to a family farm in much of the rangelands of the western U.S. Congress refused to heed John Wesley Powell’s** insights and accept the fact that 160 acres, or 320, or even 640 acres, just would not cut it in regions where 1000 acres were routinely needed to support one cow. Faced with these Congressional blind spots, a dominant but not exclusive strategy was for ranchers to simply occupy the land without benefit of title, and control it by force, through the cooperation of the western congressional delegations.

* Edward Abbey (1927–1989) is perhaps most famous for his advocacy of environmental sabotage in his book, *The Monkey Wrench Gang* (1975). A variety of environmental groups, taking a cue from this text, or not, have engaged in sabotage (referred to as *ecotage*, or even *monkey-wrenching*) against the ranching industry by destroying livestock facilities, cutting fences, and so on.

** John Wesley Powell (1834–1902) was a famous explorer, scientist, and ethnographer who wrote the prescient *Report on the Lands of the Arid Region of the United States* for Congress in 1879. Powell advocated distributing the lands of the arid western half of North America differently from the eastern half, where rain-fed agriculture was possible. He argued that land should be classified according to its productive capacity and characteristics, and that settlement should be based on what he called *hydrogeographic basins*. Instead of allocating land in small farm lots of a few hundred acres, Powell advocated community management of pasturelands, timber, and water, coupled to individual ownership of irrigated agricultural plots within a basin. In doing so, he drew on Hispano and Mormon models of settlement, and his extensive knowledge of the native peoples and geography of the West. Powell founded the Bureau of American Ethnography, and was the second director of the U.S. Geological Survey.

And although this method of claiming their place on the public domain worked extremely well for the ranchers — who enjoyed most of the benefits of control and relatively few of the disadvantages of formal title — the strategy was not unchallenged. Those who would homestead were successful in making a number of rival claims to both the unreserved, unentered public domain, and later, to the reserved public domain in national forests. An interesting book written by Helene Zahler (1941) recounts the efforts of eastern labor groups to secure homesteading legislation in order to assure a fair wage to factory workers. They claimed that the public domain land belonged first and foremost to those laborers who were trapped in slavery without the safety valve that the option of western settlement provided. Partially in response to that pressure, Congress enacted the 1862 Homestead Act, and in 1885, a law that made it illegal for ranchers to fence the public domain. More of that later.

Throughout the late 19th century, wrapping themselves in the mantle of the little guy struggling against the Cattle King, homesteaders and potential homesteaders were successful in procuring more and more advantageous terms and conditions for claiming and taking actual title to land ranchers had illegally claimed as their own. The Enlarged Homestead Act of 1909 and the Stock-raising Homestead Act of 1916 encouraged hapless would-be farmers to go west — abetted by promotional brochures from the railroads proselytizing the theory of *dry farming* — and fence in what the ranchers had tried to claim and control. Jonathan Raban's *Bad Land* (1996) is a wonderful recitation of how those homesteaders or *honyokers* made successful legal claims but could not survive economically. Gradually, the railroad towns died and the ranchers reclaimed the lands. Those who followed the morphing of the Montana railroad town of Ismay into Joe, Montana, will find Raban's volume particularly poignant.

The Taylor Grazing Act: The Zenith

With the natural endowments of the arid west on their side, ranchers prevailed over the farmers. The lack of water severely constrained row-crop agriculture. A high point in the rancher's strategy for making claims was the passage of the Taylor Grazing Act (TGA) in 1934. The entire unreserved and unentered public domain in the continental U.S. was turned over to the ranching claimants to eventually become the domain of the Department of Interior's Bureau of Land Management (BLM). The fences that were illegal in 1885 were accepted as evidence of historical use for the purposes of adjudicating rival rancher's claims to portions of the range. The land was semipermanently allocated to ranchers for grazing during specified periods of the year on a permit basis as grazing allotments. Although the TGA specifically states that it confers no title, a series of ambiguous court decisions makes clear that although formal title did not pass to the ranchers, something of value in the permit did. We are still trying to figure out exactly how control is divided between the feds and the ranchers. The claims of ranchers, illegal though they clearly were, have, with the passage of time, ripened into something that apparently cannot be altered without considerable due process and perhaps compensation.

New Claimants, Old Processes

Thus, the informal claim strategy of ranchers worked fairly well until after World War II. At that point, a different and ultimately more powerful group of claimants emerged as a factor in the ranch political economy. Recreation and environmental claimants became active for just about the first time — ranch land and BLM grazing land did not attract much attention as an environmental resource until the mid-1970s — it was, for example, completely ignored in the Wilderness Act of 1965. In the Earth Day era, the arid lands previously more or less defaulted to the ranchers were resurrected in the public view — they had many more values than previously suspected and burgeoning interest groups were forming to claim them. Wildlife habitat, recreation (not merely quiet contemplation but off-road vehicles and dirt bikes), water quality, and wilderness values were soon extensively embraced.

Early effective interests were manifest, just like those of the ranchers, in the federal congressional and regulatory arena. First, new claimants emerged in the form of advocates for the protection of wild horses and burros. At just about the same time, the Endangered Species Act passed in 1973, creating a whole group of new claimants and advocates. Slightly later, wilderness advocates were successful, as part of the Federal Lands Planning and Management Act of 1976, in asserting claims to wilderness areas managed by the BLM. Determining what specifically these claims are is a matter of some dispute, especially in Utah, but the direction of the discussion is unmistakable. Similarly, water pollution control regulations have allowed still other advocates to make claims concerning the management necessary for achieving high standards of water quality on public lands. All of these advocates can be seen as claimants to land and resources that ranchers once considered their own.

Most of these claims have been pursued in familiar, quite well-defined processes: congressional advocacy and the courts.

New Processes: The Emerging Market and the Federal Collapse

More interesting are the changes that have taken place in the claims and processes in the last 20 years. The federal regulatory and political processes have declined in importance, leaving the stage clear for a number of different arenas, actors, and approaches. For the range livestock industry, the major news has been in the decline of funding for federal agencies and the growing legitimacy of local processes and market mechanisms of decision making.

Much of this erosion of the federal process is familiar. I shall highlight one element — recently in the news — which is less discussed and arguably more important for the long-term configuration of the ranch, what I call the Land and Water Conservation Fund Bust.

The tremendous growth of government participation in public recreation that followed World War II was manifest not just in the Wilderness Act but also in the Land and Water Conservation Fund Act of 1965 (LWCF). Under the LWCF, federal funds were made available to federal agencies, states, and localities to acquire private land for recreational purposes. Ultimately, a small portion of revenues from outer continental shelf oil leasing was allocated to the fund. This constituted a direct effort to change claims and claimants by giving one set of them — recreation interests — federal funds specifically for making claims, that is, for acquisition of recreation lands by federal, state, and local governments.

This program collapsed in the early 1980s, a victim, it is frequently argued, of James Watt* and his hostility to environmental values. Funding since that time has been severely limited. I think a different story can be told: that the LWCF died not merely of Watt's hostility — which was real — but of multiple causes. Two other factors contributed: (1) growing hostility to federal ownership of formerly private land and (2) the lethal embrace of the environmentalists. Failing to see that about 30 to 40% of the funds were allocated to state and local claimants, and arguing instead that the funds were intended exclusively for the acquisition of endangered species habitat and wetlands, one wing of the environmental groups so dominated the allocation of funds that the coalition supporting it simply fell apart.

That this vacuum was filled by private groups, nongovernmental organizations able to raise money and leverage it to acquire land for open space, is well known. Growing from almost nowhere, we now have a plethora of organizations designed exclusively or primarily to acquire title to environmentally valuable land. Much of what we see appears to be designed to provide ranchers with sufficient income to stay on the land in real estate markets where the escalating value of the land vastly outstrips the value of the crops that can be produced. Ranchers are reasonable trying to develop new and more-valuable products that will raise their income. A lot of creativity and energy is consumed in both individual and group efforts along these lines. All kinds of tourism

* James Watt (1934–) was Secretary of the Interior under Ronald Reagan from 1981 to 1983. He was generally disliked by the environmental community for taking a market-oriented approach to natural resources and federal lands.

have developed to take advantage of the ranch's open space and environment. In addition, diverse marketing efforts have evolved to develop new products and new market niches to justify a higher price for those products. Green labeling of beef as hormone-free, organic, humanely produced, or produced on operations that are fair to workers; farmstead and specialty cheeses; and a variety of local and regional appellations have become a part of the supermarket and farmers' market scene.

OPINIONS OFFERED

In the face of the federal collapse, new, market-driven approaches to claiming ranches have emerged. I have two thoughts that may be worth considering.

First, most of the niche markets, farmstead cheese, and similar efforts to boost rancher return seem to be band-aids, stop-gap measures at best, which may work for some adaptable folks in some places long enough for us to think of something better. I do not see them as adequately responsive to the economic and political forces threatening continued ranching.

The second point is that the strategy with more staying power may not satisfy ultimately, either. I am fearful of the conservation easement that separates the bundle of sticks associated with property owning into two or more parcels. Perhaps as a public domain specialist, I am overly impressed by the fragmenting of the landscape that went on in the 19th century. However, one way to understand what happened is in terms of everybody going out, grabbing what they could get with very little thought about the resulting pattern of land ownership. Railroads, miners, farmers, federal agencies, and so on all grabbed what they could. The result is a mess that we decry and that makes us yearn for landscape-level management. The uniformly embraced solution seems to be to fragment the landscape further, to sever the development rights and other elements of ownership from what now appear as the more salubrious agricultural elements. It is not clear to me that the agricultural uses are rendered sustainable thereby. If the basic problem is inadequate income from ranch products, I am not sure a one-time payment will solve it, and I am fairly convinced that a further fragmenting of the landscape will not in the end prove a good idea. If all you are trying to do is stop development, then in some places and circumstances, there seems to be a temporary gain. I am concerned, however, about the long term.

A Rancher's Eye View of Grazing Native Grasslands in California

Richard R. Hamilton

I am a fourth-generation farmer/rancher from Rio Vista in Solano County. My family has a diversified farming and ranching operation, which is located in the Sacramento Delta, Montezuma Hills, and the Dixon Range area (also known as the Jepson Prairie). Our livestock operation includes both sheep and cattle, which feed off the crop residues and native grasslands that encompass our ranches.

My family's involvement in the Dixon Range of California goes back approximately 80 years. In 1920, my great-grandmother's brother, Alex Cook, purchased acreage in the Dixon Range area from the W.Q. Wright Corporation. The corporation had tried to make an irrigation district out of the Dixon Range and, in the process, created Calhoun Cut. Calhoun Cut runs through the southern end of the Solano County Open Space Preserve and our property. Alex Cook also leased ground in the Dixon Range, and he grew hay on the property, which is now Field 19 in the Solano County Open Space Preserve. This is an area where some rare vegetation can be found.

In 1956, Champion Paper Company (CPC) purchased 1500 acres in the Dixon Range; 418 acres of the purchase was from the land owned by my family. CPC was planning to build a paper factory on the property. My family leased back from CPC the property it had sold. When CPC withdrew its plans to build a paper factory, it sold the land to Southern Pacific Railroad Company (SPRC) and we continued to lease the same portion of the property from the new owners. In 1981, SPRC sold its entire property to The Nature Conservancy (TNC) and the property became known as the Jepson Prairie. Once again my family continued to lease its original acreage from TNC, and in 1983 leased the entire acreage from TNC.

Our lease agreements with CPC and SPRC were cash rent agreements with no type of grazing restriction. We manage the property much the same as the way we manage the property we continue to own. It was not until we entered into a lease arrangement with TNC that we experienced any type of grazing restrictions or plans that were derived by a landowner. For my family, this was a new experience — to be in a position where we were being questioned about our grazing practices and their threat to the sensitive plants and the environment. In his first meeting with TNC, my father's response was that we could not be bad land managers, if these sensitive plants were still around after his family had been pasturing this ground for more than 60 years. With our family history, our love for the land, and our openness to listen to new ideas, we were very committed to making our relationship with TNC work. It is true that there was a faction within TNC that wanted to lock up the property and not allow grazing (which would create a blight condition), but most of

the people from TNC realized that some form of grazing needed to occur. We appreciate the attitudes of TNC's Barbara Malloch, Owen Pollack, and Rich Reiner, with whom we have worked. They listen, and respect our opinions (see Chapter 106, this volume).

In the grazing operation on the Jepson Prairie, we incorporate TNC's grazing needs into the grazing rotation of our own properties. Following are some of the grazing restrictions on the Jepson Prairie:

1. Sheep are the only livestock allowed to graze.
2. There is no use of supplemental feed (hay or corn).
3. There is no control to stop the predation by coyotes.
4. The grazing rates of the pasture are controlled by AUMs (animal unit per month, the amount of forage needed for 1 month by an animal unit, usually a 1000-lb cow) per acre, and there are periods of no grazing. During the wildflower tour season, March to April, the sheep are moved on and off the preserve before and after weekend tours.

For our operation, our adjoining property provides the flexibility to operate with these restrictions; operators who do not have adjoining property have a harder time complying.

Each year, when we know the grazing priority, we incorporate the preserve pastures with our own pastures. The grazing pattern depends on the needs and type of vegetation control TNC desires. For example, to control grasses in the brome family and to utilize these grasses for the sheep, it is necessary to graze these grasses early in their development because that is when they are most palatable to the sheep. Once brome gets past a certain stage, sheep will not eat it. To manage these grasses, which are low in nutritional value, we use sheep that are nonproductive and able to survive without supplementation of feed. To control all grasses during the grass-growing period (January to April) thereby promoting a good propagation of wildflowers, we use high-stocking and short-duration grazing practices, which usually include ewes and lambs. To control yellow-star thistle, mustard, wild lettuce, and wild radish, we use a late-spring and early-summer grazing practice of high stocking rate and longer duration per field. To protect the desirable plants, such as bunchgrasses, we monitor closely what the sheep are eating on a daily basis; that is not too different from the way we manage our own property. The grazing practices in terms of stocking rate, time period of grazing, and frequency and duration of grazing are dependent on other factors, such as the weather. The timing of rain and temperature conditions varies each year; thus, each year's grazing schedule and types of grazing practices can never be permanently set. There has to be some flexibility in the grazing plan for the unexpected conditions, like early or late rainfall. As part of our lease arrangement with TNC we periodically get together and talk about grazing plans and we keep monthly grazing reports for each field. We assist with the maintenance of the preserve and with the conducting of grazing experiments in test plots at the University of California, Davis.

Our philosophy in the management of the grazing of native grasses on our ranches involves many factors. Making improvements to native grasslands with grazing can take up to 10 years, and there must be a way to monitor progress. The ability to make the right decisions is based on 70% practical knowledge and 30% technical knowledge. The practical knowledge comes from two sources: (1) experiencing the various climatic conditions that can affect the property, and (2) the experience of running livestock through production cycles on the property. Both the technical and practical knowledge provide the basis to help with the management of the land.

Some of the factors to consider in managing livestock in native grassland are:

1. Survey the grasses to determine the palatability to livestock.
2. Be familiar with the behavior of the livestock you are managing.
3. Have a knowledge of livestock food preferences (their priority of grasses and forbs).
4. Have a knowledge of livestock grazing routines (so you can distinguish stress from contentment).

5. Know the nutritional requirements of livestock during its life and production cycle (nonlactating vs. lactating animal, offspring vs. mature animal).
6. Multispecies grazing is often better in terms of utilization and management of native grasslands (cattle and sheep utilize different grasses on the same acreage).

The livestock segment is often blamed unfairly for the demise of native grasslands and open range. The real culprit is the ownership of the properties. The abuse of native grasslands occurs in two ways:

1. The purchase of grasslands by both public and private entities which do not develop a plan of utilization for the property; thus the property becomes a blight area.
2. The practice of establishing undesirable leases by public and private entities. Leases of short duration and high cost per acre or AUM tend to lead to high turnover of lessees, which in turn leads to mismanagement of the resources of the property. A lessee has a hard time making physical improvements and recovering his investment in short-term leases, then loses interest in the well-being and future of the land.

Finally, as private property owners of native grassland and farmland, we face a constant pressure of trespassing from both the private and government sectors on our property. The courtesy of asking for permission to gain access is hardly ever considered, and the lack of respect of fences and gates is common. It seems we are always dealing with illegal hunting during the season; out of season, we are dealing with vehicles driving through our crops and pastures, and governmental agencies and private companies not asking for permission to gain access nor stating their intentions. Over time, we have been burdened with tremendous expense in damage done to our crops, livestock, and assets such as buildings, fences, windmills, and water troughs. These problems are never caused by our neighbors. All our neighbors, including TNC, have been very respectful of our rights as property owners. Being good neighbors is very important to them.

To have success in the management of native grasslands in both the public and private sectors, long-term relationships must be formed. Our relationship with TNC and the Solano County Open Space Foundation has been a good example of how long-term relationships can be managed for the betterment of the land. As ranchers, we feel we are in the best position as keepers and historians of the environment. With our factors of production being tied to nature, and for ranchers to be successful in business, we must respect and nurture the environment.

California Grazing Lands: Science Policy and the Rancher

Jack Hanson

I am a cattle rancher from Susanville, CA, a small rural community in the remote northeast corner of our state. I would like first to briefly touch on rangelands in California, and what ranchers are doing to better manage the animals that are grazing these lands. Then I would like to broaden the subject and share with you my observation on the changing social fabric that defines the rural west, and how this change may affect the environment and the structure of the ranching industry.

I would like to share with you a glimpse of my personal history and my current situation, as I believe this will give you clearer insight into my observations. I was born and raised in the San Francisco Bay area and received my college education at a small, liberal university in the Berkeley Hills, which was, at the time, known best for its extracurricular activities and its poor football teams. After a stint as an officer in the U.S. Army, I settled into an occupation for which I had been groomed since birth: working as a stockbroker for Dean Witter, wearing a three-piece suit. I was, however, disillusioned with this calling and wanted to find a more honorable and useful way to contribute to society. To this end in 1975, I left behind my home in Tiburon, the Golden Gate Bridge, the famous three-martini lunches and the weekend golf games, and went into ranching. After 23 years in the business, and divided between three locations, I find myself, along with my wife, Darcy, and our two young sons, owning and operating a cow/calf and hay ranch in the open expanses of the Great Basin. The irony of all this, and as a demonstration of the keen insight I gained through my degree in economics from Berkeley, is that I left the brokerage business the year the market bottomed at about 490 on the Dow, and when the NYSE average daily trading volume was running around 13 million shares. I totally immersed myself in a business where the actual value of the unit of production is the same now as in 1975. However, our costs are substantially higher and our relative position in the economy is far worse.

Let me make a few quick comments about rangelands in California and their management. The U.S. has about 770 million acres of rangeland, more than 50% of which is privately owned, 43% owned and managed by the federal government, and the remainder owned by state and local governments. In California, there are over 40 million acres of land utilized for grazing; approximately one half of these acres is privately owned. Cattle grazing is the most benign, productive, economic activity that can occur on these valuable rangelands.

In addition to being the foundation for the state's livestock industry, these rangelands contribute property tax revenue, fuel load management, groundwater recharge areas, wildlife habitat and open spaces to the public. I strongly believe that the vast majority of ranchers who use these public and

private rangelands are keenly aware of the importance of maintaining the lands in a healthy condition so these landscapes will provide high-quality forage on a sustainable basis as well as clean water and an appealing appearance. Healthy, diverse ecosystems and clean water translate into healthy, more-productive cows and calves. Healthier soil and grass and greater control over livestock use patterns increase agricultural production. Good grazing practices promote plant diversity, protect waterways, reduce erosion, reduce fuel loads, and are key to the long-term health of our watersheds. There is a belief that persists among ranching and farming families that we do not inherit this land from our parents, we borrow it from our children. If you subscribe to this, you will over time do your best to treat the land with respect and use it gently.

To me, it is too bad that the poor cow is such a maligned animal in some circles today. A rancher's greatest advantage is that he raises ruminants. Cows are residue gleaners, by-product users, and an efficient way to productively use these marginal lands. On many of these acres of rangelands, it is only through the use of the cow that we can convert energy from the sun into high-quality, digestible protein for human consumption.

The key ingredients of successful management of rangelands are simple: you have to develop a vision, then design a management plan to achieve that vision. Ranchers have for years attempted to utilize informal plans, mostly developed over time and based on trial and error, and evaluated only by common sense. For the last 20 years or so, these plans have become more formal with detailed strategies applying new science and techniques. Animal behavior, plant responses, hydrology, and practicality are the basic considerations when developing a grazing strategy. I would just add the following points about grazing systems or plans and how we must view them:

1. Plans must, by their nature, be dynamic. Implement them as best you can, monitor your results, and make adjustments.
2. Keep in mind that no matter how scientific, precise, and well thought out a strategy is, you are still dealing with unpredictable variables that can humble even the best manager or most experienced scientist — the cow and mother nature — drought, flood, freezes, early grass, late grass, etc. may all necessitate adjustments. The potential need for adjustments dictates that we have alternatives and flexibility built into the plans. These are expensive. While this flexibility is necessary, it does have a cost associated with it.
3. Plans or strategies must be site specific. What works in the coastal ranges north of us will not necessarily work in the Great Basin or the high meadows of the Sierras.

Grazing systems, in their simplest form, are designed to control intensity, season of use, and frequency of grazing. It should be noted that they must consider the nuisances of specific watersheds, in specific settings, during specific weather patterns, with specific livestock and big game herds. Especially in California, it is likely that the most important and significant result of a grazing management plan is water quality. If regulators and the public are going to become more involved in the management of our private land and our grazing livestock, it will be through the concern over nonpoint-source pollution in relation to water quality. The California Cattlemen's Association has implemented a proactive approach to deal with water quality issues on rangelands. It is a voluntary program in which agencies assist ranchers in preparing a grazing plan, which ensures protection of the quality of the water. It was approved by California's Water Quality Control Board in response to the requirements of the federal Clean Water Act.

One item I mentioned earlier that is an important ingredient in a grazing strategy is practicality. If a strategy or management plan strays too far from being practical, it will not succeed. In grazing livestock, from a business sense a rancher is essentially trading time for money. A grazing strategy that takes excessive time is just as impractical as one that takes excessive money to implement. Consequently, in the final analysis, management strategies have to be accomplished within the financial and skill limitations of ranchers who ultimately have to make grazing plans work.

The previous comment, I believe, adequately transitions into discussion of the economics of the ranching business, the dynamic changes occurring in the livestock business and agriculture in

general, and how these changes are affecting the social fabric of the rural west and the fate of the rangelands. Some of these changes are not new at all. They have been occurring since the 1870s when the phrases *cattle kings* and *cattle barons* became popular. But the changes are now moving at an accelerated pace and affecting a segment of society that, by its nature, does not easily and quickly adjust to change. The changes are not necessarily good or bad but surely inevitable. They are not unique to agriculture either: consolidation, mega units, globalization, vertical integration, alliances, consumer orientation, biodiversity, ecosystem management, and nonpoint-source pollution. But what makes these changes important to everybody is the fact that they can affect the supply of safe food and the management and preservation of the resources that produce our food supply as well as the environment.

When discussing the current economic situation in the livestock industry, a little history may increase our understanding. Returns to agricultural producers have never been great. An average 3% return on investment over time was typical in the 1970s and early 1980s but it has been in a steady state of decline since. Today, only the top 20% of agricultural producers have returns on investment of 3% or more. In 1951, a beef producer received 71% of the beef dollars; in 1996, it was 45%. At the same time, retail margins have increased from 19 to 46% of the beef dollar. Along with increased retail margins, we have seen an overwhelming concentration in the beef-packing industry. In 1981, we had the four largest packers slaughtering 36% of the fed cattle. Today IBP, ConAgra, and Cargill slaughter 82% of all the fed cattle and are quickly moving into the cattle feed business. What is really going on? For years producers have been told that our cattle were cheap because of market forces: oversupply, slack demand, and competition from other meats. However, looking at 1998 as an example, we moved a near-record supply of beef at pretty good prices at the retail level. The catch is that these high consumer prices have occurred while cattle prices have been low. As Jerry Siebert, agricultural economist at the University of California, Berkeley, stated, "There is really a major and significant difference between retail and farm value. What we see is that retail prices go up, the processor or the packer price goes up, and the producer prices are relatively stable or declining." Robert Young, co-director of the Food and Agricultural Policy Institute, University of Missouri, stated the producers had always been under financial stress and going out of business, and that the trend toward larger farms will continue. In a hand-out, Young projected commodity prices from 1997 through 2007. Returns for the cow/calf unit annually over this 10-year period were all negative, except for the year 2000.

As an aside, hog prices in late 1998 hit a 50-year low, not inflation-adjusted price but an actual 50-year low. For the first time since the 1940s, live hog prices fell below \$10 per 100 lbs. Jim Winder, a rancher from New Mexico who was on a panel at the 1999 International Congress on Ecosystem Health, has stated, "These are tough times for ranchers ... although we win some of the battles, we are losing the war. We are not losing to environmentalists, we are losing to economics and demographics. If the American public ever sweeps us off the land, it will be because we are not producing enough value for society."

This brings me to what I believe is a critical point in discussing agricultural economics: that is, the erosion of the farmer's and rancher's relative position in the country's economy. What kind of value should society place on its food at the farm gate and the human and natural resources needed to produce it? Think about it. Our society has valued a 4-year-old company, with estimated sales of \$90 million and profit of less than \$50 million, at about \$25 billion. This is just below the \$26.8 billion value placed on the 1996 agricultural production in the state of California, about 12 to 13% of the national total. An even more glaring example of this anomaly is another company, which has been referred to as "an online garage sale," with earnings of less than \$6 million in 1998 on \$36 million in sales. This company is worth \$12 billion. Obviously, those astute investors in the audience who bought stock in these companies on initial public offerings know that I am referring to Yahoo and eBay. In fact, Morgan Stanley's index of 73 Web companies collectively lost \$1.5 billion last year, yet has a combined market value of \$115 billion. The online traders are an amazing group. In their world, you throw out everything you learned about rational pricing —

earnings, price–earning ratio, book values, even revenues. They are all meaningless. Do not worry about the long haul. Invest for the moment. Make a killing. With this attitude becoming more commonplace in society, many ranchers feel alienated. They find themselves with their more stable, traditional approach further from the mainstream.

Wendell Berry offers another interesting fact, which gives us insight into where farmers and ranchers fit in the big picture, in his essay “Conserving Communities.” In October 1993, the *New York Times* announced that the U.S. Census Bureau “would no longer count the number of Americans who live on farms.” California, being the trendsetter, had suspended this survey as far back as 1970. By 1950, the number of farmers had declined to 23 million, and to 4.6 million in 1991. In addition, in 1991 32% of our farm managers and 86% of our farm workers did *not* live on the land they farmed. These figures, at least on the national level, indicate we no longer have an agricultural class that can demand to be recognized by government; we no longer have a “farm vote.” From a demographic standpoint, farmers and ranchers have become statistically insignificant.

How does this play out for the environment and the social structure of rural communities? It might be dangerous, but for the sake of discussion, let us divide the farmers and ranchers into three groups: part-time farmers and ranchers, full-time family farmers and ranchers, and the so-called mega-family farms and ranchers including the corporate farms. Note that I am going to be generalizing when referring to ranchers and their situations. I am sure you realize that there are many exceptions. My comments do not refer to everybody all the time, but do reflect what I believe to be the trends in the industry.

The first group obviously is relatively small producers, who have full-time jobs off the farm. This group will survive, but does not necessarily define agriculture nor does it provide strong leadership for agriculture’s industry and infrastructure. The second group is, in my opinion, the most important group to the rural communities and the ecosystems in which its members live and work and to the infrastructure of the industry. Sadly, this is the group that is under the most financial stress. In order to survive with the current low margins, this group must bring in outside income or grow. Growth is difficult without outside capital. In fact, many in this group are eating into existing capital, just to survive. The third group has the capital to take advantage of opportunities and new technology, and its size offers the members a market advantage. They have economies of scale, which lower their production costs and allow them to continue to expand at the same time.

With this division in mind, if the current economics continue, family ranchers are in danger and, therefore, the rangelands that they own are in danger of either being subdivided or gobbled up by larger, impersonal operators for better or worse. Obviously, smaller units are not as environmentally healthy as larger ones. Larger mega or corporate units are not as desirable for the rural communities as are the more-numerous family operations where the owners live on the property. This trend in subdividing or consolidation will surely change the character of the rural West, and not necessarily for the better. People may think they would like to move to the country, but that is not what they really want. What they want is to move everything they have, the shopping malls, sewer lines, mail delivery service, and so on, into what was once the country.

What do we lose over and above the important production value when a working ranching landscape is carved up into 40-acre ranchettes? For the rancher, it is often a personal tragedy. For society in general, we lose the viability of the agricultural economy that is the lifeblood of many rural communities and an essential element of the West’s sense of place. Piecemeal subdivision of working ranch landscape threatens the viability of the dynamic ecosystem, and fragments the most productive wildlife habitat, but more importantly and sadly, it alters the relationship between humans and the land. On subdivided land humans no longer enter into an active relationship with the natural process. They are no longer stewards of the land but rather temporary tenants. Obviously, as land is divided and removed from serious production (and economics remain difficult here), we will push production offshore. Is this good? Production initially will be cheaper, but it will not necessarily be better for the planet. Dennis Avery, of the Hudson Institute, has observed that the worst

use of land through slash-and-burn techniques in underdeveloped countries is driven at least by the restrictions and reduction of more-efficient production on American farmlands themselves.

It is obviously not all bad; many of us will survive. We will be willing to work with neighbors and adapt to the changing economics. Tomorrow's ranchers must be prepared to use all the private land tools at their disposal: agricultural conservation easement, estate planning, voluntary zoning district, collaborative planning, and others. Fortunately, the rancher will not be alone in this effort. Despite a long history of conflict over management practices, ranchers, environmentalists, range managers, wildlife biologists, and others are forging new ground to facilitate change toward the common goal of adapting and sustaining ranching as a way to maintain healthy ecosystems. We must, through this new alliance, develop a mechanism to somehow recognize the nonproduction value which, in fact, working ranches give to society.

I would like to bring to your attention one initiative to do this. A new effort to ensure the preservation of rangelands and cattle grazing and to take a proactive approach in addressing environmental and resource use issues took shape recently. A group of California ranchers, including myself, started down the path to form the cattlemen's own land trust. This trip culminated with the formation of the California Ranchland Trust (CRT). While the trust was conceived within the ranks of the California Cattleman's Association, it is a stand-alone organization run by a board composed of cattlemen. Even though the number of land trusts in California doubled to 120 over the past 10 years, I believe CRT can fill a unique niche in the preservation of open space in California and keep ranchers on the land. Since this organization will have a good understanding of the needs of ranchers and also a sensitivity of what society gains from healthy rangelands and open spaces, it can provide a vehicle by which society can recognize those nonproduction values of ranches, and in some fashion apply that recognition to keeping families on ranches and cattle grazing on the rangelands. During its formation, we worked diligently to gain support from groups outside the livestock industry that share our concern for the fate of the rangelands and ranchers. In this I think we have been successful, but we have a long way to go. On the other side, many ranchers are skeptical of land trusts that do not understand the livestock and that may not be interested in perpetuating livestock grazing as a practice on their rangelands. We hope that CRT can bring these parties together in an atmosphere of trust, mutual understanding, and common goals and ideals, in other words a win-win situation.

In summary, we do not want government programs or hand-outs. These are almost always abused and unfairly applied. But during this era of globalization of our economy and huge multinational food companies with near-monopolistic control over certain commodities, what we want is not only a free and fair trade, but also a level playing field when dealing with imports and large food-processing corporations, and realistic and practical environmental requirements that are fairly and evenly applied. Most importantly, through the market mechanism, society will put a higher valuation on our products at the farm gate and somehow recognize the nonproduction value of having us as the stewards of these rangelands and as a crucial ingredient in the fabric of the rural West.

One more thing. It is still an honorable profession. I am proud to be a rancher and proud to represent my family and my industry. Obviously, I have faith that we will survive and prosper.

Reinventing the Range: To Graze or Not to Graze Is Not the Question

Lynn Huntsinger

INTRODUCTION

Domestic livestock can be used to maintain and improve ecosystem health. Grazing is a complex interaction between herbivore and vegetation that can be done to “prescription” in order to meet ecosystem management needs. Herein is discussed the ecological dimensions of what can be called “grazing to prescription” in Mediterranean California. The chapter is organized loosely by scale, starting at the landscape level, then going to the community level, then to the individual plant level, and, finally, returning to the landscape level to close. This chapter is not an attempt to argue the desirability or appropriateness of grazing for any particular site or situation, but only to explain some of the possibilities of livestock grazing management and what it can offer in stewarding diverse and changing ecosystems.

California’s most productive rangelands, the Mediterranean-type grasslands and woodlands, are in the majority privately owned. They are increasingly at risk of conversion to residential housing as the population grows, commuting and telecommuting become commonplace, and wealthy retirees seek retreats in the countryside. California ranchers own most of these lands. Of late, open space and biodiversity advocates have become interested in finding out how they can work with these landowners to protect California’s landscapes. In addition, conservation easements and land trusts are becoming more common on ranchlands. California has more acres in conservation easements than any other state, some 1.25 million acres. For these conservation efforts to work, it is important to understand how these “working landscapes” can be managed for the objectives of landowners and investors in easements.

The purposes of grazing have been reinvented many times to fit the political, economic, or social ends of the times. For the Spanish who settled California starting in 1769, livestock were grazed to produce hides and tallow for export, and to support colonization and missionary efforts. Throughout the 19th century, Spain and the U.S. used livestock as a visible means of occupying and claiming territory. For New World speculators toward the close of the century, grazing and the land grabs that went with it was a way of producing returns for distant investors. In the progressive era after 1900, grazing livestock to produce food and fiber for a flourishing and ever-more-populous young nation was widely accepted as its highest purpose; as a corollary to that, the highest and best use of rangelands was to graze livestock.

The costs and benefits of livestock grazing are weighted with the purposes of the past, but today must include the role of grazing in conserving and supporting cultural heritage, wildlife habitat, open space, water quality, scenic amenities, recreation areas, fire resistant landscapes, and community well-being. Too many times, although the various demands on rangelands are recognized as complicated, grazing itself is approached as simply a question of “to graze or not to graze.” This is a disservice to what we understand about ecosystem dynamics and herbivory. Grazing is not a black box, but is a complex set of interactions with ecosystem processes that creates multiple effects. We need to know what kind of grazing, where, when, to whose benefit, and for what purpose, in order to make decisions about what the role of grazing in an ecosystem management scenario should be. The quality of the answers depends on the quality of information about the ecosystem and its response to the various impacts of grazing, as well as the quality of the decision-making process.

THE CHANGING RANGELAND LANDSCAPE

California’s rangelands renew themselves annually, with a unique mix of herbaceous species in response to patterns of rainfall and temperature. California’s oak woodlands, savannas, grasslands, and shrublands make up the state’s Mediterranean-type rangelands. Forage for livestock is generally the annual grasses, broad-leaved plants, and shrubs that grow during the wet, mild winter and spring. Rainfall is highly variable, from year to year, north to south, and with elevation. San Diego’s average precipitation is about 250 mm per year; Eureka, in the north, averages 1000 mm per year. Forage production can vary from almost nothing to 7000 lbs per acre, and among the annuals, can be vastly different in species composition from year to year and place to place. Attempts to predict rainfall and hence forage production and composition have generally been unsuccessful, regardless of their sophistication. About 70% of the rainfall comes in the winter, and summers are characteristically hot with a drought that lasts from 2 to 11 months.

The rangelands of California are also undergoing change over a longer time frame. About 2% of the Earth’s surface has a Mediterranean climate, including the region around the Mediterranean Sea and parts of Chile, Australia, and South Africa. Today, California shares much of its flora and fauna with these parts of the world. Walk out on a rangeland in southern Spain and you are likely to see a familiar grassland. Wild boar, several kinds of deer, pheasants, and other fauna have immigrated to California and are flourishing. Commercial hunting, particularly during the Gold Rush, severely reduced the numbers of native tule elk and pronghorn antelope, the major native range herbivores.

Burcham (1981) diagrammed what he thought were likely dates of invasion of several important rangeland plant species into California, beginning with Spanish colonization in 1769 (modified as Figure 104.1). Many of these species, particularly annual grasses and legumes, though competitors

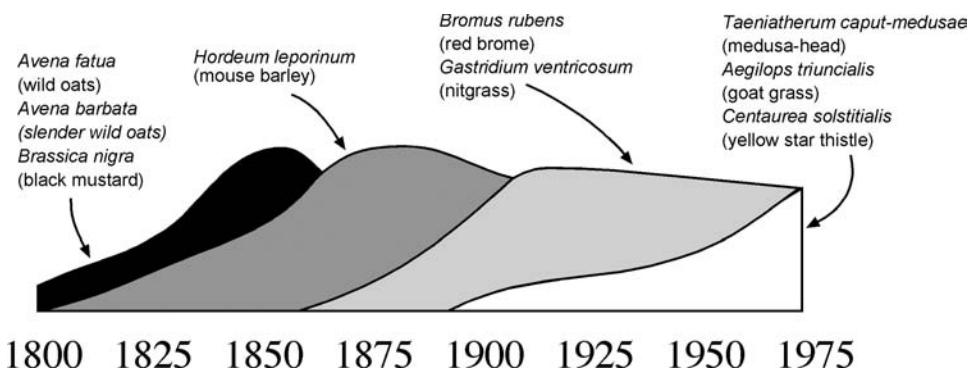

Figure 104.1 Plant species invasions into California. (Modified from Burcham, L.T., *California Range Land: A Historico-Ecological Study of the Range Resources of California*, Center for Archaeological Research 7, University of California, Davis, 1981 [1957].

with the native flora, have at least proved valuable as forage. Some of them, such as yellow star thistle (*Centaurea solstitialis*), are considered major pests without economic or ecological benefits. In the 1960s, there was an estimated 1.2 million acres of star thistle in California; in the 1980s, 7.9 million acres. Today, the species is thought to extend over more than 20 million acres. The nonnative flora that has been successful here is characterized by competitive aggressiveness and an exceptional capacity to cope with disturbance, perhaps most notably, periods of drought.

There are no comprehensive vegetation surveys available for the period prior to Spanish settlement, and as a result, there is considerable debate about what the native herbaceous flora was like and what happened to it. The perceived wisdom has often been that California was once carpeted by an evergreen bunchgrass flora, predominantly *Nassella pulchra* or purple needlegrass. Recent work suggests a more varied grassland, with a high annual component in some areas and bunchgrasses concentrated in more mesic environments (Hamilton, 1997; Webster, 1981). What we do know with certainty is that today a rich mixture of natives and nonnatives makes up the California rangeland flora. If number of species per unit area is used as the measure, it is among the most diverse floras in the world. In most places, native grasses are present, though often difficult to spot in a sea of nonnative annual grasses. Where endemic soils restrict the nonnatives, the native species flourish. The heterogeneous soils, microsites, aspects, and elevations characteristic of California rangelands contribute to their diversity.

The California rangeland landscape is a new and renewing landscape. It is unprecedented, and continuing to change.

COMMUNITY LEVEL GRAZING EFFECTS

Grazing affects vegetation at the plant community level in a number of ways, but perhaps most notably by influencing the relationships among plants growing together. Around the world, drought, fire, and grazing by livestock or wildlife are major disturbance factors for Mediterranean rangeland plant communities. Because of the high productivity and long dry period on California rangelands, fire has been common for millennia, ignited by lightning or by people. Like burning, grazing by native and nonnative herbivores removes vegetation and redistributes nutrients. But grazing is also quite different, in part because it is a selective process.

Selection

Grazing animals *select* the plants and the plant parts they eat. This selection is influenced by the species, age, and physiological status of the animal; the time of year; the availability and physiological status of the plant; and so forth. While fire may not burn everything, or burn evenly, it is not as selective by species as grazing. Much of what we believe about the influence of grazing on plant communities is predicated on the idea that this selection influences the competitive interactions among plants: to put it simply, plants that get eaten are at a disadvantage compared with plants that grazers avoid. This can be used to advantage. For example, cattle can be used to control grass growth around young trees, as long as the grasses are more attractive to the livestock than the trees. Goats are becoming popular for controlling brush, because they preferentially consume shrubs.

In some cases, and in perhaps much of California's rangelands, climatic and other abiotic effects outweigh the effects of grazing on plant-to-plant relationships (Westoby et al., 1989). The disturbance (most notably drought) and variability characteristic of California rangelands may overwhelm the influence of selection by grazers. This is no doubt true when considering relationships among annual plants.

An alternative model widely used in California considers only that grazing removes vegetative matter, and what influences the composition and structure of the returning plants is the amount of

biomass left on the soil through the summer, termed *residual dry matter*. This dry matter protects soil and creates microsites that encourage the growth of particular annual species in the coming growing season. A large amount of dry matter encourages plants that can come up through a thick layer of dead vegetation, often creeping wild rye (*Leymus triticoides*) in much of California. Grazing until there is little dry matter left results in a very different species composition as seeds germinate in drier, lighter, conditions. All this in turn, of course, can have very local effects on wildlife populations. Small rodents flourish under a thick thatch of dry grass. Raptors like the red-tailed hawk are seen waiting at the fence line or overlooking a patchily grazed rangeland, snagging the rodents when they venture out from beneath the protective cover into grazed areas.

Perevolotsky and Seligman (1998) argued that intermediate grazing intensities result in the greatest biodiversity on Mediterranean rangelands. This follows from the intermediate disturbance hypothesis, which states that intermediate levels of disturbance foster diversity. Intermediate disturbance prevents any one plant or group of plants from dominating the ecosystem everywhere or all the time, maximizing the diversity of the vegetation as a broader variety of plant species and structural types can find niches.

For each grazing application, the model or combination of models of ecosystem dynamics upon which management prescriptions are based needs to be carefully considered and subject to ongoing evaluation.

Animal Distribution

Variable impacts on plant communities are also caused by the behavior of animals in distributing themselves across the landscape, referred to as *animal distribution*. Grazing animals use plant communities and plants to different degrees depending on slope, aspect, proximity of fences, size of pasture, location of water, predator presence, and so forth. Where animals spend the most time, more grazing tends to occur. Cattle like low-lying areas, horses and goats the uplands, all of them like to spend time under the tree canopy during hot weather, and so forth. This can have consequences for soils, if animals concentrate in particular areas, and for the redistribution of nutrients.

As an example, sometimes when much of the grassland is brown and fairly dry, the area under an oak tree is still quite green. These areas often green up earlier in the season compared to areas outside the canopy. *Fog drip* and species differences due to the canopy have been used as explanations. Other explanations that have been put forth are that concentrations of grazing animals seeking shade have left more nutrients under the trees, or that intensive grazing under the trees results in a different species composition or different levels of residual biomass, affecting the timing of when the herbaceous understory turns green. Some believe that the tree itself acts as a “nutrient pump,” bringing nutrients up from the depths to the surface. The explanation or combination of explanations probably varies from locale to locale.

A recent article by Fuhlendorf and Engle (2001) suggests that grazing can be managed to enhance biodiversity, by managing for patchy effects. Though the usual paradigms of range management emphasize even livestock distribution and use of vegetation, managing for biodiversity may instead mean managing for heterogeneity, including allowing an uneven distribution of grazing use. They argue that this is more in line with the grazing patterns with which plant communities and ecosystems evolved.

THE PLANT LEVEL

Though California has only a 230-year history of livestock grazing, it has a history of fire and herbivory that goes back thousands of years. California native plants, as well as introduced Mediterranean species, are generally well equipped to cope with fire. Native herbivores, such as elk and deer, once roamed in huge herds (McCullough, 1971), so the native grass and shrub species

also have reason to be adapted to some kinds of herbivory. Many of the adaptations and coping mechanisms that help plants respond to fire also help plants respond to grazing.

Annual species simply grow back from seed after a disturbance, such as fire. They mature quickly and can produce large volumes of seed in a short period of time. The perennial native bunchgrasses resprout after fires that are not intense enough to damage the deep root crown. One of them, purple needlegrass, today is often observed on what appear to be highly disturbed sites — on road cuts, for example.

Many shrub species resprout from the base or from stems. With herbivory, they are able to develop shapes and structures that control grazing impacts and allow them eventually to grow to a height where they are safe from grazing. Rhizomatous growth forms and tough, fibrous stems and leaves are found in some species. Many native shrubs are full of toxins and oils that give them a bad taste. Some species are sensitive to grazing at certain times of the year, but are relatively unaffected most other times. For example, research has found that purple needlegrass is most sensitive in the spring when it is putting out its flowers (Huntsinger et al., 1996). Other studies show that grazing influences native species in different ways at different times (Dennis, 1989). Knowledge of the ecology of the plants of interest is needed to develop grazing prescriptions.

PRESCRIPTIONS

Traditionally, range managers have developed four principles that should be considered in planning a grazing program:

1. The kind and class of animal
2. The spatial distribution of animals
3. The temporal distribution of animals
4. The number of animals

The kind and class of animal is important, because as discussed earlier, different kinds of animals prefer different kinds and amounts of forage. Goats and deer tend to browse shrubs; cattle and elk graze grasses. Pronghorn antelope often seek broad-leaved herbs. Animals of different ages and in different physiological states also have dietary differences.

The spatial distribution of animals is important. The more spread out animals are, the more selective they can be. A lot of animals confined to a small pasture do not have much opportunity to be picky, either in choice of plants or in where they congregate. Some grazing systems use this to reduce selective effects, keeping a large number of animals in small pastures for short periods. Placement of water, fences, and salt blocks can be used to influence animal distribution and keep animals away from sensitive species or soils.

The timing of grazing can also be important. It can affect the types of plants present and their edibility, hence the choices of the grazing animals. Some plants are more sensitive to grazing during certain times of year, during flowering or in the growing season. During wet season, some soils are more vulnerable to trampling. In the dry season, livestock are more likely to concentrate on the moist riparian areas. The length of time animals are in an area also affects the grazing choices they make.

The number of animals per unit area affects the intensity of grazing. For example, when managing to leave residual dry matter, particular intensities of grazing will result in different amounts of biomass being left behind at the end of the season. A large number of animals on a unit area for a long period will result in more removal of plant parts than will a few animals. Removal of a lot of the vegetation results in a homogeneously grazed look, somewhat like a golf course. Under this scenario the grazing animal cannot be particularly selective. As the grazing intensity gets lighter, the grassland will look less smooth, more heterogeneous, as animals pick and

choose what they eat, or happen to concentrate in one place or another. Typically, range managers manage for an intermediate grazing intensity, removal of about half of the forage, but that varies a great deal depending on management goals. This can achieve a patchy effect. Light grazing can also make the vegetation look patchy, or it may not even be easily detectable. Animals will select the plants and places they prefer, leaving many places and plants untouched.

Example: Forest Grazing

An example of how grazing can be used to achieve particular goals can be drawn from studies of using cattle as a vegetation management tool to reduce shrub competition with young trees in conifer plantation (Huntsinger, 1996; Allen and Bartolome, 1989). For the system to work, of course, the shrubs and the grasses needed to be selectively grazed by the cattle. To test this, cattle were fenced in to areas and forced to graze at a high intensity. They still avoided the less-palatable pines and firs, and ate only the shrubs and grasses that grew among them. By studying the response of the shrubs to the timing, intensity, and frequency of grazing, it was found that the timing of grazing was not so important within the late spring through early fall season, but the frequency and the intensity (proportion of edible twigs removed) was. On the basis of the results, it was possible to develop prescriptions for grazing for at least three different kinds of objectives at this particular site:

1. To suppress competing shrubs as much as possible requires repeated, intense grazing during the grazing season. If started when shrubs are seedlings, this could eliminate most shrubs. This would also reduce fire hazard.
2. To maintain balanced shrub and tree growth, providing lots of wildlife and cattle forage while accepting slower tree growth, the area can be grazed heavily, removing all succulent stems, but only once or for a very limited period during the season. This would keep the shrubs low, producing a high proportion of edible and reachable forage, but would allow them to continue to grow. This would reduce fire hazard, but not as much as Prescription 1.
3. To allow shrubs to grow to their full size, light grazing, removing half or less of the succulent stems, still results in rapid growth of the shrubs. These shrubs would not produce as much succulent or reachable forage as the ones in Prescription 2, but they would produce a thick understory cover. Tree growth would be slow.

There are a wide variety of management goals for which grazing prescriptions might be developed, including controlling poison oak, reducing grass competition with oaks, encouraging flowers or native plant species, and reducing fire hazard. Some of California's native species benefit when the heavy growth of introduced annuals is opened up by grazing.

GRAZING AND CHANGE

At the landscape, community, and plant levels, livestock grazing interacts with ecological features and processes and can be manipulated to achieve particular effects. Knowledge of the dynamics of landscapes, plant communities, and plant species, as well as an understanding of herbivores and their activities, is needed to create grazing prescriptions for particular goals. Even so, unpredicted changes will occur year to year and over the long term. The effects of prescriptions or management activities need to be monitored and must be adjusted over time, to reflect the inevitable changes in the ecosystem, and in goals.

An understanding of the complex set of grazing effects in ecosystems is also important to the conservation of wild herbivores and their habitat. The grazing of wild herbivores takes place within ecosystems that have profoundly changed in the last 200 years, and will continue to change. A dispassionate look at the effects of wildlife grazing is needed, rather than operating on the blind

assumption that any grazing by wild herbivores is “natural,” and hence always benign in its effects on ecosystem characteristics. The factors outlined in this chapter can help sort through the likelihood of certain types of ecosystem change in response to changes in the behavior, habitat, or numbers of wild herbivores.

The activity of management can minimize conflicts and help achieve goals. This chapter does not attempt to grapple with the social complexities of setting goals for rangelands; that is left for others. The salient fact is that when rangeland changes to housing development, vineyards, or freeways, it is, for all intents and purposes, the final change. The wide spectrum of environmental goods and services that can come from an extensive range are lost, as it is reinvented for more singular purposes.

California Grazing Lands: Wither They Go*

Albert G. Medvitz

INTRODUCTION: ISSUES IN THE MANAGEMENT OF GRAZING LAND IN CALIFORNIA

Forty years ago, L.T. Burcham provided “An Historico-Ecological Study of the Range Resource of California” (1957), in which he discussed the history of livestock production in California. In that work, he described range degradation and growing threats to the continuing economic development of livestock production in a state with a rapidly growing population. Thirty years later, the California Department of Forestry and Fire Protection (Ewing et al., 1988) published “California’s Forest and Rangelands: Growing Conflicts over Changing Uses,” a comprehensive assessment of the state’s forests and rangelands in which it laid out not only the economic and social issues, but also the new (post–World War II) prominent concerns of environmental quality and habitat maintenance. Since then, the problems and conflicts over rangeland in California have continued, as have the plethora of research and policy documents. Examples of the conflicts include debates about:

- The appropriate strategies for addressing the continuing expansion of yellow star thistle
- The appropriateness of rules to protect watershed management
- Public protests and political actions when oak trees are removed to install vineyards in Santa Barbara
- Efforts to demand expensive environmental impact reports (EIRs) from East Bay ranchers who wish to continue to graze lands they have customarily grazed for years
- The efficacy and safety of applying urban sewage sludge to grazing land

In this conflicted environment, developing effective policies to promote the management of grazing lands in California to achieve ecosystem health is difficult. This chapter discusses three factors important to the problem of developing and implementing public policy which would lead to the management of California rangelands to achieve environmental goals. These factors are the economic conditions of livestock production in California, patterns of rangeland ownership, and rapid population growth.

* This is a revision of an unpublished paper presented at the 1999 Annual Meeting of the American Association for the Advancement of Science, Anaheim, CA, January 24, 1999.

DOMESTIC GRAZING ANIMALS AND THE LAND

Grazing animals* in California are a substantial economic component of the state's agriculture. In 1999, grazing meat animals — primarily beef cattle and sheep — accounted for \$1.3 billion in California farm-gate sales, that is, about 4% of the state's total agricultural sector output (CDFA [California Department of Food and Agriculture], 2000). Cattle and calves alone are the state's fourth-ranked commodity in dollar terms, following milk and cream, grapes, and nursery products (CDFA, 2000). With an inventory of 2.3 million beef cattle and calves at the beginning of 2001, California ranked second nationally in beef cattle and calf inventory, and second in sheep and lamb inventory with 840,000 head (USDA [U.S. Department of Agriculture], 2001).

The most recent (1997) Census of Agriculture (USDA, 1999) more readily allows us to see patterns of beef cattle ownership. It reports that in 1997 roughly 12,000 farms in California reported owning at least one beef cow, calf, or steer, and about 3000 reported owning sheep (USDA, 1999). Relatively few operations, however, own medium to large herds or flocks of grazing animals. Only 3000, or just under 25% of California cattle owners, own more than 100 head (USDA, 1999). Only 445, or 11%, of 3014 California sheep operations reported having an inventory of 100 or more sheep or lambs (USDA, 1999). Large flocks or herds are managed by an even smaller minority of operators.

Consistent with the large number of domestic grazing animals in California are the large amounts of land devoted to them. Ownership of this land is divided between privately owned farms and ranches, and publicly owned forests, grasslands, scrubland, and desert. The distributions of ownership described here suggest that grazing animals in California occupy private lands ranging from small fenced-in plots to larger fields of irrigated and nonirrigated pastures, to stubble remaining after crop harvests, to large and extensive ranches, as well as publicly owned forests, rangelands and deserts.

Because of the diversity of California's topography and climate and the size and dispersion of livestock operations in the state, describing grazing animals and rangeland in California is complex. California is a large state with about 100 million acres (156,000 mi²) of land within its borders. Few Californians realize that roughly half of all land in the state is owned by their governments; 44.1 million acres are owned by the federal government alone (Bureau of Land Management, 1998). Ownership patterns are shown in Table 105.1 and Figure 105.1A (Ewing et al., 1988; California Department of Forestry and Fire Protection—FRAP, 2001).

Table 105.1 California Land Ownership by Vegetation Type (in thousands of acres)

Type	Private	Public ^a	Private/Public	Total
			(%)	
Conifer	7645	15,368	33.2	23,013
Hardwood	6785	2762	71.1	9547
Shrub	8359	10,792	43.7	19,151
Grass	8391	1166	87.8	9557
Desert	5058	16,220	23.8	21,278
Alpine barren and rock	288	1832	13.6	2120
Total	36,526	48,140	43.1	84,666
Agriculture and urban				15,000

Note: Hardwood and grassland ecosystems in California are overwhelmingly privately owned. These systems are largely used for the production of grazing animals.

^a Lands administered by the U.S. Forest Service, Bureau of Land Management, U.S. National Park Service, other federal, state, and local agencies.

From Ewing, R.A. et al., California's forests and rangelands: growing conflict over changing uses (an assessment prepared by Forest and Rangeland Resources Assessment Program [FRRAP]), California Department of Forestry and Fire Protection, July 1988.

* For purposes of this chapter, consideration of grazing livestock is limited to beef cattle and sheep. Dairy cows are by and large confined, and unconfined horses, burros, goats, and other species are small in number. Inclusion of these nonbovine species would not substantially change the description or conclusions of this analysis.

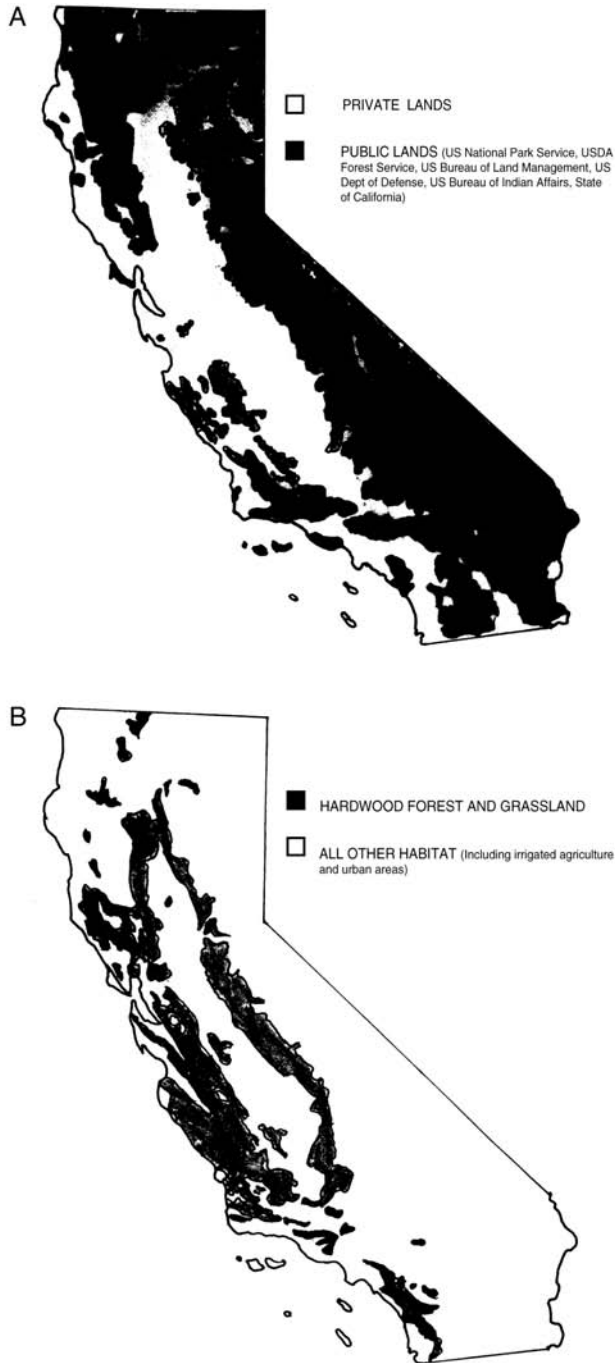

Figure 105.1 Private lands and grazing land in California. Private land in California makes up about 50% of the state. Most private land is in the agriculturally rich central and coastal valleys and in coastal plains (A). Grassland and hardwood forests (B) provide 78% of grazing forage for livestock, are largely privately owned, and are located mostly in the hilly regions of the central and coastal valleys, regions undergoing rapid population growth. (From Ewing, R.A. et al., California's forests and rangelands: growing conflict over changing uses (an assessment prepared by Forest and Rangeland Resources Assessment Program [FRRAP]), California Department of Forestry and Fire Protection, July 1988; and California Department of Forestry and Fire Protection—FRAP, California Major Land Cover Classes, map (http://frap.cdf.ca.gov/data/browsegraphic/frapwhr10_map.gif), and Government Ownership, map (<http://frap.cdf.ca.gov/data/browsegraphic/govtownmap>), 2001.)

As a place of great tectonic activity on the western edge of the continent and spanning roughly 10° of latitude, California contains enormous diversity in climate and habitat. Eighty-five percent of the land can be classified as forest and rangeland, and the state also can be characterized as being part of at least five major vegetation regimes plus those lands which have been transformed by agriculture and urbanization (Ewing et al., 1988). Overall, roughly 40 million acres of these lands are grazed by domestic livestock. About 18 million of these acres are private lands and 23 million acres are publicly owned. Although more public lands are used by grazing animals, the vast majority of the forage consumed by the grazing animals, 91%, is on private lands (Ewing et al., 1988). Grasslands and hardwood forests are the most prolific sources of forage, generating about 78% of all the forage consumed. About 71% of hardwood forests (6.8 out of 9.5 million acres) and 88% of grasslands (8.4 out of 9.6 million acres) are privately owned (Ewing et al., 1988) (Figure 105.1B). Thus, 13.2 million acres of hardwood forests and grassland, or nearly two thirds of these specific habitats, are under private management for animal production.

These ownership patterns are of profound significance in developing strategies for ensuring ecosystem health for California's hardwood and grassland habitat. A comparison of Figures 105.1A and B shows that California's habitats under private grazing management are proximate to areas of rapid population growth in the central and coastal valleys, as well as Southern California.

THE DYNAMICS OF RANGELAND DEVELOPMENT IN CALIFORNIA

The dynamics of the evolution of ranching and the human use of rangelands in California is intimately tied to the rapidly growing population and to a rapidly evolving, highly technological agricultural system. California's population growth over the last century and a half has been very rapid and largely urban based (Medvitz, 1999; Olmstead and Rhode, 1997; Rothstein, 1999). Figure 105.2 shows California's population growth from 1850 to the present. For 150 years of California's history, its population growth has exceeded an exponential growth rate of 3% per year. Although in the past 20 years the rate has declined to about 2% per year, it is still high by international standards, and some of the county growth rates are very high indeed, as shown in Table 105.2. There is little doubt that this growing population will continue to increase well into

Figure 105.2 California population 1850–2000, extrapolated to 2040 under varying assumptions of future growth. Projection assumptions: (1) 2.29% per year = average from 1980 to 1990; (2) 1.8% per year as continuation of 1992 rate; (3) 1.24% as continuation of 1993–1994 rate; (4) 0.9% per year scenario with no foreign or domestic immigration and slight outmigration as a continuation of 1994–1995 rate.

Ecuador	2.1	Great Britain	0.3
Stanislaus	2.0	Russia	0.1
Mexico	2.0	Italy	0.1

Note: California and its counties are growing rapidly in population. Historical population growth rates of California as a whole have exceeded those of many developing countries. Many counties in California have population growth rates that are very high in world terms. Over the past few years, California’s population growth rate has varied between that of Mexico and China.

^a California and county rates calculated for the period 1990 to 1995 are mean yearly rates. They are somewhat less than 1980 to 1990 averages and are based on Department of Finance estimates rather than U.S. census counts. Country estimates are 1990 to 1995 averages from the World Bank’s *World Population Projections: 1994–95*.

the 21st century; the population will almost certainly double by 2050. Even a historically low rate of 1.09% will increase California’s population to 50 million people in about 50 years.

This rapid population growth, the character of the immigrants who made it up, and the unique conditions of California’s climate have generated a highly technological, large-scale agricultural system with strong links to international trade (Olmstead and Rhode, 1997; Rothstein, 1999). After initially exploiting the unfenced wildlands of the state to produce small grains (wheat and barley) and livestock, by the late 19th century, California farmers had mastered reclamation of delta lands and irrigation and had begun the continuing evolution toward increasing crop variety and the transformation of drylands to irrigated lands. This trend continues today. Figure 105.3 uses existing census bureau data to show the trends in agricultural land use during the 20th century: Figure 105.3A shows the dramatic changes in grazing land since 1950; Figure 105.3B correlates these changes to population growth. It is worthwhile noting that the changes in farmland and numbers of farms have varied over time in relation to population growth.

From the period of statehood through the 1960s, California’s growing population was associated with an expansion of agricultural lands. Agriculturalists, with the aid of massive irrigation projects, continued to expand not only irrigated lands, but also grazing lands. It was not until the 1960s that the supply of farmland began to diminish in the face of continuing population pressures and a growing desire to maintain large segments of the environment in more or less wild states.

Despite a declining land base, California agriculture continued to increase production in the latter half of the 20th century. The effects of the land loss have been compensated for by enhanced technologies, new crops, and new management strategies. In terms of production, the effects of the continuing loss of land and changing management are shown in Figure 105.4. Clearly, the trends

Figure 105.3 California farmland changes and population growth. California's population was approximately 15 million in 1960, and reached approximately 30 million in 1990. After an extended period of increasing numbers of farms and land in farms (acres) with growing population, farmland and numbers of farms have been decreasing at the expense of grazing land. (A) Changes in farmland, 1910–1997. (B) Farmland changes related to population. (From Bureau of the Census, Censuses of agriculture, Department of Commerce, Washington, D.C., 1925–1994.)

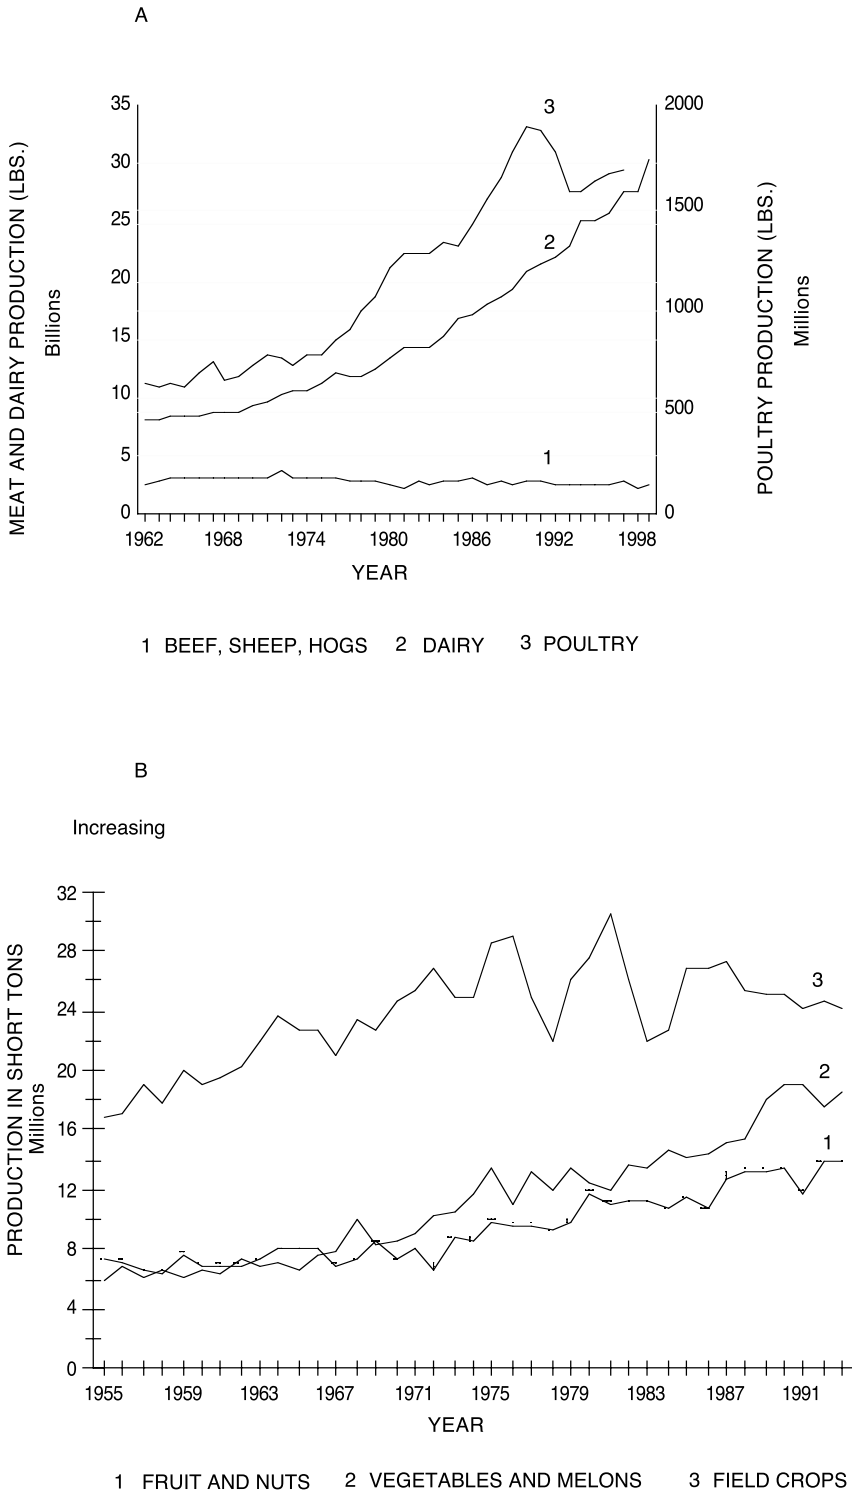

Figure 105.4 California agricultural production trends, 1962–1999. Increasing production of intensive irrigated crops and intensive livestock production are correlated with decreased production from extensive rangeland field crops. (A) Annual total production of dairy, red meat, and poultry, 1962–1999. (B) Annual production of field crops, fruits and nuts, and vegetables, 1955–1993.

are for increased production in intensive crops and livestock (poultry and dairy) production, and steady and declining production in extensive crops and grazing livestock. Privately owned grazing lands that remain in agriculture continue to give way to orchard and tree crops, intensive livestock facilities, or to housing developments. Obviously, the trends in production are the results of many causal factors besides population pressures. The changing nature of international markets, new transportation, food processing and distribution technologies, and price volatility in livestock markets related to institutional structure of production and processing and distribution are all powerful forces in pushing change in agriculture.

A simple extrapolation of Figure 105.3A shows that if population growth continues at high rates (1 to 2%) and technology and markets continue to evolve as they have in the past, then we can expect privately owned rangelands in the state to decline by another 5 million acres, or 46% or so in the next 30 years, thus increasing pressures for environmental maintenance on remaining rangelands lands, both public and private.

A major concern in this scenario is that urban pressures along with environmental demands and industrially concentrated, highly volatile livestock markets will ultimately push livestock agriculture to operations of confined animals nourished by feed produced through intensive irrigation. It would also speed the conversion of important grasslands and forestlands to urban or suburban development. It is difficult to imagine this scenario as contributing to the maintenance of the health of California's rangeland ecosystems.

RECONCEPTUALIZING THE FARM AND RANCH

The traditional social contract of the farmer in Western society has been that society allows ownership of land and associated environmental resources for the farmer or rancher to manage. The farmer or rancher then purchases inputs, provides labor, and acquires knowledge and experience to produce tangible products of food and fiber, which are sold in open markets. Some ranchers also sell entertainment by providing "dude" experiences. The contract allows the farmer to keep the market earnings and to pay for inputs and social costs and services, taxes and rent, and to support herself or himself. There is also a strong tradition that owners of farmland may sell it for nonfarm purposes, for whatever reason they choose. The currency and operation of commodity and land markets under this social contract have come to be widely understood, even to the extent that when they operate unfairly, as in the case with concentrated markets, both farm and nonfarm populations can agree to intervene in markets to make them fair.

In recent years, a new and very undefined market of California rangeland values has developed: the market for environmental benefits. The new market has arisen from a new set of social values demanding the designation and protection of special wild species,* the maintenance and protection of clean air and water, and the preservation of aesthetically pleasing landscape. Not only are good husbandry and sustainable production desired outcomes of the new social contract with farmers, but also detailed and specific environmental outcomes. But the transaction system for this market is not clearly defined: methods of pricing, of conveying value to producers, or, indeed, even of identifying production are not all precisely known. In the absence of a clearly defined market mechanisms, other than expensive fee purchase (and more recently experiments in conservation easements) on land, society has developed a set of regulatory burdens on farmers to obtain newly defined environmental value from farmlands. These burdens increase social benefits but at increased costs of operation for the farmer. The regulatory system does not allow farmers to benefit from the newly defined goods. Because the nature of agricultural commodities and the institutional structure of agricultural livestock markets prohibits passing additional costs on to consumers, some of these new environmental market interventions can dramatically reduce the asset value of rangeland. For

* These species include not only endangered species, but other species that, for whatever reason, have acquired political champions: wild horses and burros, predators such as coyotes, feral cats, etc.

example, by defining a parcel rangeland as habitat for an endangered species, the parcel can lose both urban development and agricultural value, depriving operators of wealth and hence potential loan collateral with which to obtain working capital. In any case, the regulatory burden often dramatically increases management and labor costs in addition to opportunity costs. Such burdens push livestock operators and landowners to change agricultural land use to higher-value crops or to convert land for residential or recreational purposes. In so doing, they undermine the integrity of the grazing land ecosystem.

This analysis suggests that adequate protection of ecosystem health of California's grasslands and hardwood forests demands more than continued learning of the technical management of grazing animals to achieve environmental health. It demands deep study and understanding of the social history and the economics of the interactions of commodity and land markets in the context of a rapidly growing population. With this understanding and a political will to proceed, explicit market structures need to be developed to reframe ranching from an enterprise of simple commodity production to one of environmental management where income from environmental outcomes can be made part of the income stream of livestock agriculture.

Protecting the Biodiversity of Grasslands Grazed by Livestock in California

Richard J. Reiner

INTRODUCTION

California annual grasslands are found in wide-open expanses, as well as interspersed in many of California's vegetation types. They are best represented in portions of the Great Central Valley, the Sierra and Cascade foothills, the Coast Range, and the Transverse Range. Annual grasslands represent a huge portion of the undeveloped California landscape, supplying tens of millions of California residents with open space, clean water, recreation, beef, and wool. They are also important contributors to California's biodiversity, providing an ecosystem composed of plants and animals adapted to frequent fires, summer drought, little shade, and intense herbivory. Kuchler's (1964) map of the potential natural vegetation of the U.S. shows 5.35 million ha of grassland in the Central Valley and surrounding foothill ranges, and an additional 3.87 million ha with an oak overstory.

Early references to the botanical composition of California grasslands are sketchy at best. The first accounts simply describe it as excellent pasture (Heady, 1988). Most scientists concur, however, that a large percentage of the original upland valley grassland was composed of perennial grass species, especially purple needlegrass (*Nassella pulchra*). Early writings also indicate that the original grasslands were rich in native wildflowers that most likely occurred in the spaces between bunchgrasses. In April 1868, John Muir wrote of the Santa Clara Valley, "the hills were so covered with flowers that they seem to be painted" (Adams and Muir, 1948). On the same trip, Muir referred to the Central Valley as a "garden of yellow Compositae" (Heady, 1988).

Grasslands provide society many benefits. The most obvious products, such as meat, are easily valued in familiar currency. Other products, such as clean water, open space, and biodiversity, are more difficult to value monetarily. Yet it is these environmental services that are becoming important in the discussion regarding the future of our remaining grasslands.

THREATS TO GRASSLANDS

To date, the greatest threat to grasslands is outright conversion to other land uses. Nearly all of the grasslands in the Central Valley were lost to cultivation near the turn of the 20th century and, as of 1987, only 1% of the valley grassland remained. The current large expanses of grassland

almost exclusively reside in large private ranches in foothill regions and many of these ranches are now in the process of being subdivided. The reasons for the demise of these ranches include housing development, poor returns in the cattle market, and subsequent conversion to other land uses such as vineyards. Some ranches are being broken up because California tax laws make intergenerational transfer prohibitively expensive.

The spread of nonnative species also threatens the diversity of California grasslands as the abundance of these weeds has increased dramatically. The grasslands observed today are only a shadow of their former selves, having been invaded by annual grasses from Europe and other Mediterranean climates. Some of these species, such as wild oats and bromes, are so well established in today's grassland that they are considered naturalized. With careful management, the percentage of these species can be decreased in favor of natives, but it is unlikely that they can ever be eradicated. Grasslands with the highest native species composition are now found in areas where annual grasses are least successful, such as vernal pools, serpentine soils, and rocky landscapes.

Most troublesome to biodiversity are newer weed arrivals such as star thistle (*Centaurea solstitialis*), medusa head (*Taeniatherum caputmedusae*), and goatgrass (*Aegilops triuncialis*). These species threaten to eliminate the remaining native species and, because they are not desirable forage, livestock production is decreased. It is critical that we begin to make significant progress on stabilizing grassland weeds. If current trends continue, it is entirely possible that conservationists could expend huge sums of money protecting ranches from development and still lose their biodiversity to introduced weeds.

BIODIVERSITY AND LIVESTOCK GRAZING

After hearing such a bleak view of the condition of California grasslands, many people are surprised that the remaining grasslands are so extensive and biologically diverse. To be inspired, one need only to drive through the coastal and Sierran foothills during a wet spring to view the spectacular wildflower displays. In addition to wildflowers, there are many animals that are specialized for life in grasslands. Some of those animals, such as black-tailed hare (*Lepus californicus*), Beechey ground squirrels (*Otospermophilus beecheyi*), and burrowing owls (*Athene cunicularia*) are visible to the casual viewer. Many others, such as San Joaquin kit foxes (*Vulpes macrotis*) and California tiger salamanders (*Ambystoma tigrinum* subsp. *californiense*), are best viewed with a spotlight at night.

Research from grassland sites as varied as South Africa and the American Midwest indicate that grasslands are dynamic systems influenced by natural disturbance regimes (Collins and Barber, 1985; McNaughton, 1994). Among the best-understood disturbance regimes affecting grasslands are fire and grazing. Both of these natural disturbances are patchy, reduce the standing biomass of vegetation, and occur on varying scales. Each temporarily affects the balance between organisms competing for space, light, water, and nutrients. Research in mixed-grass prairie (Collins and Barber, 1985) shows that if grasslands are subjected to moderate levels of multiple disturbances, they contain greater biodiversity (Figure 106.1). In other words, grasslands that are protected from fire and grazing eventually lose species.

Examples of grasslands being degraded by the removal of grazing and fire are numerous both in the literature and in practice. In a study of a rare population of the Sonoma spine flower (*Chorizanthe valida*), Davis and Sherman (1992) found that the population dramatically declined when protected from livestock. On the other hand, it appears clear that grasslands that are periodically grazed and burned have fewer weed species and greater abundance of native species (Kan, 1998).

The fact that properly managed livestock grazing and biodiversity can be mutually compatible is significant. Livestock grazing not only becomes another tool that can be used against the threat of weed species, it adds an important strategy for conserving large grassland landscapes.

Figure 106.1 A generalized model showing the relationship between disturbance and diversity in grasslands. The area that is shaded represents the increase in diversity when both grazing and fire are represented on the landscape.

THE JEPSON PRAIRIE EXPERIENCE

Jepson Prairie, located 12 miles south of Dixon, CA, is an outstanding example of Central Valley grassland. It is an especially diverse landscape with sizable remnants of purple needlegrass (*Nassella pulchra*) grassland and high-quality vernal pool communities. At last count, the preserve had 212 species of plants belonging to 45 families. The preserve is habitat for many extremely rare plants and is one of only two known locations for Solano grass (*Tuctoria mucronata*). It is also home to many rare and interesting animals, such as the California tiger salamander, and the only known population of delta green ground beetle (*Elaphrus viridis*). The Nature Conservancy (TNC) recognized the importance of Jepson Prairie and purchased it in December 1980.

Jepson Prairie had been grazed by livestock since before the turn of the 20th century and the question of how to manage it has been controversial from the time of its initial purchase by TNC. The Hamilton family had operated a sheep operation there for over 100 years and when TNC contemplated removing sheep, the family quickly pointed out that they saw no need for change since the native species we were most interested in protecting still existed under their long-term livestock management. Yet, some people in the environmentalist community argued that TNC was advocating livestock grazing because of political pressure from the locals and a desire for rent income. Tempers flared, emotional letters were written, and the agricultural and conservation communities were further distanced.

TNC temporarily eased the friction caused by livestock on the prairie by excluding a portion of the preserve from sheep. This area, known as the Docent Pasture, became the focus for public visitation and included a self-guided nature trail. TNC also began to engage the University of California in grazing research, and in 1987 funded a study to investigate further the effect of grazing and fire on the prairie grasslands. Over a 5-year period, it became clear to all involved that without fire and grazing the Docent Pasture was being invaded by weeds, and that biodiversity was indeed decreasing. The nature trail became infested with yellow star thistle, prickly lettuce (*Lactuca serriola*), and medusa head. The beautiful spring wildflower displays that still occurred on the sheep-grazed pastures were no longer found on the “protected” land.

Research at the University of California, Davis, led by John Menke and later by Kevin Rice and their students, began to shed light on the mechanisms that caused a decline in biodiversity in the Docent Pasture. A major factor was competition with the introduced annual grasses and especially the effect of the buildup of annual grass mulch. Without grazing and fire, the previous years' grass production was left matted on the ground, leaving the native California species in an environment where germination conditions were poor. Even worse, weed species were encouraged by these conditions.

Weeds quickly became the common focus of both biodiversity and livestock interests at the prairie, and therefore formed the foundation of a management plan. The plan was developed in a team atmosphere with input from a broad group of stakeholders including TNC; the University of California, Davis; Solano County Farmlands and Open Space Foundation; Hamilton Brothers Livestock; U.S. Forestry Service Pacific Southwest Research Station; California Department of Fish and Game; and the Jepson Prairie Docents. Such a broad base of involvement led to a very holistic set of planning goals and a greater appreciation from all involved as to the complexities of managing the prairie.

The plan focuses on biodiversity objectives while recognizing the need to keep the sheep operation as profitable as possible. It lays out a clear set of objectives, a grazing and burning schedule for each pasture, and a monitoring protocol. The plan recognizes the need for flexible grazing schedules as weather patterns change and different weeds wax and wane. One of the first actions under the plan was to reduce grazing to increase the fuel load in a pasture infested by medusa head, and then to burn the pasture in the early spring. Oren Pollak and Tamara Kahn of TNC studied the effect of the fire and found a 100% reduction of medusa head in the first year. By the third year, the weed had regained some ground, but was still reduced to below the pre-burn levels (Kan, 1998).

One point that should not be overlooked from our experience managing Jepson Prairie is the importance of working with local knowledge. From the Hamiltons we learned management tricks it would have taken years to learn on our own; specifically their local knowledge regarding the diets and behavior of sheep proved invaluable. They knew from years of experience at the prairie which season sheep would select specific weeds. Rip-gut brome (*Bromus diandrus*), for example, would have to be targeted early in the year because sheep rarely eat it after its three-leaf stage. The Hamiltons also understood sheep behavior. When we became concerned that sheep would impact rare plants in vernal pools, we learned that sheep really do not like to get their feet wet. They would avoid vernal pools if we waited until the pools were full of water before putting the sheep out.

A workable plan also needed to consider sheep–public interactions. Having sheep in the pastures during high visitation periods proved to be problematic. We had weathered several wildflower seasons of fiery letters, condemning both the sheep and TNC's management of the preserve. A solution was found by considering the need to concentrate and rotate livestock during the spring season. Working with the Hamiltons, we developed a spring schedule that assigned wildflower-viewing pastures to be grazed from Monday through Thursday. Sheep were then concentrated on a back pasture during the high visitation weekends.

The Jepson Prairie experience convinced TNC that working closely with livestock operators could be to the advantage of both. Our view of the conscientious livestock producer thus changed from that of resource consumer to resource steward.

LANDSCAPE-SCALE CONSERVATION STRATEGIES ON GRAZED GRASSLANDS

TNC recently completed an analysis that indicates that the remaining grasslands in California's coast ranges, Central Valley, and Sierra foothill regions are mostly on large, privately owned ranches. It is becoming increasingly clear that saving grassland biodiversity will require protecting large private ranches from being broken up and sold off to subdivisions or other land uses. The need to work on a very large scale is especially evident when one considers the conservation of large native mammals such as elk and mountain lions.

TNC has developed a systematic approach to identifying and protecting threatened natural communities. In the case of grasslands, the first step is a recognizance-level study that identifies portfolios of examples of each native grassland community that, if protected, could preserve the natural community into the future. At least three examples of sufficient size of each community type are selected for the portfolio. Once the properties are identified, a team of scientists and planners identify the major ecological systems, land tenure, and connectivity to other large protected areas. They then determine a minimum project size to assure the protection, maintenance, or restoration of large-scale ecological processes such as fire and grazing.

After identifying the threats to a portfolio site, the team attempts to isolate the sources of those threats. Most threats have more than one source. For example, if the threat is subdivision, one source might be due to a landowner's financial debt with no ability to reap income except from the highly volatile and cyclic livestock market. A second threat might be related to intergenerational transfer taxes. An effective conservation solution must then be a strategy that helps landowners reduce debt and one that allows transfer of the land to their children.

One of the most promising conservation tools being used today by TNC and others is the purchase of conservation real-estate easements from private landowners. The purchase of easements enables a conservation group to identify, value, and purchase certain rights to a property. These rights are permanently removed from the property deed. For example, the right to subdivide a property or the right to convert the property to intensive cropping can be stripped from a property deed. Conservation easements are promising in that they can be written to address specific threats unique to a property, while allowing the owner to continue income-producing activities such as ranching and hunting.

CONCLUSION

It is evident that the long-term interests of organizations concerned with protecting biodiversity and those making a living raising livestock are not mutually exclusive. The Nature Conservancy has successfully owned and held conservation easements on livestock-grazed grasslands for nearly 20 years. In 1999, TNC purchased conservation easements on over 100 mi² of grazed grasslands.

TNC is working to help new land trusts become established. In 1997, TNC donated Jepson Prairie Preserve to the Solano County Farmlands and Open Space Foundation along with a stewardship endowment to fund ongoing management. A promising new organization is California Cattleman's Association Rangeland Trust. Ranchers are realizing that the purchase of conservation easements is a way of placing monetary value on the environmental services their properties provide to society. Perhaps most important, the recognition of the value of these environmental services can form the catalyst for environmentalists and ranchers to creatively work together to protect large ranching landscapes in perpetuity. Long live the great wide open.

ACKNOWLEDGMENTS

I would like to thank Kevin Rice, John Menke, and their students, Oren Pollak, Tamara Kan, Mark Homrighausen, Robin Cox, Ann Dennis, and Pam Muik for their input and ideas.

SECTION III.1

The Colorado River Delta Ecosystem, U.S.–Mexico

Overview: The Colorado River Delta Ecosystem: Ecological Issues at the U.S.–Mexico Border

Daniel W. Anderson

The continuing loss of natural habitats to human settlement is the principal cause of declining biodiversity in North America and the largest impediment to conservation. Consequently, the key to effective conservation and long-term maintenance of biodiversity is habitat conservation and restoration, but in a context of sustainability and wise use (Bildstein et al., 1991; Brady, 1988; Howe, 1987; Zedler and Powell, 1993; and others). This means that many habitats, although forever altered from their natural states, are still capable of supporting rich natural biodiversity. Wetlands, because of high primary and secondary productivity, have long been attractive sites for human settlement or intense human activities, and consequently are some of the most disturbed natural habitats in North America, and the world. Howe (1987) and Dahl (1990) documented the extensive wetland losses in North America. In Mexico, habitat changes are occurring rapidly, and many of Mexico's coastal wetlands are now degraded and severely threatened by human activities. The Río Colorado delta region (CRDR), which spans the U.S.–Mexico border, was noted by early biological explorers to have the greatest biological diversity and natural productivity in the southwestern United States and northwestern Mexico (Sykes, 1937). But today, the region may be one of the most ecologically degraded in North America.

This section contains chapters based on research papers identifying some of the current problems threatening the ecological health of this region, as well as potential conflicts and problems likely to emerge as enhancement occurs or expands.

Several interesting contrasts emerge from these chapters. First, the CRDR is extremely changed and ecologically degraded from its original condition; but in contrast to this, the region still represents critical and important habitat for fish and wildlife. Second, many ecological threats (past and present) exist in the CRDR; some of these seem sufficiently immense and complex to discourage any kind of response. Generations of husbandry and environmentally oriented management will be required to rectify problems, and no simple solutions are apparent. But in contrast to this discouraging scenario, abundant opportunity remains in the CRDR for sound and sustainable natural resource management and restoration.

But perhaps most apparent in analysis of this ecosystem and its threats is the physical–biological connectedness of various parts of the CRDR. Because many of the problems in the CRDR ecosystem are entwined in international political policies and practices, the management and restoration of the region must be considered in an international context, and the CRDR must be considered as a singular whole in future natural resource management activities. Nowhere else is a need for close

international collaboration and coordination for successful future improvements more apparent than in the Colorado Delta ecosystem.

ACKNOWLEDGMENTS

I acknowledge the following colleagues for providing critical manuscript review: S. Alvarez-Borrego, C.J. Bahre, D.E. Blockstein, W.M. Boyce, M. Friend, E.P. Glenn, O. Hinojosa-Huerta, S.N. Hurlbert, J.O. Keith, M.A. Mora, R.D. Ohmart, and T.E. Rocke. The University of California Institute for Mexico and the United States, Riverside, CA, was the unifying and driving force in bringing people and organizations together; the institute also kindly provided funds supporting this series of research papers. We especially thank Kathryn Vincent, Juan-Vicente Palerm, and all the others at UC MEXUS for continuing support and encouragement.

Physical and Biological Linkages between the Upper and Lower Colorado Delta

Saúl Alvarez-Borrego

INTRODUCTION

In 1539, Hernán Cortés sent Francisco De Ulloa with three ships to explore north from Acapulco. De Ulloa reported that the island of Calafia (Baja California) was in reality a peninsula. De Ulloa circumnavigated the Gulf of California and named it *Mar Bermejo*, the Vermilion Sea, because of the reddish color of the muddy waters of the Colorado Estuary (León-Portilla, 1972; van Andel and Shor, 1964). The Gulf of California is very fertile, mainly due to upwelling and tidal mixing (Alvarez-Borrego et al., 1978).

The only river in the northern Gulf of California is the Colorado. The record of flow of Colorado River water across the Mexico–U.S. border shows that before 1935, when the filling of the Hoover Dam (Lake Mead) began, the large amounts of fresh water that were discharged into the Upper Gulf had a seasonal modulation with peak discharges in June. After construction of the Glen Canyon Dam, regular input of Colorado River water to the Upper Gulf stopped. During 1979–1987, water releases became necessary due to abnormal snowmelts in the upper basin of the river (Lavín and Sánchez, 1999). Water releases also occurred in 1993 and 1997–2002. Due to the construction of dams, the delta is a negative estuary (Alvarez-Borrego et al., 1973), with the exception of years with very high precipitation or abnormal snowmelts in the upper river basin. It behaves as a very fertile coastal lagoon (Hernández-Ayón et al., 1993).

The modern investigation of the gulf began with the E.W. Scripps cruise in 1939, which made a series of 53 hydrographic stations throughout the gulf (Sverdrup, 1941). In March 1939, salinity of the northernmost hydrographic station, some 70 km from the Colorado River mouth, was 35 ppt. Thus, only a very weak dilution effect of the Colorado River fresh water was evident in the Upper Gulf during the period Lake Mead was being filled (February 1935 to July 1941).

The Upper Gulf of California is the shallow, northernmost part of the gulf (Figure 108.1). It has unique oceanographic characteristics. Maximum registered spring tidal range at San Felipe is 6.95 m (Gutiérrez and González, 1989), with even larger amplitudes at the entrance to the delta. Depth is less than 30 m, with shallower waters at the Baja California side than at the Sonora side. Tidal current speeds exceed 1 m s^{-1} (Alvarez-Sánchez et al., 1993). It has a vertically mixed coastal regime due to tidal stirring. Tidal energy dissipation rates are very high, more than 0.5 W m^{-2} (Argote et al., 1995).

Figure 108.1 The Upper Gulf of California and Colorado River delta. Circles are the sampling locations of Hernández-Ayón et al. (1993). Bathymetry in m.

There are no towns immediately at the shores of the Colorado River estuary, and there is only a small city and a small town at the shores of the Upper Gulf. San Felipe is on the Baja California side, with a population of ~15,000; and El Golfo de Santa Clara is on the Sonora side, with a population of ~600. The economy of both towns is sustained with fishing and recreational activities. The Upper Gulf and the delta comprise an area of reproduction and nursery for many fish species, some of which are considered in danger of extinction, such as the endemic totoaba (*Totoaba macdonaldi*) (Cisneros-Mata et al., 1995). Marine mammals and some commercial shrimp species are also abundant. This area is part of the habitat of the endangered small dolphin, *Phocoena sinus*, commonly known as *la vaquita*, another endemic species. Due to this, the Mexican government decreed this area as a Reserve of the Biosphere in June 1993 (Reserva de la Biósfera del Alto Golfo de California y Delta del Río Colorado). Part of the Reserve of the Biosphere is comprised of important delta wetlands supported by agricultural drainage water, with Ciénega de Santa Clara in the core zone. Cohen et al. (Chapter 112, this volume) present a description of these wetlands and some restoration alternatives. The present chapter is mostly concerned with the estuary and the Upper Gulf.

HYDROLOGY OF THE ESTUARY

Development and evolution of the Colorado River delta has been controlled by the interaction of two opposing geologic processes: the Colorado River with a sediment supply calculated to have been on the order of 160×10^6 ton year⁻¹, and a tidal regime considered to be among the largest in the world. The interplay of these constructive and destructive processes has yielded a delta dominated by tidal processes (Carriquiry and Sánchez, 1999). Human intervention has led to almost total elimination of water and sediment discharge into the delta (Meckel, 1975).

In the absence of new sediment supply from the river, the delta has become subject to destructive processes such as strong tidal currents and wind waves. A suspended sediment budget at the mouth of the Colorado River reveals that the system is now exporting sediments to the northern Gulf of California at rates similar to those when the river was active. The exported sediments are derived from the delta itself, which is eroding. The entire northern Gulf is the “Colorado River sedimentary province” (Carriquiry and Sánchez, 1999; Cupul, 1994; van Andel and Shor, 1964).

The fluvial channel of the Colorado River rapidly widens, forming a 50-km-long estuarine basin. It is 16 km wide at the mouth and constricts to 2 to 8 km wide for most of its length. The semidiurnal tidal regime produces tidal currents with maximal velocities of 3 m s^{-1} inside the estuarine basin and 1.5 m s^{-1} in the shallow marine platform adjacent to the delta (Cupul, 1994). Although the Colorado River is responsible for having excavated one of the deepest canyons of the world, it is now tamed. The construction of the major dams in the Colorado River, the Hoover Dam and the Glen Canyon Dam, had the most drastic effect upon the amount and timing of the fresh water that reached the Gulf of California. In spite of the great ecological impact caused by the construction of dams, life is abundant in the inverse-estuary. Due to sediment resuspension, the water in the estuary looks brownish. Microalgae are abundant in the estuary, possibly because of turbulence and low tides that allow enough light for a healthy growth. Crustaceans and mollusks are abundant there. Dolphins are seen often inside the estuary.

Hernández-Ayón et al. (1993) reported salinities and nutrients measured in the estuary during 1989–1990 (sampling locations are shown in Figure 108.1). During winter, salinity increased from a minimum of about 36 outside the estuary to about 39 off the northern end of Montague Island, and then decreased to about 34 at the internal extreme of the inverse-estuary. During summer, salinity increased from about 38 outside the estuary to about 40 off the northern end of Montague Island, and then decreased to about 39 at the northernmost few kilometers of the inverse-estuary.

Nutrient concentrations are high in the estuary waters throughout the year, with no clear seasonal pattern and lower values toward the oceanic region. Maximum nutrient values were 15, 53, 12, and $92 \mu\text{M}$, for NO_2 , NO_3 , PO_4 , and SiO_2 , respectively. Most values were under 2, 40, 5, and $60 \mu\text{M}$, respectively. NO_3 vs. salinity diagrams often showed a “U” shape with both variables increasing from the oceanic locations to those near the northern end of Montague Island; then salinity decreased while NO_3 increased toward the internal extreme (Figures 108.1 and 108.2) (Hernández-Ayón et al., 1993). Agricultural drainage water is carried from Mexicali Valley to the estuary through the Hardy and Colorado Rivers (Glenn et al., 1999). Relatively low salinity and high NO_3 concentrations at the internal extreme of the inverse-estuary are an effect of this flux.

HYDROGRAPHIC CONDITIONS IN THE UPPER GULF

The northern half of the gulf is dry and desertlike. The number of rainy days per year is about 5 from the central Baja California coast to the Upper Gulf. The estimated mean evaporation rate for the northern Gulf is 1.1 m year^{-1} , while the yearly mean precipitation is almost nil (Lavín et al., 1998). The bathymetry of the Upper Gulf of California is irregular with channels and shoals oriented northwest–southeast. Close to Montague Island, navigation is difficult for boats with draft greater than 1 m, especially for those not familiar with the area and its tidal currents. Montague and Pelicano Islands are low and flat and covered by water at high spring tides. Large areas of lowlands are flooded periodically with the tides, on both the western and eastern shores.

The surface horizontal temperature gradient reverses at the beginning of spring and fall due to the annual cycle of atmospheric temperature. Surface temperature increases from the southeast to the northwest in summer, while the opposite occurs in winter (Figure 108.3a,b). Minimum and maximum surface temperatures have been recorded west of Montague Island: 8.25°C in

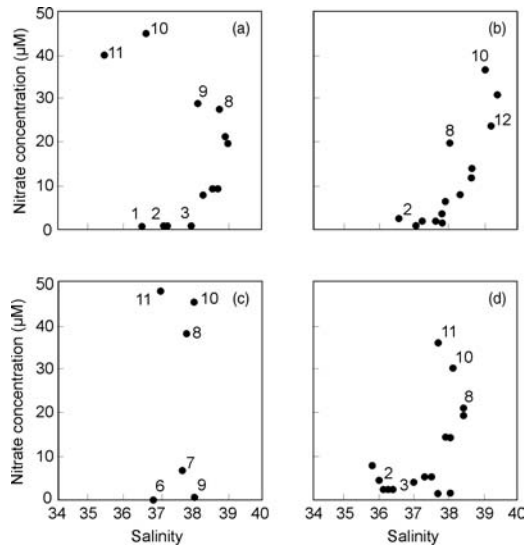

Figure 108.2 Nitrate vs. salinity for (a) June, (b) August, (c) November, and (d) December 1989. The numbers next to the symbols correspond to the locations shown in Figure 108.1. (From Hernández-Ayón, M. et al., Nutrient concentrations are high in the turbid waters of the Colorado River delta, *Estuarine Coastal Shelf Sci.*, 37, 593–602, 1993. With permission.)

December and 32.58°C in August. In the deeper waters of the southeast region, the seasonal range is 17 to 30.75°C. A monthly hydrographic sampling carried during 1972–1973 (years of no Colorado River water release) showed that salinity in general maintained a surface gradient with values increasing northwestward (Figure 108.3c,d). It ranged from a minimum of 35.28 in October to a maximum of more than 38.50 in July (Alvarez-Borrego et al., 1973). With data obtained between December 1993 and June 1996, this hydrographic behavior has been shown to persist essentially the same at present (Lavín et al., 1998), when there is no Colorado River freshwater release. Lavín et al. (1998) reported that density maintains the same horizontal gradient throughout the year with values increasing from the southeast to the northwest. In spite of higher temperatures during summer off Baja California, density is higher there than off Sonora due to the higher salinity values. Density is highest in winter and lowest in summer. Surface dissolved oxygen varies from a minimum of 1.33 ml l⁻¹, north of Montague Island in October, to supersaturating values higher than 130% in the more southern and central regions, during different times of the year (Alvarez-Borrego et al., 1973). This type of thermohaline behavior clearly indicates that any kind of input of high saline and warm water into the Upper Gulf could have a drastic ecological impact, with extreme effects during summer. Recently, there have been discussions about the possibility of carrying Salton Sea water into the Upper Gulf (the exchange solution for the Salton Sea). Concern has been expressed about potential negative effects on the ecology of the Reserve of the Biosphere through this type of thermal pollution (Alvarez-Borrego et al., 1999).

Lavín and Sánchez (1999) used the opportunity provided by the Colorado River freshwater release of March to April 1993 to observe the effect of the positive-estuary behavior on the Upper Gulf. In spite of the 1993 discharge being only ~25% of the mean discharge before 1935 (in m³ s⁻¹), and of very short duration, a clear hydrographic impact was recorded. In opposition to the “normal” inverse estuarine situation, salinity and density decreased toward the head. Dilution was detectable in a coastal band flowing to the right-hand side of the river discharge, up to San Felipe, some 70 km from the river mouth (Figure 108.4). Stratification was established during neap tides, in an estuarine salt-wedge structure. Surface salinity decreased from 35 near San Felipe to 32 at ~10 km south of Montague Island, their northernmost sampling location. Surface temperature was

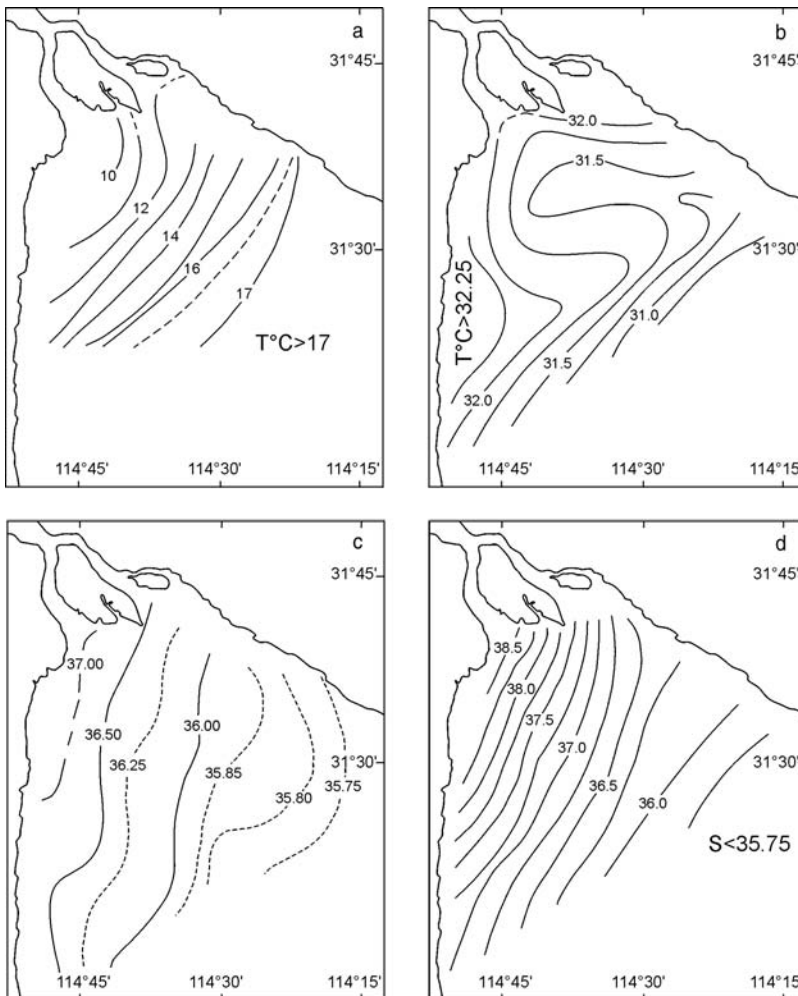

Figure 108.3 Upper Gulf surface temperature and salinity distributions: (a and b) temperature for December and August, respectively; (c and d) salinity for January and August, respectively.

normal for the time of year. This type of hydrographic behavior was relatively common until the early 1960s, but since filling of the Glen Canyon Dam (Lake Powell) began in March 1963, the inverse estuarine behavior predominates.

Rodriguez et al. (2001) used faunal and isotopic evidence to reconstruct the zone of freshwater influence caused by Colorado River flow prior to the construction of dams. The bivalve mollusk *Mulinia coloradoensis* is a brackish-water species that was very abundant when the river flowed into the Gulf. Shells of *M. coloradoensis* dating from before the construction of the dams have $\delta^{18}\text{O}$ values significantly more negative than those from species living in the delta at present. Radiocarbon- and amino acid-dated shells range in age from 215 to 650 radiocarbon years old (Kowalewski et al., 1998). Macrofaunal evidence indicates a mixing zone extending as far as 65 km south of the river's mouth along the western shore of the Upper Gulf. Average $\delta^{18}\text{O}$ values in shells of *M. coloradoensis* become more positive with increasing distance from the river's mouth, reflecting the greater dilution of river water with gulf water. The zone of influence of the Colorado River fresh water extended beyond 65 km during times of spring snowmelt (Rodriguez et al., 2001). This agrees very well with Lavín and Sánchez's (1999) report on the effect of the freshwater release of March to April 1993.

Figure 108.4 Upper Gulf salinity distribution in April 1993. (From Lavín, M.F. and S. Sánchez, On how the Colorado River affected the hydrography of the Upper Gulf of California, *Continental Shelf Res.*, 19, 1545–1560, 1999. With permission of Pergamon Press.)

In the northern gulf, there is a net heat flux from the water to the atmosphere during winter. However, the annual mean of the net surface heat flux was found to be into the sea ($\sim 100 \text{ W m}^{-2}$) (Castro et al., 1994). These results require an oceanic export of heat and salt out of the northern gulf to achieve a balance, and imply that the annual mean thermohaline circulation must have an inflowing component at depth. This has a profound ecological implication, because inflowing deep water has higher inorganic nutrient content than outflowing surface water. Thus, thermohaline circulation in the northern gulf is a natural fertilization mechanism. Very high tidal energy dissipation rates in the Upper Gulf are another fertilization mechanism. Tidal turbulence brings sediments into suspension and mixes the nutrient-rich pore waters with surface waters. Surface nutrient concentrations are usually high in the central and northern Gulf of California. Alvarez-Borrego et al. (1978) reported PO_4 , NO_3 , and SiO_2 surface concentrations in the ranges 0.7 to 1.0 μM , 0.0 to 4.0 μM , and 6.1 to 18 μM , respectively, for the northern Gulf of California. Their northernmost station was a little south of 31°N . In the area of the Upper Gulf adjacent to Montague Island, values range from 0.3 to 3.1 μM and 3.3 to 18.3 μM for PO_4 and NO_3 , respectively (Hernández-Ayón et al., 1993).

Nieto-García (1998) compared nutrient concentrations in the Upper Gulf for the springs of 1993 (wet year) and 1996 (dry year). She found that NO_2 , NO_3 , and PO_4 were lower in spring of 1993, with freshwater input, than during 1996. Only silicate was significantly higher during 1993, indicating a clear influence of river water. A possible explanation for the relatively low NO_2 , NO_3 , and PO_4 values in 1993 is that the river flow diluted the agricultural drainage water carried from Mexicali Valley and also “cleaned” the surface sediments of the estuary.

MARSH VEGETATION AND PLANKTON

The intertidal wetlands have a marsh vegetation restricted to a dozen halophyte species that can survive the hypersaline seawater of the Upper Gulf. Endemic saltgrass, *Distichlis palmeri*, predominates and produces an edible grain that was harvested by the indigenous Cucapá people up to the 20th century. There are some 3×10^4 ha of *D. palmeri* marshes in the delta. They are

feeding stations for birds that prey on crabs and small fish in the marshes, and are nurseries for juvenile stages of fish and invertebrates (Glenn et al., 1999; Kniffen, 1931).

Using coastal zone color scanner (CZCS) imagery, Santamaría-Del-Angel, Alvarez-Borrego, and Muller-Karger (1994) generated time series of phytoplankton pigment concentrations for a series of locations throughout the gulf, from November 1978 to June 1986. The time series for the Upper Gulf showed that pigment concentrations are, in general, greater than 4 mg m^{-3} and a seasonal cycle is not evident. The effect of strong tidal mixing is superimposed on seasonal variation in the Upper Gulf. Eight days chlorophyll *a* concentration (Chl) time series were generated by direct water sampling, in September 1990 and February and May 1991, for locations near El Golfo de Santa Clara, Sonora, and San Felipe, Baja California. In spite of high turbidity, Chl may reach values higher than 5 mg m^{-3} , and on occasion, higher than 20 mg m^{-3} (Figure 108.5). These high values are typical of very rich coastal waters. In both locations Chl varied irregularly with time, sometimes changing by a factor of two within a few hours. This is the result of a patchy phytoplankton distribution.

Zooplankton biomass (B dry organic weight per m^3) in the Upper Gulf of California had no clear seasonal cycle during October 1972 to October 1973. The highest B values (as high as 154 mg m^{-3}) were always found in the channels around Montague Island. In general, B values increased

Figure 108.5 Chlorophyll *a* concentration time series from locations off El Golfo de Santa Clara and San Felipe. Upper graph: September 1990; middle graph: February 1991; and lower graph: May 1991. Numbers on the horizontal axis are the dates; the vertical lines between numbers mark midnight. Sampling was done every 4 h. Closed circles represent data from San Felipe. Numbers in parentheses are maximum values of the peaks off scale.

westward or northwestward. In general, calanoid copepods were the most abundant taxonomic group, numerically and in biomass. Summer B values were similar to those of the rich central Gulf of California; values for the channels around Montague Island were as high as those of estuaries and coastal lagoons (Farfán and Alvarez-Borrego, 1992).

FISH AND INVERTEBRATES

The Mexican government recognized the importance of this part of the gulf as an area of reproduction and nursery for fish species adjacent to the Colorado River mouth, and decreed a permanently closed season for fishing in 1955. This was done based on a few direct observations without any systematic study. Berdegué (1955) reported on the totoaba fishery of San Felipe, Baja California, and indicated that this area was almost totally unknown biologically.

Guevara-Escamilla et al. (1973) concluded that there is a clear spatial distribution pattern of juveniles of different fish species, with most present in the area north of a line connecting El Golfo de Santa Clara, Sonora, with a point 5 nautical miles north from San Felipe, Baja California (Figure 108.1). The outstanding characteristic of this area is the high turbidity that may provide fish juveniles with protection and food. Félix-Pico and Mathews (1975) also concluded that this area is very important for juvenile blue shrimp (*Litopenaeus stylirostris*).

Using commercial shrimp boats, Guevara-Escamilla et al. (1973) sampled the Upper Gulf in the summer of 1973. They reported a total of 73 fish species identified with the help of R.H. Rosenblatt by comparison with specimens of the Scripps Institution of Oceanography collection. All of these species were collected from soft bottoms. They reported that 13 of these species had not been collected outside the gulf and therefore they might be endemic; 31 species had been collected in California waters; the other 29 species were categorized as panamic fauna.

Since Berdegué's (1955) report, the totoaba has been treated with special interest in the scientific literature because it supported an important fishery in the Upper Gulf. This fishery started in 1929 and declined drastically at the end of the 1960s. Annual total catch was 2261 metric tons in 1942 and only 58 metric tons in 1975 (Flanagan and Hendrickson, 1976). It was this decline that made people aware of the possibility of extinction of the species. The Mexican government declared an indefinite fishing moratorium for totoaba in 1975. The totoaba is the largest member of the family Sciaenidae; maximum reported lengths are almost 2 m and weights exceed 135 kg. Totoaba fishing was done mainly for the swimming bladder, to prepare a gourmet soup. Guevara-Escamilla et al. (1973) reported a total of 247 totoaba juveniles caught, with total length between 7 and 27 cm, and this was a clear indication of damage the shrimp fishing nets were doing to the totoaba population. Greatest totoaba abundance was found in the channels around Montague Island and off Baja California near the island.

In April to June 1994, the School of Marine Sciences of the Autonomous University of Baja California developed a field technique that permitted successful capture and transport of totoaba broodstock from the Upper Gulf to the laboratory at Ensenada (True et al., 1997). They were able to keep these specimens of totoaba alive and made them reproduce successfully. In October 1997, they set 250 juveniles back into the Upper Gulf. These specimens were 4 months of age and 20 to 25 cm long.

Félix-Pico and Mathews (1975) studied the invertebrates sampled in the collections with the shrimp nets in 1973. They identified 17 of the most abundant species around Montague Island and 48 in the oceanic region. Their list includes species of Cnidaria, Mollusca, Arthropoda, and Echinodermata. Together with that of Guevara-Escamilla et al. (1973) for fish species, it gives an approximation of the variety of species that were being devastated by shrimp fishery (trawlers) before the decree of the Reserve of the Biosphere.

The problem of ecological alteration of the Upper Gulf of California due to changes in the Colorado River flow has been ignored by government agencies. Galindo-Bect et al. (2000) explored

the relationship between the shrimp catch landed in San Felipe (>90% *L. stylirostris*) during 1975–1997, and the Colorado River flow at the Mexico–U.S. border. They found a significant statistical correlation ($p = 0.003$) between shrimp catch and the logarithm of the previous year's river flow. The log of river flow explained 45% of the shrimp catch variance. Their analysis showed that the base catch in the absence of flow into the Upper Gulf is ~200 tons year⁻¹, and it increases to ~600 tons year⁻¹ or greater following years of freshwater input.

MARINE MAMMALS AND BIRDS

Few studies of marine mammals have been conducted in the Upper Gulf. Silber et al. (1994) carried a total of 1715 km of boat-based surveys and 1521 km of aircraft-based surveys from 1986–1989 to assess the distribution, relative abundance, and ecological relationships of cetaceans in the Upper Gulf and adjacent areas (1986–1987 was the end of a freshwater release period). On four occasions, surveys were conducted 4 to 12 km into the Colorado estuary. Their primary objective was to characterize habitat use and distribution of the vaquita. Seven cetacean species were seen: common dolphins, *Delphinus delphis* (total individuals seen 14,239); bottlenose dolphins, *Tursiops truncatus* (1416); fin whales, *Balaenoptera physalus* (215); vaquitas, *Phocoena sinus* (110); killer whales, *Orcinus orca* (17); Bryde's whales, *B. edeni* (7); and gray whales, *Eschrichtius robustus* (3). Common dolphins were numerically dominant and bottlenose dolphins were seen most often. Bryde's whales and vaquitas had the smallest group sizes. Bottlenose dolphins were the only marine mammals seen in the Colorado estuary and in waters as shallow as 2.5 m. Common sea lions, *Zalophus californiensis*, are abundant in the Upper Gulf. An important colony is found on Roca Consaga off San Felipe. Fishermen report that they often find sea lions eating from their gill net catches.

Before experiencing changes in freshwater fluxes, the Colorado River delta was important for waterbirds. Now the area is considered to be of moderate to poor quality, although still offering important habitat for winter waterfowl. Because of the importance of the delta for shorebirds, it was one of the first two Mexican sites incorporated into the Western Hemisphere Shorebird Reserve Network. A January 1992 aerial survey detected 163,744 shorebirds in the area (Morrison et al., 1992). The vast majority were sandpipers (80%) (mainly *Calidris mauri*), but included over 9000 American avocets (*Recurvirostra americana*) and nearly 8000 willets (*Catoptrophorus semipalmatus*). The small shorebirds were found mainly on mudflats at the southern end of Montague and Pelicano Islands. The medium and large shorebirds were found mainly on the western margin of the delta on somewhat harder mudflats. A seasonal study showed a clear pattern of maximum waterbird counts in winter (>100,000 with 36 species) and minimum in summer (~500 with 15 species) (Mellink et al., 1997). The avifauna of the Colorado River delta is dominated by Charadriiformes that congregate there to rest and feed during the winter, but the area is also important to seabirds. Brown pelicans (*Pelecanus occidentalis*) were by far the most common seabirds observed during early winter. Anderson et al. (this volume, Chapter 109) give a detailed regional perspective for migratory wildlife resources of this region.

POLLUTANTS

One of the major threats of the Colorado River delta wetlands is selenium, which can be bioaccumulated to levels toxic for wildlife and causes high rates of embryonic mortality and deformity. Selenium is a naturally occurring element originating from cretaceous formations in the upper Colorado River and, due to its high solubility, is distributed along the Colorado River waters (Presser et al., 1994).

Low concentrations of mercury in fish and clams have been detected in the Rio Hardy wetlands. However, high levels of selenium, boron, and arsenic were found in birds from the same area. Dissolved selenium in water samples collected in 1997–1998 from the Hardy/Colorado wetlands (range 9 to 71 $\mu\text{g l}^{-1}$) was up to 14 times the Environmental Protection Agency's criterion for the protection of freshwater aquatic life. Bioaccumulation factors for several fish species ranged from 350 to 900 times the average waterborne concentration, depending on the tissue and species (Valdés-Casillas et al., 1998, and others cited therein). Samples of fish, mollusks, amphibians, and aquatic insects were collected from the Cienega de Santa Clara, the El Doctor, and the Rio Hardy wetlands and from the mainstream of the Colorado River from spring 1998 to summer 1999. Selenium concentrations in these samples did not exceed significantly the 4 ppm toxic threshold. The highest selenium concentration was detected in samples from the Rio Hardy wetlands (Garcia-Hernandez et al., 2000). Further sampling of biota in the area is needed to determine levels of this element that constitute risk for fish, birds, and humans.

One study analyzed the concentrations of Cu, Mn, Zn, Al, Cd, As, and Se in specimens of the mussel *Modiolus capax* sampled from a coastal site near San Felipe (Punta Estrella) and from other places around the Baja peninsula (Gutierrez-Galindo et al., 1999). Manganese, zinc, aluminum, and selenium concentrations were higher in specimens from Punta Estrella than in samples from the other sites, and this was attributed to the effect of sedimentary material from the Colorado River delta. Selenium concentrations were <4 ppm. Concentrations of all these metals were considered to be low, reflecting natural levels at the sites studied.

Since the early 1970s, there has been concern about the possibility of pesticide transport from the Mexicali Valley into the Upper Gulf. The first study to assess pesticide levels in organisms of the Mexicali Valley irrigation canals and the Upper Gulf of California was conducted in 1972–1973. Guardado-Puentes et al. (1973) reported on DDT metabolites in specimens of the clam *Chione californiensis* from a location at the southern end of Montague Island and another one 30 km north from San Felipe, at shore. They reported that, on average, total DDT (the sum of all detected metabolites of DDT) in *C. californiensis* was 0.067 $\mu\text{g g}^{-1}$ dry weight for specimens from Montague Island and 0.145 for specimens from the other location, with opDDD the most abundant metabolite. These concentrations were between one and two orders of magnitude lower than those in specimens of the freshwater clam *Corbicula fluminea* from the irrigation canals of the Mexicali Valley sampled the same year by these authors.

In 1985–1986, more than 10 years later, Gutierrez-Galindo and co-workers (1988) sampled specimens of mollusks for pesticide analysis. They sampled *C. fluminea* from the irrigation canals of the Mexicali Valley, *Chione californiensis* from the beaches of El Golfo de Santa Clara, and specimens of the mussel, *M. capax*, from a location some 20 km south from San Felipe. Again, the specimens from the Mexicali Valley had total DDT concentrations one order of magnitude greater than the marine specimens. However, total DDT concentrations were much lower compared to those reported for the specimens sampled in 1973. Gutierrez-Galindo and co-workers (1988) analyzed a wide range of organochlorinated pesticides and polychlorinated biphenyls. In the marine environment, only ppDDE was found. Its concentrations in *C. californiensis* were 0.005 to 0.011 $\mu\text{g g}^{-1}$, and in *M. capax* were 0.008 to 0.009. Given the persistence of the organochlorinated pesticides in the environment, their presence in the Mexicali Valley and the Upper Gulf of California in 1985–1986 was due to their use in the past. Mora et al. (this volume, Chapter 111) more thoroughly evaluate contaminants in the Colorado Delta region.

CONCLUSION

Due to almost total elimination of water discharge into the Colorado River delta, the delta behaves as an inverse-estuary most of the time. The semidiurnal tidal regime produces tidal currents with maximal velocities of 3 m s^{-1} inside the estuarine basin. This causes resuspension

of sediments and mixing of porewaters with the water column, which in turn increases nutrient concentrations in the water column. Nutrient concentrations are high in the estuary waters throughout the whole year. Agricultural drainage water is carried from the Mexicali Valley to the estuary through the Hardy and Colorado Rivers. Relatively low salinity and high NO_3 concentrations at the internal extreme of the inverse-estuary are a result of this flux. Phytoplankton and zooplankton abundances are high in the estuary and the adjacent Upper Gulf of California. These support a rich marine ecosystem with abundant and diverse fauna, including birds and marine mammals. These waters appear to be relatively clean of pollutants, with low levels of pesticides and heavy metals. However, more detailed studies are needed concerning metals in the estuary and coastal waters and their effect on biota. Charismatic endemic species, such as the totoaba and the vaquita, are now protected under the regime of the Reserve of the Biosphere. However, studies are needed to find and describe other endemic invertebrate and fish species and characterize the situation of their populations. Due to very saline and warm waters during summer, this ecosystem is very much under stress and any other anthropogenic factor, such as the input of hot brines, could be catastrophic.

Migratory Bird Conservation and Ecological Health in the Colorado River Delta Region

Daniel W. Anderson, Eduardo Palacios, Eric Mellink, and Carlos Valdés-Casillas

Ecological integrity can be defined as the maintenance of the structural and functional attributes of a particular ecosystem.... Our present human society globally has reached its level of affluence and density because of two life support systems — one technological and the other ecological. However, the events since the beginning of the Industrial Revolution clearly indicate that most human societies place far more value on the technological life support system than on the ecological one. In the last few decades, the shift has been toward a recognition of the duality of the life support system and an attempt to give more value ... to the ecological life support system.... Ecological restoration is a means of buying more time for human society to develop life styles less threatening to natural systems and for ecologists to develop more robust methods for restoring the earth's damaged ecosystems.

John Cairns, Jr. (1994)

THE COLORADO RIVER DELTA REGION: A HABITAT MOSAIC OF RICH PAST AND PRESENT BIODIVERSITY

The Colorado River Delta region (CRDR) was historically one of the richest areas for biodiversity in western North America; it included desert, riparian, estuarine, and marine environments. As stated by Felger (1976) in a little-known but important volume regarding conservation in the CRDR and the Gulf of California:

This was the life-center of the Gulf, and probably the delta was biotically the richest place in the southwestern part of the North American continent (citing Sykes, 1937).

Originally there were well over 500 species of plants (aquatic and terrestrial), and currently the best representation of this former biodiversity is near Cienega Santa Clara, where about 400 species are known (see also Ezcurra et al., 1988). California condors (*Gymnogyps californicus*) once flew over the CRDR (Murphy, 1917); Leopold (1966) told of jaguars (*Panthera onca*) in the delta; and Funcke (1919; Murphy, 1917) collected pronghorns (*Antilocapra americana*) nearby on the periphery. Endemic vegetation includes the saltgrass, *Distichlis palmeri*. Yuma clapper rail (*Rallus longirostris yumanensis*), now classified an endangered species, is also endemic in the CRDR. It has been estimated that Cienega Santa Clara alone supports a significant

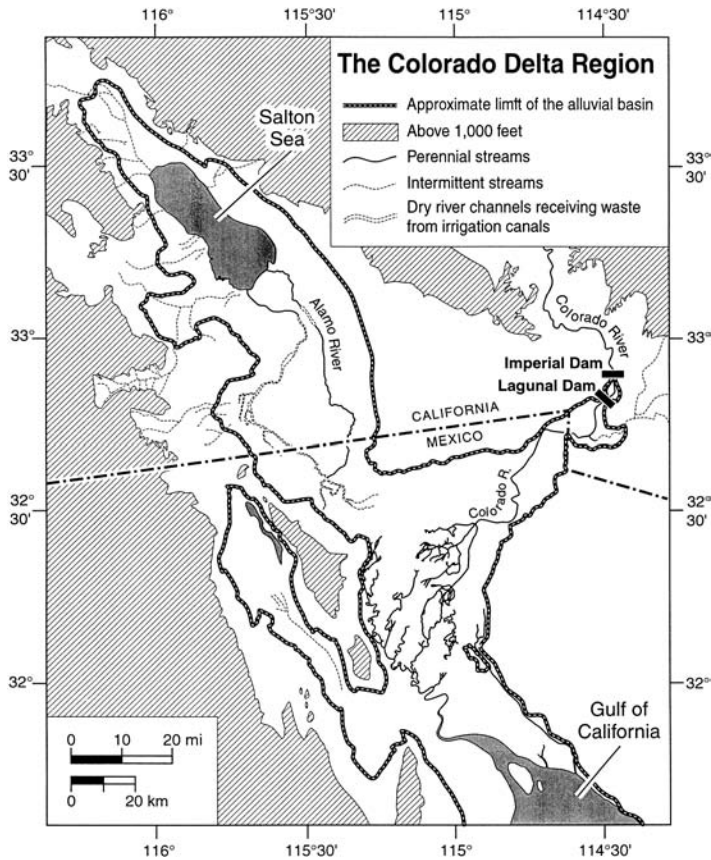

Figure 109.1 Map of the Rio Colorado Delta region, redrawn from Sykes (1937) to show the extensive wetlands of the area in the early 1900s. The map is simplified; consultation of the original map for specific details is recommended.

percentage of the total Yuma clapper rail population (Hinojosa-Huerta, O., personal communication, 2000). Hundreds of thousands of shorebirds and other waterfowl still pass through and utilize this area as a wintering or stopover area in migration (Shuford et al., 2000; Patton et al., 2000; Alvarez-Borrego, Chapter 108, this volume).

Yet this high productivity and richness has not gone unnoticed to land developers, especially agricultural interests (Bonillas and Urbina, 1912, 1913; Lumholz, 1912; Fradkin, 1981; Sykes, 1937). Ironically, even agriculture made a small contribution to the biodiversity of the region (Rosenberg et al., 1991; Mellink, 1995). Present habitat diversity in the delta hints at what was there in the past and it includes marine habitats, marine coastal habitats, deltaic islands, intertidal and upland wetlands, riparian zones, vernal pools, coastal deserts, and modified habitats, such as aquaculture ponds, salt works, agroecosystems, tourism facilities, and urban/industrial areas.

Explorers and naturalists recognized early that the lower CRDR was an integrated and diverse wetland ecosystem, comprised of interacting and connected parts (Grinnell, 1914; Murphy, 1917; Sykes, 1937; Goldman, 1951; Leopold, 1966), including the local separation of many of its hydric and mesic parts by expanses of more xeric habitats. All this formed a local mosaic of physical diversity that provided unparalleled, seasonally variable biodiversity to the region. This region (Figure 109.1) included:

1. The entire lower Colorado River and associated wetlands, today defined as riparian habitats and wetlands that extend as far as the first major dam north on the Colorado (Rosenberg et al., 1991).
2. The diverse delta area and associated wetlands (Glenn et al., 1996).

3. The northern part of the Gulf of California itself (Hendrickson, 1974; Maluff, 1983; Farfan and Alvarez-Borrego, 1992; Hernandez-Ayon et al., 1993; Santamaria-del-Angel et al., 1994).
4. The more recently formed Salton Sea (Sykes, 1937).
5. The incidentally formed Cienega de Santa Clara, the largest remaining wetland in the CRDR along with several other important wetlands nearby, but with an unknown future (Glenn et al., 1992).

Sykes (1937) delimited the CRDR an area of some 860,000 ha (Figure 109.1), not including the related marine zone of the upper Gulf of California, which is even larger in area, depending on where one delineates strictly oceanic influence (Figure 109.2). The present-day core area of the lower CRDR (comprised mostly of wetlands in Mexico, but not including the Salton Sea and associated wetlands, the Colorado River and associated wetlands, or the expansive terrestrial areas to the north) has about 250,000 ha. Thus, the CRDR is mainly comprised of the present mouth of the Colorado River with its intertidal flats and regularly flooded islands (Islas Montague-Gore and Pelicano), Esteros Santa Clara and La Ramada, Ciénegas de Santa Clara and El Doctor, Laguna del Indio, Pescaderos and Hardy Rivers, the remaining riparian corridor along the Colorado River, and various drainage canals such as the Wellton-Mohawk Canal and Riito-Santa Clara canal (Glenn et al., 1996; Briggs and Cornelius, 1998; Valdés-Casillas et al., 1998a). The lower CRDR also includes an important portion of native riparian vegetation, today estimated at about 1650 ha (Valdés-Casillas et al., 1998a, 1999), which recently has been identified as an important corridor for migratory neotropical birds, such as the willow flycatcher (*Empidonax trailii*).

Alvarez-Borrego (this volume) terms the northern Gulf of California the *sedimentary province*, and his analysis places the northern gulf within the direct ecological influence of the CRDR and its uplands. The core aquatic components in this system are interconnected by riparian corridors

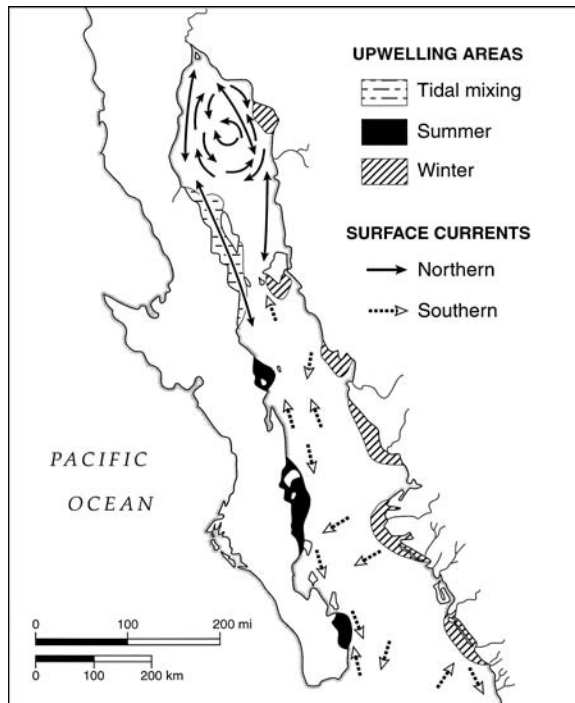

Figure 109.2 Surface water characteristics of the Gulf of California, showing the distinctiveness of the northern region. The northern gyre and likely more of this oceanic region are closely linked ecologically to the CRDR. (See references in text; redrawn from Maluff, L.Y., Physical oceanography, in *Island Biogeography in the Sea of Cortez*, Case, T.J. and M.L. Cody, Eds., University of California Press, Berkeley, 1983, pp. 26–45. With permission.).

(but much more extensively in the past); other aquatic components are separated by expanses of desert; and in the northern Gulf of California, zones of primary productivity are delineated by sediment and nutrient deposition patterns and current patterns. Yet most potential barriers to dispersal are transcended by the mobile avifauna that occupy the CRDR during various times of their annual cycles.

There is also an inter- and intraseasonal nature to the less-mobile biota of this region. CRDR habitat mosaics supported, to a much greater degree than currently, a rich biota of less-mobile species, whose viability was largely dependent on size, diversity, and local connectivity of habitat patches. These local aspects of habitat structure, based largely on the dynamics of patch size, patch quality, and connectivity, are currently of major interest in modern conservation biology (Harrison and Bruna, 1999) and are likely to be key issues in conservation strategies for restoration in the CRDR.

Changes in the Colorado River basin involve extreme ecological modifications in one of the largest and most spectacular past watersheds in western North America (Findley, 1973; Fradkin, 1981; Reisner, 1986). Most of these changes were brought about by activities that had little or no regard for the natural and sensitive floral and faunal elements of this large system. The lower components of the Colorado River basin have been modified most in the watershed, partly because of their low or terminal position, but also because the CRDR spans the U.S.–Mexico border and for many years was not considered a U.S. issue.

Saunders and Saunders (1981) conducted long-term U.S. Fish and Wildlife Service (USFWS) waterfowl surveys in Mexico from the late 1930s through the early 1960s, mostly because of interests in the status of hunted migratory waterfowl populations. Their surveys were essentially the only data available from the coastal ecosystems south of the U.S.–Mexico border through that period. Regarding the CRDR, they remarked:

The Rio Colorado Delta is very disappointing as a waterfowl wintering ground . . . it has few ducks in comparison to its great flights of earlier years.

Today, wetlands in the CRDR vary considerably in extent, depending almost entirely on unpredictable floodwaters, agricultural drain waters, and municipal wastewaters; based on figures given by Glenn et al. (1996) we estimate that less than 3% of the original wetlands remain today. However, more recent studies using remote sensing techniques have identified more than 60,000 ha of active wetlands present in years of adequate water, representing about 20% of the original extent; however, this figure includes modified habitats and areas with salt cedar (*Tamarix* spp.) intrusion (Valdés-Casillas et al., 1999).

...the Delta has probably been made safe for cows, and forever dull for adventuring hunters. Freedom from fear has arrived, but a glory has departed from the green lagoons (Leopold, 1966).

The picture that is so very different today in the CRDR is characterized by widely scattered and reduced wetlands that are changed and degraded, dominated by exotic plants and animals, challenged by many human-induced ecological problems, some newly created by wastewater disposal (Glenn et al., 1996; USFWS, 1997; Mellink and Ferreira-Bartrina, 2000). Conflicts over water are, in fact, an ongoing *worldwide* issue in conservation biology today. *World Conservation* (volume 30, 1999) is devoted entirely to the issue of water needs in wetland conservation.

A remarkably similar scenario has been described in Australia (Kingsford and Johnson, 1998), where large water diversions have resulted in universal population declines of aquatic birdlife and widespread degraded natural habitats. Referring to the Aral Sea, Kindler (1998) aptly stated, “The time to address freshwater challenges is running out.” This applies everywhere. Views on conflicting uses of water in the CRDR are discussed by Rosen (1992), Morrison et al. (1996), Stephens (1997), and others. The messages are all abundantly clear: which will be the uses of scarce water supplies?

Today, another integral part of the CRDR, the Salton Sea, having unique problems of its own as well as problems common to all similar wetlands in western North America (USFWS, 1997; Cohen et al., 1999; UC MEXUS, 1999), remains one of the few dominant wetlands of this once vast and rich ecosystem (Ornithological Council, 1998), along with those remnant wetlands (mentioned previously) south of the U.S.–Mexico border. Anywhere in the CRDR, ample opportunity still exists for significant restoration (highlighted by Glenn et al., 1996; Briggs and Cornelius, 1998; Valdés-Casillas, 1999; Luecke, 1999).

THE PACIFIC FLYWAY: A BROAD MOSAIC UNIFIED BY MIGRATORY BIRDS

The most far-reaching biogeographical connectedness of the CRDR, however, involves migratory birds that come from nearly every part of North America, including elements from the Paleartic (Bellrose, 1980; Linduska, 1964; Shuford et al., in press), although that connectedness might be severely challenged by many of the factors mentioned. For want of a better definition, the classic representation of the Pacific Flyway is depicted in Figure 109.3 (Linduska, 1964; Hawkins et al., 1984). Although the original flyway concept was based largely on band recoveries and distributional data from hunted migratory ducks and geese (Lincoln, 1935; Hawkins et al., 1984), in reality (and from an ecological viewpoint representing many more migratory bird species), a flyway is more realistically and perhaps more theoretically a dynamic, ever-changing mosaic of avian movement patterns within and among habitat patches over space and time. For migratory birds and other mobile fauna, total connectivity in such a system is based largely on their life-history requirements: *availability of suitable habitat* plus its distribution or *accessibility* (see Haig and co-workers, 1998, and Plissner and co-workers, 2000, for specific discussions of these concepts in the conservation of specific migratory birds). It is a system of connected and accessible habitats: wetlands, riparian corridors, or terrestrial habitats (connected by movements in the case of migratory or mobile birds). Each species of bird responds to the presence and accessibility of suitable habitat patches (managed refuges and natural areas, remnants of natural habitat not yet destroyed, patches of restored habitat, artificial and unnatural habitats, agricultural habitats, and sometimes even by other man-modified habitats*). Thus, habitat patterns in such a system must be of sufficient diversity and variety to enable these patches and edges to support a wide variety of bird (and other wildlife) species over the portions of their annual cycles that overlap any given geographical area, and they must be accessible. On a geographic landscape, these patterns merge into a conceptual picture (Figure 109.3) and, therefore, still serve as useful management units for resource managers, and as conceptual units in conservation biology (e.g., combining concepts put forth by Hawkins et al., 1984, and Haig et al., 1999).

For purposes of resource management and administration, the North American continent has been divided into four flyway-based units (administrative flyways, as Hawkins and co-workers, 1984, call them), separated on the basis of state legal jurisdictions (still based, however, mostly on economically valuable bird species, such as hunted migratory waterfowl). Bartonek (1984) described the administrative structure and history of the administrative Pacific Flyway. The definition of their habitats was based largely on hunted migratory waterfowl, but this does not seriously detract from conservation needs of other nonhunted migratory bird species, such as passerines, herons, grebes, pelicans, cormorants, and others, because these species utilize different aspects of the same general habitat mosaics and *all* are protected by the Migratory Bird Treaty Act. Each flyway is managed on a separate basis (recommendations come from knowledgeable expert biologists appointed to each Flyway Council) and the entire system is managed by appropriate federal agencies (Canadian Wildlife Service, U.S. Fish and Wildlife Service [USFWS], and Secretaría de Medio Ambiente y Recursos Naturales [SEMARNAT] in Mexico), working together primarily

* For example, waterfowl communities comprised of wintering species on the Lower Colorado River have been influenced and enhanced by downstream habitats associated with dams (Anderson and Ohmart, 1988).

Figure 109.3 The most recent depiction of the Pacific Flyway. Key central and southern subregions within this broad mosaic include (in rough order of current importance to migratory birds): Sacramento Valley, Klamath Basin and associated areas, San Joaquin Valley, marshes of mainland Western Mexico, Rio Colorado Delta region, San Francisco Bay Delta region, inland lake system in western Nevada, and marshes of western Baja California. (From the U.S. Department of the Interior; taken from Linduska, J.P., Ed., *Waterfowl Tomorrow*, U.S. Fish and Wildlife Service, Washington, D.C., 1964.)

under the Migratory Bird Treaty Act, the Endangered Species Act, and the North American Wetlands Conservation Act.

Recently, significant advances in wetland conservation in the flyways have been made through the North American Waterfowl Management Plan, which includes the CRDR in its Mexican Priority Wetlands designation (Williams et al., 1999) as well as the Wetlands for the Americas programs (Patterson, 1995). North American management plans are now being developed for shorebirds and colonial waterbirds (Kushlan, J., U.S. Department of the Interior, personal communication, 2000). Schmidt and co-workers (1999) have summarized these approaches and philosophy for current migratory bird management in North America.

Regardless of the precise definition of a Pacific Flyway (taxonomic, administrative, ecological, or some artificial combination of the three), it is abundantly clear that the CRDR, despite its current state of ecological degradation, remains a critical stopover habitat for migratory birds in the southern Pacific Flyway (Ornithological Council, 1998). In fact, most other areas of current or previously suitable migratory bird habitat in the Pacific Flyway to the north of the CRDR are

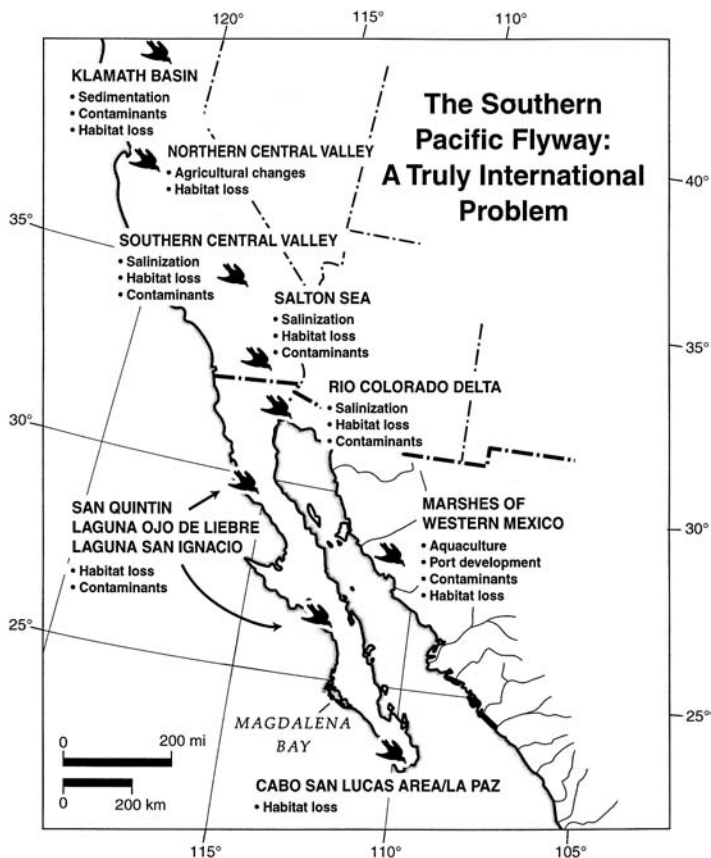

Figure 109.4 Map of the central and southern Pacific Flyway region (western U.S. and Mexico), showing the major general, human-related ecological factors that have impacted habitats for migratory birds. This map was summarized from the many references cited in the text and personal experiences of the authors.

also challenged by many factors related to their degradation, water development projects and related habitat losses being one of the major concerns throughout the western U.S., plus numerous factors in areas to the north (Figure 109.4) and south (Figure 109.5) of the CRDR. In fact, wetlands throughout western North America have been considerably reduced and changed (Gilmer et al., 1982, 1995; Nichols et al., 1986; Glenn et al., 1996). Most of the remnants of such habitats remain as state or National Wildlife Refuges, or in some cases as private land (e.g., hunting clubs in California; Gilmer et al., 1982). It is also clear that the remnants of these habitats are highly modified, human-influenced systems (Anderson, 1995; Mellink and Ferreira-Bartrina, 2000). The agriculture-wildland interface is not likely to change much in the future; these habitats are no longer free of the influences of human development. In fact, an agriculture and wildland interface is probably the dominant characteristic in the central and southern portions of the entire Pacific Flyway.

The far-reaching ecological connections of this region are increasingly important to all migratory birds of the Pacific Flyway, which is still a vast and ever-changing system of migratory corridors and critical wintering and stop-over habitats (both wetland and terrestrial) for birds from all parts of this continent. Native riparian vegetation corridors have largely disappeared or are disappearing along the lower reaches of the Colorado River system (Rosenberg et al., 1991) due to outright destruction resulting from factors mostly related to water use and management, the invasion of

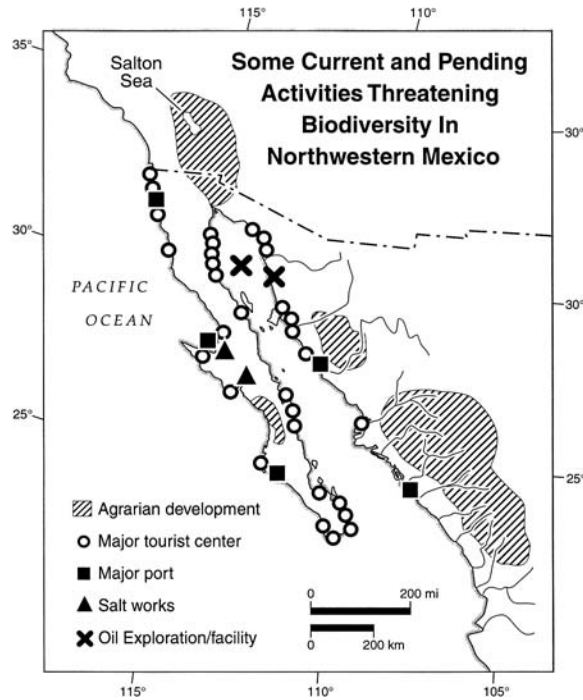

Figure 109.5 Map of the Gulf of California, summarizing the range of human-related activities that threaten ecological connectedness and integrity in this part of the Pacific Flyway. This map was summarized from the many references cited in the text and personal experiences of the authors.

exotic plants and animals, and other factors (Glenn et al., 1996; Valdés-Casillas, 1999; Luecke et al., 1999). Although most highly migratory bird species do not require continuous habitat corridors, less migratory species do; and small, isolated oases are important for migrating birds as well as for local breeding populations (Hinojosa-Huerta, O., personal communication, 2000; Skagan et al., 1998).

Harrison and Bruna (1999), in reviewing habitat fragmentation theory, have concluded that neither corridors nor configuration can substitute for overall habitat loss. If improvements are to be made, no more native or even altered habitat that is suitable for wildlife need be further degraded; instead, wetland habitats need to be enhanced and restored (Zedler and Powell, 1993). If migratory birds are to be protected and enhanced, it is clear that, for the most part, the southern Pacific Flyway must enter an era of restoration and *increased* protection (Glenn et al., 1996; Briggs and Cornelius, 1997; Briggs and Cornelius, 1998).

In the northern Gulf of California, still a part of the CRDR (Figure 109.2), native avian biodiversity is rich and abundant, comparatively unchanged (Anderson, 1983; Velarde and Anderson, 1994; Everett and Anderson, 1991; Mellink et al., 1997; Ruiz-Campos and Rodríguez-Meraz, 1997; Patten et al., 2000). Yet, here one of the world's most endangered marine mammals, the vaquita or *little cow* (*Phocoena sinus*), still resides in very low and dwindling numbers (Vidal, 1995) and a formerly important commercial fish species, the totoaba (*Totoaba macdonaldi*), is now also threatened by human activities and habitat loss in the CRDR (Cisneros-Mata et al., 1995). In fact, the general region of the CRDR and northern Gulf of California faces continuing threats of degradation and ecological decline (Anderson et al., 1976; Tershy et al., 1977; Glenn et al., 1996; Galindo-Bect et al., 1999).*

* Some interesting newspaper accounts, mostly relating to the Gulf of California, can be found in a series of articles by Tom Knudson, *Sacramento Bee*, 1995 and 1999; <http://www.sacbee.com/news/projects/dyingsea>.

THREATS TO BIODIVERSITY AND ECOLOGICAL HEALTH IN THE COLORADO RIVER DELTA REGION

What happens in one part of the CRDR potentially affects its other parts, even outside this geographic area. What happens to migratory birds in this region has potential to affect their populations in distant places; linked to that are the dominant and modifying influences of past and present human activities.

Ohmart and co-workers (1975) clearly recognized the potential for properly managed riparian wetlands of the Lower Colorado River, for both land bird and waterbird conservation. Briggs and Cornelius (1997) have stated, "Despite the tremendous changes that have occurred in the Colorado River Delta, it is important to emphasize that the delta is not beyond recovery." Saunders and Saunders (1981) similarly stated, "Undoubtedly many thousands more ducks and geese would winter in this area if conditions were more favorable."

Ohmart and co-workers (1975) and their many colleagues recognized the ecological values of this region some 30 years ago; they conducted intensive management and restoration research activities along the lower Colorado River (Rosenberg et al., 1992) that will serve as a model for future restoration.

Understanding the mechanisms whereby human-induced and natural variables affect a system and its components, how negative effects can be alleviated and positive effects enhanced, is the major goal of conservation biologists, resource managers, governmental leaders, and the people who utilize or otherwise interact with these resources. Whether and how these systems ultimately become managed and conserved rest in the uneasy realm between knowledge and reality, policy and politics; necessarily, it includes the aspects of use (conservation is most commonly defined as "wise use") (Bildstein et al., 1991; Cairns, 1994), as well as some major readjustments in the way things are currently done.

Numerous problems concerning the conservation and population viability of CRDR migratory birds and other wildlife have been identified by various authors (Anderson et al., 1976; Velarde and Anderson, 1994; Glenn et al., 1996; USFWS, 1997; Valdés-Casillas, 1998b; Cohen et al., 1999; and others). Based on our experiences in the region over the past several decades, we have attempted to summarize threats that might in various combinations apply to most categories of wildlife and wildlife habitat (including migratory birds) in the CRDR and Gulf of California region (Figure 109.6). Importantly, they encompass the following general factors, ranked by us in order of importance:

1. Outright habitat destruction and loss of connectivity through water diversions; flooding by poor quality wastewaters, and other water development activities; development of shoreline facilities; drainage of coastal wetlands; agricultural and urban developments.
2. Undesirable habitat modification and degradation through the introduction and subsequent competition from exotic plants and animals, eutrophication, pollution from agriculture and aquaculture (see Naylor et al., 1998; Páez-Osuna et al., 1998; Mellink and Ferreira-Bartrina, 2000), salinization, introduction of exotic diseases, sedimentation, and habitat destruction (Watling and Norse, 1998).
3. Direct mortality of wildlife (Rocke and Friend, Chapter 110, this volume) through unmanaged exploitation, further disease or contaminant interactions, incidental or accidental "take"; or through pollution *per se* (Mora et al., Chapter 111, this volume): direct toxic effects of biocides, salts, toxic levels of nutrients, oil, and other chemicals.
4. Interferences and disturbances, sublethal effects of contaminants, simple disturbances in various wildlife concentration areas, feeding areas, loafing areas, and breeding areas (such as recreational and vehicular traffic on beaches and areas adjacent to wetlands), competition with fisheries, aquaculture, and agriculture (also note that some of these interactions occasionally have a positive effect on some species of wildlife).
5. Shortsighted planning and lack of understanding of ecosystem functions.

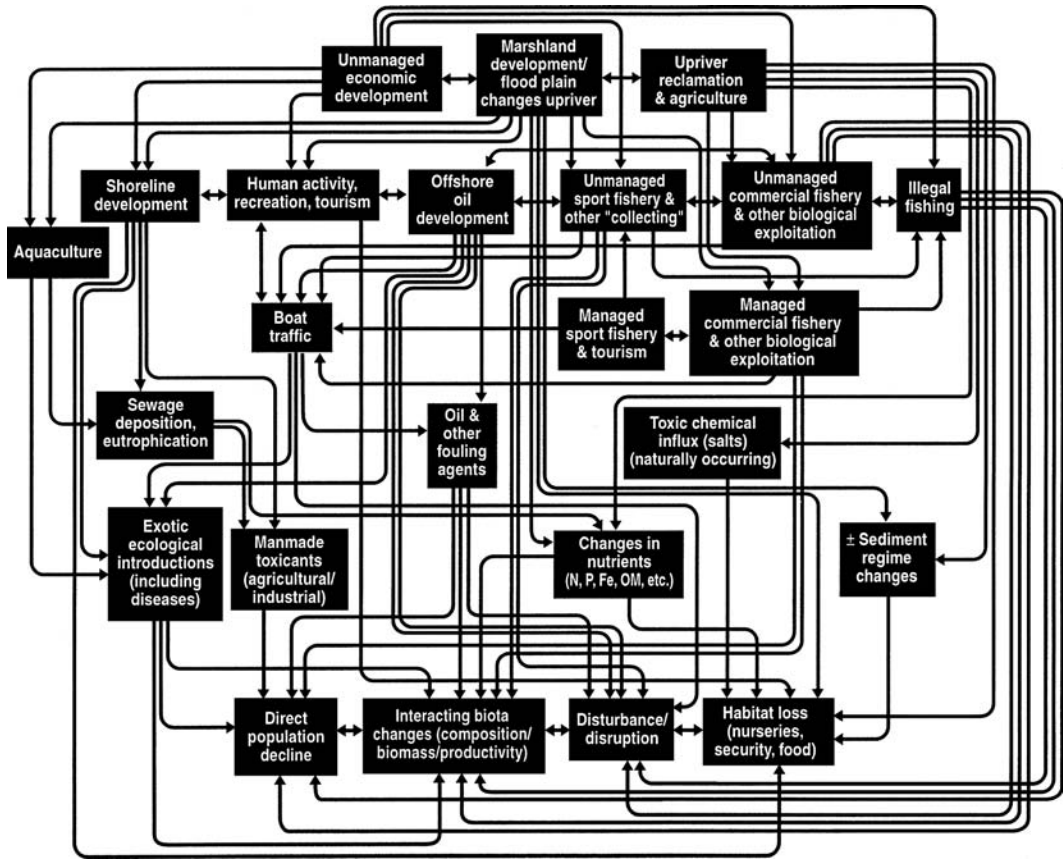

Figure 109.6 A conceptual flow diagram summarizing the interrelatedness of the various threats to biodiversity in the CRDR. Different biotic elements in the system are affected through various pathways that lead to ultimate population decline and biodiversity loss.

Interestingly, this condensed list, although specifically drawn from the CRDR, reads almost like a catalog of world migratory-bird conservation problems. We cannot go into specific detail here, outlining each and every situation (if even all were known). But in a general sense, it can be seen that different categories of wildlife (migratory birds in this discussion) would follow different and multiple pathways to their degradation. A purely single-species approach would in most cases be “too-little, too-late.” We need to ask questions such as “what happens when we are confronted with an extinction of habitats as has been shown to be associated with many endangered freshwater, aquatic communities in interior North America” (Moyle and Williams, 1990). Whole-system or watershed approaches and philosophy are ultimately needed (National Research Council, 1992). This has been a new trend in conservation programs, such as the World Wildlife Fund and Nature Conservancy ecoregional approach. It can and should be done, also considering the “small pieces,” such as very specific management plans for local habitats (marshes, blocks of riparian vegetation, offshore islands, or even single species in certain instances).

Cairns (1994) advocates that only a “top-down” approach, starting with the entire system and working down to components, will ultimately succeed. Cairns states, “The component-by-component approach is not as effective when a dense population with high per capita energy consumption is competing for an ever-diminishing natural resource base.” And that is just what the CRDR represents. Yet CRDR complexity suggests that in order to solve large problems, step-by-step solutions and approaches need to be identified soon. This will require strong commitments from governments and local communities. Some situations, such as conservation for the vaquita, seem

simple but may in reality be highly complex and difficult for strictly nonbiological reasons, such as illegal fishing activities and net-entrapments, open access, and lack of economic alternatives (Vidal, 1995; Rojas-Bracho and Taylor, 1999) (Figure 109.6). This critically endangered marine mammal requires a “bottom-up” emergency approach as a prelude to more encompassing approaches in the overall conservation and management of the CRDR system. Other situations indicate that a large suite of regional problems might eventually contribute to a degradation of some specific aspect of the system; this seems to be the case for migratory birds (Figure 109.6; a large proportion of the illustrated factors contribute to overall population declines). Once a societal commitment to conservation of biodiversity is secured for the CRDR, individual problems can be attacked one by one. Emergency situations, such as high gill-net mortality in the vaquita, still need immediate attention.

When dealing with the potential population effects of habitat deterioration, developers and politicians often argue that migratory birds will merely move elsewhere (Anderson, 1999). This question can be addressed for the CRDR by simply stating that habitat deterioration is characteristic of the entire CRDR region and for most of the Pacific Flyway (Figures 109.4 and 109.5). Sutherland (1998) has proposed a quantitative framework for evaluating habitat deterioration effects on global populations of migratory birds and other species. Regarding widespread regional deterioration, he states, “as the population is displaced from the site of local deterioration, there will be increases in density in other sites resulting in density-dependent mortality”; this will extend to breeding success elsewhere with the ultimate degradation of species’ populations. Sutherland’s (1998) framework requires much knowledge and information (basic research) to derive various terms in his equations, but it can be extended to any species. Yet in many cases, there may not be enough time to gather all the ecological data necessary to adequately quantify a complex model.

Worse, however, are occasions where there is no “elsewhere” for displaced birds, and this may well be the case for some species of CRDR birds. For much of the CRDR, the idea can be simply stated as “more protections and more restorations are needed, in as many places as possible” (our paraphrase). We know of no other situation so similar in an ecological, political, and social milieu of the CRDR as the Aral Sea, where river deltas have also historically been the most productive and richest parts of the ecosystem and where “linking environmental and economic objectives is not an easy task if one takes a short time perspective” (Kindler, 1998). Kindler proposes, as a first step in mitigation, the creation of “wetland belts (wetland buffer zones)” in the ecologically important delta areas, but difficulties arise because upland water uses and delta ecological needs are separated by political boundaries. Yet wetland belts and riparian areas function in one importantly defined “ecological service”: they significantly improve water quality in flow-through waters (Gilliam, 1994).

BIODIVERSITY CONSERVATION IN THE CRDR

The major foundation for migratory bird conservation in North America is the Migratory Bird Treaty Act of 1936 (with modifications in 1972). Specifically in the CRDR and the Gulf of California, efforts toward conservation of wildlife resources and associated habitats are active on both sides of the U.S.–Mexico border, in some cases utilizing a whole-system or “top-down” approach. These efforts are being supported by strong bottom-up approaches through species- or local-area-specific management plans. Conservation approach in Mexico has been mostly a matter of top-down, whole-ecosystem conservation and management rather than by single species or groups of species, such as migratory waterfowl. Yet, interspecies aggregations, categories of birds or mammals, and single species have recently come to represent immediate and short-term conservation problems that have remained unsolved. Much conservation-oriented activity is occurring in the CRDR, although much of it depends on opportunistic supplies of water that come south more by accident or stochasticity than by design (Glenn et al., 1996; Briggs and

Cornelius, 1998). The USFWS has participated with SEMARNAT and several institutions through the North American Free Trade Agreement (NAFTA) for more effective international wildlife management. More recently, the Department of the Interior has entered into a cooperative agreement with SEMARNAT to enhance U.S.–Mexico collaboration (Babbitt and Carabias, 1997). One of these collaborations is through the “sister reserves,” which coordinate activities between the Biosphere Reserve of the Upper Gulf of California and the Imperial Valley National Wildlife Refuges. Other efforts include assessments of abundance, distribution, and habitat use of the Yuma clapper rail in the CRDR, as well as monitoring of waterbirds in the Biosphere Reserves. The North American Wetland Conservation Council is also supporting projects for conservation and restoration of wetlands in the CRDR.

In Mexico in the last decade, several bioregional plans to manage and conserve that nation’s resources have grown through the Biosphere Reserve concept (Halfter, 1980; Dyer and Holland, 1991). In 1993, Mexico established the Reserva de la Biosfera Alto Golfo de California y Delta del Río Colorado (together with an adjacent reserve, the two form one of the largest protected areas in the world) (see figure in Alvarez-Borrego, this volume).^{*} In 1995, Biosphere Reserve plans for this area were recognized as a biodiversity management plan by the Mexican federal agency, SEMARNAT.

In 1985, Mexico became a contracting party to the Convention on Wetlands of International Importance (RAMSAR Convention) and, in 1996, Mexico designated these same marshes (Colorado Delta) as one of two new worldwide RAMSAR sites called “Humedales del Delta del Río Colorado” (Hubert and Frazier, 1997). The RAMSAR Convention is a treaty among various governments to conserve the world’s wetlands (Frazier, 1996). During 1998–1999, in support of the program, “Partners in Flight,” a series of workshops throughout Mexico was carried out for the definition of important bird areas (IBAs). The riparian corridor and wetlands of the lower RCD were put on the list of IBAs for northwestern Mexico.

In 1992, the lower CRDR wetlands (along with the Marismas Nacionales, 1200 km south) were the first sites in Mexico to be designated “international reserves” in the Western Hemisphere Shorebird Reserve Network. Ducks Unlimited, Inc., Memphis, TN, and the Canadian Wildlife Service are currently assisting Mexican ornithologists to produce a Mexican Shorebird Conservation Plan that includes the CRDR as one of the most important shorebird habitats in all of Mexico (McKnight, K., personal communication, 2000). And in 1994, Mexico also became a cooperator in the North American Waterfowl Management Plan. The many restoration opportunities, consequences of water use, and feasibility of enhanced water acquisition for wetland use are outlined by Glenn et al. (1996) and Briggs and Cornelius (1997). There is yet another active program involving cooperation among many U.S. and Mexican institutions aiming to restore the Rio Hardy wetlands (Figure 109.1; Valdés-Casillas et al., 1998b, 1999; Payne et al., 1991).

Another biosphere reserve, the Islas del Golfo de California, Zona de Reserva y Refugio de Aves Migratorias y Fauna Silvestre, whose regional offices are in Guaymas, Ensenada, Loreto, and La Paz, operates mainly regarding management, protection, and research on the many islands in the Gulf of California (a management plan is currently in draft) (SEMARNAT, 1999; Zavala, A. and Figueroa, A.L., personal communication, 1999; <http://uib.gym.itesm.mx/>). A third reserve, the Reserva de la Biosfera, El Vizcaino operates on the Pacific Coast of Baja California in the San Ignacio Lagoon area (Sanchez-Sotomayor, V., Director, personal communication, 2000).

In the U.S., additional programs are emerging that combine the international aspects of migratory bird conservation and management. In 1994, the USFWS initiated an ecosystem-approach policy to address national fish and wildlife issues. The Salton Sea Science Subcommittee is considering logical steps for ecological restoration of the Salton Sea, mostly under

^{*} There are also two issues of *CEDO News* (summer 5(2)1993 and fall/winter 6(2) 1994) that describe this significant event (Ramirez, 1994). *CEDO News* is a bilingual, educational newsletter published by the Intercultural Center for the Study of Deserts and Oceans, P.O. Box 249, Lukeville, AZ 85341.

a recently passed House of Representatives bill, the Sonny Bono Memorial Salton Sea Reclamation Act. It is also developing plans that include wetland restoration projects and fisheries enhancements (Sziij, L., California State Polytechnic University, Pomona, personal communication, 2001; Salton Sea Authority and U.S. Bureau of Reclamation, 1998). The Environmental Protection Agency (USEPA) is executing an "Environmental Plan for the Mexican-U.S. Border Area" that involves environmental protection and pollution reduction under a 1990 agreement between Mexico and the U.S. (USEPA, 1992; Mumme, 1992), also called "Programa Ambiental Frontera 21." The UC MEXUS (University of California Institute for Mexico and the United States) Committee and Pacific Institute, nongovernmental organizations (NGOs)* involved in Rio Colorado Delta problems (Cohen et al., 1999; UC MEXUS, 1999), have provided additional guidelines for management and restoration of the region's resources, including the proposal for new partnerships between agricultural and natural resource interests (such as proposed in the San Francisco Bay Delta, CALFED Program; Meadows and Goetz, 1999). Another major recommendation of these two NGOs is to expand the view of problems at Salton Sea to the entire CRDR.

SOME COMPARISONS WITH OTHER PROGRAMS

We do not have space here to discuss this issue adequately, but as a beginning, we have briefly compared the Colorado Delta programs with two other well-known conservation and management programs, the Great Lakes Water Quality Agreement (Gilbertson, 1997, 1999; Gilbertson et al., 1999) and the CALFED San Francisco Bay Delta Program (Table 109.1). Some outstanding features of effective international and regional programs like these include (1) long history of interest in the region on both sides of the border, (2) long- and short-term international agreements (that include international working bodies) with continual evolution, (3) heavily shared resources in the system, (4) shared and equal responsibility for the resources and their uses, and (5) a strong funding commitment. Apparently, successful programs involve many additional attributes (Table 109.1).

Most importantly for the Colorado River Delta, strong international cooperation and aid are needed to bolster the advancing but sometimes uncoordinated conservation programs of the region. Working in mostly restored and forever-altered ecosystems is a major challenge for conservationists in the CRDR wetland areas (Glenn et al., 1996). It will be necessary for agricultural and natural resource interests to work together more closely than in the past (UC MEXUS, 1999). We believe it would be better to substitute large engineering projects with large-scale, international habitat-restoration projects and land stewardships, guided by an international coordinating commission. Techniques for the restoration of native vegetation in these habitats were pioneered by Rosenberg et al. (1991), Zedler (1995), and others; activities such as these must be an active element in the future conservation biology of the area (Environmental Defense Fund, 1996; Briggs and Cornelius, 1997, 1998; Valdés-Casillas et al., 1998a).

Ingram and co-workers (1995) have aptly stated: "Environmental problems have become so large that they can be intelligently grasped and dealt with only on a scale that transcends national boundaries." Szekely (1992) has studied and proposed a trilateral convention and treaty among the U.S., Canada, and Mexico to deal with current and future environmental problems. For wildlife and ecosystem health, we believe an international commission is needed to coordinate these efforts.

Yet, in Mexico there has been little long-term planning for enforcement activities. The creation of reserves and management plans is still in its infancy; funds are generally insufficient or lacking;

* UCMEXUS is the University of California Institute for Mexico and the United States (University of California, 3324 Olmsted Hall, Riverside, CA 92521; www.ucr.edu/ucmexus/). The Pacific Institute for Studies in Development, Environment, and Security (654 13th Street, Preservation Park, Oakland, CA 94612; www.pacinst.org) is an NGO dedicated to sustainable development and international security.

Table 109.1 Some Subjective Comparisons between Large-Scale Ecosystem-Oriented Restoration and Management Programs in North America and Developing Ecosystem Restoration Programs in the Rio Colorado Delta Region

Characteristic	Great Lakes	CALFED Bay Delta	Rio Colorado
Ecological crisis defined	X	X	X
Long-term treaties or agreements negotiated, continually refined	X	(X)	0
Realistic, attainable goals, objectives ^a	X	X	(X)
Associated programs integrated, allowed to continually evolve	X	(X)	0
High economic or social value of resources involved	X	X	X
Program involves "top-down" approach	X	X	X
Program involves "bottom-up" approach	X	X	(X)
Multiple stressors approached	X	X	0
Resources heavily shared by many parties, with mutual benefits	X	X	(X)
Lack of control by either party; lack of or weak differential access to resources	X	X	0
Outstanding, extensive database; continuing scientific study; "hard science" (basic and applied)	X	X	0
Healthy debate on issues	X	X	0
Results (e.g., population recoveries) have been and continue to be seen	X	X	0
Generous, enviable, funding; strong societal commitment	X	X	0
Long-term commitment	X	X	(0)
Protected zones part of solution	X	X	X
Relatively less demand for water itself	X	0	0
Extensive local involvement	X	X	(X)
"Inspired" team of lawyers and biologists	X	X	(0)

Notes: Characteristics of each regional situation are subjectively compared in their major defining characteristics and will hopefully serve as a basis for further discussions. References for the Great Lakes and CALFED (San Francisco Bay Delta) are mainly from this volume and Gilbertson (1997, 1999). Symbols under each category are strictly subjective and generally represent: X = we think that this characteristic is strongly present in the program, (X) = we think this characteristic is weakly or potentially present in the program, 0 = we think this characteristic is absent from the program, and (0) = we think this characteristic is potentially absent from the program.

^a This is, of course, dependent on who defines these objectives; we are using "ecological health" objectives discussed in the text.

implementation of specific management plans is slow or lacking; protection and monitoring of endangered species are almost nonexistent; and the ecology and avifauna of many of the wetlands remain little studied and cataloged. The problem of wetland and biodiversity conservation in the region is complex and any conservation strategy must consider the following aspects:

1. Governments must ensure the protection of these ecosystems through enforcement, using data from academia for better decision making.
2. Support for essential research, such as biodiversity monitoring and basic ecological studies, will be essential.

3. Direct conservation of natural habitat must continue to be an important approach, and it should be followed by completion and implementation of management plans.
4. Cooperative programs among the U.S., Canada, and Mexico should expand, but solutions to the problems must be site-specific and operational, taking into account not only the biological importance of the resources but also the uses made of them by local inhabitants and their importance to local economies.
5. Local residents must not feel deprived of their rights and resources.
6. Enforcement should be complemented with a nonregulatory management program, which can also be adaptive with a participatory approach.

Regarding the Salton Sea but applicable to the entire CRDR, Hurlbert (personal communication, 1999) mentioned four natural-resource management objectives that appear achievable for the CRDR:

1. The protection and restoration of viable and functional wetlands and associated habitats
2. A continuing but environmentally sensitive agriculture
3. Commercial fishing ventures
4. Sportfishing and outdoor recreation activities

The Department of the Interior (USDI) has begun a process that more fairly allocates water supplies from the Colorado River for bioconservation purposes (*ENN News*, 5 August 1999, "California deal cuts use of Colorado River water"). The USDI also recently signed an agreement with Mexico for a binational watershed plan for the nearby San Pedro River Basin (*ENN News*, 23 June 1999, "U.S., Mexico team up to protect watershed"). Yet, we have to ask whether the powerful and influential water-use interests of the large cities of southern California, the extensive monotypic and polluting agricultural uses of Colorado River water, golf courses, resort and casino development with high-impact recreational uses on the Salton Sea and Lower Colorado River, a growing aquaculture industry, and burgeoning human populations will prevail at the cost of biodiversity, ecosystem health, and local human populations. Furthermore, will both the U.S. and Mexico, now being aware of the unique ecological and economic importance of the CRDR, allow for its further degradation and disappearance?

ACKNOWLEDGMENTS

This chapter originated in 1995 as a lecture by DWA on Gulf of California seabird conservation at the Cooper Ornithological Society and Mexican Section of Birdlife International (CIPAMEX) joint meeting in La Paz, Baja California, and then became the basis of a briefing to southern California congressional representatives in Washington, D.C. in 1996. It was further developed at a UC MEXUS workshop, a USFWS workshop, U.S. Geological Survey (BRD) workshops, a Pacific Institute workshop on the Salton Sea and Rio Colorado Delta area in 1997–1998, various workshops and meetings facilitated by the Salton Sea Science Subcommittee and then into its finalized form here. This contribution also represents a project of the New World Pelican Working Group of the World Conservation Union and Wetlands International (DWA, co-chair with A. Crivelli). Support for CV-C was provided by the North American Wetland Conservation Council, PRONATURA Sonora, the Sonora Institute, and the Summit and Compton Foundations. The UC MEXUS Program was a unifying and driving force for all of this. Thanks also go to Juan Guzman-Po and Lloyd Kiff for setting up the original paper, and to Milton Friend and others of the Salton Sea Science Subcommittee for encouragement and support along the way. Claudia Graham produced the illustrations.

NOTE ADDED IN PROOF

At the initial writing of this review, conservation activities in the CRDR were moving so rapidly that it was difficult to keep up and we feared this chapter would be outdated by the time it was published. Ironically, since 2000, little has happened and our chapter remains more current than we had imagined. One recent book adds to the CRDR literature:

Pattern, M.A. and McCaskie, R.G., *Birds of the Salton Sea: Status, Biogeography, and Ecology*, University of California Press, Berkeley, 2002.

Several scientific journals have produced or will be producing issues devoted wholly or in part to the CRDR: *Hydrobiologia*, 466, 2001; *J. Arid Environments*, 49, 2001; *Hydrobiologia*, 473, 2002; *Studies in Avian Biology*, in press, 2003.

Wildlife Disease in the Colorado Delta as an Indicator of Ecosystem Health

Tonie E. Rocke and Milton Friend

INTRODUCTION

Ecosystem health and management are relatively new paradigms for environmental management (Costanza et al., 1992) and will be continually redefined and reevaluated relative to their purpose and utility in serving human society (Costanza et al., 1992; Sutter, 1993; Grumbine, 1994; Lackey, 1998, 1999). The stimulus for ecosystem management is often associated with sustaining or restoring ecosystem health to provide values sought by humans (Costanza et al., 1992). We accept the concepts of ecosystem health and management as useful precepts. However, we argue that the orientation in serving human values often has resulted in inadequate attention being given to nonhuman species. The need to address ecosystem health for the benefit of all species that share Planet Earth is noted by Merchant (1997). This humanistic viewpoint also has economic benefits that are part of the wealth that we will pass on to future generations (Pulliam, 1995). Despite the viewpoints just noted, disease occurrence in wildlife receives inadequate consideration with regard to perspectives of ecosystem health and as a focus for ecosystem management. Evidence for this view is the limited resources allocated for wildlife disease programs and prevention efforts, and persistent attitudes within the wildlife conservation community that disease is a “natural event,” not influenced by environmental conditions or anthropogenic insults (May, 1988; Friend, 1995).

Wildlife species are frequently viewed to serve as the “canary in the coal mine” for protecting and predicting human health problems, particularly in association with monitoring zoonotic diseases (Korch et al., 1989; Reisen et al., 1997) and chemical contamination of the environment (University of Connecticut, 1979; Beyer et al., 1996). However, the complexity of interacting factors that result in health impacts from contaminants requires more than measuring the presence of chemical residues in animal tissues or the environment (Anderson, 1998). Likewise, detecting antibody for infectious diseases in animals or virus in insect vectors does not directly translate to cases of human disease. Clinical cases of animal disease are generally of greater importance as an index for human health risks.

The recent resurgence of infectious diseases within human populations and concerns related to changing patterns of disease associated with predicted global climate change (Colwell, 1996; McMichael et al., 1996; Patz et al., 1996) have also created renewed interest in wildlife diseases as indices for human health (Epstein et al., 1998). However, disease emergence during recent years among free-ranging wildlife populations (Murphy, 1994; Friend, 1995, 1999) has not been seriously considered

as an index of ecosystem health for wildlife. In general, the response to wildlife disease events has been typical of the response to other catastrophic events, focusing on cleanup and documentation of the event, rather than stimulating a collective focus on the environmental conditions that are influencing disease outcomes. We contend that greater attention to the health of free-ranging wildlife will provide substantial benefits for wildlife and humans alike. This philosophy goes beyond the common perspective of wildlife serving as the canary in the coal mine or as an index to impending doom for humans. We argue that wildlife disease occurrence, in addition to being a component of an environmental distress syndrome for human values (Rapport and Whitford, 1999), has important considerations for wildlife conservation (sustainability) and species biodiversity (Friend et al., 2001).

We use the Salton Sea in southern California as a case study of an ecosystem where an increase in documented disease occurrence in wild birds and fish is an obvious indicator of declining ecosystem health. In addition, we contend that, for migratory birds, the concept of ecosystem health should be expanded from individual units to that of nested but disparate units (wetlands and flyways) that provide for species well-being during the entire annual migration cycle. We also describe recent findings on wetland characteristics associated with avian botulism in waterbirds to illustrate the point that environmental indices can be used to assess and perhaps reduce the risk of disease in specific ecosystems. Our viewpoints are based on our personal opinions of what constitutes ecosystem health and are influenced by our experiences as practitioners dealing with disease in free-ranging wildlife populations.

DISEASE AS AN OUTCOME

Traditionally, population and evolutionary biologists have generally viewed infectious diseases as agents of natural selection in higher organisms (Levin et al., 1999) and, in some cases, we concur that disease agents may act in this capacity. However, this concept of disease as solely a natural event fails to recognize that disease is an outcome rather than a cause (Friend, 1995). In a very simple model (Figure 110.1), disease is a product of interactions

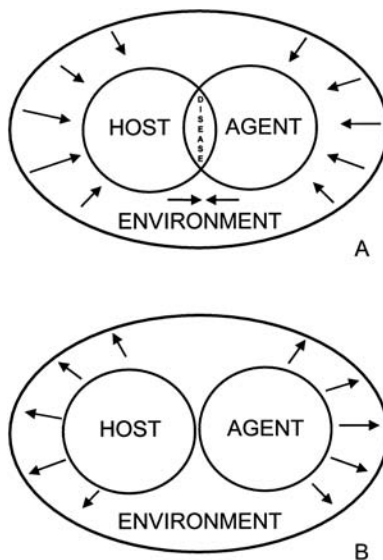

Figure 110.1 (A) Disease may be generically thought of as an outcome of interactions (area of overlap) between susceptible hosts, agents capable of causing disease, and environmental factors. In many instances, environmental conditions are the dominant factor. (B) Understanding and managing the environmental component of this triad in a manner that minimizes the potential for major disease outbreaks is a basic ecosystem management need for the conservation of wildlife populations.

between a host population, one or more agents, and environmental factors, which encompass insect vectors for transmission of some diseases, nutritional factors that affect susceptibility, and other considerations too numerous to list. Because environmental conditions play such a major role in the outcome of host-agent interactions and can influence the outcome for better or worse (from the perspective of the host population), it is reasonable to consider disease occurrence and ecology as parameters for evaluating ecosystem health, regardless of the etiologic agent involved.

Human health has benefited greatly from application of this concept. Environmental standards for sanitation are testimony to the recognized relation between environmental quality and disease outcomes that periodically reappear in the scientific literature (Dubos, 1958, and Van Cleave, 1945, as notable examples). These lessons are continually relearned as a result of infrastructure destabilization and breakdown due to war, political turmoil, and catastrophic natural disasters (Kohn, 1995; Maurice, 1995). Human-induced changes in environmental conditions are the major reason that environmental standards are needed to protect human health. Nevertheless, the relation between disease occurrence and environmental conditions has largely been ignored in the application of ecosystem health concepts to nonhuman species. An exception is the common focus on chemical contaminants. Thus, it is noteworthy that the first annual meeting of the Society for Conservation Biology included a symposium titled, "Conservation and Disease." During the meeting, it was stated that:

Given the conspicuous role that diseases have played, and in many parts of the world continue to play, in human demography, it is surprising that ecologists have given so little attention to the way diseases may affect the distribution and abundance of other animals and plants. Until recently, for example, ecology textbooks had chapters discussing how vertebrate and invertebrate predators may influence prey abundance, but in most cases you will search the index in vain for mention of infectious diseases (May, 1988).

We contend that the conservation (sustainability) of wildlife is a valued function and product of ecosystems. Therefore, we view some wildlife mortality events as a reflection of declining ecosystem health that may negatively impact wildlife conservation, biodiversity, and human benefits derived from those ecosystems. However, the mere presence of disease in a population, even an event causing catastrophic losses, is not necessarily an indicator of poor ecosystem health. Rather, evaluations should be based on changes in the frequency of disease occurrence, the etiologic agents involved, and the magnitude of disease losses in relation to the capacity of an ecosystem to sustain its wildlife species and populations. Further, we do not advocate the absence of disease as necessarily being a desirable aspect of ecosystems, especially for diseases caused by endemic infectious agents. Actually, species naivety to some infectious organisms can result in enhanced vulnerability to disease outbreaks. Also, some host-parasite interactions may truly function to regulate populations (Jellison et al., 1958; Bell and Reilly, 1981; Hudson, 1986; Dobson, 1988), as hypothesized for other causes of mortality, such as predator-prey interactions (Crawley, 1992; Greenwood and Sovada, 1996). Depending on the functional relations of the affected species within an ecosystem, disease impacts (or lack of disease) may result in broader ecosystem perturbations.

We have emphasized two key points: (1) the outcome of disease in human and nonhuman species alike has a strong linkage to environmental quality, supporting the need for disease evaluations as an index for ecosystem health; and (2) disease impacts on wildlife populations can, in some cases, reduce their recreational, economic, and aesthetic value to human society. Therefore, evaluations of ecosystem health and ecosystem management should consider the effects of disease on the sustainability of wildlife populations at levels consistent with human values (consumptive and nonconsumptive uses).

AVIAN DISEASE AND THE SALTON SEA

The Salton Sea, located in the Imperial Valley of southern California, is a unique ecosystem. A brief review of its history will provide the necessary context for our discussion. This largest inland water body in California is of recent origin. In 1901, water was diverted from the Colorado River to irrigate the Imperial Valley and was quickly followed by settlers who cultivated the land. Flooding by the Colorado River resulted in a breach of an irrigation structure in March 1905 and extensive water flow into the Salton Trough. Unprecedented multiple flood events resulted in further diversion, eventually causing the entire flow of the river to discharge into the Salton Trough. Following Herculean efforts to close the breach, the Colorado River was finally returned to its riverbed on February 10, 1907 (Kennan, 1917). Left behind was a freshwater lake with a surface elevation 195 feet below sea level. By 1925, evaporation exceeded inflows, and the sea subsided to 250 feet below sea level (Laffin, 1995). The sea is currently stabilized at 227 feet below sea level, augmented primarily by increased irrigation plus wastewater from industry and sanitation. Evaporation and inflows have equilibrated at about 1.363 million acre-feet (Tetra Tech, Inc., 1999), resulting in a current sea that is 35 miles long, 9 to 15 miles wide, with a surface area of 380 square miles, and a volume of approximately 7.3 million acre-feet. The sea has a maximum depth of 51 ft and an average depth of about 31 ft (Cohen et al., 1999).

Since its formation, the salinity of the sea has risen to approximately 44 ppt due to precipitation of salts upon evaporation of surface water. This level of salinity exceeds ocean water by 26% and is increasing at a rate of approximately 0.5% per year (Figure 110.2) due to an annual input of approximately 5.2 million tons of dissolved salts (Tetra Tech, Inc., 1999). In addition, nutrient loading from the inflows has created a highly eutrophic water body. Approximately 15,000 tons of nutrients such as nitrogen and phosphorus annually flow into the sea (Cohen et al., 1999). Despite the hypersaline, eutrophic conditions, the Salton Sea supports the most productive sportfishery in California inland water bodies based on angler success (Black, 1985) and is habitat for an extraordinary number of bird species. With more than 400 species of birds reported at the sea and

Figure 110.2 Projected increases over time in the level of Salton Sea salinity based on continuation of the current inflow of 1.363 million acre-feet of water. The annual rate of increase is approximately 0.5%. (Salinity graph provided by P.A. Weghorst, Principal Hydrologic Engineer, Salton Sea Reclamation Project, Bureau of Reclamation.)

surrounding environs (Shuford et al., 1999), the avian biodiversity of this ecosystem is greater than nearly all other wetlands in the contiguous U.S.

Avian disease is not new to the Salton Sea. An outbreak of “duck sickness” was reported at the Salton Sea as early as 1917 (Kalmbach and Gunderson, 1934), and correspondence of the Bureau of Biological Survey in the National Archives indicated major die-offs of waterfowl and other waterbirds in the mid-1920s (Holmes, 1933). The focal points for these events were the deltas of the New and Alamo Rivers at the southern end of the sea. Initial descriptions of sick birds and field signs strongly suggest type C avian botulism as the causative agent, a disease that was diagnosed as the cause of major mortality events at the sea during 1933 and 1934 (Kalmbach, 1938). A review of the Salton Sea National Wildlife Refuge (now the Sonny Bono National Wildlife Refuge) narrative reports from 1939 to the present (no reports could be located for the period from 1930 [year of establishment] to 1939, nor during the war years from 1942 through 1946) disclosed periodic occurrences of avian botulism and little else until the 1980s (Friend, 2002).

Avian cholera (*Pasteurella multocida*) first appeared within the Salton Sea ecosystem during 1978. The following year, the first major epizootic from avian cholera killed several thousand waterbirds (Brand and Duncan, 1983). The next appearance of avian cholera did not occur until February 1983, when a small event resulted in the collection of 170 carcasses. In 1984, 312 carcasses were collected during an October die-off that the California Department of Fish and Game, Wildlife Disease Investigations Laboratory diagnosed as avian botulism. Salton Sea National Wildlife Refuge records indicated an estimated loss of 500 birds from avian cholera in 1987. The following year, an estimated 2000 birds died from avian botulism and an additional 600 from avian cholera. Three different diseases were reported during 1989: 215 birds were found dead from avian botulism, approximately 50 died from avian cholera, and more than 4500 birds died from salmonellosis at a wetland near the sea.

The 1990s stand in marked contrast to the losses reported during most of the previous decade. Disease outbreaks have been reported at the Salton Sea during every year of the 1990s, and the frequency of events, magnitude of losses, and variety of causes is unprecedented for any previous decade (Tables 110.1 and 110.2). The most noteworthy of these mortality events, in 1992, is the estimated loss of 155,000 eared grebes (*Podiceps nigricollis*), approximately 7% of the North American population of this species. A similar number may have perished during a 1989 die-off that was not investigated (Jehl, 1996). The causative agent for most of these deaths remains unknown, although algal toxins are suspected of playing a role in those die-offs and in losses of thousands of grebes since then. During 1996, more than 15,000 waterbirds died from avian botulism. Approximately 9000 of those that died were white pelicans (*Pelecanus erythrorhynchos*), a loss that was estimated at between 10 to 15% of the western population of this species (U.S. Fish and Wildlife Service, 1997), and more than 1200 that died were endangered California brown pelicans (*P. occidentalis californicus*), making this the largest recorded loss from disease of an endangered species. Virtually the entire production of nestling double-crested cormorants on Mullet Island in the Salton Sea died from Newcastle disease during 1997. A similar event occurred the following year killing an estimated 6000 birds and, although virus was not isolated from dead birds, the clinical and field signs (Figure 110.3) were strongly suggestive of Newcastle disease as the cause of mortality.

Frequent large-scale fish kills that range from tens of thousands to a million or more fish (Figure 110.4) have also occurred during the 1990s, some of which have also been linked to parasites and other microbial pathogens, such as *Vibrio* spp. (National Wildlife Health Center, unpublished data), *Amyloodinium* infestations (Kuperman and Matey, 1999), and algal toxicoses. An estimated 7.6 million fish succumbed during the first week of August 1999 (Sonny Bono National Wildlife Refuge, unpublished data). These massive fish kills have been linked to disease mortality in birds, at least for the occurrence of botulism outbreaks in fish-eating birds (Rocke, unpublished data). We believe this drastic increase in mortality in fish and birds at the Salton Sea is reflective of an

ecosystem in severe stress (Rapport and Whitford, 1999). Certainly, the magnitude of bird losses during the past decade can only be viewed as a decline in the functional ability of this ecosystem to provide for the sustainability of some of its species. Studies are in progress to define the factors contributing to those disease events and to provide a foundation for management and restoration of the sea.

ECOSYSTEM HEALTH AND MIGRATORY BIRDS

We have used the Salton Sea as an example where changes in wildlife disease patterns reflect declining ecosystem health and have noted the challenges imposed by those diseases for the affected species. Another important consideration for migratory species is that their sustainability is dependent upon more than one geographic location. Therefore, since the scale of an ecosystem

is determined by the management problem at hand (Lackey, 1999), an area much greater than the Salton Sea must be considered for migratory birds, including all of the geographic areas that provide for critical stages in the species' annual migratory cycle. Since these geographic areas are not contiguous, nested ecological units at disparate locations (e.g., wetlands within flyways) should be considered the functional management units (ecosystems) for the various species involved. The functional processes and products to be provided from each of these ecosystems are related to the life stage needs of those species. The collective contributions from each of these disparate ecosystems provide for species sustainability. For migratory waterbirds using the Salton Sea, this would necessitate consideration of wetlands along both the Pacific and Central Flyways, as well as wetlands and coastal areas to the south in Mexico and along the Gulf.

ENVIRONMENTAL INDICES FOR EVALUATING DISEASE RISK IN ECOSYSTEMS

Because environmental conditions play such a key role in defining the occurrence and outcome of host–disease agent interactions, in some cases environmental indices other than disease mortality or morbidity can be used to assess the potential risk of disease outbreaks in specific ecosystems. To illustrate this concept, we considered recent findings regarding wetland characteristics associated with type C avian botulism outbreaks in interior wetlands (Rocke and Samuel, 1999). Avian botulism, a paralytic disease caused by ingestion of a neurotoxin, often kills thousands of waterbirds in a single outbreak, with annual continental losses in North America approaching the hundreds of thousands to millions (Rocke and Friend, 1999). In recent years (1994 to 1997), outbreaks of avian botulism killed more than 4 million waterfowl in Canada and the U.S. (National Wildlife Health Center, unpublished data), and focused renewed attention on the potential effects of this disease in North American waterfowl populations. This is particularly relevant for species like the northern pintail (*Anas acuta*), which has accounted for a large portion of the recorded botulism mortality (15 to 20%) and has failed to show increased population levels despite generally favorable breeding conditions (U.S. Fish and Wildlife Service, 1998).

The disease is caused by a neurotoxin produced by *Clostridium botulinum* type C, an anaerobic bacterium that forms dormant spores in aerobic or other environmental conditions adverse to the bacterium (Smith and Sugiyama, 1988). These spores are highly resilient (Hofer and Davis, 1972) and are widely distributed in wetland sediments (Smith and Sugiyama, 1988). In addition, spores are highly prevalent in the tissues of aquatic invertebrates (Jensen and Allen, 1960) and vertebrates (Reed and Rocke, 1992). However, despite the ubiquitous distribution of botulinum spores, outbreaks of avian botulism are unpredictable, often occurring annually in certain wetlands but not in adjacent ones. In one study conducted on a northern California wetland, no relationship was found between botulinum cell and spore density and the occurrence of botulism outbreaks (Sandler et al., 1993). This finding suggests that density of the agent is probably not a limiting factor in the occurrence of outbreaks. Instead, results of studies conducted in wetlands with ongoing botulism outbreaks and paired control wetlands throughout the U.S. suggested that the relative risk of a botulism outbreak was predicted by complex relations among redox potential, pH, and temperature measured at the sediment–water interface (Rocke and Samuel, 1999).

To illustrate these findings, a series of predictive models was developed that relate environmental conditions to the relative risk of botulism outbreaks in wetlands (Figure 110.5). A similar risk assessment for avian botulism is currently being conducted for both fresh and brackish wetlands associated with the Salton Sea. These risk models can potentially provide a new method to identify wetlands with high risk of botulism outbreaks, to develop and evaluate alternative strategies for reducing the risk of botulism in high-risk areas, and to evaluate the effect of current wetland management practices on the risk of botulism outbreaks. A substantial advantage provided by these models is that evaluation of different management strategies can be based on the predicted relative

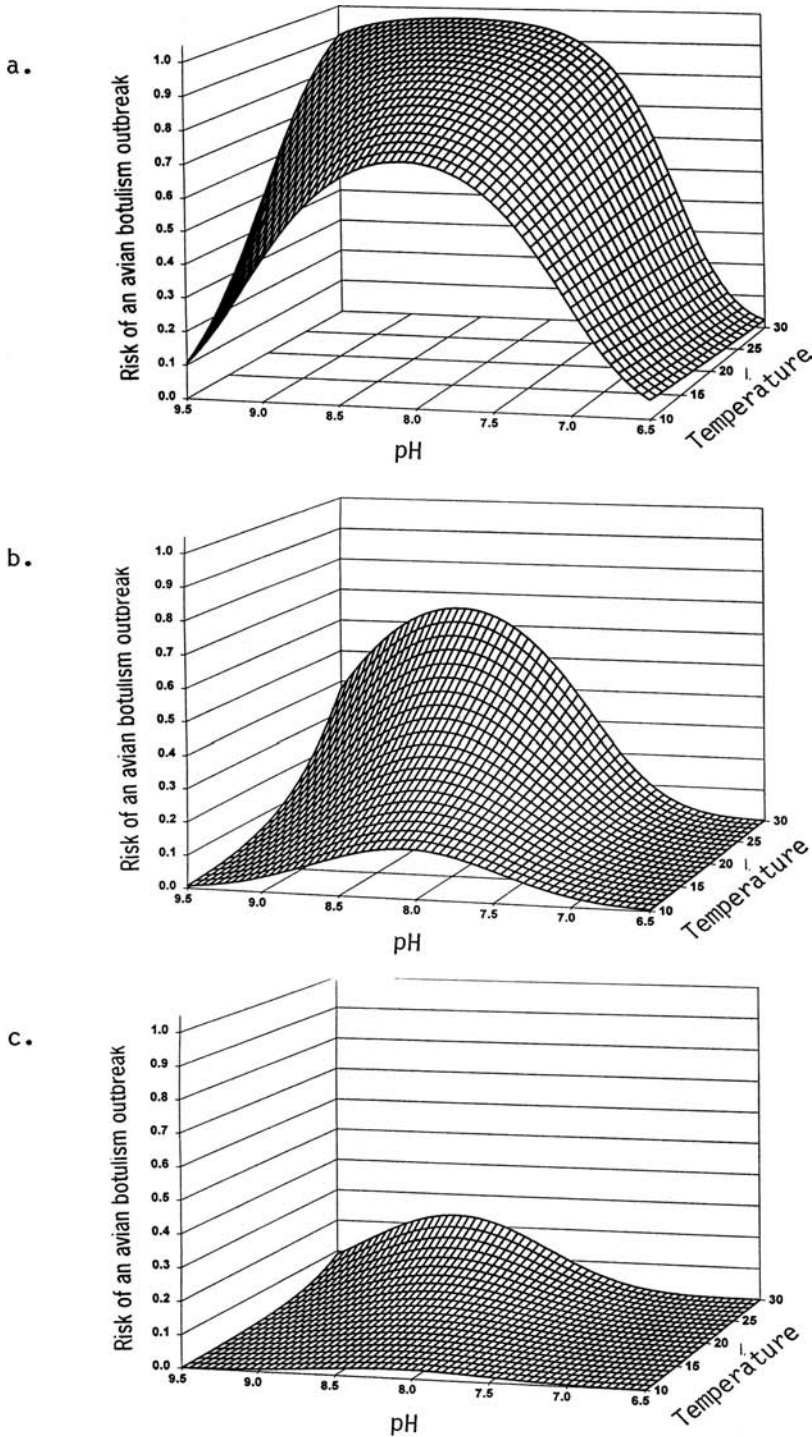

Figure 110.5 Predictive models showing the relationship between water pH and temperature, and the relative risk of botulism outbreaks in U.S. wetlands with water redox potentials of (a) -200 mv, (b) 100 mv, and (c) 300 mv. We predicted relative risk of botulism outbreaks using average water values (pH = 8.17, redox potential = -65.38 mv, standardized redox potential = 2.61 mv) for outbreak wetlands as the baseline. (From Rocke, T.E. and M.D. Samuel, Water and sediment characteristics associated with avian botulism outbreaks in wetlands, *J. Wildl. Manage.*, 63, 1249-1260, 1999. With permission.)

risk of an outbreak and would not be dependent on the occurrence of avian mortality from botulism. With additional research, these risk models also may be useful in evaluating the suitability of specific wetland acquisition and management actions in providing for the conservation of wetland-dependent avifauna.

CONCLUSION

The contemporary paradigms of ecosystem health and management are conceptually debated and perused on the basis of perspectives that address values for human society; both are useful but arbitrary concepts in the manner in which they are considered and applied. We offer perspectives that expand the considerations and application of these concepts to evaluations of wildlife health as an end point in itself; expand the concepts from evaluation and management of a single ecosystem to the need for considering nested, but disparate ecosystems when addressing the sustainability of migratory wildlife populations, and suggest that the occurrence of some diseases and environmental indices for the risk of disease can be used for evaluating ecosystem health. We challenge the notion that all wildlife disease events are “natural” regulators within ecosystems. We consider that disease is an outcome rather than a cause and note two important associations: (1) environmental conditions are a primary factor underlying disease occurrence, and (2) ecosystems in which disease occurrence is of sufficient prevalence to be of concern are rarely “natural systems.” These systems are often altered by human actions or are human-created systems. Human interventions that created the alterations frequently change the relationship between hosts, disease agents, and the environment. Disease outbreaks within altered environments tend to have more-lasting negative biological impacts and can seriously challenge the ability of the ecosystem to support the wildlife values sought by human society.

Unfortunately, much of the world’s wildlife habitat has undergone significant human-induced alterations and an increasing amount is human-created habitat, such as the Salton Sea. This trend will continue for the foreseeable future due to landscape changes and other actions associated with the continual growth and changing demography of human populations (Vitousek et al., 1997; Ayensu et al., 1999). Greater attention must be given to defining ecosystem health and the application of ecosystem management to these altered and created systems as habitat for the sustainability of wildlife populations and biodiversity. In many ways, these “ecosystems” are different from natural ecosystems and must be evaluated and managed in their own image and purpose, not against standards established for natural systems. In both instances, human values are the motivation for outcomes to be derived.

If contemporary society is to serve humankind and the other species of our world, we must view all natural, altered, and human-created ecosystems as important components of the mosaic that is our environment and not pit one against another as superior and inferior components. To do less would express arrogance regarding our level of understanding of ecosystem health and our ability to manage it. To place this statement in context for wildlife and ecosystems, we quote Aldo Leopold (1933). For wildlife:

... doctoring is of recessive importance in health control ... the real determinants of disease mortality are the environment and the population, both of which are being “doctored” daily, for better or for worse, by gun and axe, and by fire and plow (Leopold, 1933).

For ecosystems:

The effort to control the health of the land has not been very successful.... In general, the trend of the evidence indicates that in the land, just as in the human body, the symptom may be in one organ and the cause in another. The practices we now call conservation are, to a large extent, local alleviations

to biotic pain. They are necessary, but they must not be confused with cures. The art of land-doctoring is being practiced with vigor, but the science of land-health is a job for the future (Leopold, 1941).

The underlying thesis for Leopold's land-health evaluation is society's failure to understand and respond to cause rather than symptom. We close by asking the question: how far have we come relative to Leopold's statements of more than a half-century ago regarding our understanding and ability to address wildlife and ecosystem health? Our answer: not nearly far enough; the science of land health still remains a challenge for the future.

Contaminants without Borders: A Regional Assessment of the Colorado River Delta Ecosystem

Miguel A. Mora, Jaqueline García, Maria Carpio-Obeso, and Kirke A. King

INTRODUCTION

The Colorado River Delta Region (CRDR) is comprised of large agricultural areas in the U.S. (Imperial and Yuma districts) and Mexico (Mexicali and San Luis districts), the Salton Sea, and the Lower Colorado River from southern Arizona to the Gulf of California (Valdés-Casillas et al., 1998). Before agricultural development, the lower delta comprised large riparian and wetland areas (Sykes, 1937; Glenn et al., 1999). Currently, most water from the Colorado River below Imperial Dam is used for irrigation in California and Mexico, and only remnants of the former CRDR wetlands remain. However, the Cienega de Santa Clara and the Rio Hardy wetlands (Figure 111.1) provide important habitat for many resident and migratory birds, including endangered species such as the desert pupfish (scientific names are provided in Table 111.1) and the Yuma clapper rail (Abarca et al., 1993; Mellink et al., 1997). Detailed descriptions of the CRDR and its wetlands are provided elsewhere (Sykes, 1937; Glenn et al., 1995; 1999; Friederici, 1998; Valdés-Casillas et al., 1998).

The CRDR is affected by multiple contaminant stressors, including pesticides and heavy metals from agriculture and other anthropogenic activities. The Mexicali Valley in Mexico is located just south of the Imperial Valley in California. Approximately 70% of the cultivated land in Mexicali (182,000 ha) is irrigated by gravity with water from the Colorado River (Secretaría de Agricultura y Recursos Hidráulicos, 1984). Because most water is used first for agriculture in Mexico and the U.S., it is likely that organisms using wetlands in the CRDR are exposed to considerable amounts of pesticides and other contaminants. Runoff from the Mexicali Valley is discharged directly to drainages and to the Rio Hardy. The Rio Hardy also receives brine waste, with potentially high concentrations of arsenic (As) and boron (B), from a geothermal energy plant located at Cerro Prieto, approximately 30 km south of the city of Mexicali (Comisión Federal de Electricidad, 1987, unpublished report); however, the plant stopped releasing this brine to the river in 1989 (Campoy, J., SEMARNAP, personal communication, 2000). The Cienega de Santa Clara also receives runoff from the Wellton-Mohawk irrigation and drainage district located near the confluence of the Gila and Colorado Rivers in the U.S. (Figure 111.1; Burnett et al., 1993).

This chapter reviews studies of contaminants conducted from 1970 to the present in the environment and biota of the CRDR, including published papers, unpublished reports, and unpublished data of the coauthors. The earliest studies were conducted in the mid-1970s on

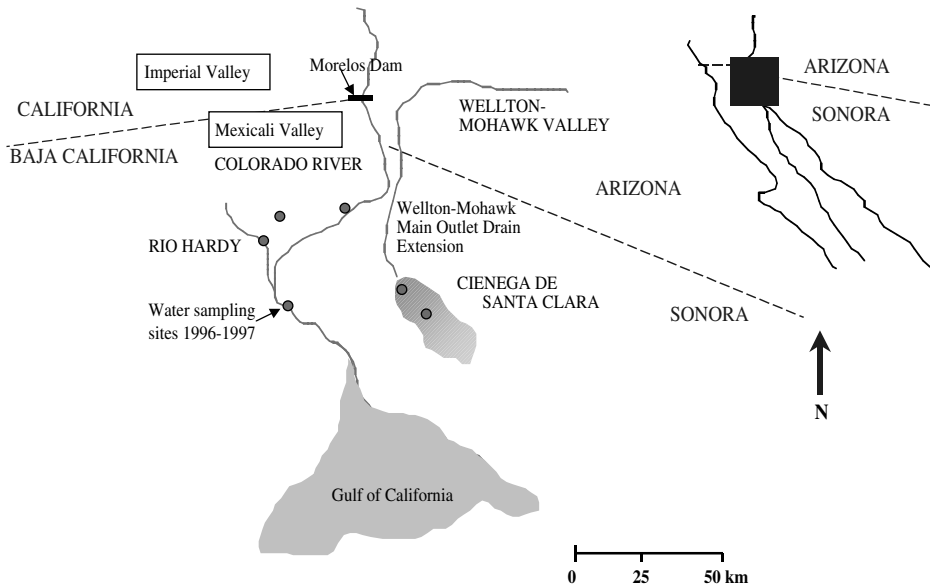

Figure 111.1 Map of the Colorado River Delta Region (Mexican side) showing locations of Cienega de Santa Clara, Rio Hardy, and water sampling locations.

Table 111.1 Scientific Names of Species Mentioned in Text and Tables

Group	Common Name	Scientific Name
Birds	Pied-billed grebe	<i>Podylimbus podiceps</i>
	Double-crested cormorant	<i>Phalacrocorax auritus</i>
	Black-crowned night heron	<i>Nycticorax nycticorax</i>
	Least bittern	<i>Ixobrychus exilis</i>
	Green heron	<i>Butorides virescens</i>
	Cattle egret	<i>Bubulcus ibis</i>
	Great egret	<i>Ardea alba</i>
	Mallard	<i>Anas platyrhynchos</i>
	Ruddy duck	<i>Oxyura jamaicensis</i>
	Yuma clapper rail	<i>Rallus longirostris yumanensis</i>
	Sora	<i>Porzana carolina</i>
	Common moorhen	<i>Gallinula chloropus</i>
	American coot	<i>Fulica americana</i>
	Mourning dove	<i>Zenaida macroura</i>
	Southwestern willow flycatcher	<i>Empidonax traillii extimus</i>
	Great-tailed grackle	<i>Quiscalus mexicanus</i>
Red-winged blackbird	<i>Agelaius phoeniceus</i>	
Fish	Desert pupfish	<i>Cyprinodon macularius</i>
	Tilapia	<i>Tilapia</i> spp.
	Mullet	<i>Mugil</i> spp.
	Carp	<i>Cyprinus carpio</i>
	Channel catfish	<i>Ictalurus punctatus</i>
Invertebrates	Largemouth bass	<i>Micropterus salmoides</i>
	Clams	<i>Corbicula fluminea</i>

aquatic invertebrates and fish from irrigation canals and drainages in the Mexicali Valley (Guardado-Puentes, 1976; Gutierrez-Galindo et al., 1988a,b). However, contaminant-oriented studies in northwest Mexico were conducted until the mid-1980s (Mora and Anderson, 1991; Mora et al., 1987). These studies assessed hazards of environmental pollution in northwest Mexico

on migratory and local wildlife, and investigated variations in seasonal dynamics of pollutants in coastal and inland wetland ecosystems. Initial studies with waterfowl suggested the occurrence of some locally contaminated areas in northwest Mexico (Mora et al., 1987). Subsequently, the levels of contaminants in CRDR wildlife were evaluated from 1985 to 1989 (Mora, 1991; Mora and Anderson, 1991, 1995).

In the 1990s, residues of selenium (Se) and other trace elements in water, sediments, and biota of the Cienega de Santa Clara were measured (García-Hernández, 1998). Those efforts continue and are focused on evaluating bioaccumulation of Se and mercury (Hg) and their potential threats to wildlife of the Colorado delta in general. Other contaminant monitoring studies have been conducted over the years along the lower Colorado River and in the Salton Sea in the U.S. (White et al., 1987; Rasmussen, 1988; Setmire et al., 1990; King et al., 1993). Additionally, water, sediment, and fish samples from eight stations in the lower Colorado River and New River were analyzed for organic and inorganic contaminants during 1995–1996 as part of a binational study (Crane et al., 1996). In this chapter, we emphasize studies conducted during the past 30 years in the CRDR on the Mexican side, and we make some comparisons with data collected in the U.S.

CONTAMINANT STUDIES IN THE COLORADO RIVER DELTA

Pesticides

The use of the organochlorine insecticide DDT (1,1,1-trichloro-2,2-bis[*p*-chlorophenyl]ethane) in Mexico declined considerably during the 1970s but continued in agriculture at least until 1978 (Fertilizantes Mexicanos, 1981). In 1972, approximately 220,000 kg of DDT were used on cotton in the Mexicali Valley (Alvarez-Borrego et al., 1973). Another 275,000 kg of DDT were used in all of northwest Mexico during 1978 (Fertilizantes Mexicanos, 1981). During the 1980s, production of DDT in Mexico averaged 5000 tons per year, with its use restricted for malaria control (Lopez-Carrillo et al., 1996).

The earliest organochlorine (OC) contaminant data from the Mexicali Valley were obtained from analyses of sediments and clams in the 1970s and 1980s (Table 111.2; Alvarez-Borrego et al., 1973; Guardado-Puentes, 1976; Gutierrez-Galindo et al., 1988a,b). In the early 1970s, sediments from the upper Gulf of California had *p,p'*-DDT and *p,p'*-DDE concentrations of 4.4 and 7 ng/g dry weight (dw), respectively (Alvarez-Borrego et al., 1973), whereas clams from the Mexicali Valley had mean levels of DDE, the most persistent metabolite of DDT, as high as 7.7 µg/g wet weight (ww) (Table 111.2; Guardado-Puentes, 1976). By the mid-1980s, mean DDE in clams and fish collected from drains and canals in the Mexicali Valley were all <0.2 µg/g ww (Table 111.2;

Table 111.2 Mean DDE Concentrations in Sediments (µg/g dw) from the Gulf of California, and Clams and Fish (µg/g ww) from the Mexicali Valley, Mexico

Table 111.3 Geometric Mean DDE Concentrations ($\mu\text{g/g ww}$, ranges in parentheses) in Carcasses of Birds from the Mexicali Valley, Mexico, 1986

Species	N	Summer	N	Winter
Pied-billed grebe	2	1.2		
Double-crested cormorant	1	11.5	8	1.8 (0.8–4.2)
Cattle egret	7	2.0 (1.0–1.4)	8	1.0 (0.5–2.0)
Great-tailed grackle	6	3.1 (1.3–7.0)	8	4.1 (1.8–9.4)
Red-winged blackbird	4	1.7 (0.5–6.1)	4	1.0 (0.4–2.6)
Mourning dove	6	0.04 (0.02–0.09)	9	0.03 (0.02–0.07)

Compiled from Mora and Anderson, 1991.

Gutierrez-Galindo et al., 1988; Gutierrez-Galindo et al., 1988a,b). In 1998, levels of DDE in clams from three sites in the CRDR were also $<0.2 \mu\text{g/g ww}$ (Table 111.2; King, unpublished data).

In a detailed study of the accumulation of OCs in wildlife, 63 specimens from 6 bird species (pied-billed grebes, double-crested cormorants, cattle egrets, mourning doves, great-tailed grackles, and red-winged blackbirds) were collected from agricultural fields in the Mexicali Valley and from the Rio Hardy during July–August (summer) and December (winter) 1986 (Mora and Anderson, 1991). Results showed that many OCs were present in carcasses in low amounts, but DDE was present at the highest concentrations with mean levels ranging from 0.04 to about $12 \mu\text{g/g ww}$ (Table 111.3). Mean DDE concentrations were not different between summer and winter. Hexachlorocyclohexane (HCH) concentrations (not shown in Table 111.3) were higher in mourning doves (up to $1.4 \mu\text{g/g}$) and grackles (up to $0.27 \mu\text{g/g}$) during the winter, indicating some winter accumulation of HCH at Mexicali. The mean DDE concentrations reported by Mora and Anderson (1991) were similar to those reported in carcasses of birds from the southwestern U.S. in general (Clark and Krynitsky, 1983; Henny et al., 1985; White and Krynitsky, 1986). Mean DDE concentrations in eggs of cattle egrets from Mexicali were lower than those in egrets and herons from the Salton Sea; however, these differences might be due to differences in diets rather than differences between sites (Table 111.4; Mora, 1991; Ohlendorf and Marois, 1990).

Mora and Anderson (1991) also sampled in the Yaqui and Culiacan Valleys, and found exposure of birds to DDE and other OCs to be lower than in the Mexicali Valley. The Yaqui and Culiacan Valleys are located at approximately 850 and 1400 km south, respectively, from the Mexicali Valley. On average, 52,070 ha per year were cultivated with cotton at Mexicali from 1978 to 1988 (Covarrubias, D., SARH, personal communication, 1989). Consequently, application of OC insecticides in this valley may have been more intense than in other areas of northwest Mexico which produce less cotton. One conclusion from this study was that some wetland habitats and agricultural ecosystems of northwest Mexico represented potential contamination sites for wintering and resident birds.

Table 111.4 Geometric Mean DDE Concentrations ($\mu\text{g/g ww}$, ranges in parentheses) in Bird Eggs from the Colorado River Delta Region

Species	Location	N	DDE	Year	Ref.
Cattle egret	Mexicali Valley	40	3.2 (2.3–4.5)	1987	Mora, 1991
		10	3.5 (2.1–5.7)	1988	Mora, 1991
Great egret	Salton Sea	10	24 (16–48)	1985	Ohlendorf and Marois, 1990
Black-crowned night heron	Salton Sea	10	8.6 (2.5–20)	1985	Ohlendorf and Marois, 1990

In 1995 to 1996, a binational study measured organic and inorganic contaminants in water, sediments, and fish from the lower Colorado River and New River (Crane et al., 1996). The lower Colorado River monitoring stations were located at the All American Canal, Northern International Border, Yuma Main Drain, Gila River, and Wellton-Mohawk Drain. The New River monitoring stations were located at Mexicali, Calexico, and Westmoreland. In all, 59 fish (carp, channel catfish, and largemouth bass) were collected and composited into 17 samples that were analyzed for trace and organic chemicals. Fish were not collected from Wellton-Mohawk, Gila River, and Mexicali. Some of the OC concentrations in fish exceeded selected criteria (set concentration values for the protection of aquatic life, wildlife, and human health) at some monitoring stations. Particularly, carp and channel catfish from the Westmoreland site in the New River and the Yuma main drain exceeded the National Academy of Sciences (NAS) recommended guidelines of 0.1 $\mu\text{g/g}$ ww for toxaphene and endosulfan and 1 $\mu\text{g/g}$ ww for total DDT (Crane et al., 1996). Of 88 pesticides analyzed in water, 6 (chlorpyrifos, EPTC, simazine, diazinon, pronamide, and DCPA) were detected in the lower Colorado River at concentrations ≤ 0.1 $\mu\text{g/l}$; and 13 (fonofos, malathion, atrazine, metribuzinsencor, trifluralin, linuron, disulfoton, and penid-methalin, and those detected in the lower Colorado River) in the New River had concentrations ≤ 0.21 $\mu\text{g/l}$ (M. Carpio-Obeso, unpublished data).

Heavy Metals and Metalloids

The accumulation of heavy metals and metalloids on biota of the Colorado River delta has been addressed more frequently than the accumulation and effects of organochlorine contaminants and other organic chemicals. Heavy metals and metalloids have been detected in irrigation drain water in some areas of the southwestern U.S. at concentrations that are associated with reproductive, teratogenic, and behavioral anomalies in birds. For example, increased bird mortalities were linked with high concentrations of Se at the Kesterson Reservoir in California (Ohlendorf et al., 1986a). Agricultural ecosystems in northwest Mexico (i.e., Mexicali and San Luis Rio Colorado valleys) are intensively irrigated and have great potential for accumulation of elevated concentrations of trace elements in drainwater. Consequently, high concentrations of some elements in these areas could also result in detrimental effects on resident and migratory birds and other wildlife of the Colorado River delta.

Until the mid-1980s, there had only been a few studies on fish and clams that evaluated the environmental hazards and concentrations of trace elements on wildlife of the Mexicali Valley and Colorado delta. Concentrations of Hg in fish and clams from irrigation canals and drainages of the Mexicali Valley were measured to evaluate the extent of Hg contamination by the geothermal energy plant at Cerro Prieto (Gutierrez-Galindo et al., 1988). Mercury concentrations in fish and clams (0.05 and 0.11 $\mu\text{g/g}$ dw, respectively) (Gutierrez-Galindo et al., 1988a,b), were low and not of public health concern.

During 1985 and 1986, in order to determine accumulation of trace elements in birds, a portion of liver was taken from 61 carcasses collected from the Mexicali Valley (Mora and Anderson, 1995). Fish samples from tilapia and mullet were also collected during the same period. Selenium concentrations were significantly higher ($p < 0.05$) in double-crested cormorants and lower in mourning doves than in other species (Table 111.5). This is not surprising because cormorants are the most aquatic of the species sampled and Se accumulates primarily in aquatic food chains (Ohlendorf et al., 1986a,b; Saiki et al., 1993). Selenium concentrations were similar among cattle egrets, great-tailed grackles, and red-winged blackbirds. These species are all intermediate in type of habitat used (aquatic-terrestrial) and probably share some common food sources. The concentrations of Se in double-crested cormorants from the Mexicali Valley were near or above the threshold at which reproductive effects were apparent in American coots at the Kesterson Reservoir during 1984 (Ohlendorf et al., 1987), and were 1.3 to 2.5 times less than those reported in birds from the Salton Sea in 1986 (Table 111.6; Setmire et al., 1990; White

Table 111.5 Geometric Mean Concentrations ($\mu\text{g/g dw}$, ranges in parentheses) of Selenium and Boron in Livers of Birds from the Mexicali Valley, Mexico, 1985–1986^a

Species	N	Se	B
Double-crested cormorant	9	16.7 A (9.5–23.9)	13.8 AB (9.5–26.9)
Cattle egret	15	4.6 B (1.8–7.8)	18.9 B (9.3–27.8)
Red-winged blackbird	8	5.1 B (3.8–15)	13.3 AB (8.9–27)
Great-tailed grackle	14	5.3 B (3.3–10.6)	7.6 A (4–25.2)
Mourning dove	15	2.3 C (0.7–3.3)	32.7 C (14.1–93.2)

^a Compiled from Mora and Anderson, 1995. Means not sharing the same letter (among species) are significantly different.

Table 111.6 Mean and Individual Selenium Concentrations ($\mu\text{g/g dw}$, ranges in parentheses) in Livers of Cormorants from the Colorado River Delta Region, 1986–1987

^a Taken from Martinez, 1994, and Rusk, 1991.

^b Geometric means.

et al., 1987). Selenium levels in livers of cormorants from the CRDR were on average $27.3 \mu\text{g/g dw}$, similar to those reported in pied-billed grebes from the Imperial National Wildlife Refuge (NWR). However, they were 1.5 to 10 times higher than residues in most aquatic birds from Mittry Lake and Imperial NWR in the lower Colorado River (Tables 111.6 and 111.7; Rusk, 1991; Martinez, 1994). These differences among species may be related more to differences in diet than location.

Boron was another element of concern because of the possibility of elevated discharges of brine from the geothermal energy plant at Cerro Prieto and because agricultural drain waters are consid-

ered major sources of B (Eisler, 1990; Saiki et al., 1993). Mora and Anderson found that B was significantly greater in livers of mourning doves (mean = 32.7 $\mu\text{g/g dw}$; $p < 0.05$) than in any other species (Table 111.5). Since mourning doves are mostly seed-eaters, it is likely that the main source of B resulted from high concentrations in agricultural seed crops, but no documentation of B in seeds was possible. Adult mallards fed B in the diet at 300 $\mu\text{g/g dw}$ had mean residues in liver of 17 $\mu\text{g/g dw}$ (Smith and Anders, 1989). Therefore, it is reasonable to assume that mourning doves at the Mexicali Valley were probably ingesting B at mean levels greater than 300 $\mu\text{g/g dw}$. The toxicological significance of B concentrations observed in mourning doves from the Mexicali Valley has not been addressed. As indicated earlier, high concentrations of B in the Mexicali Valley also could have resulted from brine discharges from the Cerro Prieto geothermal energy plant during its operation until 1989 when discharges stopped. Concentrations of B in water from 14 wells near the plant averaged 12.09 $\mu\text{g/g}$ in 1972 (Alvarez-Borrego et al., 1973). Levels of B in Rio Hardy sediments reached maximum concentrations of 26 $\mu\text{g/g ww}$ in 1986 at the site closest to the brine discharge from the geothermal plant (Comisión Federal de Electricidad, 1987, unpublished report). Concentrations of B diminished with increasing distance from the discharge point, but remained high for most of the river throughout the valley.

Heavy metal data for fish also suggest elevated exposure to Se in the CRDR (Table 111.8). Concentrations of 6.4 and 6.8 $\mu\text{g/g dw}$ Se in fish from the Mexicali Valley were above the U.S. national mean of 0.42 $\mu\text{g/g ww}$ (approximately 1.7 $\mu\text{g/g dw}$) in whole fish during 1984 (Schmitt and Brumbaugh, 1990), but were lower than the maximum concentration observed in common carp (2.3 $\mu\text{g/g ww}$, approximately 9 $\mu\text{g/g dw}$) from the lower Colorado River, Arizona (Schmitt and Brumbaugh, 1990), and the average (10.8 $\mu\text{g/g dw}$) measured during the same year in tilapia from the New River (Setmire et al., 1990; Table 111.8). Selenium residues in tilapia from the Mexicali Valley were about two times higher (3.8 $\mu\text{g/g dw}$) than levels found in tilapia from the Cienega de Santa Clara 10 years later (García-Hernández, 1998). Selenium residues in other fish species from the Cienega de Santa Clara were similar to those in tilapia from Mexicali, and below the dietary levels which are known to cause mortality or negative reproductive effects on birds (Skorupa and Ohlendorf, 1991).

Clams collected in the Mexicali Valley in 1998 showed concentrations of Se of 1.6 $\mu\text{g/g dw}$ (King and Garcia, unpublished data). Water, sediment, invertebrates, plants, and fish were collected during 1996 and 1997 in the Cienega de Santa Clara, Colorado River, and Rio Hardy wetlands for a study of Se bioaccumulation in the Colorado River delta (García-Hernández, 1998). Selenium concentrations in water ranged from 5 to 19 $\mu\text{g/l}$ in the Santa Clara Cienega and from 7 to 28 $\mu\text{g/l}$ at six stations in the Santa Clara, Rio Hardy, and Colorado River wetlands (Figure 111.1). These concentrations in water exceeded the EPA (Environmental Protection Agency) criterion of

Table 111.8 Mean Selenium Concentrations ($\mu\text{g/g dw}$) in Fishes from the Colorado River Delta Region

5.0 µg/l for the protection of aquatic life (U.S. EPA, 1987). However, Se levels in sediment (0.8 to 1.8 µg/g dw), aquatic plants (0.03 to 0.17 µg/g dw), and fish (1.5 to 6.6 µg/g dw) did not exceed threshold levels (García-Hernández, 1998).

In the binational study of 1995–1996, the following trace elements were detected in the water column at stations in the lower Colorado River: aluminum, arsenic, barium, boron, chromium, copper, iron, manganese, mercury, molybdenum, nickel, selenium, uranium, vanadium, and zinc (M. Carpio-Obeso, unpublished data). Only manganese at the Gila River station exceeded the California Safe Drinking Water Act standards. Arsenic was detected in all samples although at low concentrations. Arsenic concentrations exceeded the maximum tissue residue levels established by the California Water Control Board in fish tissues from the Northern International Border station, and in two samples from the All American Canal (Crane et al., 1996). The highest concentrations of B were detected in water samples from the Wellton-Mohawk station that collects the agriculture discharges from some areas in Arizona.

CONCLUSION

Monitoring studies of organochlorine pesticides in biota of the Colorado River delta have been few. The only major studies in wildlife in the mid-1980s suggested some concern for elevated concentrations of DDE and possible accumulation of other OCs during the winter. The most persistent OC, *p,p'*-DDE, was detected in wildlife at levels that could be of concern for top predators, particularly raptors and fish-eating birds. Data from clams in the CRDR (Alvarez-Borrego, this volume) suggest that DDE levels, at least, have declined in recent years. More current assessments of OCs in wildlife are needed to determine if DDE residues have generally declined in the Colorado delta, as has been observed in other areas of the southwestern U.S. (Mora and Wainwright, 1998). Also, new-generation and more-toxic organophosphorus and carbamate pesticides are currently in use in the Mexicali and San Luis Rio Colorado Valleys. However, the potential hazards of new-generation pesticides on wildlife of the Colorado have not been addressed. Addressing the impacts of a broader range of contaminants on endangered species such as the Yuma clapper rail, southwestern willow flycatcher, and the desert pupfish in the Colorado River delta, should be an international priority for the near future.

In contrast to the fewer studies of chlorinated pesticides in the Colorado River delta, monitoring studies of trace elements, particularly Se, have been more abundant. Selenium concentrations were elevated during the 1980s in samples collected in the Mexicali Valley, Salton Sea, and a few other areas in the CRDR. Most Se data seemed to indicate a general pattern of Se contamination in the CRDR. King et al. (1993) noted that mean Se concentrations remained high in fish from the lower Colorado River from 1976 to 1989 and pointed out that there was widespread Se contamination of lower Colorado River backwater habitats. A similar observation applies to fish and other biota samples from the Colorado River delta in Mexico. Data from 1986 and 1996 also support the assumption that Se concentrations in biota of the Colorado River delta remain high. Overall, Se concentrations in biota of the CRDR have not decreased in the past 30 years. In some cases, Se levels in biota were near the threshold for effects on the species themselves or in predators at the top of the food chain that may feed on such species.

King et al. (1993) proposed a “single unified contaminant monitoring plan” for the Colorado River wildlife refuges in the U.S. We propose that an integrated approach for contaminant research should also be followed in the Colorado River delta, so that a single unified contaminant monitoring plan is implemented for the whole Colorado River delta ecosystem. This monitoring should be uniform and include samples that represent the whole ecosystem, from water to sediments, and species at the top of the food chain. Selected locations in the U.S. could include portions of the lower Colorado, Alamo, and New Rivers, as well as the Salton Sea. Sites in Mexico could include the Rio Hardy and Santa Clara wetlands, Rio Nuevo, and selected drainages and canals in the Mexicali Valley. The implementation of

this plan would require the participation of federal and state agencies in both the U.S. and Mexico, as well as nongovernmental organizations from both countries.

Conservation Value and Water Management Issues of the Wetland and Riparian Habitats in the Colorado River Delta in Mexico

Michael Cohen, Edward P. Glenn, Jason Morrison, and Robert J. Glennon

INTRODUCTION

Human activity has disrupted most of the world's large river ecosystems. Arid rivers are especially at risk due to their modest base flows and the many human demands on their waters. An example is the Colorado River, which is a major source of water for the desert region of the southwest U.S., northwestern Mexico, and the southern California coastal plain. Approximately 23 million people now use Colorado River water (Morrison et al., 1996). The delta of a regulated river system, below the last dams and diversions, is the natural collecting place for wastewaters and surplus flows exiting the watershed. The delta is the depositional section of the river, where the reduction in grade broadens the floodplain and permits the expansion of wetland and riparian habitats. It is also the mixing zone with the ocean, which is enriched by brackish and freshwater sources from land. River deltas may retain natural functions that have disappeared from upstream stretches. That is certainly true of the Colorado River delta, which supports a large riparian habitat (Glenn et al., 1996, 1999; Valdes-Casillas et al., 1998, 1999). The Colorado River delta is a binational resource, located mainly in Mexico, yet supplied primarily by water from the U.S.

On the lower Colorado River from Grand Canyon to the border with Mexico, dams built since 1935 have regulated the river flow and prevented overbank flooding which previously germinated seeds and washed excess salts from the river banks. Other disturbances have included channelization and dredging of the river and clearing of floodplain land for farming (Szaro, 1989; Stromberg and Patten, 1991; Bush and Smith, 1995; Briggs, 1996). As a consequence, the quality of the riparian habitat has declined dramatically. Along most of the river, the native riparian forest of *Populus fremontii* (cottonwood) and *Salix gooddingii* (willow) trees has been replaced by drought- and salt-tolerant shrub vegetation. By 1997, only 100 ha of the riparian zone in the U.S. were still classified as gallery forests. The most common plants along the river are now *Tamarix ramosissima* (salt cedar), an introduced species, and *Pluchea sericea* (arrowweed) (Ohmart et al., 1988). The decline of the native forest vegetation has reduced the habitat value of the riparian zone for many of the native fauna (Ohmart et al., 1988).

Human use has also had a severe impact on the delta of the Colorado River, from Morelos Dam (site of the last major diversion in Mexico) to the mouth of the river in the Gulf of California. Before the construction of upstream dams, the delta contained several hundred thousand hectares

of riparian and wetland habitat that supported numerous species of plants and animals and provided a critical ecological interface with the Gulf of California (Sykes, 1937; Leopold, 1949; Glenn et al., 1996). Most of this habitat disappeared after the construction of the Hoover and Glen Canyon Dams and the diversion of water for human uses (Fradkin, 1981; Richardson and Carrier, 1992). In the past 20 years, however, an interesting phenomenon has taken place in the delta. Surplus flows of river water plus agricultural drainage water from the U.S. have reestablished a vegetated floodplain from Morelos Dam south to the intertidal zone in the Gulf of California (Glenn et al., 1996, 1999; Valdes-Casillas et al., 1998, 1999). We describe below the source of the surplus flows, the wetland and riparian habitats they support, and the research and management tasks needed if these resources are to be conserved for future generations.

DELTA WATER SOURCES AND HABITATS

Extent of the Delta Floodplain and Sources of Water

A series of earthen, flood control levees were constructed along the channel of the Colorado River in Mexico in the 1980s to contain flood releases from the U.S. following the filling of Glen Canyon Dam (Glenn et al., 1996). Inside the levees, agriculture and settlement are for the most part prohibited, and riparian and wetland vegetation are the dominant plant associations. The floodplain enclosed between the levees is narrow as it passes through the agricultural zone, but widens to greater than 30 km as it approaches the Gulf of California (Figure 112.1). This area encompasses approximately 170,000 ha, of which 60,000 ha is at least partially vegetated while the remainder consists of extensive tide flats (Valdes-Casillas et al., 1998).

Water discharged into the floodplain comes from two main sources: surplus river flows released from the Hoover Dam by the U.S. Bureau of Reclamation, and agricultural drainage water from the U.S. and Mexico. The Bureau of Reclamation releases Colorado River water based on a three-tiered system of priorities: (1) flood control and river regulation, (2) off-stream diversions, and (3) hydroelectric power generation (U.S. Bureau of Reclamation, 1996). With the exception of 1993, flows generated by flooding along the Gila River, Colorado River instream flows in the delta are a direct result of flood control releases from the Hoover Dam (Figure 112.2). In addition, the influence of seawater extends 35 km up the mouth of the river due to the high tidal range that characterizes the upper Gulf of California. An additional source of water is upwellings of freshwater springs (*pozos*) onto the mudflats from artesian sources. These water sources support a variety of riparian and wetland habitats, which are briefly described later.

Cienega de Santa Clara

Cienega de Santa Clara is perhaps the largest example of emergent wetland habitat in the Sonoran Desert. It has been created by the discharge of agricultural drain water into the eastern part of the delta (Glenn et al., 1992, 1995; Zengel et al., 1995). Most (85%) of the water originates from the Wellton–Mohawk Irrigation and Drainage District in the U.S. Drain water from Wellton–Mohawk originates from a series of shallow wells which are pumped to control the depth and salinity of the water table in this irrigation district. Since 1977, this water has been conveyed in a 80-km lined canal (the Main Outlet Drain Extension) to the southeast part of the delta in Mexico where it is deposited in a former small-marsh system that drains into the intertidal zone of the Gulf of California. The mean annual discharge is approximately 1.8×10^8 m³ per year at a salinity of approximately 2940 ppm, but there has been a trend toward decreased volume and salinity over the years, perhaps due to more-efficient irrigation practices in the irrigation district. This discharge is augmented by 3.2×10^7 m³ per year of local irrigation return water from the Riito Drain, with a mean salinity of approximately 4000 ppm.

Figure 112.1 Vegetated portion (gray area) of the Colorado River delta floodplain in Mexico. Arrows show the floodplain’s main entry and exit points of water. (A) Colorado River flood release flows from the U.S.; (B) Mexicali agricultural drainage water entering Rio Hardy; (C) Colorado River flows exiting to intertidal zone and Laguna Salada (not shown); (D) San Luis Valley agricultural drainage water entering El Indio wetlands; (E) Wellton-Mohawk water entering Cienega de Santa Clara wetland; (F) river water and tide water mixing at the mouth of the Colorado River; and (G) water from Cienega de Santa Clara mixing with tidewater in the intertidal zone.

Figure 112.2 Annual flows in the Colorado River at the southerly international boundary, below Morelos Dam, the last diversion point of water on the Colorado River.

The drain waters have created a densely vegetated *Typha domingensis* marsh covering approximately 4200 ha. Besides *Typha*, the Cienega contains 23 other species of emergent and submerged wetland plants. Water flowing through the marsh increases in salt content due to water lost to evapotranspiration; at the southern end the salinity exceeds the tolerance limit for *Typha*. Ultimately, the discharge exits onto the mudflats below the Cienega, where it mixes with tide water from the Gulf of California.

The Cienega supports a rich fauna, including crustaceans and fish, upon which numerous migratory and resident waterfowl feed. A recent study (Hinojosa and DeStephano, unpublished data) shows that as many as 5000 individuals of the endangered Yuma clapper rail (*Rallus longirostris yumanensis*) are resident in the Cienega, many more birds than are found anywhere else in the Lower Colorado River ecoregion. The backwater areas of the Cienega also support large populations of the endangered desert pupfish (*Cyprinodon macularius*) (Zengel and Glenn, 1996).

The El Doctor Wetlands

These pocket wetlands are supported by artesian springs along the eastern escarpment of the delta, where it joins Gran Desierto. The water originates as rainfall in the Pinacate Mountains and migrates under the Gran Desierto dune fields to the delta, where it bubbles to the surface in isolated pozos, which support a unique assemblage of wetland and halophytic plant species (Felger et al., 1997). Although these wetlands cover only 500 to 750 ha, they are important because they are among the few natural wetlands remaining in the delta. Because their source water is less saline than the drain water entering Cienega de Santa Clara, the pozos support a wider variety of plant life. The El Doctor wetlands contain 29 plant species, including *Cyperus*, *Eleocharis*, and *Hydrocotyle* species not found in the Cienega. Some of the same birds as are found in the Cienega are found in the El Doctor wetlands. In June 1999, the southwest subspecies of willow flycatchers (*Empidonax traillii extimus*), an endangered species, were documented in these wetlands, but they appeared to be migrant, as they were no longer present during the July nesting season (Vanda Gerhart, University of Arizona Environmental Research Laboratory, unpublished data).

Rio Hardy Wetlands and the Intertidal Marshes

The Rio Hardy drains the northwest corner of the Mexicali Valley and joins the Colorado River approximately 50 km from the mouth of the river. The source water for the Rio Hardy is agricultural drain water from the Mexicali Valley. About half of the valley's agricultural discharge enters the Rio Hardy, while the remainder flows north in the New River to the Salton Sea. The flows in the Rio Hardy are not well documented, but were reported to be 1.3×10^8 m³ per year with a mean salinity of 4200 ppm in the 1970s (Valdes-Casillas et al., 1998). The Rio Hardy has a perennial water supply, and it supports bird habitat as well as recreational fishing and aquaculture. It is basically a brackish marsh system, with the emergent reed, *Phragmites australis*, growing along the water line and with *Tamarix ramosissima* thickets dominating the exposed banks.

Downstream from the junction with the Rio Hardy, the Colorado River becomes increasingly saline due to tidal influence. Along the lower reach of the river near the mouth and on Montague Island there are approximately 33,000 ha of *Distichlis palmeri* flats. This saltgrass is the only endemic grass species in the Sonoran Desert. It produces a large seed that was harvested as a grain by the indigenous Cocopa people (Felger et al., 1997) and it supports nesting shorebirds (Mellink et al., 1997).

Riparian Corridor of the Colorado River

The perennial portion of the Colorado River ends at Morelos Dam, which diverts water into Mexico's Alamo Canal, the last major diversion on the river, located 1.8 km downstream from the

northerly international border between the U.S. and Mexico. Below Morelos Dam, the river flows only when excess water must be released from upstream impoundments. From 1964 (when Glen Canyon Dam was completed) to 1981, virtually no excess water was released because Lake Powell behind the dam was not filled to capacity. Any excess water in the river system could simply be stored behind the dam. After 1981, however, there have been several major releases of water during wet, El Niño cycle years (Figure 112.2). In fact, during the period 1981–1998, mean annual flows past Morelos Dam have been approximately 20% of the total river flows.

As a result of these flood release flows, a 1997 preliminary study (Valdes-Casillas et al., 1998, 1999) revealed that the delta now supports more riparian habitat than the perennial stretch of river from Grand Canyon to the international border, even though that stretch of river is five times longer. Although the riparian corridor is dominated by *T. ramosissima*, several thousand hectares of native gallery forest have also reestablished in the delta.

Wildlife Habitat Value of the Delta

Only a few surveys have been conducted on wildlife in the delta. However, it is clear that the delta and its estuary now provide habitats for several U.S. and internationally listed endangered species, including desert pupfish (Eddleman, 1989; Abarca et al., 1993; Zengel and Glenn, 1996), vaquita porpoise (*Phocoena sinus*), totoaba fish (*Cynoscion macdonaldi*) (Glenn et al., 1996), Yuma clapper rails (Eddleman, 1989; Abarca et al., 1993), southwestern willow flycatchers and other endangered species of birds (J. Campoy, SEMARNAP, Mexico, unpublished data). It is a major stop on the Pacific Flyway for migratory waterfowl (Mellink et al., 1997) and nesting birds (Mellink et al., 1996). Due to its importance, much of the delta is included in the core zone of the Biosphere Reserve of the Upper Gulf of California and Colorado River delta and in the Western Hemisphere Shorebird Reserve Network. More recently, it was designated a RAMSAR site (Valdes-Casillas et al., 1998). These wild areas coexist with a local population of nearly 1.5 million people in Mexicali and San Luis, Mexico.

MANAGEMENT NEEDS FOR DELTA HABITATS

Although the delta riparian and wetland ecosystems are the largest, most important examples of these habitat types left on the Colorado River, and despite their location in a Biosphere Reserve, they have received little study and limited binational management attention. Indeed, these critical ecosystems are the inadvertent creation of water management decisions made in the U.S. and Mexico. In the future, these habitats face severe threats; yet they present remarkable opportunities. Threats include population increases along both sides of the border and, in the Mexicali Valley, a conversion from a predominantly agricultural to an industrial economy, which removes the rural character of the region. In the U.S., competition for Colorado River water is fierce. Cities, farmers, and Native American tribes seek larger pieces of an already over-allocated pie, while environmental organizations and federal wildlife agencies push for policies that would protect and enhance the environment. It is unclear how these pressures will impact management of the river and, ultimately, the flows that reach the delta. Water that now flows to the delta habitats is the unintended result of upstream management decisions and is not guaranteed for the future. Active management is necessary in order to conserve and enhance these habitats.

Although the threats are substantial, so too are the opportunities for binational management of the river to protect the ecosystems of the delta. Mexico has an interest in augmenting flows to the delta and Gulf of California in order to improve the health of the shrimp fishery (Galindo-Bect et al., 2000). Although located in Mexico, the delta wetlands and associated fauna are a major environmental asset for the U.S. as a reservoir of species diversity for the entire Southern Basin and Range Ecoregion (Felger et al., 1997). The delta is a major stop for birds on the Pacific Flyway

and for resident shorebirds. Given the number of threatened and endangered species in this region, the U.S. Fish and Wildlife Service has an opportunity to enforce the Endangered Species Act by approving a Habitat Conservation Plan that includes assurances of flood flow releases and continued agricultural drain flows to the delta.

Despite the fact that some of the delta habitats are in a Biosphere Reserve, for the most part these natural areas are not well protected. The riparian corridor in Mexico is controlled by the Comisión Nacional de Agua (CNA), whose primary responsibility is to distribute irrigation water and control property damage when water is released below Morelos Dam. CNA has engaged in clearing large areas of native trees and channeling sections of the riverbed to mitigate damage to roads and bridges during flood flows. It has been suggested (Valdes-Casillas et al., 1998) that the riparian corridor could be designated as a wildlife management zone, or incorporated into the buffer zone of the Biosphere Reserve, so that environmental considerations are taken into account before the habitats are altered. The Cienega de Santa Clara and the El Doctor wetlands, though inside the core zone of the Biosphere Reserve, are also highly affected by human use. Cattle grazing in the El Doctor wetlands reduces the vegetation to stubble height wherever it is accessible. Cattle also graze along the edges of the Cienega, and in winter the *Typha* is sometimes deliberately burned off to increase penetration by cattle the following spring. Burning appears to improve the quality of the marsh when it regrows but, unfortunately, burning often takes place during the Yuma clapper rail nesting season, which must impact the population of these birds (Campoy, J., Biosphere Reserve manager, personal communication).

The most serious external threat to the delta wetlands is from water management decisions made in the U.S. that affect the flows of water to these areas. The lower Colorado River delta has no explicit water entitlement. Water that has reached the riparian corridor in recent years has done so solely because flood release flows have exceeded the diversion capacity of upstream users. Nor does the Cienega enjoy a legal entitlement to Wellton-Mohawk drainage. The Yuma Desalting Plant was constructed to treat this drainage, to bring the U.S. into compliance with a 1973 treaty with Mexico addressing the salinity of water delivered to Mexico (Getches, 1985). Because the U.S. has been able to satisfy these salinity requirements without treating Wellton-Mohawk drainage, this water has been routed to the Cienega. Similarly, the flood release flows in the Colorado River are threatened by U.S. water management decisions. The Bureau of Reclamation is currently reviewing several proposed changes to Colorado River management, including the development of surplus (and shortage) criteria, off-stream storage, and diverting a portion of flood release flows into the Salton Sea to reduce its salinity. Each of these proposals would likely reduce the quantity and frequency of flood release flows reaching the delta.

The delta wetlands need to receive binational management attention. In Mexico, the riparian corridor which is outside the Biosphere Reserve would benefit from protected status, since this area contains the largest remaining stands of native riparian forest, and appears to serve as a migration corridor for migratory songbirds. The Cienega de Santa Clara and The El Doctor wetlands within the Biosphere Reserve would benefit from a more-active management program than is now in place, one which would restrict grazing and other human impacts (Campoy, J., personal communication). The potential for wildlife poisoning from heavy metals and pesticides must be monitored and addressed throughout the delta habitats. In particular, the Rio Hardy wetlands, supported by agricultural drainage water from Mexico, may present a selenium hazard to wildlife (Mora and Garcia, this volume). This portion of the floodplain receives restricted flushing during floods because it is above the juncture with the Colorado River. However, flushing to reduce loads of selenium and other toxins could conceivably be accomplished using control gates and pump stations that were installed during the floods of the early 1980s to move backed-up floodwaters from the Rio Hardy system into the Rio Colorado system to prevent flooding of fields (Valdes-Casillas et al., 1998).

The most urgent need is to develop a binational water management plan for flood release flows and agricultural wastewaters that cross the international border. Even without any explicit management attention, these flows now support the most valuable examples of wetland and riparian habitat left in

the Lower Colorado River ecoregion. A management plan might not involve providing *more* water to the delta; it might only require that the timing of flows be adjusted to provide maximum ecosystem benefit, in a way that is still consistent with operation of the river system for irrigation, power generation, recreation, and flood control. However, such a management plan will require much more knowledge of the vegetation and hydrology of the delta ecosystems than is currently available, so research must precede action.

IMPEDIMENTS TO BINATIONAL MANAGEMENT

A host of institutional impediments challenges the implementation of a binational conservation plan. The present system of water appropriation for the Colorado River is the result of a complex history of conflict and negotiation among U.S. water users, and between Mexico and the U.S. (Hundley, 1966; Getches, 1985; Getches and Myers, 1986). Flows of the Colorado River are controlled and regulated based on a complex legal framework of treaties, interstate compacts, state and federal laws, regulations, Supreme Court decisions, and contracts, known as the Law of the River (Hundley, 1975; Getches, 1985; Glennon, 1995). The degree of institutional control of the river cannot be overstated; the 1983 flood has been the only instance since the construction of the Hoover Dam in 1935 when discharge from the dams was not completely controlled. Furthermore, environmental considerations have only recently been included in water management decisions (Bolin, 1993).

Legal Impediments

Controversy over rights to Colorado River water has been a major theme in the 20th century history of the American West and of the relations between the U.S. and Mexico. Fights between and among states have led to legendary court battles. The State of Arizona first sued California in the 1930s and the dispute is ongoing. As the population of the West has mushroomed, competition for the Colorado's water has intensified. This will increase because demographers predict continued rapid population growth in the West (Case and Alward, 1997). The fight over water is not just over high-quality supplies, but extends even to poor-quality water such as the saline, agricultural drainage water from Wellton-Mohawk that currently sustains Cienega de Santa Clara (Glenn et al., 1992).

The Law of the River has created legal rights in the Colorado River basin states and in Mexico to over 18 million acre-feet ($22,200 \times 10^6 \text{ m}^3$ [mcm]) per year of water from the Colorado, even though the mean flow of the river over the past century has been only 15 million acre-feet (18,500 mcm) per year (Pontius, 1997). The first task in attempting to develop a water management plan is to determine how the various existing water rights may impact management of the river and to secure sufficient wastewater for the Cienega de Santa Clara and flood release flows to maintain the ecosystem in the delta.

To date, Upper Basin states have yet to divert their full entitlement, enabling California to divert as much as 18% more than its legal entitlement. Increases in Upper Basin consumption rates and Lower Basin population, and proposed changes in river management intended to address these changes, will reduce the availability of flood release flows for the delta region in the future. Under the Law of the River, the U.S. is required to deliver 1850 mcm per year of Colorado River water to Mexico (2009 mcm in years when a surplus is declared). Demand for water in Mexico's cities of Mexicali and San Luis, and for irrigation in the Mexicali Valley, already exceeds supply; the shortfall is partially met by unsustainable pumping of groundwater (Morrison et al., 1996). Projected population and industrial growth in the region will place additional strain on limited water resources (Ganster, 1996). In the absence of binational agreement, these factors reduce the likelihood that Mexico would allow future flood release flows to reach the delta.

While the struggle over the Colorado has largely involved issues of water *quantity*, the rise of the environmental movement in the past 30 years has produced new legal obligations and constraints. In the U.S., the Clean Water Act, the Endangered Species Act, the National Environmental Policy Act, and the Colorado River Basins Salinity Control Act focus on issues of water *quality* and environmental protection. In Mexico, a large portion of the delta and upper Gulf of California are now part of a protected Biosphere Reserve. As noted earlier, human-induced changes in the river in terms of dams and diversions have wreaked havoc with the natural riparian system, and have destroyed or substantially degraded the habitat of various species of animals and plants. Degradation of habitat is one of the main factors that has contributed to the listing of species as threatened or endangered under the Endangered Species Act. Such listing triggers obligations on the part of federal agencies to attempt to protect the habitat of the particular species and to take other measures to ensure its continued existence. In the Colorado River basin, these requirements have resulted in the Upper Basin Recovery Implementation Program and, in the Lower Basin, the Lower Colorado River Multispecies Conservation Program (LCR MSCP).

In 1997, after consultation between the U.S. Bureau of Reclamation and the U.S. Fish and Wildlife Service, a Biological Opinion was released that concluded that existing operations of the Lower Colorado River dams were likely to jeopardize the continuing existence of the bonytail chub, razorback sucker, and southwestern willow flycatcher. The LCR MSCP currently applies only to the section of the river within the borders of the U.S.; yet the environmental issues, particularly with respect to endangered species, do not stop at the border. There is considerable interest among federal agencies and environmental groups in developing information and exploring alternatives to requirements of the Endangered Species Act. In particular, an unanswered legal question is the extent to which the Endangered Species Act would permit considering the ecosystems of the delta as part of the solution for promulgating a Habitat Conservation Plan for the lower Colorado River.

Even assuming that the Endangered Species Act would allow for the consideration of the ecosystem beyond the territorial boundaries of the U.S., there remains the problem of assuring that the wastewater and surplus flows that cross the border into Mexico ultimately reach the delta region. The U.S. government and the Colorado River basin states will want assurance from Mexico that such flows will not be diverted for agricultural irrigation or to supply the burgeoning municipal demands of Mexicali and San Luis.

As a matter of Mexican law, issues of water allocation are determined by federal law, not by the laws of the states of Sonora or Baja California Norte. The relevant binational agreements are the Mexican Water Treaty of 1944; Minutes 218, 241, and 242 of the International Boundary and Water Commission; the North American Free Trade Agreement (NAFTA); and the Colorado River Basin Salinity Control Act of 1974. There is some support for an argument that the 1944 Water Treaty would allow for water releases for environmental purposes and not require changes to the treaty. However, our working hypothesis is that the best solution for ensuring that such flows reach the delta would be an explicit agreement between Mexico and the U.S. Such an agreement is a realistic option because both countries have an interest in maintaining the ecosystem of the delta.

The complexity and specificity of the institutions governing the management of the Colorado River frustrate efforts to implement binational conservation strategies. The Law of the River is flawed by its arbitrary division of the Colorado River based on political boundaries rather than watersheds. Distinct federal and state agencies separately regulate surface and groundwater resources, while yet other agencies monitor water quality, an arrangement that complicates comprehensive water management efforts (Morrison et al., 1996). Efforts to manage the basin in a coordinated comprehensive manner have been frustrated by institutional inertia and political opposition. In 1978, the U.S. Congress rejected a call for a comprehensive environmental assessment of the basin, due to fears of a centralization of power in federal hands and opposition from agriculture (Fradkin, 1981).

OPPORTUNITIES FOR BINATIONAL MANAGEMENT

Although the institutional barriers described above hinder efforts to implement binational conservation efforts for the Colorado delta, several recent developments suggest opportunities for change. Public recognition and support for water left instream, as demonstrated by the growing body of environmental and instream flow protections (Howe, 1996) provide a foundation for binational conservation efforts. Comments by the U.S. administration indicate a new willingness to consider binational management of the watershed. Upon Mexico's declaration of the Colorado River Delta and Upper Gulf of California Biosphere, former U.S. Secretary of the Interior Babbitt remarked that "[b]oth nations have an interest in setting aside some of these lands and in acknowledging the environmental linkages that connect us" (Wilson, 1994). In June 1999, during a speech at the Natural Resource Law Center in Boulder, CO, former Secretary Babbitt said, "It is time to acknowledge that the natural values of river systems can no longer be treated as table scraps, left over after every conceivable consumptive appetite has been fully satisfied."

A series of legal precedents supports the establishment of dedicated flows for the delta. Mexico and the U.S. have entered into several formal and informal agreements regarding management of binational resources. Agenda 21, a binational environmental initiative signed in 1992, calls for management of water resources at the basin level (Wilson, 1994). The Border XXI Framework Document of 1996 establishes a foundation for dedicated flows to the delta. Further precedent is established by the 1996 agreement between the U.S. and the United Mexican States on Cooperation for the Protection and Improvement of the Environment in the Border Area; the 1992 Rio Declaration on Environment and Development, Convention on Biological Diversity; the 1994 North American Agreement on Environmental Cooperation; and the 1997 Letter of Intent between the U.S. Department of the Interior and the Secretariat of Environment, Natural Resources, and Fisheries of the United Mexican States for joint work in natural protected areas on the U.S.–Mexico border. These precedents bolster recent calls for the establishment of instream flows for the delta (Wilson, 1994) through such mechanisms as a Minute (a subsidiary agreement) to the 1944 Treaty Respecting the Utilization of Waters of the Colorado and Tijuana Rivers, and of the Rio Grande (Snape, 1998).

The recently concluded negotiations between the Metropolitan Water District of Southern California, the Imperial Irrigation District, and the Coachella Valley Water District, purportedly facilitating water transfers from agricultural to urban users, offer another useful precedent for the delta. Although significant institutional obstacles remain, the potential exists for negotiating long-term lease agreements with U.S. water-rights holders to guarantee instream flows for the delta. Other parties to such long-term lease agreements are the potentially water-rich yet cash-poor sovereign Indian tribes, whose water rights continue to be the source of contention and litigation.

Finally, recent commentary has suggested the need for changes in the management of the Colorado River. As noted above, Colorado River management is fragmented and often arbitrarily divided among a variety of different federal and state agencies, each with its own focus. The limited binational cooperation further impedes efforts to manage the region sustainably. Pontius (1997) has proposed creating a Colorado River Basin Coordinating Council, while Getches (1997) has advocated a new type of management of the river that would require an interstate compact between and among the Colorado River basin states. Meeting this potential will require broad changes in the institutions governing the Colorado River.

SECTION III.2

Canadian Prairie Ecosystem

Overview: Sustainability of the Semiarid Prairie Ecosystem, Canadian Prairie Ecosystem Study (PECOS)

Darwin W. Anderson

The Prairie Ecosystem Study (PECOS) involved the University of Saskatchewan and the University of Regina in an interdisciplinary study that included the natural, agricultural, and health sciences. PECOS was funded by the Tri-Council Ecosystem Research Program (TRICERP), a granting council to administer Green Plan funding from Environment Canada. TRICERP projects were available only to universities, and had to include research in at least two of the three areas of the national granting councils: the Natural Sciences and Engineering Research Council (NSERC), the Social Sciences and Humanities Research Council (SSHRC), and the Medical Research Council (MRC, now the Canadian Institute for Health Research). PECOS involved more than 40 professors and research scientists, guiding the graduate study of 29 students, as well as 5 postdoctoral fellows, several undergraduate research assistants, research associates, health professionals, and technicians. PECOS was community based in that residents of the study area made suggestions about the overall design of the study, helped to connect PECOS with the community, participated in a community canvass to encourage completion of a questionnaire discussed in the chapter by McDuffie et al., and served as subjects in several health-related studies.

Because of the breadth of the PECOS study, investigators decided to manage the large and complex research effort by forming focus groups. Focus 1 concentrated on social, economic, and cultural aspects, with an emphasis on the attitudes of the PECOS-area residents on conservation and environmental issues, and the health of rural communities. Focus 2 concentrated on human health; specifically, the environmental effects of pesticide exposure on health. Focus 3 dealt with the health of the land and the biota. To avoid the potential for creation of divisions within PECOS along lines paralleling focus group content, investigators created study-wide programs through publication of a newsletter and scheduling of inclusive activities such as seminars and field excursions.

The objective of PECOS was to assess the sustainability of the semiarid prairie ecosystem, particularly the Palliser Triangle — the semiarid grassland region of southwestern Saskatchewan and southeastern Alberta. The Palliser Triangle, or mixed grassland ecoregion, is the northernmost extension of the Great Plains — the huge region just to the east and in the rain shadow of the western mountains. The Palliser Triangle is an area of more than 500,000 km²; PECOS elected to study a smaller and representative area, Agricultural Census District 3BN. The PECOS study included an area of 15,700 km² in southwestern Saskatchewan, with 14 rural municipalities

(RMs), and a human population of 30,000. About one half of the people live in the one urban center, Swift Current.

The PECOS area included 2775 farms in 1996, a decline from 2970 in 1991, which reflected a continuing trend to larger farms that began soon after settlement, and that has intensified since the 1970s, particularly in the 1990s. The average farm is just over 500 ha (1 ha = 2.47 acres) in size; 795 farms are larger than 900 ha, and 146 are six sections (1550 ha) or larger. About 70% of the land is cultivated in wheat (hard red spring and durum), barley, oil seeds (flax, canola, and mustard), pulse crops (lentil, pea, and chickpea), and canary seed. Cattle are raised on 1200 farms or ranches, using mainly native grasslands for grazing. Several large, modern hog-producing operations were established in the area in the 1990s, with farmers as major shareholders in arrangements that permit sale of feed grains such as barley to the hog operation, as well as providing local opportunities for employment.

Despite its appearance as a reasonably well maintained agricultural landscape with generally large, prosperous-looking farms, the area is in crisis. The health of the ecosystem is compromised, which is particularly evident when it is evaluated within the broad context of biophysical, economic, and social dimensions (Nielsen, 1999).

When the PECOS proposal to TRICERP was being prepared in 1992, the area had just experienced several years of drought. Prices for cereal grains at that time were extremely low, a consequence of depressed world prices for wheat and other cereals. Government support programs and emergency (drought) aid contributed more to the agricultural incomes than sales from crop production. Proponents justified reduction of subsidies on the basis of elimination of budgetary deficits, both provincially and federally. A consistent movement favoring fewer government subsidies for agriculture — at least directly to farmers — began in the 1990s. In Saskatchewan, for example, direct government support for agriculture has been reduced by 71% since 1991–1992, according to the Provincial Auditor's report for 1999.

Several years of above-average rainfall in the middle-to-late 1990s resulted in better yields of cereal grains. Crops including canola and pea that have been grown generally in more-humid regions of the prairies replaced wheat on a substantial part of the land. Yields of the new crops were good, a consequence of the moist growing seasons and of reduced disease pressure. The changes appeared to mark a new period of prosperity, but the effect was short-lived. Declining prices for almost all crops, and steadily increasing costs of production inputs, became common by the late 1990s. The elimination of the rail transportation subsidy known as the Crowsnest Pass rate, which had been in effect since the 1880s, resulted in considerably higher freight charges for shipping grain to ocean ports. Profit margins for export grains became even smaller or disappeared, particularly in parts of Saskatchewan that are distant from Atlantic and Pacific ocean ports. Government officials have predicted that farm incomes will remain low for the near future.

Many farms expanded, with considerable investment in large machinery, particularly new technologies such as zero tillage or minimal tillage equipment. The new technologies offer the promise of improved soil conservation, greater efficiency (at least in terms of labor), and lower costs of production. Calculations by farm management specialists suggest that many of the large tractors, conservation tillage equipment, and combine harvesters should be used on farms of no less than 2000 to 3000 ha in order to reconcile their high initial cost.

The increase in farm size has resulted in fewer farmers, and a recent trend among farmers to rent rather than own a substantial proportion of their cropland. In fact, many farmers who retire or stop farming are not able to sell their land for what they consider a fair price, and instead rent the land to neighbors. The steadily declining farm population, and the increasingly common practice of consolidating farm supply outlets in only a few large centers, as well as a markedly reduced number of grain delivery points, have resulted in a marked decline in the on-farm population and smaller farming communities.

The changes have been described by proponents as the industrialization of agriculture, the progressive process of moving agricultural production from dependence on biological systems

and the attendant vagaries of nature to a more-predictable production system modeled on the factory. The industrial system depends on high yields obtained from greater use of purchased inputs such as fertilizers and pesticides, in comparison to earlier practices that were lower yielding and more dependent on the nutrients provided free (and generally without natural replacement) by the soil and nature. In 1999, these changes coupled with low commodity prices resulted in a renewed crisis in farming, and instigated the call for substantial government aid for farmers in serious financial difficulty.

Four chapters are presented in the case study. In the chapter “Ecosystem Level Functional Changes in Breeding Bird Guilds in the Mixed Grassland since Agricultural Settlement,” Todd Radenbaugh, a Ph.D. candidate at the University of Regina, describes the ecoregion and examines the change in bird populations using mainly historical data. Cultivation and related changes have altered the character of the prairie landscape and the birds that utilize the prairie as habitat. The research demonstrates that ecosystems change over time, and that the health of present systems cannot always be evaluated using a standard of a past, supposedly pristine condition.

MacDonald and Remus’ chapter, “Health and Well-Being in a Changing Environment: Perceptions of a Rural Senior Saskatchewan Population,” presents a broad assessment of the largest single group of residents, those over 55 years of age. Generally, the survey found that most older people consider their health as good or excellent, particularly those with higher incomes. Most residents were satisfied with their lives — in spite of declining conditions in their communities and related commercial, health, and educational services — pointing to the great resiliency of those who have lived and prospered in this uncertain environment. Despite the present uncertainty, most seniors remain optimistic about the future, a marked contrast to the high school students who see little or no economic or cultural prospects within the rural areas (Butler, 1998).

The chapter by McDuffie et al., “Prairie Ecosystem Study (PECOS): From Community to Chemical Elements, the Essential Role of Questionnaires,” discusses the involvement of the local community and health-science researchers to advance our understanding of potential human health risks associated with pesticide exposure. The essential role of questionnaires is stressed, as are the impediments and benefits of interdisciplinary research. The data gathered by questionnaires are conceptual links between different researchers but it is the interaction and discussion of the data that challenges the conventional wisdom inherent in each specialty, and leads to new insights concerning the broader picture.

In their chapter, “Evaluating Agroecosystem Sustainability Using an Integrated Model,” Belcher and Boehm discuss a research approach for making the dynamic linkages between system components. A computer simulation model has been developed to dynamically integrate the ecological (a soils submodel that simulates soil quality and crop growth parameters) and economic components. The chapter examines biophysical constraints to agroecosystem sustainability, as well as the implications of the constraints for policy development.

The chapters are representative of the research done in PECOS. The Belcher and Boehm and Remus and MacDonald papers are from Focus 1, in which emphasis was placed on the social, economic, and cultural dimensions of evaluating the health of ecosystems. McDuffie et al., of Focus 2, deal with human health aspects, and discuss the process of working in an interdisciplinary way, especially by learning the language of related disciplines. Radenbaugh’s chapter is part of his Ph.D. study, based in Focus 3. All studies in Focus 3 were graduate research projects, making the integration and discussion that promote interdisciplinarity even more important. Interestingly, perhaps not encumbered by the many years of discipline-based research, the students were more completely interdisciplinary than their professors, not only taking ownership of their individual projects, but also appreciating those of fellow students. PECOS and TRICERP shared a common objective: for the interdisciplinary perspective developed by students to follow them as they develop their own careers, helping them to remain conscious of the many interrelated dimensions of assessing the health of ecosystems.

Historical Land Use and Ecosystem Health of the Canadian Semiarid Prairie Ecosystem

Lisa L. Dale-Burnett and Darwin W. Anderson

INTRODUCTION

The Palliser Triangle is an area of about 500,000 km² in southwestern Saskatchewan and southeastern Alberta coinciding with the Mixe Grassland Ecoregion of the Prairie Ecozone and the Brown Soil Zone (Acton et al., 1998). The southern boundary of the Palliser Triangle corresponds with the international boundary at 49°N latitude; however, ecological conditions of the land to the south in Montana and western North Dakota are similar. The Palliser Triangle was the focus of a major interdisciplinary study that examined the sustainability of the semiarid prairie ecosystem from the perspective of the health of the land and the well-being of the people, the Prairie Ecosystem Study (PECOS). The subject of this chapter is the history of land use and agriculture in the PECOS area, and the larger Palliser Triangle from the late 1800s until the present. It emphasizes the history of agricultural development, explores the difficulties that have periodically resulted in unhealthy ecosystems, and, finally, discusses today's ecosystem health in relation to the past.

EVALUATION OF THE PECOS AREA BY EARLY EXPLORERS

The Palliser Triangle was explored by an expedition financed by the British government and led by Captain John Palliser in 1857–1859 (Spry, 1968). The objective of the expedition was to explore and evaluate the settlement potential of the lands in western Canada that were then under the control of the Hudson Bay Company. Palliser's party traveled through the area during a decade that was warmer and drier than average. In his final report to the British government, Palliser described a triangular area as “desert, or semidesert in character, which can never be expected to become occupied by settlers” (Spry, 1968).

Palliser's view of the region was echoed in the report from H.Y. Hind, who led a Canadian expedition that explored western Canada in 1857–1859. Hind described “that part of the Canadian Plains west of the Missouri Coteau from the character of its soil and aridity of its climate ... as permanently sterile and unfit for the abode of civilized man” (cited in Mackintosh, 1934). Hind considered the region as the northern extension of what was described as the Great American Desert.

Two decades later, John Macoun, a botanist accompanying an 1879–1881 railway survey team, traveled through the southern part of the Palliser Triangle, probably during a moist period. He described the area quite differently from Palliser and Hind:

The appearance of the country passed through was altogether different from what I expected, having been led to believe that much of it was little else but desert.... [F]uture settlers will prefer the prairie as there is less broken land, less marsh and swamp and less labour required to make a home. The open treeless prairie generally condemned to sterility is by far the best farming land (Macoun, cited in Waiser, 1989).

The transcontinental Canadian Pacific Railway (CPR), which was originally routed through the northern fertile belt, was rerouted through the Palliser Triangle at about 50°N latitude. Although the influence of Macoun's reassessment of the agricultural potential of the semiarid region in this relocation has been questioned (Waiser, 1985), his opinions certainly strengthened the CPR's decision. The relocation of the CPR mainline was the first step in the agricultural development of the semiarid prairie region that is the economic basis of the PECOS area.

EARLY HISTORY

Archaeological evidence indicates that the Prairie Ecozone has been inhabited for several thousand years (Potyondi, 1995). Aboriginal hunting pressure probably contributed to the extinction of species, such as a larger type of bison, thousands of years ago. Fire was used to manage the grasslands by the aboriginal peoples, who periodically burned the prairie to encourage new vegetative growth, which in turn attracted the bison. Many recognize today that it was fire combined with a very dry climate that kept trees from growing on the prairie.

Potyondi (1995) summarized the influence of the aboriginal people on the prairie ecosystem as follows:

As many as seven different native groups frequented the area until the 1870s. Typically, they used the oases on its borders more than they did its interior, which was poorer in natural resources and therefore less hospitable to people. As they had for millennia, the Native Peoples depended primarily on the herds of buffalo that ranged through southwestern Saskatchewan seasonally. The abiding abundance of animals suggest that the native population did not exceed the natural carrying capacity of the land, and their semi-nomadic way of life, linked intimately to the seasonal availability of sustenance, helped to maintain the ecological balance.

Between 1830 and 1880, major change came to the area in the form of buffalo hunts. Metis hunters and traders from the Red River settlement in southern Manitoba traveled by ox cart to southwestern Saskatchewan to systematically harvest the buffalo. Hides were collected and buffalo meat was used to make pemmican. For the first time, the buffalo were seen to have economic value rather than as a source of meat and clothing for the local Indian tribes (Potyondi, 1995). This commodification resulted in the hunting of the buffalo to virtual extinction by 1880.

THE RANCHING PERIOD

In the 1880s, cattle replaced bison in the Palliser Triangle. The first ranchers were the Metis and French Canadians who, with the decline in the bison herd and the related activities of freighting and trading, began to graze cattle on the now-unused prairie (Potyondi, 1995). Markets were limited, however, with main sales being to the government. About the same time, some American ranchers

moved their cattle north to graze because of increased pressure on the Montana range. Some held Canadian government grazing leases, but others simply took advantage of the open range and herded their cattle north. By the 1890s, thousands of American cattle, ranging as far north as the CPR, grazed Canadian grass.

In the late 1880s and 1890s, the Canadian government encouraged ranching in the Palliser Triangle by granting inexpensive, long-term grazing leases. By 1888, Sir John Lister-Kaye had started to establish three large ranch-farms in the vicinity of the PECOS area. Lister-Kaye's company was known as the Canadian Agricultural, Coal and Colonization Company, or the "76" for the brand displayed on many of the cattle that had been purchased in the U.S. The farms were initially set up as mixed operations with grain, cattle, sheep, and hogs, but after 2 years of crop failure it was decided to specialize in cattle and sheep. The 76 was only the first of several large ranches that were established in the PECOS area. In 1902, the Cresswell Cattle Company, an American outfit, trailed 25,000 cattle and 600 horses from South Dakota into what was to become southwestern Saskatchewan and southeastern Alberta. The ranch was known as the Turkey Track, for the shape of its brand.

The harsh winters of 1903–1904 and 1906–1907, combined with government support for homesteading, spelled the end of the 76 and Turkey Track ranches. The cattle had grazed year round on the unfenced range through the mild winters of the 1890s. But during the long, cold winter of 1906–1907, 60 to 70% of the range cattle were lost (Potyondi, 1995). The era of the open range ended as settlers arrived to homestead quarter- or half-section entitlements.

An exception to the demise of the large ranches was the Matador Land and Cattle Company, a Scottish-owned ranching company which was part of a larger U.S.-based ranching company of the same name. In 1905, the Matador obtained a 21-year lease to 50,000 acres (20,000 ha) of grazing lands north of the South Saskatchewan River. The Matador's Canadian range was essentially a giant finishing operation for 2- and 3-year-old steers. Shipped into the area by rail, they grazed on the rich pasture for 2 or 3 years, and were then sold as 4- or 5-year-olds, either back to the U.S. or to Great Britain, depending on the price and tariffs of the day. High American tariffs that were imposed after World War I, coupled with generally depressed prices, resulted in the close of the Matador's Canadian operation in 1922.

Today, a provincially owned community pasture takes up much of the Matador range. An ecological reserve owned by the University of Saskatchewan is also within the original leasehold area. As part of the International Biosphere Program, the university established a major research project on grassland ecology, known as the Matador Project, on this reserve in the 1970s.

THE HOMESTEADERS

Although there were a few farmers in the PECOS area before, general agricultural settlement did not take off until the first decade of the 1900s. The CPR mainline went through the PECOS area in 1882–1883, but construction did not resume until 1911 when a number of branch lines were started. Railway construction continued until the early 1930s. In the PECOS area, much settlement preceded branch line construction. Settlers lived far from established towns, transportation, and postal services. The arrival of a railway meant not only the development of grain elevators for the more convenient marketing of grain and other agricultural products, but also regular mail service, delivery of commercial goods, and easier travel to larger centers.

Often the last branch rail lines constructed in the PECOS area were the first to be abandoned as better road transportation and larger farms obviated the need for many small communities and grain delivery points. One example is the Mawer to Main Centre line, which served the east-central part of the PECOS area just south of the South Saskatchewan River. Built in 1930–1931, it was taken up in the late 1960s, and most of the villages along this route have disappeared.

The rural population* of the PECOS area was 3395 in 1906, and rapidly increased to just over 30,000 in 1931. At this time, there were 19 incorporated towns and villages and one city (Swift Current) in the study area. After a peak in 1931, the rural population of the PECOS area began a decline that continues to this day.

The agricultural methods and implements brought by settlers from more humid regions were poorly suited to the semiarid climate of the PECOS area. A classic example was the use of the plow for tilling the soil. Appropriate in more-humid regions, moldboard plows buried crop residues and left the soil in a dry, pulverized condition, easily eroded by wind. Within two decades of agricultural settlement, marked deterioration of the soil was becoming apparent. Inappropriate tools and techniques led to soil erosion, loss of organic matter, and lowered fertility (Shutt, 1925). In fact, many homesteaders had tried and given up farming within a few years, especially on poorly suited lands such as the Seward Sand Hills, west of Swift Current.

The droughts and hardships of the 1917–1926 period were particularly harsh. Concerns arising from soil-drifting and loss in soil fertility resulted in the Better Farming Conference held by professional agriculturists and farmers at Swift Current in 1920 (Anstey, 1986). A month after the conference, a provincial government royal commission was established to investigate the conditions surrounding the drought and farm abandonment in southwestern Saskatchewan. Also in 1920, the federal government established an agricultural research station based in Swift Current to research and develop cropping and range-management strategies suitable for semiarid regions (Campbell, 1971). In 1921, the Better Farming Commission made several recommendations, including the establishment of a soil survey for Saskatchewan and more comprehensive collection of meteorological records (Province of Saskatchewan, 1921). These actions enhanced the scientific side of farming, and gradually dryland farming methods evolved that slowed the process of soil deterioration and stabilized production to a considerable degree.

In the early years of agricultural settlement, the main approach to dryland farming was based on the better application of summer fallow. Summer fallowing is the practice of letting a field lay idle once every 2 or 3 years and tilling it to keep the weeds down on the fallow year. It was believed that loosening the soil allowed rain to penetrate to the subsurface, while a fine dust-mulch protected this subsoil moisture from evapotranspiration. Working the soil also killed moisture-loving weeds. In this way, a portion of rainfall in the fallow year was retained for the following growing season. From the beginning, summer fallow was recognized as a major contributor to the loss of soil organic matter or fiber, which increased susceptibility of the soil to wind erosion, but it was still recommended because alternatives were not yet available (Shutt, 1925).

The comparative success of summer fallow as a risk-averse cropping system that exploited reserves of plant nutrients in soil organic matter was undoubtedly a reason for its general adoption in the region. Historically, about 40% of the cultivated land in the PECOS area was in summer fallow, but in recent decades this proportion has been smaller. Decomposition leading to decreased organic matter also released large amounts of nitrogen as nitrate. Because of these high levels of nitrate in the soil, wheat grown after summer fallow had high protein content even without applying fertilizer. In the first years of cultivation, the amount of nitrate mineralized from the reserve stores was generally adequate to supply crops. Overall, the practice of summer fallow led to a loss of nitrate, however. A large proportion of the nitrogen removed from the prairie soils since cultivation cannot be accounted for by crop uptake. A great deal of soil nitrate has been lost either through leaching beyond the root zone, or by loss back to the atmosphere by denitrification. In the past few decades, the use of nitrogen fertilizer has become common in the PECOS area.

The 1930s was a period of drought and economic depression when all three components of the prairie ecosystem, the biophysical, socioeconomic, and human well-being were consistently unhealthy. An estimated 10,000 farm families left the semiarid region of Saskatchewan in the 1930s, some leaving farming, but others moving to the forest areas in the north to homestead again under very

* Rural population is defined as people living outside of the boundaries of any city, town, or village and including those living in communities of fewer than 100 people.

difficult conditions. The farmers and ranchers who remained in the semiarid region endured considerable hardship. Year after year, events conspired to deprive farmers of an income. If there was enough moisture for a crop, then the grasshoppers invaded; if there was a good harvest, then prices were low. Records of low wheat yields, low prices, and high unemployment were set during the 1930s.

In 1935, the Canadian government established the Prairie Farm Rehabilitation Administration (PFRA) by an act of parliament. PFRA's mandate was to provide for the rehabilitation of the drought and drifting areas, and to develop and promote systems of farm practice, tree culture, water supply, land utilization, and land settlement that would lead to greater economic security for the agricultural region of western Canada (PFRA, 2000). One early PFRA program was the setting up of community pastures on eroded, low-quality lands that had been inappropriately used for farming.

GRADUAL CHANGE IN AGRICULTURE

The generally more benign climate and more favorable economic prospects of the 1940s through the 1960s was a period of recovery for farming in the PECOS area. Part of the change was the gradual increase in farm size and the related reduction in number of farms. The number of farms decreased from a maximum of 6960 in 1931, to 5911 in 1946, and to 4052 in 1961. The trend continues, with 2942 farms in 1991, and 2775 in 1996.

The increase in area of land farmed by individual farmers was made possible by the mechanization of farming, generally declining real prices for grain, and the comparatively low productivity of land in the Brown soil zone. PECOS area farms were consistently larger and more mechanized than the Saskatchewan average. The transition from horse to tractor power was almost complete in the PECOS area by 1945, unlike the rest of Saskatchewan; combine harvesters replaced threshing machines in the PECOS area before the province as a whole.

Although some government programs have supported smaller, more-diversified farms, there has been a consistent philosophy (whether intended or simply expedient) that the farming sector will be better off as smaller farms become absorbed by larger, more technically refined producers.

Today, the model of prairie agriculture most often recommended by agricultural scientists and many farmers is the large, highly mechanized, capital-intensive farm. These farms operate on a narrow margin (small profit per acre or per animal) in an intensely competitive global market. Survival depends on the efficiency of the farmer in managing thousands of hectares or hundreds of animals. This shift in farming from a nature-dependent activity, susceptible to natural variations, to a highly managed, technologically dependent activity has been referred to as the industrialization of agriculture. For example, in industrial agriculture the nitrogen requirements of a crop are provided by fertilizers, not animal or green manure; and pests are controlled by pesticides, not natural predators. In essence, agriculture becomes more like a factory, with greater stability but, interestingly, less resiliency. Stability is considered to be the ability of a system to resist or withstand change or disturbance, whereas resilience is the capacity of a system to return to an optimum state following a stress, as when a willow bends in the wind but does not break.

RECENT TRENDS IN PECOS AREA AGRICULTURE

Ranching and farming have substantially altered the prairie ecosystem. In the PECOS area, 61% of the land had been broken by 1961. Today, about 70% of the prairie has been converted to cropland, resulting in the loss and fragmentation of habitat. Habitat loss is linked to the extirpation (loss of a species from a particular area) of animal species, such as the swift fox and prairie dog, and reductions in numbers of many others, such as the sharp-tailed grouse and burrowing owl.

Certain plant communities are almost completely gone. The wheatgrass-junegrass type that was characteristic of the clayey lacustrine soils in the Brown and Dark Brown soil zones (Coupland

and Rowe, 1969) remains in only a few small protected areas such as the Matador Grassland. These clay soils and landscapes are particularly well suited to dryland farming because of their fertility and high moisture-storage capacity, and so are very desirable as farmland.

Evaluations of soils under different cropping systems have consistently shown that erosion and the loss of soil organic matter are more severe in rotations where tilled summer fallow is used frequently. Summer fallowing every second year, which was a common practice in the Palliser Triangle for many decades is considered to be the worst-case scenario. Organic matter contents of surface horizons are only about one half of the level found in native grassland soils, with related decreases in nutrient supplying power or fertility, soil tilth, and resistance to soil erosion. Intensively farmed soils have fewer and less stable soil aggregates than soils under grass. Poorly aggregated soils are more difficult to till, more easily eroded, and take in water more slowly than well-aggregated soils. Cultivated soils are less porous than soils under prairie, with fewer large pores or macropores that are so important to the intake of water. Water from rain or snowmelt that does not enter the soil cannot be stored for future use by crops, and runs off, thereby increasing the potential for water erosion. Crop rotations that avoid tilled summer fallow and increase the amount of crop residues or manures added to the soils are likely to result in increased soil organic matter, better soil aggregation, and more-efficient use of scarce moisture supplies.

Many farmers, particularly in the driest parts of the Palliser Triangle, continue to summer fallow about one half of their land each year as a moisture conservation strategy. Increasingly in recent years, herbicides are used to control weeds on summer fallow rather than tillage. This practice is known as chem-fallow. When combined with seeding methods that disturb the soil minimally, chem-fallow maintains a cover of crop residues that protects the soil from wind erosion.

The present-day increase in land under conservation tillage reflects a transition to a more efficient farming system (one farmer can farm more land) that conserves soil and is generally more productive. Conservation tillage is a general term used to describe farming methods that protect the soil by maintaining a protective cover of crop residues or stubble from previous crops, yet use little or no tilling. Zero tillage is a tillage system that completely avoids tillage, except for the minimal disturbance made when fields are seeded. The proportion of land in the Rosetown area (generally typical of the PECOS area) seeded using conventional tillage methods decreased from 88 to 60% between 1994 and 1998, as reported in a recent field survey completed by PFRA (Haak, D., PFRA, Rosetown, Saskatchewan, Canada, personal communication, 2000). There was a related increase in zero tillage from 3.3 to 12.2%, and in minimal tillage from 6 to 18%. Both zero-till and minimum till are described as direct seeding methods, in that there is no cultivation prior to seeding the land. Broad-spectrum herbicides such as glyphosate are used to control weeds. These recommended methods are increasingly dependent on the more intensive use of agrichemicals, particularly herbicides, pesticides, and fertilizers. More fertilizers, especially nitrogen fertilizers, are needed as the supply of nitrogen present in the soil organic matter is used up, and as farmers move to continuous cropping with conservation tillage.

The general reduction in area of land in summer fallow and the adoption of conservation tillage are considered to be indicators of a more-sustainable agriculture, an agriculture that maintains or enhances soil and ecosystem health (Acton and Gregorich, 1995). In a recent report on the environmental sustainability of Canadian agriculture, McRae and co-workers (2000) write:

The risk of erosion on the Prairies declined by about 30% from 1981 until 1996, with two-thirds of the decline occurring between 1981 and 1991. About three-quarters of the reduction can be attributed to a change in tillage practice. The remainder is mainly the result of changes in cropping practices, specifically less summer fallow.

However, farming methods that require greater use of pesticides raise concerns about both the health of the environment and the people applying or otherwise exposed to the agrichemicals. Studies of surface water bodies, particularly farm dugouts or reservoirs that collect surface runoff

from cultivated land, found herbicides in the water months after their application to crops (Cessna and Elliott, 2000).

Technologies for conservation tillage are expensive and have resulted in a marked increase in the size of “economically viable” farms, a further reduction in the number of farms, and declines in communities supported by farms. Livestock production has become more intensive, concentrated in large mechanized operations that themselves present environmental and social problems.

Recent decades have seen a welcome trend to farming systems less dependent on wheat. Although spring and durum wheats are still the main crops in terms of area planted, there has been a substantial and continuing increase in land under pulse crops, especially lentil, pea, and chickpea. The increases are most evident on the agriculturally superior clay soils (PFRA, 2000). Pulse crops generally result in better economic returns and require less nitrogen fertilizer, an important factor as energy prices and the cost of inputs dependent on fossil fuels continue to increase.

THE PECOS AREA IN 2000

Despite large, prosperous-looking farms, an agricultural landscape that seems to be well cared for, and uses improved soil conservation practices, there is little doubt that the semiarid prairie region is a community in crisis. This crisis is particularly clear when ecosystem health is evaluated within the broad context of biophysical, economic, and social dimensions (Nielsen, 1999). In the early 1990s, when commodity prices were low and the area had just experienced several years of drought, government support programs and emergency aid contributed more to agricultural incomes than did production. Beginning in the 1990s, there has been a consistent trend to fewer agricultural subsidies at both the national and provincial levels. These cutbacks have been justified on the basis of eliminating budgetary deficits. In Saskatchewan, for example, direct government support for agriculture has been reduced by 71% since 1991–1992, according to the provincial auditor’s report for 1999.

A period of above-average rainfall in the mid- to late-1990s resulted in the expansion of crops, such as canola and pea, from more-humid regions of the prairies into the more-arid areas, and in better yields overall. These changes, plus the introduction of new crops such as chickpeas appeared to mark a new period of prosperity, but the effect was short-lived. By the late 1990s, declining crop prices and steadily increasing costs of production canceled most gains.

In 1983, the elimination of the Crowsnest Pass Agreement, a transportation subsidy that had been in effect since the late 1880s, resulted in income margins for export grains becoming even smaller or disappearing, particularly in parts of Saskatchewan that are distant from both Atlantic and Pacific ocean ports. The wheat economy, the mainstay for most Saskatchewan farmers, relied on two subsidies. First was the Crow Rate, which moved grain to ocean ports at considerably less than the actual cost; second was the natural subsidy of nitrogen reserves stored in the soil organic matter, which allowed farmers to grow high-quality wheat without fertilizer.

With considerable investment in large machinery to support new practices such as zero or minimal tillage, many farms became even larger. The new technologies offer the promise of improved soil conservation, greater efficiency (at least in terms of labor), and lower costs of production. Calculations by farm management specialists suggest that many of the large tractors, conservation tillage equipment, and combine harvesters should be used on at least 5000 or 6000 acres each year, in order to reconcile their high initial cost.

The increase in size of farms has resulted in fewer farmers and the growing importance of farmland rental as opposed to ownership. In fact, many farmers who retire or stop farming are not able to sell their land for what they consider a fair price, so the land is rented to neighbors. This change in land tenure is of concern to those who deal with soil conservation. Studies have shown that farmers with a long-term stake in land (e.g., owners) are more likely than renters to adopt soil-conserving management strategies.

There are also concerns about persons being interested in farming in the future. Most farmers in the area today, as in most of western Canada, are older and thinking of retirement. There are few young people who anticipate a career in farming, or even a career in the rural areas where employment prospects are limited (Butler, 1998).

As described in this chapter, agriculture in the PECOS area has moved from a way of producing food that was dependent on biological systems and the attendant vagaries of nature to a more-predictable, industrial production system modeled on the factory. The latter industrial system depends on high yields obtained from greater use of purchased inputs, such as fertilizers and pesticides, as opposed to the former practices that were more dependent on the preexisting soil nutrients that were free, but generally without natural replacement. These changes, coupled with a return to low commodity prices in 1999–2000, have resulted in a renewed crisis in farming and the call for substantial government aid for farmers in serious financial difficulty.

Health and Well-Being in a Changing Environment: Perceptions of a Rural Senior Saskatchewan Population

Mary B. MacDonald and Gail Remus

INTRODUCTION

Environmental sustainability has become a major concern throughout the world. The purpose of the Prairie Ecosystem (PECOS) interdisciplinary research project was to gain a better understanding of the interactions between humans and the environment. A description of the PECOS project, *Sustainability of the Semiarid Prairie Ecosystem: Imperatives for Agriculture, Environment, and Rural Communities*, is covered in the overview.

Concern has been expressed about the lack of services and supports for rural seniors. Commonly reported stressors for rural elderly people include loss, isolation, financial concerns, and decreased ability to manage (Johnson et al., 1993).

Better understanding of the needs of older rural women is also a challenge. The proportion of older women living in rural areas is increasing. Previous research has shown that older rural women have more chronic illnesses than do their urban counterparts (Palmore, 1983–1984). “Their increasing age and susceptibility to disability, along with limited access to acute and chronic care facilities, present a challenge for health care providers” (Dietz, 1991).

Self-reliance and independence have been demonstrated as strong characteristics of rural dwellers. Rural residents often manage on their own or turn to family and friends for assistance rather than to formal agencies for health care (Bushy, 2000; Stewart, 1997). As more of the younger generation migrate from the rural area, the question arises whether older residents can continue to have their health care needs met in rural areas.

The stressors experienced by rural elderly people are related not only to personal characteristics, but also by the physical and social environment in which they live (Bushy, 2000). Thus, there is a need to better understand this population.

The purpose of the study was to determine seniors’ perception of their health, satisfaction with life, and optimism regarding the future for residents living within the study area.

METHODOLOGY

Data were obtained through a telephone survey done by a marketing firm using a stratified random sampling technique. In all, 1000 residents within the study area were surveyed: 508 (51%) men and 492 (49%) women. Respondents had to qualify on the basis of gender and rural municipality residence to assure representativeness and parallel “the actual distribution of people as given in the 1991 Statistics Canada data” (Dickinson, 1998/1999).

The questionnaire used in the telephone survey was developed by a multidisciplinary team of researchers, including faculty and graduate students in the areas of health, sociology, and economics. Issues related to health and well-being, health care reform, crime and security, education and work, agricultural practices, and environmental ethics were explored.

This chapter addresses those aspects of the study related to health and well-being of seniors (ages 55 and over) within the study area.

RESULTS

Demographic Data

Of the seniors surveyed, 195 (51%) were men and 187 (49%) were women, aged 55 to 95. Most of the respondents (80%) lived in town, defined as being other than living on a farm. Of a total of 72 widowed seniors, 13 were men and 59 were women. When analyzed for marital status, more widowed residents lived in town (94%) than did single persons (80.5%) or married persons (77%) ($p = 0.004$) (Table 115.1). Further analysis of the data according to gender showed that place of residence was significant for women ($p = 0.002$), but not for men. For women, 97% of the widows as compared to 81% of those who were single and 75% of those who were married lived in town (Table 115.1); 75% of the women and 70% of the men had retired; 27% of those who had retired had changed their place of residence, while 28% of those who had not yet retired planned to change their place of residence upon retirement. More men than women had changed their place of residence since retiring (Table 115.1).

Gross income was significantly different for those living in town vs. on the farm ($p < 0.0001$) (Table 115.2). Most town residents (58%) earned \$15,000 to less than \$40,000 per year, whereas

Table 115.1 Place of Residence of Seniors, Stratified Based on Selected Attributes

Male (%)	9	58	24	9
Female (%)	22	46	26	5

most of the farm residents earned \$40,000 to less than \$80,000 per year (35.5%). More farm residents (26%) than town residents (3%) had a gross income of \$80,000 or more per year. There was also a significant difference in gross income according to gender ($p = 0.004$). Generally, there was a higher or similar portion of men than women for each income category except for that of \$15,000 or less per year; 22% of the women and only 9% of the men earned less than \$15,000 per year. There was also a significant difference between gross income and education level ($p = 0.006$). Regardless of education level, most seniors had a gross income between \$15,000 and under \$40,000 per year. More seniors with at least some elementary school education earned less than \$15,000 per year (30%), compared with those with more education. More of the seniors earning \$40,000 to less than \$80,000 per year had some college or university undergraduate education (31.5%) or had completed at least a university undergraduate degree (35.5%).

Perception of Health

Overall, the residents' perception of their health was positive. Of the total senior population surveyed, 71% rated their health as good or excellent. This remained unchanged regardless of gender, marital status, or whether one lived alone, with a spouse, or with extended family.

Perception of health was definitely affected by gross income ($p = 0.0002$) (Table 115.3). As gross income level improved, so did the percentage of persons who perceived their health to be excellent or good. Perception of health according to gross income was significant for both genders, but particularly so for men ($p = 0.002$). This was most evident in the income category of less than \$15,000 where 71% of the men rated their health as fair or poor while most of those earning

Table 115.3 Percentage of Senior Residents Who Perceive Themselves to Be in Excellent/Good Health and Fair/Poor Health, in Relation to Income, Education, and Satisfaction with Life

Related Factor	Excellent/Good Health	Fair/Poor Health

Dissatisfied	54	46
Satisfaction with Life (males)		
Satisfied	72	28
Dissatisfied	36	64

\$15,000 or more per year rated their health as excellent or good. Most women in each income level rated their health as excellent or good ($p = 0.02$), although for the lowest income level (less than \$15,000 per year) only 58% rated their health as excellent or good.

Other than for the lowest educational level, most residents rated their health as excellent or good. As expected, more of those with the lowest education (e.g., not having attended high school) perceived their health to be only fair or poor, compared with those who had at least some high school ($p = 0.0005$) (Table 115.3). There was a similar pattern for men ($p = 0.03$) and for women ($p = 0.04$).

There was a significant difference in perception of health according to satisfaction or dissatisfaction with life ($p = 0.05$). Of those who were satisfied with their lives, 73% rated their health as excellent or good, while only 54% of those who were dissatisfied with their lives rated their health as excellent or good (Table 115.3). When analyzed for gender, there was no significant difference in perception of health between women who were satisfied with their lives and those who were dissatisfied. However, for men there was a significant difference in perception of health according to satisfaction with life ($p = 0.014$). Most men who were satisfied with their lives (72%) rated their health as excellent or good, while only 36% of those who were dissatisfied with their lives rated their health as excellent or good.

There was no significant difference in perception of health whether one was neutral, agreed, or disagreed with the statements that (1) availability of a local physician was an important factor in where they lived and (2) availability of the hospital was an important factor in where they lived. Most of the residents rated their health as excellent or good regardless of their opinions about the importance of the availability of a physician or hospital in determining where they lived. This view remained unchanged regardless of gender. As well, most of the residents agreed with the statements, "The availability of a doctor in my community is an important factor in determining where I live" (75%) and "The availability of a hospital in my community is an important factor in determining where I live" (78%).

When analyzed according to residents' optimism or pessimism in regard to the future, perception of health was not significant. There was no significant difference in perception of health whether residents had changed their place of residence since retirement or planned to change their place of residence after retirement.

Satisfaction with Life

Most of the residents were satisfied with their lives. There was no significant difference in satisfaction with life when analyzed in terms of gender, marital status, or agreement that availability of a doctor or hospital was important in determining where they lived. Regardless of whether children, or other family, lived within 50 miles, most residents were satisfied with their lives. Those living alone or with spouses were significantly more satisfied with life than those who lived with extended family (98, 94, and 77%, respectively; $p = 0.01$) (Table 115.4).

Level of education was not significant in terms of satisfaction with life for the total senior population or when analyzed by gender. The same was found for gross income level and satisfaction or dissatisfaction with life.

Agreement with the statement "upcoming retirement causes me stress or worry" and satisfaction with life was significant ($p < 0.00001$). More of the residents who were not worried about their upcoming retirement were satisfied with their lives (97%) than those who were worried about their upcoming retirement (79%). This was significant for men ($p = 0.0002$) and for women ($p = 0.0001$) (Table 115.4).

Optimism Regarding the Future

Table 115.4 indicates a significant difference ($p = 0.009$) in satisfaction with life depending on whether or not one was optimistic regarding the future. While most residents were satisfied with

Table 115.4 Percentage of Seniors Who Are Satisfied/Dissatisfied with Life and Optimistic/Pessimistic about the Future

Related Factor	Satisfied with Life	Dissatisfied with Life
Living Arrangements		
Lives alone	98	2
Lives with spouse	94	6
Lives with extended family	77	23
Worry about upcoming retirement	79	21
Not worried about upcoming retirement	97	3
Optimism about the Future		
Optimistic	96	4
Pessimistic	88	12

their lives regardless of their optimism or lack of optimism regarding the future, 96% who were optimistic about the future were satisfied with their lives, compared with 88% who were pessimistic about the future yet satisfied with their lives.

Most people were optimistic about the future regardless of their level of education ($p = 0.02$). However, more residents with at least an undergraduate degree were optimistic about the future (85%) as compared with those who were pessimistic about the future (15%) (Figure 115.1). A similar pattern existed for each gender but was significant only for men ($p = 0.02$). Those men with the least amount of education were more pessimistic regarding the future (47%) than those with more education. Although not significant, most people were also optimistic about the future regardless of income level.

More seniors who had not changed their place of residence since retirement were optimistic regarding the future (83%), compared with those who had changed their place of residence (69%; $p = 0.03$). However, when analyzed by gender there was no significant difference. There was no significant difference in optimism or pessimism regarding the future for those who planned or did not plan to change their place of residence after retirement.

DISCUSSION

Income status and education have been identified as key determinants of health (Epp, 1986; World Health Organization et al., 1986; Federal, Provincial and Territorial Advisory Committee

Figure 115.1 Seniors' optimism regarding the future according to education level ($p = 0.02$).

on Population Health, 1994; Saskatchewan Provincial Health Council, 1996). The results of this study support the importance of these two health determinants. Overall, the perception of health by rural seniors was positive. However, more of those in the lowest income category (52%) rated their health as fair or poor. Generally, as income level increased, so did the proportion who rated their health as excellent or good. Men in the lowest income bracket were more likely to perceive their health as fair or poor than were women, although a high percentage of each gender in this income category perceived their health as only fair or poor. The reason for this could not be explored because the data were collected by questionnaire. Future studies, however, need to determine whether individuals are in the lowest income categories because of poor health or if poor health is a result of having a lower income. Level of education was also linked to perception of health. Those with less education perceived their health as being poorer than those with a higher level of education. Mookherjee (1992) also found that those with less education perceived their health as only fair or poor.

Most of the residents perceived their health as excellent or good regardless of whether they were satisfied or dissatisfied with life. However, when men and women were looked at separately, satisfaction with life was significant in terms of perception of health for men. Although 28% of men viewed their health as fair or poor, they still indicated that they were satisfied with life. For those dissatisfied with life, 36% perceived their health as excellent or good, while 64% perceived their health as fair or poor. Again, future studies need to explore whether poorer health leads to feeling dissatisfied with life, or vice versa.

Most of the residents were satisfied with their lives and were optimistic about the future. Interestingly, more residents were satisfied with life if they lived alone or with a spouse than if they lived with extended family. This finding might be linked to seniors' desire to be independent, although the study did not explore this aspect.

As might be expected, residents who were not worried about their upcoming retirement were most satisfied with their lives. Of those who had already retired, those who had not changed their place of residence were more likely to be optimistic about the future. The reason for change in residence was not explored, but if it was because of failing health or increasing dependence, it would stand to reason that seniors would be less optimistic about the future. Residents were asked their perceptions of their health, but were not asked to indicate specific illnesses or chronic conditions.

It would appear from the results of this study that the majority of seniors in the study area perceived their health as good to excellent, were satisfied with their lives, and were optimistic about the future. Some of the literature, generally from the U.S., suggests that elderly people in rural areas have lower incomes and are in relatively poorer health (Eggebeen and Lichter, 1993; Johnson et al., 1993; Mainous and Kohrs, 1995; Birchfield, 1996; Henson et al., 1997). While comparisons cannot be made because of differences between the two health care systems, this did not seem to be true for our study population. A recent Canadian study (Johnson et al., 1995) also found a high percentage of the sample perceived their health as excellent or good (81%) and determined that there was not a significant difference between rural and urban settings in terms of perception of health. A qualitative study by Stewart (1997) looked at senior women in the PECOS study area. She found that social and family support systems were key determinants for perceived health and well-being for these women and for their sustainability in a rural environment.

In the study, 72% of the seniors were retired. Of these, only 27% had changed their place of residence and only 28% of those who had yet to retire planned to change their place of residence. This would suggest that most of the seniors were satisfied with their present place of residence and plan to remain in their home community. In order to provide appropriate health services to seniors in rural areas, it is important for health care workers and administrators to have an understanding of the perceptions of residents living in that area. Policy makers need to be aware of the relationship between education and income on perception of health. The factors that have been reported in this

and other studies need also to be considered when making decisions regarding the provision of health services and improving the health of the population.

The role of nurses in rural health and the skills needed by nurses in our changing environment, as well as the health needs of seniors in rural environments, were not explored in this study. However, more research is required in these areas. As nurses, we need to assess each individual community for assets and barriers to health promotion, as each rural population varies in age of residents, income level, occupation, culture, and health status (Long, 1993). As the population decreases and young people continue to move away from rural communities, we must assess the needs of the remaining population, and be creative and innovative in determining the services essential to maintaining a healthy and satisfying lifestyle.

Prairie Ecosystem Study (PECOS): From Community to Chemical Elements, the Essential Role of Questionnaires

Helen H. McDuffie, K.M. Semchuk, Margaret M. Crossley, A. Senthilselvan,
Alan M. Rosenberg, Louise Hagel, Allan J. Cessna, D.G. Irvine, and D.L. Ledingham

INTRODUCTION

An evaluation of the sustainability of the semiarid prairie ecosystem, including the land, the biota, and the people, was the primary objective of the Prairie Ecosystem Study (PECOS). To further our understanding of potential human health risks associated with pesticide exposure, we selected a defined, rural geographical area and, in cooperation with the residents, we designed and undertook a study to:

1. Characterize human environmental and occupational exposure to pesticides by analyzing data from questionnaires and by analysis of blood samples
2. Assess pulmonary function using spirometry
3. Examine neuropsychological function using a battery of psychometric tests
4. Evaluate the frequency of autoimmunity as reflected by the presence of antinuclear antibodies
5. Assess the determinants of unintentional injury in this rural population
6. Determine the concentrations of 44 chemical elements in drinking water samples

In design, execution, statistical analyses, and interpretation of our results, all were completed with the consensus of a multi-, trans-, and interdisciplinary study group which included community representation. The objective of this chapter is to provide an overview of the complexity of the study design and methodology. Limited results are included for illustrative purposes.

THE PROCESS AND THE PROJECT

Community Involvement

Details of the organizational aspects and recruitment of community involvement in this project have been previously published (Semchuk et al., 1998a; Rosenberg et al., 1999). Briefly, the investigators engaged the cooperation of Saskatchewan rural residents in defining priorities for

research into the sustainability of the semiarid prairie ecosystem by holding meetings in their communities. We encouraged a diversity of opinions by inviting farmers, their families, professionals in the agricultural and health disciplines, members of local government, and interested citizens to express their views. The ideas generated during these encounters were incorporated into our research protocol.

Community members agreed to support the research, provided that (1) they had continuing representative involvement in design, conduct, and interpretation of the study and (2) they would not be "guinea pigs." In all, 93 community members served as representatives on various study committees, publicists, organizers, canvassers, and research and phlebotomist technicians. The local health board provided space to conduct the study within its centrally located facilities.

Questionnaires

For the purposes of this study, pesticides are defined as chemicals specifically formulated to kill or control pests. Our definition was further restricted to herbicides, insecticides, and fungicides. To evaluate environmental and occupational exposure to pesticides, with permission, we used modified versions of a questionnaire previously utilized and validated by Hoar-Zahm et al. (1986) in a study of the association of rare tumors and pesticide exposure in Kansas.

We used two versions of the questionnaire: baseline (February and March 1996) and retest (June and July 1996). The modifications from Hoar-Zahm's telephone-interview questionnaire maintained the structure of the conditional questions and included conversion to a self-report, structured, written version (baseline) and to a personal interview (retest) format, with the subject volunteering the names of chemicals to which he or she was exposed between February and March, and June and July 1996. In addition, the Hoar-Zahm questionnaire had previously been modified, with permission, by McDuffie et al. (1994) to incorporate names of pesticides licensed for use in Canada, deleting those that were not licensed in Canada, and adding names of pesticides that were classified by the IARC (International Agency for Research on Cancer, 1980, 1986, 1987, 1991) as possible or probable human carcinogens.

The baseline questionnaire solicited information on occupational and environmental exposure to 52 herbicides, 38 insecticides, and 14 fungicides during an individual's lifetime. If an individual indicated exposure to a specific pesticide, supplemental questions designed to permit dose-response characterizations (quantity, time frame, days per year, which crops or pest, indoor vs. outdoor application) were asked. Accidental spills on skin or clothing, inhalation, and acute illness were assessed by general questions, with supplemental questions concerning which pesticide was involved and when the incident occurred. The use of personal protective equipment and hygiene practices were assessed without reference to specific pesticides. The methods most often used to apply herbicides, insecticides, and fungicides, without further categorization by chemical group, were also determined.

In addition to detailed characterization of pesticide exposure, the baseline questionnaire requested demographic and health information, smoking history, source of drinking water, and occupational history. The requested demographic information included date of birth, sex, handedness, farm or nonfarm residence, and level of education. Health variables collected were related to vision, hearing, sense of touch, and hand coordination, responses (yes or no) to a list of respiratory, cardiovascular, and neurological chronic conditions, and consumption of cigarettes, alcohol, and caffeine-containing beverages, as well as prescription and nonprescription medication, and dietary supplements. The baseline and retest questionnaires also incorporated two measures of neuropsychological functioning: the Brief Symptoms Inventory (BSI) (Derogatis et al., 1993) and the Cognitive Failures Questionnaire (CFQ) (Broadbent et al., 1982). The BSI is a 53-item self-report questionnaire that includes the Global Severity Index (GSI). Evaluation of the GSI combines the number of symptoms reported and the intensity of reported distress. Scores on the GSI are a sensitive indicator of psychological distress. The Cognitive Failures

Questionnaire measures self-reported frequency of commonly experienced errors in perception, memory, and motor functions. Scores of the BSI and CFQ are interpreted by comparison to well-established normative values. Table 116.1 outlines the similarities and differences between the baseline and retest questionnaires (McDuffie et al., 1997).

Table 116.1 PECOS: From Community to Chemical Elements Comparison of Baseline and Retest Questionnaires

Baseline Questionnaire	Retest Questionnaire

	Protective gloves or clothing
Pest controlled	Safety practices
	Pest controlled

Study subjects who participated in pulmonary function screening at baseline and at retest completed an additional short questionnaire that focused on respiratory and cardiovascular symptoms and conditions.

Recruitment of Participants

Participants were recruited (Semchuk et al., 1998a) by 29 community residents who personally visited each town or farm household within three towns and three rural municipalities, and delivered a letter explaining the study and a postage-paid reply card. Residents of long-term care facilities, boarders, and students who were studying away from home were excluded. Residents of 259 households (62% farm, 38% town) returned the reply card and expressed interest in obtaining more information about the proposed study. Each of these households was contacted by telephone, a census of household members was completed, and additional information concerning the study design and objectives was provided. The respondent households included 490 adults (farm 321, town 169) and 94 children (farm 80, town 14) between 12 and 17 years of age. All of these individuals were invited to participate by completing questionnaires, by providing blood samples for antinuclear antibody testing and pesticide concentration, and by having objective assessments of their pulmonary and neuropsychological functioning. Those individuals who agreed to participate were mailed baseline questionnaires.

After completion of their retest assessments, study subjects were asked if they would consent to participate in a study of unintentional injuries. When the response was positive, most individuals preferred to participate immediately and the interviewer arranged appointments for the remainder. The injury questionnaire was interviewer administered. It was designed to capture details of farm work exposure as well as any unintentional injury which necessitated medical attention, or which resulted in 4 hours or more away from regular activities within the 2 years prior to the interview. It also was designed to utilize information collected in the baseline questionnaire to minimize duplication.

The sections of the injury questionnaire that elicit descriptions of the major factors of interest, the injury and farm work exposure questions, as well as medication use and lifetime serious injury, were taken verbatim from a questionnaire published in the doctoral dissertation of Dr. Jane Elkington (1993) with permission of her supervisor, Dr. Susan Gerberich. Additional questions concerning exposure to motor vehicles, recreational vehicles, and sports were developed, tested, and validated by Hagel (1998). Factors of interest in the injury study stratified by injury questionnaire and by the baseline questionnaire are outlined in Table 116.2.

Biological Testing

The detailed methodology related to the biological testing aspects of our study have been published or presented elsewhere (Rosenberg et al., 1999; Semchuk et al., 1998b; Senthilselvan et al., 1998, 2000; Crossley et al., 1998, 1999a,b). Only a short summary of each aspect is included in this chapter.

Pulmonary Function Measurements

Participants were offered pulmonary function testing at both baseline and retest sessions (Senthilselvan et al., 1998, 2000). The pulmonary function tests were conducted using Sensor Medics volume displacement spirometers and following American Thoracic Society guidelines (1987). The variables measured were forced expiratory volume in one second (FEV1), forced vital capacity (FVC) and the mid-maximal flow rate (MMFR). The ratio of $FEV1/FVC \times 100$ was calculated. In addition, height, weight, blood pressure, and age of each subject were recorded. The study excluded 17 subjects because of pregnancy, high blood pressure, recent chest or abdominal surgery, or chest

injuries. Participants received the results of their pulmonary function tests and an evaluation of their respiratory health immediately following completion of the tests.

Neuropsychological Functioning

Participants completed objective tests of higher brain function such as memory, attention, motor strength and speed, somatosensation, problem solving, and general intellectual ability at baseline and retest sessions (Crossley et al., 1997, 1998, 1999a,b). The function measured, the names of the tests, and references are outlined in Table 116.3. The tests were administered by six specially trained psychometricians according to the standardized procedures described in published manuals for the respective tests. Two psychologists provided professional supervision and support to the psychometricians. At the Centre for Agricultural Medicine, the test data were hand or computer scored and coded, and subsequently double-entered into a computer database.

Antinuclear Antibody (ANA) Assay

Participants were requested to donate blood samples for antinuclear antibody assays on two occasions, baseline and retest. Sera from consenting persons were assayed for ANA by indirect

immunofluorescence on a Hep-2 cell substrate (Antibodies Incorporated, Davis, CA) (Rosenberg, 1988) using polyclonal antihuman immunoglobulin conjugated to fluorescein isothiocyanate. Unequivocal immunofluorescence at a dilution of 1:40 as observed independently by two readers was considered positive. Complete details of the methodology are provided in Rosenberg et al. (1999).

Environmental Testing: Chemical Elements in Drinking Water

One member of each household provided a sample of drinking water drawn from their kitchen faucet into containers provided by us. We collected one sample per household in midwinter. The water sources were community based (groundwater and surface water) and private wells. We conducted chemical elemental analyses using inductively coupled plasma mass spectrometry (ICP MS) (Jarvis et al., 1992). Quantification of the concentrations of 44 chemical elements in ppb was included in the assay. We grouped the elements (McDuffie et al., 1998) into (1) those nine tested for which there are Saskatchewan municipal drinking water objectives (boron, chromium, arsenic, selenium, cadmium, barium, mercury, lead, and uranium); (2) those with known or suspected human toxicity, teratogenicity, or carcinogenicity when exposure occurs in sufficient dose (chromium, nickel, copper, zinc, arsenic, selenium, strontium, molybdenum, cadmium, antimony, barium, lead, thorium, and uranium); and (3) those present in high concentration or with wide variation in concentration in samples of four herbicide formulations supplied by area farmers (Song, 1997). The herbicides were Fortress[®], Achieve[®], Sencor[®], and Edge[®]. The concentrations of each of sodium, magnesium, phosphorus, sulfur, calcium, chromium, manganese, iron, copper, strontium, silicon, titanium, and arsenic differed by an order of magnitude or more among the herbicides. The concentrations of barium, aluminum, cadmium, and lead also varied substantially. Figure 116.1 shows an example of the graphic information provided to each participant describing the household water quality with respect to elements for which there are municipal drinking water objectives. In addition, a written report was provided that described the municipal drinking water objectives and provided information related to further testing if the sample had exceeded any objective.

Quality Control and Ethical Approval

Prior to commencement of the study, each potential participant was provided with detailed written information concerning the study design, the proposed use of the information obtained,

* Saskatchewan Municipal Drinking Water Quality Object

Figure 116.1 An example of the graphic information provided to each participant describing household water quality with respect to elements for which there are municipal drinking water objectives.

and the assurance of confidentiality of personal data acquired by the researchers. When individuals presented at the health centers in their community with a completed baseline questionnaire, they were registered by a postdoctoral fellow or an occupational health nurse, and given a code number that identified the individual's information. Stickers were provided to each individual with his or her code to be presented to each interviewer or technician as the individual moved from station to station.

As quality control measures, all data obtained by questionnaire or through biological testing were reviewed for internal consistency before being computer-coded using double-entry by two independent coders (Ledingham et al., 1998). Discrepancies were resolved by review by the appropriate researchers. For questionnaire data, we used a custom-designed data entry program, SPSS-DE® (1998). We present limited descriptive results relating to the evaluation of lifetime and recent (interval between February and March, and June and July 1996) pesticide exposure. Figure 116.2 demonstrates the connections among various aspects of our project.

The study received ethical approval from the University of Saskatchewan, Royal University Hospital, and the regional Health Board.

ILLUSTRATIVE RESULTS

Information obtained by questionnaire permitted us to classify exposure to pesticides on several different levels. The range included:

1. Minimal environmental exposure
2. Exposure to broad classes such as herbicides, insecticides, fungicides

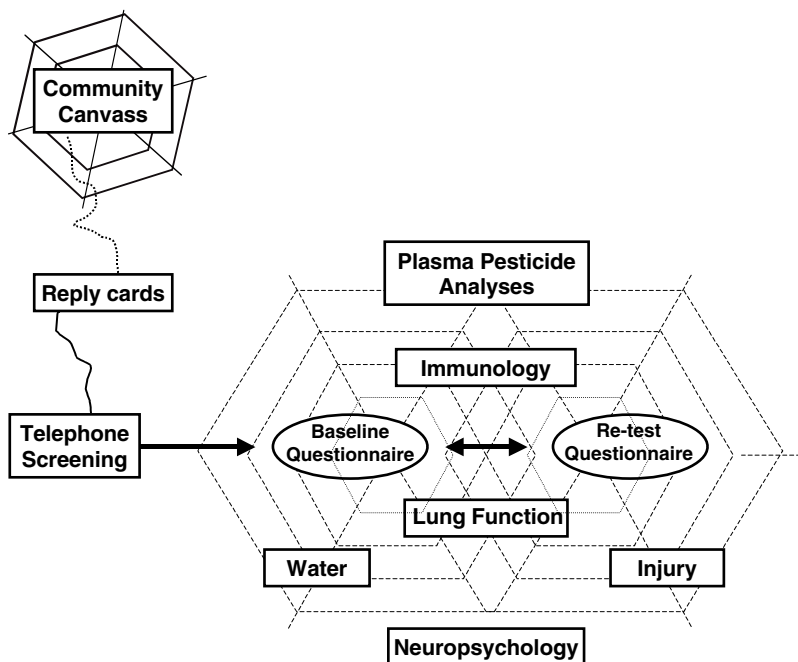

Figure 116.2 Connections between various aspects of the project.

3. Exposure to specific chemical classes such as phenoxyherbicides, carbamates, chlorinated hydrocarbons
4. Exposure to specific chemicals such as 2,4-D
5. Use of protective equipment or clothing to minimize exposure
6. Accidental dermal contact or inhalation which would maximize exposure

Table 116.4 describes the exposure to pesticides by applicators classified broadly during two time periods (lifetime and recent). An applicator was defined as an individual who personally applies or mixes pesticides as part of an occupation. This definition excluded individuals who mix or apply pesticides for use in their home, garden, or personal greenhouse. Table 116.5 describes data obtained from the baseline questionnaire concerning occupational use of pesticides organized into chemical classes and individual compounds. Table 116.6 describes the use of personal protective equipment and clothing while handling pesticides, and the frequency of accidental inhalation and dermal exposure to pesticides by applicators.

The study design facilitated exploring relationships among the biological tests (pulmonary function, autoimmunity, neuropsychological measurements, plasma concentrations of selected pesticides), environmental assessments (concentrations of chemical elements in drinking water),

and exposure to pesticides as determined by questionnaire. For example, Rosenberg et al. (1999) examined the possible association of environmental and occupational exposure to pesticides using the hierarchy described above and the presence of antinuclear antibodies. In univariate statistical analyses, antinuclear antibody detection at sample dilutions of 1:40 or greater (positive) was significantly associated with lifetime exposure to insecticides, specifically carbamates, organochlorine group A (chlordane, dieldrin, endrin, heptachlor, and lindane, excluding DDT and methoxychlor), pyrethroids, and with phenoxyacetic acid herbicides. In multivariate statistical analyses, including adjustment for age, sex, and other insecticide exposures, antinuclear antibody positivity was associated with a history of oilseed production and with exposure to pyrethroid insecticides.

DISCUSSION

The overall study design and methodology benefited from the expertise of dedicated and committed community members who have been and continue to be active on PECOS management and human health committees. Their input led to sharpening of the research questions and to an enhanced sensitivity by the researchers to the community's real-life concerns. Additional questions were formulated to accommodate community members, and the format of other questions was altered to respect their knowledge of local conditions. We highly recommend inviting community representatives to be partners in conducting complicated research and in investigating issues as complex as sustainability of an ecosystem.

Our team of researchers decided to operate by consensus. This was an important early decision, as many of us had not previously been involved in multidisciplinary research. At first, the process of achieving consensus was prolonged and difficult. Gradually, an interdisciplinary approach

evolved that respected the integrity and standards of each discipline. We began to understand the traditions and language of other disciplines. In the beginning, each of us used words with definitions explicit to our own discipline without realizing that others used the same words to describe entirely different phenomena. Eventually, we developed mutual trust.

Two years of planning were required before commencing field studies due to the complexity of our study design and methodology, and the researcher transportation and housing logistics associated with collecting data in very small communities 2 hours' drive from the university. Three intensive and coordinated data-collection periods within 8 months resulted in equally intensive and coordinated data scoring, coding, and computer entry using custom-designed data-entry programs, which facilitated the integration of the various components of the study. Subcommittees with specialized knowledge in consultation with the entire research team guided the statistical analyses of these data.

There are many studies that focus on the occupational exposures to pesticides of adult males and health indicators (Blair et al., 1985; Hoar et al., 1986; Hoar-Zahm et al., 1990). Fewer have included female farmers (McDuffie, 1994; Zahm, 1994; Fincham et al., 1994). Occupational studies usually define exposure by industry (agriculture), by occupation (farming), by broad categories of pesticides (herbicides), by use of specific chemical classes of compounds (phenoxy-herbicides), or by reported use of specific compounds (2,4-D). We have incorporated all these categories in our research, while also including home and garden exposures to pesticides and variables to measure extent of exposure, including accidental spills or inhalation incidents. For specific statistical analyses, we further subdivided participants by their recent and lifetime exposure to pesticides (1) at work, (2) as a family member of a pesticide applicator, and (3) other study participants. The majority of the occupational pesticide applicators were men, each of whom handled a variety of different chemical pesticides. The most commonly used chemical classes of herbicides (lifetime) were phenoxyacetic acids, thiocarbamates, phosphonic acid (glyphosate) and dicamba; of insecticides, carbamates, organochlorines, and organophosphorus compounds; and of fungicides, amides and dithiocarbamates. Although the primary focus of our research was acute and not chronic health effects of exposure to pesticides, several of the most commonly used pesticides have been declared possible or probable human carcinogens by the IARC (1980, 1986, 1987, 1991).

The use of personal protective clothing or equipment by occupational pesticide applicators while mixing or applying pesticides was inconsistent. Few reported using safety goggles or self-contained respirators. Accidental spills of pesticides on skin or clothing and accidental inhalation into the lung were relatively frequent occurrences. The lack of use of protective equipment and the accidental spills and inhalation incidents potentially increase the absorbed dose of pesticides.

Explicit and detailed characterization of exposure to pesticides by questionnaire was the conceptual link between baseline and retest measurements of neuropsychological functioning, of assessment of pulmonary health, of measurement of autoimmunity, and the detection and quantification of herbicide levels in human peripheral blood samples.

ACKNOWLEDGMENTS

This study was funded by the Tri-Council Secretariat of Canada through the EcoResearch Programme and through a National Health Canada Research Scholar Award to Dr. K.M. Semchuk, the lead investigator. The substantial contributions of our fellow researchers, Dr. D. Anderson, Dr. J.A. Dosman, Dr. K. Arbuthnott, Ms. M. Masley, Dr. R. Kerrich, Dr. V. Laxdal, Mr. Juorio, and our community representative, Mr. P. Hanke, are gratefully acknowledged. We thank Mrs. S. de Freitas for formatting the questionnaires and for secretarial support. We reserve our greatest appreciation and thankfulness to members of the community who helped us design, conduct, and interpret this study, as well as provided us with information and biological samples.

Ecosystem-Level Functional Changes in Breeding Bird Guilds in the Mixed Grassland since Agricultural Settlement

Todd A. Radenbaugh

INTRODUCTION

There is considerable concern that human activities are having detrimental impacts on Earth's biological diversity and the function of biophysical systems. These human processes may influence, interact with, alter, and even control the operations of biophysical functions at many levels of biological organization. Studies have shown that within many ecosystems, human activities have roles directly controlling entire biophysical systems (such as land-use practices that alter native habitat and expatriate species) (Kaiser and Gallagher, 1997; Tilman et al., 1997; Vitousek et al., 1997). Examples of direct human alteration of ecosystems include desertification of marginal lands (Schlesinger et al., 1990; Mainguet, 1994), eutrophication of lakes (Schindler et al., 1990) and coastal areas (Lapointe and O'Connell, 1989), loss of coral reefs in the Caribbean (Hughes, 1994), loss of soil organic matter due to agriculture in the Great Plains (Seastedt, 1995) and collapse of marine fisheries (Botsford et al., 1997). Many times, however, impacts are indirect, such as changes in regional species composition and the addition of pollutants to the soil, surface and groundwater, and atmosphere. Indirect effects are a secondary result of direct species interactions and may alter species composition and community structure and as such may have strong effects through natural selection (Miller and Travis, 1996; Rosemond, 1996). Recent studies have shown that both direct and indirect effects have large impacts on the functioning of ecosystems, thus affecting human health (Botsford et al., 1997; McMichael, 1997).

At lower ecological levels, human-caused direct and indirect influences have altered species abundance and distribution of local species assemblages and have allowed invasion of species into a region (Naeem et al., 1994; Nee and May, 1997). Further, ecological function of local species assemblages has been shown to change with declining diversity (Tilman, 1996). More specifically, function depends on the role of the species in the particular system of which it was a member (Valentine and Jabonski, 1983; Jackson, 1994; Symstad et al., 1998). Not all species in an assemblage, however, are equal in terms of how they function in an ecological system; some species have disproportionate roles, e.g., keystone species, dominant herbivores, and system engineers (Lawton, 1987). In species assemblages, studies suggest that it is not simply declining species diversity but the functional diversity within the species pool that best explains variations in system function (e.g., plant biomass and productivity) (Grime, 1997; Hooper and Vitousek, 1997; Tilman

et al., 1997). Further, human-controlled processes act on biotic systems at many levels but it is the broadscale influences that affect ecosystem integrity the most. Thus, measurements of regional functional diversity may be better indicators of ecosystem health than the traditionally used measures of local species richness or diversity.

This chapter explores the broadscale influences of human interactions within a complex hierarchical system in North America's northern Great Plains (specifically the Mixed Grassland Ecoregion of Saskatchewan) by examining breeding bird guilds. The baseline for this study is the introduction of European agricultural methods early in the 1900s. Although there has been an aboriginal presence recorded in the region for the past 10,000 years, this earlier system is assumed to have been in a relatively steady state (compared to changes in the past 100 years) and serves as the template to measure modern change. From the early 1900s to the mid-1990s, approximately 80% of the northern Great Plains has been converted from native habitats to other land cover types (Samson and Knopf, 1996; Selby and Santry, 1996). Moreover, since the late 1880s the two dominant structuring forces, fire (Rowe, 1969; Wright and Bailey, 1980; Collins and Wallace, 1990; Collins, 1992) and large grazing ungulates (Frank et al., 1998; Knapp et al., 1999), have been eliminated or heavily managed. The magnitude of these and other impacts raises concerns about changing functional roles in this ecosystem.

Spatial Scales

Because biotic processes operate at many spatial and temporal scales, a hierarchical approach is taken here where multiple ecological scales are identified. This study then examines only the broader ecosystem level processes or the "big picture," thus eliminating some of the confusing "ecological noise" caused by local fluctuations and stochastic processes that operate at species assemblage and population levels. This approach allows for the investigation of the broad-scale changes that agricultural settlement has imposed on both vegetation and animals. The focus of this study is a physiologically and ecologically similar region, the Mixed Grassland Ecoregion of Saskatchewan (defined in ESWG, 1995; Acton et al., 1998) and was investigated as a whole unit in terms of system attributes. Although data were collected at lower levels (e.g., species assemblage and bird populations), no attempt was made to interpret data at these levels. Because processes at different levels occur at different rates (Allen and Starr, 1982; Salthe, 1985), processes at lower levels appear to occur more rapidly than those occurring at the focal level (and vice versa for higher levels). Thus, in order to investigate focal-level processes and functions, the inputs of lower levels must be scaled up. This scaling up is achieved through the averaging of inputs so that cycles and fluctuations are taken into account. This is done by grouping together species into vegetation classes and guilds that occur within fixed time periods. In this way, the detailed and dynamic nature of lower-level processes may be bypassed.

Breeding Bird Guilds

Breeding birds were used as indicators of broad regional changes for many reasons. First, this group has historical abundance data available. Second, as a group they use the majority of the habitats in the ecosystem for nesting and foraging. Most birds in this region are highly mobile, often moving when conditions are severe or resources become low. Moreover, approximately 80% of the bird species in the northern Great Plains are migratory, and winter in the southern U.S., Central America, or South America. Thus, bird populations are spatially dynamic on an annual or even a monthly basis. For all these reasons, averages over multiple years were taken when estimating bird abundance. Last, breeding birds were used to study regional functional roles because they generally spend the 3-month growing season in limited areas defending territories, choosing mates, and raising fledglings. During the summer, breeding bird populations have a significant impact in terms of resource, space, and food utilization.

Because birds are highly mobile and use many of a region’s resources, as a group they can be used as a broad indicator of ecological changes. Further, due to cascading effects within the regional interactions web, broad changes in one group will usually show up in others that are linked spatially. To analyze ecological functions and measure change on a broad scale, guild theory (Root, 1967) was used to group species into functional categories. Guild is defined as Root (1967) used it: a group of species that exploits the same class of environmental resources in a similar way without regard to taxonomic position. Thus, a guild is composed of those species that use similar ecological resources or employ similar strategies for access to resources such as nesting sites and feeding strategies. Thus, changes in guilds in terms of their relative abundance may be used to indicate broad changes in functional roles in an ecosystem.

METHODS

Study Site

The study site encompasses the entire Mixed Grassland Ecoregion of Saskatchewan (Figure 117.1). This ecoregion was chosen as the geographic area of study because historically

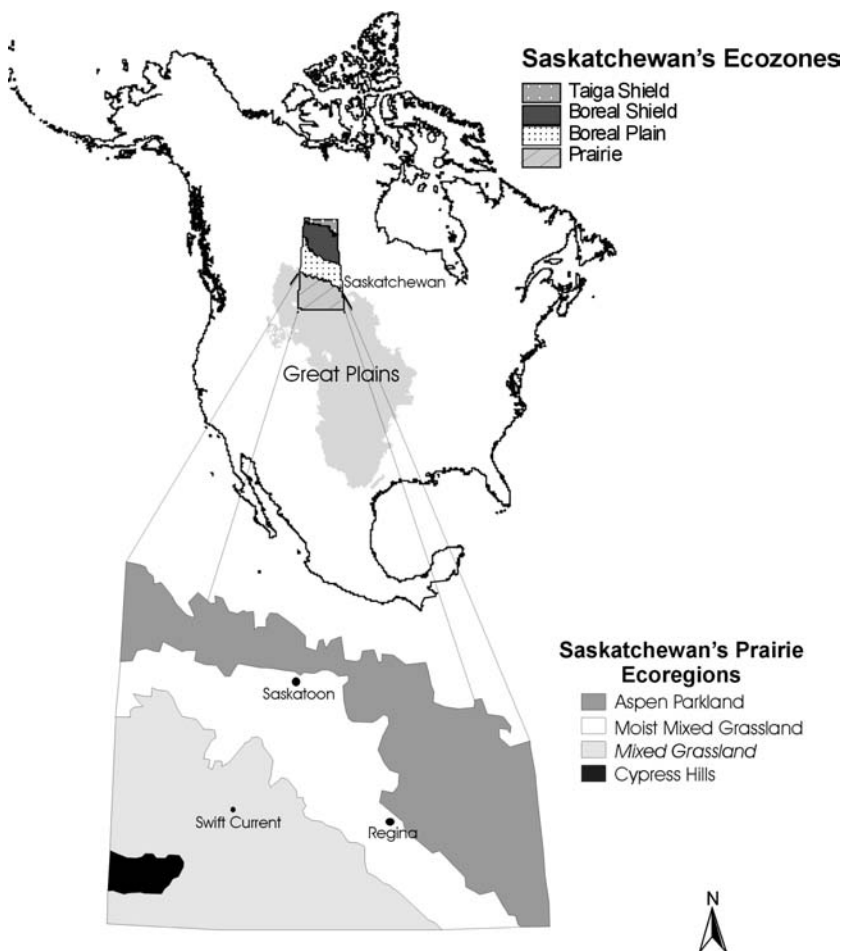

Figure 117.1 Study site: the position of Saskatchewan’s Mixed Grassland Ecoregion within the Great Plains of North America and the Prairie Ecozone.

(past 5000 years) it has had limited species assemblage diversity (Axelrod, 1985). Prior to agricultural settlement, the primary vegetation types were limited to grasslands, wetlands, and brushlands, with no extensive forests or other major vegetation types (Watts, 1960; Archibold and Wilson, 1980). The dynamics controlling the ecosystem structure are also suggested to be relatively simple (i.e., climate, fire, and grazing) (Coupland, 1961; Joern and Keeler, 1995; Knapp et al., 1999). In the past 100 years, vegetation patterns have increasingly become influenced by human interactions. The majority of this influence in this study region is due to agriculture rather than multiple land uses such as forestry, urban development, or large-scale strip mining, although human habitation (villages, towns, and one city) and road construction also have significant impacts. The limited types of human activities allow a focus on the effects of agroecosystem development. Since social institutions and land-use practices can vary in different political systems, the political borders of Saskatchewan define the extent of the study area in the Mixed Grassland.

Vegetative Habitats

To examine how society has modified this region, four major vegetative habitats were studied between ca. 1900 and the 1990s. Vegetation habitats were used due to the sessile nature of plants, which makes them relatively easy to identify and assess in geographic terms. Moreover, many bird populations are dependent on these specific assemblage types for mating and foraging; thus, changes in major vegetation habitats also could influence bird populations.

Unfortunately, few accurate historical documents give an account of vegetation distribution. The best data sources are the Dominion Lands Survey and Statistics Canada's Agricultural Censuses. Statistics Canada, however, provides farm-related vegetation categories, which are defined using Census Canada definitions. When Saskatchewan became a province in 1905, the prairie region had been divided into townships and ranges, local improvement districts (LID), and later rural municipalities (RM). These are the smallest units reported in Agricultural Censuses and are the units used to report vegetation categories.

Four vegetation habitats were recorded for each LID or RM in Saskatchewan's Mixed Grassland Ecoregion including:

1. Native and reestablished grassland or native pasture
2. Woodland/brushland
3. Wetland, "waste" areas, and open water
4. Improved land (includes cultivated, summerfallow, and improved pasture)

Although these categories are not individual plant assemblages, they were used because they are the reported categories in both the Dominion Lands Survey and most of the Canada Agricultural Censuses.

The following general definitions are used to classify vegetation types:

- *Grassland or native pasture*: Areas of vegetation dominated by native herbaceous grasses and forbs, covered by less than 10% trees or shrub.
- *Woodland/brushland*: Areas of vegetation dominated by short trees and shrubs that comprise greater than 70% of the total vegetation, and in a relatively closed stand.
- *Wetland/waste*: Areas of low-lying land that are submerged or inundated periodically by fresh or saline water, or land areas recognized as poor farming areas such as salt flats and open water.
- *Improved land*: Areas where existing vegetation has been removed for the cultivation of target species mainly used for agricultural production, including land in summer fallow; also land that has been drained and seeded into pasture to produce improved pasture.
- *Unimproved land*: The sum of native pasture, woodland/brushland, and wetland/waste.

To measure vegetation changes within the mixed grassland, the major vegetation categories were estimated as a time series from pre-European settlement to the 1990s; ca. 1880 was chosen

as a baseline because it is just prior to the massive influx of European settlers. Archibold and Wilson (1980) reconstructed the native vegetation ca. 1880 by using the Dominion Lands Survey’s township and range maps. These maps document major landscapes and vegetation of southern Saskatchewan using vegetation types similar to those used by Statistics Canada. To compare these data to Statistics Canada data, the township and range data of Archibold and Wilson (1980) were scaled up into LIDs and RMs. This is possible since each LID and RM is defined in terms of townships and ranges. To complete the time series, the vegetation types in later periods were based on reported condition of occupied land using eight Agricultural Censuses (1881, 1886, 1921, 1936, 1941, 1971, 1991, and 1996).

Breeding Bird Guilds

The goal of the guild analysis was to construct a reasonable ecological grouping of species that “exploit the same class of environmental resources in the similar way” (Root, 1967, p. 335). A list of breeding birds for Saskatchewan’s Mixed Grassland Ecoregion was compiled using Smith’s *Atlas of Saskatchewan Birds* (Smith, 1996). This list is provided in Appendix 117.I and references to bird species are listed as common names but use the standard by Godfrey (1986) for taxonomic classifications. Only bird species that breed in significant numbers annually (i.e., not “hypothetical,” “incidental,” or “sporadic”) were included. The breeding bird lists reported all confirmed and probable breeders, but excluded any species listed as “possible.” Additional species were added to the list when published accounts from the 1990s back through the 1860s showed that a species historically bred in the study region in significant numbers.

Guild Characterization

Four broad breeding bird guild types were identified because they indicate resources or characteristics important to the survival of breeding bird populations: foraging method, foraging habitat, nesting habitat, and diet. Within each of these guild types, four to eight guilds were then identified based on recurring habitat use, food items, or bird foraging behaviors (Table 117.1) and are described later. These guild types provide an overall measure of resource use in the Mixed Grassland Ecoregion. Any significant change in these guild types may also indicate a functional change in the ecology of the entire region.

Foraging Method Guilds

An exploratory data analysis was conducted to identify the type and number of foraging method guilds. First, as species accounts were searched for the development of the bird database, all methods that authors used to describe foraging methods and behaviors were recorded. The terms and definitions of how species acquired food grew to more than 20 potential guilds. This list was reduced to eight guilds after careful investigation of bird behavior and expansion of categories to include similar groups. The resulting eight guilds were dabbler, diver, gleaner, picker, prober, sallier, stalker, and swooper, as defined in Table 117.3.

Table 117.1 Guild Types and Guilds Used for Studying Breeding Birds in the Mixed Grassland Ecoregion of Saskatchewan

Guild Type	Guild
Foraging method	Dabbler, diver, gleaner, picker, prober, sallier, stalker, swooper
Foraging habitat	Woodland/brushland, grassland, wetland, other
Nesting habitat	Cavity, cliff, ground, floating mat, vegetation
Diet	Aquatic invertebrates, aquatic vertebrates, aquatic vegetation, omnivore, seeds, terrestrial invertebrates, terrestrial vertebrates, terrestrial vegetation

Table 117.2 Breeding Bird Guilds and Their Assignment Based on Specialty

Guild Type	Specialist	Opportunist	Generalist
Foraging Method	One primary method and rarely switches to another	One primary method but may use up to three	Uses three or more methods based on local food abundance
Foraging Habitat	Forages in only one habitat	One primary habitat but able to feed in others	Multiple habitats used
Nesting Habitat	Only one nesting type	One primary nesting type but able to switch to another	Nesting type not limited
Diet	One primary food category	Ability to switch, may have two primary food categories any many secondary	Large diet range with no primary food category

Foraging Habitat Guilds

Foraging habitat guild types were divided into guilds based on units used by the U.S. and Canadian Wildlife services (Sauer et al., 1999). Table 117.2 defines the four broad vegetation types identified as foraging habitats and includes grassland, woodland/brushland, wetland, and other. The other category includes cliff and urban foraging species but also includes species without any clear habitat associations.

Nesting Habitat Guilds

Nesting habitat guilds were defined using an exploratory data analysis similar to the one described for foraging method guilds. Out of a potential list of ten guilds that included both human-constructed and native habitats, five guilds were defined because half the terms were similar and, thus, able to be grouped together (e.g., nest boxes and tree cavities or building and cliff habitats). Five nesting guilds were used: cavity, cliff, ground, floating mat, and vegetation (Table 117.3).

Diet Guilds

To find the important breeding bird diet guilds, 15 food categories were identified that recurred in the literature (seven animal, seven plant, and one refuse categories). Next, for each species, the food categories eaten by a species were ranked qualitatively from 1 to 4 (1 = primary food). To develop diet guilds from food categories, the food category rank for each species was counted. Following this, the percentage and total number of times a food category was the primary source for a species (i.e., a score of 1) was calculated. Any food category that received over 15 hits and was a primary food source for more than 30% of the species was considered for guild status. Six food categories were identified as important: seeds, grain, terrestrial vertebrates, aquatic vertebrates, terrestrial insects, and aquatic insects. There were, however, species that had more than one primary food source; thus, an omnivore guild was created that encompassed most of the species that utilized multiple primary-food categories. Food categories that were not earmarked as significant were added to a similar food category (such as seeds and grain) in an identified diet guild. The results of this method created eight guilds: aquatic invertebrates, aquatic vertebrates, aquatic vegetation, omnivore, seeds, terrestrial invertebrates, terrestrial vertebrates, and terrestrial vegetation (Table 117.3).

Migration Classes

Concern over possible declines in many North American long-distance migrant species or neotropical migrants (Sauer and Droege, 1992; Sherry and Holmes, 1996; Latta and Baltz, 1997) prompted

Table 117.3 Definitions of Bird Guilds and Migratory Classes Used

Guild	Interface	Description
Foraging Method		
Dabbler	Water surface to water surface or just below	Moves bill side to side or back and forth on mudflats or in shallow edges of wetlands probing mud for plant or animal material including tipping for submerged vegetation
Diver	Water surface to depth	Feeding submerged at depths of 0.5 to 10 m on plants or animals
Gleaner	Vegetation to vegetation	Forages in vegetation by picking seeds, berries, or insects from branches, leaves, bark, or other vegetation
Picker	Ground to ground	Forages about using bill to dig or pick at ground, branches, carrion, or plants
Prober	Probed cavity or mud	Uses bill to search cavities for plant or animal material
Sallier	Ground or air to air	Chases and catches insects in flight; also hovering to glean berries or insects (flycatcher)
Stalker	Water	Stands motionless at water's edge, darts bill downward to seize prey
Swooper	Air to air or ground	Dives from a height to catch prey in bill or talons, prey on land, water, or wing

Foraging Habitat	
Guild	Description
Brushland/ woodland	Primary diet is found in areas dominated by short trees and shrubs that comprise greater than 70% of the total vegetation
Grassland	Primary diet is found in herbaceous grasses and forbs, covered by less than 20% trees or shrub
Wetland	Primary diet is found in aquatic areas and low-lying land that is submerged or inundated periodically by fresh or saline water
Other	Primary diet is found in all other vegetation types

Nesting Habitat	
Guild	Description
Cavity	Nests found in cavities (i.e., trees and nest boxes)
Cliff	Nests made on cliff faces, ledges, and bridges and sides of buildings
Ground	Nests made on ground
Floating mat	Nests constructed of vegetation that floats on water or in vegetation just above water surface
Vegetation	Nests constructed in vegetation above the ground in trees, shrubs, or forbs

Diet

Diet guilds: Aquatic invertebrates, aquatic vertebrates, aquatic vegetation, omnivore, seeds, terrestrial invertebrates, terrestrial vertebrates, terrestrial vegetation

Migration Class	
Class	Description
Resident	Lives in Mixed Grassland ecoregion year round
Short-distant	Winters in southern U.S.
Long-distant	Winters south of the continental U.S. (neotropical migrants)

analysis of trends in three migration classes (Table 117.3). The three migrant classes investigated were resident birds (live in the study region throughout the year), short-distance migrators (winter in the southern U.S.), and long-distance migrators (winter in Central and South America).

Guild Specialty Assignment

Each bird species was then assigned to one guild in each of the four guild types that were based on resource use and natural history accounts. Within each guild type, a particular species was associated with one primary guild. However, in nature many species exhibit opportunistic behavior and participate in more than one guild. To quantify this, each species was assigned to one of three specialization ranks (specialist, opportunist, and generalist) using the rules outlined in Table 117.2.

Guild Trends

To test whether society has altered breeding bird guilds in the Mixed Grassland Ecoregion of Saskatchewan, guild trends over the past 100 years were examined. Trends for each guild were explored using relative abundance ranks derived from records dating ca. 1900 and the 1990s. To standardize bird abundance, many ornithological groups (e.g., American Ornithologist's Union and the Federation of New York State Bird Clubs) have developed strict guidelines for estimating bird numbers in a region based on sightings (see Godfrey, 1986; DeSante and Pyle, 1986; Smith, 1996). These guidelines are used to define abundance ranks, so that bird numbers for large geographic regions may be qualitatively estimated. Regardless of the organization that uses them, most abundance rank standards are similar in that they are an estimate of abundance for a given species based on its detectability by a "competent observer" observing at the "appropriate time." Because of these similarities, it is possible to make conversions and comparisons between standards. They also take into account yearly and monthly variations in local distribution due to habitat and food source availability. However, these abundance ranks are designed to be relative and are not defined using mathematical precision.

Breeding bird trends were calculated using historical accounts of relative bird abundance ranks, but when conflicts were found, expert opinion was used to identify the appropriate rank (e.g., consulted Canadian Wildlife Service or estimated abundance on amount of primary habitat available at the time). The abundance rank standards from the different sources were converted into DeSante and Pyle's (1986) four categories (common, fairly common, uncommon, and rare). The abundance ranks were collected for two periods: ca. 1900 (pre-European settlement) and the 1990s.

Circa 1900 (Native Prairie) Abundance Ranks

By the early 1900s, ornithological experts had compiled extensive breeding bird lists for Saskatchewan including records of their relative abundance (Richardson and Swainson, 1831; Hind, 1860; Selwyn, 1874; Coues, 1878; Raine, 1892; Houseman, 1895; Macoun, 1900; Bent 1907, 1908). Agricultural change had begun by the time of Bent's 1906–1907 surveys (Bent, 1908), but he generally recorded bird abundances prior to the major settlement period. Therefore, only studies conducted prior to 1908 were used to develop the native bird species accounts. Any breeding occurrence recorded prior to this date was assumed to be a "native" mixed grassland species. New species listed in literature after this date were recorded as "not present" in the early ca. 1900 native ecosystem.

1990s Abundance Ranks

The 1990s abundance ranks were based on Price and co-workers (1995), Roy (1996), and Smith (1996).

Quantifying Abundance Ranks

A relative abundance score (RAS) was used to quantify species abundance rank data between each period. The RAS was based on the "percentage of days that a few to many birds are expected

Table 117.4 Relative Abundance Score (RAS) Assigned to DeSante and Pyle’s (1986) Abundance Rank Standards^a

Abundance Rank	Description	RAS
Common	Always or almost always encountered	0.70
Fairly common	Usually or often encountered	0.50
Uncommon	Not usually encountered	0.20
Rare	Generally not expected	0.05
Not present	Not present or does not breed in area	0.00

^a Based on the “percentage of days that a few to many birds are expected to be seen” at the appropriate time and in their appropriate habitat.

to be seen” as defined by DeSante and Pyle’s (1986) abundance rank standard. Table 117.4 gives the RAS assigned to each of the relative abundance ranks.

As seen in Equation 117.1, the relative change for each guild ($T_{Abundance}$) may then be calculated for the past 100 years.

$$T_{Abundance} = [(\Sigma A_t) - (\Sigma A_i)]/\Sigma A_i \tag{117.1}$$

where A_i denotes the RAS in the ca. 1900 period of the paired combination; A_t denotes the RAS for the later 1990s; and the summation extends over all species within a guild. These calculations were conducted for each of the 25 guilds in Table 117.2.

RESULTS

Vegetation Habitats

Vegetation changes within the Mixed Grassland Ecoregion of Saskatchewan were estimated as a time series from pre-European settlement (ca. 1880) to the present. Using the original percentages for each township estimated by Archibold and Wilson (1980), the percent coverage was calculated for five vegetation classes within the study area. Figure 117.2 shows that 95.8% of the region was dominated by grasslands covering 8,276,764 ha. The remaining 4.2% of the area comprised the four other vegetation classes: woodland (0.3%), brushland (0.5%), wetland (1.1%), and open water (2.3%) (inset of Figure 117.2). The grassland figure, however, may be a slight overestimate because

Figure 117.2 Vegetation cover types ca. 1880 based on Dominion Lands Survey township and range maps as compiled by Archibold and Wilson (1980). Inset graph details the percent cover for vegetation classes other than grassland.

Table 117.5 Area (Acres) and Percent Cover of Vegetation Classes in the Mixed Grassland Ecoregion of Saskatchewan^a

Year	Total Area Improved		Estimated Land Use (as reported on farms)											
	Acres	%	Farm Area Acres	%	Improved Area Acres	%	Native Pasture Acres	%	Wood/ Brushland Acres	%	Wetland/ Waste Acres	%	Unimproved Acres	%

^a As reported on farms from the Canadian Agricultural Census.

Figure 117.3 Percentage of total land area classified as improved land, unimproved land, and native pasture in the Mixed Grassland Ecoregion of Saskatchewan, as reported by Canadian Agricultural Censuses from 1885 to 1996.

the line transects used were separated by 1 mile, and thus underrepresented many of the small sloughs and wooded coulees (see Archibold and Wilson, 1980).

Eight Agricultural Censuses (1885, 1881, 1921, 1936, 1941, 1971, 1991, and 1996) were used also to estimate the condition of occupied land. For each census, up to four vegetative habitats were recorded in each LID or RM in the study region, including (1) native and reestablished grassland (native pasture), (2) woodland/brushland, (3) wetland, “waste” areas, and open water, (4) cultivated and improved pasture and summer fallow. Because of changes in both the survey questionnaires used and how terms were defined, not all of the vegetation data are available in each census. Table 117.5 shows the areas and the percent coverage for vegetation classes on farms. Improved lands in the study region dramatically increased from 0.5% of the study region in 1885 to 50% in 1936. During the Depression in the 1930s, the breaking of sod leveled off but by the 1970s, it was on the rise again; by 1996, 65% of the region was classified as improved land. Figure 117.3 illustrates the large increase in improved lands in the study region over the past 111 years, from 0.5% in 1885 to more than 65% in 1996.

Since the reported vegetative cover for each agricultural census includes only land classified as farmland (areas organized for farm activity), areas not listed as farms, such as parks (national and regional), large water bodies, road rights-of-way, and urban areas are not reported. Because of this, the area of unreported land changed over time. The percentage of farm-related activity grew rapidly until 1936 when it reached 80.4% of the ecoregion. After this, area converted into farms slowed but continued. By 1991, more than 94% of the study area was reported as farmland by the census.

Figure 117.3 also graphs the native pasture (grassland) against the total unimproved land in the study region as reported on farms from agricultural censuses. These curves illustrate the dominance that grassland areas had in the region until 1921. At this time, improved lands bypassed native grassland as the most-abundant vegetation cover.

One enigma in using census data deals with how vegetation categories are reported in each census. Because the many rules for defining categories were “redefined” between census years, direct comparisons between vegetation classes could not always be made (note the missing data in Table 117.5). To investigate these classes, Figure 117.4 subtracts both the improved land and native pasture (curve with triangle data points) from the total farm area. This remaining vegetation cover is a small percentage of the total and shows a slightly decreasing curve from 2.7% in 1921 to 2.4% in 1996. This indicates that not only does most of the census data account for land as either improved land or native pasture, but these land uses have remained generally constant since the 1920s. However, the wetland and woodland/brushland curves in Figure 117.4 are moving in opposite directions for the three censuses (1921, 1936, and 1941) in which both wetland and woodland/

Figure 117.4 Percentage of farmland not classified as improved land or native pasture, with lands classified as wetland and wood/brushland, in the Mixed Grassland Ecoregion of Saskatchewan, as reported by Canadian Agricultural Censuses from 1885 to 1996.

brushland data are available, with the largest decline in wetland/waste area correlating with the largest increase in woodland/brushland. This trend has continued into the 1990s, based on 1994 LANDSAT data that estimated woodlands covered 1.9% and wetland 1.6% of the ecoregion (Prairie Farm Rehabilitation Administration, GIS division, personal communication).

Breeding Bird Guilds

Table 117.6 lists the richness in bird species by season visited for those species that breed (confirmed and probable) and migrate through the study area (transient). A total of 135 bird species (51%) was recorded as confirmed or probable breeders. Of these, 81.5% are summer visitants (110 species), and the remaining 18.5% are permanent residents (25 species). Appendix 117.I lists each of the 135 breeding bird species found in the Mixed Grassland Ecoregion of Saskatchewan, along with their migration patterns and relative abundance ranks.

Table 117.7 lists the number of bird species found in each guild for the four guild types (foraging method, foraging habitat, nesting habitat, and diet). It also divides each guild into specialization classes. In each guild type, generalists had the lowest membership percentage with 3.7% by foraging method, 20.7% by foraging habitat, 4.5% by nesting habitat, and 14.8% by diet guilds. Thus, to keep analysis simple, guilds were analyzed as a single unit since guild-switching generalists occupied the minority of all the guild types, and analysis by specialty is not examined further in this chapter.

The number of bird species in the three migratory classes is shown in Table 117.8. By far the largest group was short-distance migrants, comprising 54%, or 73 species. Resident birds make up the smallest class, comprising only 13%, with long-distance migrants at 33%.

Relative Abundance Ranks

Table 117.9 lists the five relative abundance ranks for the two periods, the number of bird species assigned to each, and the percentage of bird species in each rank. From ca. 1900 to the 1990s, species classified as common and rare declined from 30% (41 species) and 24% (32 species) to 20% (27 species) and 19% (25 species), respectively. During this period, however, the species ranked as fairly common and uncommon substantially increased by 34 to 35% and 10 to 25%, respectively. Moreover, since the early 1900s, 25 species were introduced or expanded their ranges into the study region.

Figure 117.5 summarizes relative abundance trends (RAT) by guild. Overall, of the 25 guilds, 10 had positive trends, 11 had negative, and 4 showed no trend (RAT between 0.1 and -0.1). Of the foraging method guilds, two (gleaner and sallier) showed large increasing trends, while three primarily associated with wetland habitats decreased (foraging method guilds: divers, probers, and stalkers) (Figure 117.5A). Figure 117.5B shows that during this period, two of the four foraging habitat guilds increased (woodland and other) and two decreased (grassland and wetland). The five nesting habitat guilds (Figure 117.5C) had three increasing guilds (cavity, vegetation, and cliff) and two decreasing guilds (ground and floating mat). Finally, with regard to diet (Figure 117.5D), four of the guilds (aquatic invertebrates, aquatic vegetation, aquatic vertebrates, and terrestrial vegetation) showed large decreasing trends and only two increasing (seeds and terrestrial invertebrates). Interestingly, for each guild type those associated with aquatic habitats or wetland diets showed the largest declines.

Figure 117.6 plots the relative changes in three migration classes (resident, short-distance, and long-distance), showing that the three migration classes increased in the study region over the past 100 years. The largest RAT increase was in resident birds (0.62), followed by long-distance migrants (0.16). Short-distance migrants increased only slightly, with a relative change score of 0.03.

DISCUSSION

Vegetation Cover

The vegetative cover of the Mixed Grassland Ecoregion of Saskatchewan has changed significantly over the past 100 years. According to Archibold and Wilson's (1980) original estimation of late-19th century survey maps, over 90% of the study region was covered in grassland. By the mid-1990s, native grassland had been reduced to less than 28%. Further, woodland and brushland have increased since the late 1800s (due to the loss of grazing pressure, control of fire, and the promotion of growing shelterbelts), while wetland area has decreased (due to increasing cultivation).

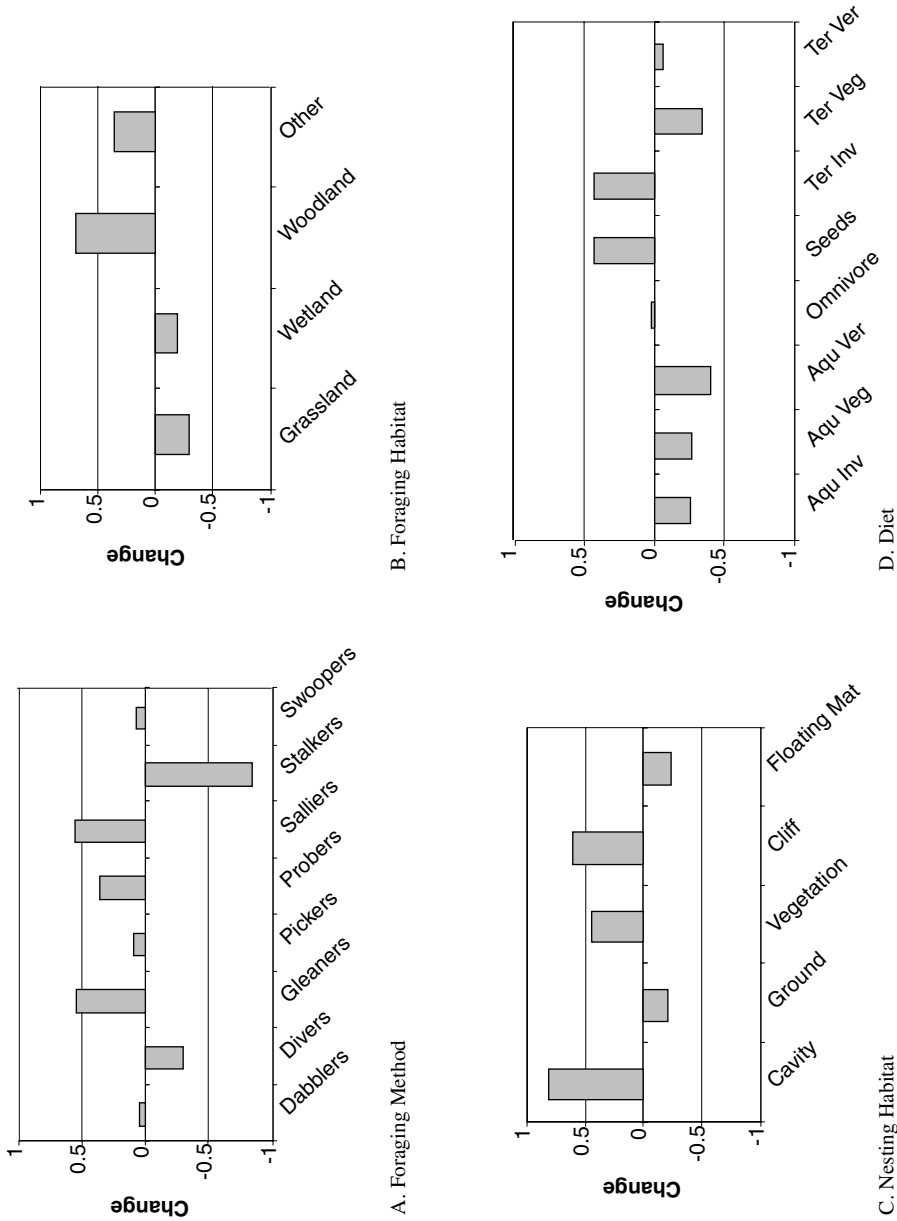

Figure 117.5 Relative abundance trends in breeding bird guilds from ca. 1900 to the 1990s for the four guild types in the Mixed Grassland Ecoregion of Saskatchewan.

Figure 117.6 Migration class relative changes in the Mixed Grassland Ecoregion of Saskatchewan from ca. 1900 to the 1990s.

The dominant land cover in the 1990s was improved farmland, which comprises nearly 70% of the land area of the study region (Table 117.5).

Guilds and Relative Change Ranks

Since agricultural settlement, there have been many changes in breeding bird guilds. The early 1900s began a period of rapid change in bird populations on the northern prairies. This was observed as early as 1907, when Bent (1908, p. 407) observed that the opening up of new lands for agricultural settlement was “making such rapid and marked changes in the great wild-fowl breeding grounds of northwest Canada.” He continued, “Even during the one year intervening between my two visits to this region, the change was so striking as to indicate the passing away within the near future of nearly all the great breeding resorts of the interesting region.”

This change, however, has not been due to losses in bird diversity. Table 117.10 shows that between ca. 1900 and the 1990s there has been an overall increase of approximately 21% in species richness and 12% in diversity. Therefore, if there were no new selection pressures, each guild trend should have increased. However, along with the RAT increases there were decreases. For example, in foraging method guilds, there were large RAT increases in gleaners, probers, and salliers, with moderate increases in the traditional picker, dabbler, and swooper guilds, while there were large decreases in the diver and stalker guilds. For the foraging habitat, the grassland and wetland guilds had declined RATs, while the trends for both woodland and other guilds increased.

Ten of the 25 total guilds exhibited decreasing trends (RAT > 0.1). Of these, all but three (grassland foraging, ground nesting by habitat guild types, and terrestrial vegetation by diet) were associated with aquatic environments (i.e., divers, stalkers by foraging method, wetland by foraging habitat, aquatic invertebrate, aquatic vegetation, and aquatic vertebrate by diet) (Figure 117.5). This indicates the importance of wetland and lacustrine environments to regional breeding bird populations, confirming that their numbers have drastically declined since the early 1900s (Smith, 1996; Igl and Johnson, 1997).

In bird diet guilds, RATs increased for the seeds and terrestrial invertebrates guilds (Figure 117.5D). The omnivore and terrestrial vertebrate guilds had minor increases and the remaining four diet guilds (aquatic invertebrates, aquatic vegetation, aquatic vertebrates, and terrestrial vegetation) had large negative trends. Of the four diet guilds exhibiting negative trends, three were associated with aquatic habitats, indicating a decline in aquatic food sources.

Table 117.10 Breeding Bird Species Richness and Diversity (ca. 1900 and the 1990s) in the Mixed Grassland Ecoregion of Saskatchewan

Index	Circa 1900	1990s
Species Richness	110	133
Species Diversity ^a	1.89	2.11

^a Calculated using the Shannon–Weaver index; relative abundance values were substituted for number of individuals.

Each breeding migratory class (resident, short-distance, and long-distance) showed a positive RAT. Thus, migratory classes have little influence on negative guild RATs observed. Further, although the resident bird class comprises the fewest bird species, it had the largest relative change. In the 1990s data, there were seven more resident species living in the study region, an increase of 41% from ca. 1900. The increase in resident birds is primarily due to seven introduced species, two of which (gray partridge and ring-necked pheasant) were directly introduced into the study region. The remainder expanded their range from other parts of North America, i.e., greater prairie chicken from the southern prairies, and house sparrow, northern mockingbird, and rock dove from eastern North America. Moreover, in the ca. 1900 period, resident species that were important on the open grasslands had by the 1990s dropped sharply in abundance, such as the sage grouse (fairly common to rare), and the sharp-tailed grouse (common to fairly common). During this time, however, the introduced house sparrow and rock dove became common species.

Long-distance migrants had a RAT of 0.16; this increase was mostly due to woodland native songbirds, such as house wren, veery, least flycatcher, and the western kingbird, becoming more abundant. The least-affected class was the short-distance migrants (RAT = 0.04), but it also contained 54% of all bird species (73 members). The slight increase in short-distance migrants is due primarily to the range expansion of eastern deciduous forest species, such as the American robin and cedar waxwing and the introduced European starling and mourning dove, all of which have experienced large population increases.

Changing Habitat

Most of the changes observed in breeding bird guilds have been due to changing habitats since agricultural settlement. In terms of nesting habitat, breeding bird guilds that have benefited from human activity include vegetation, cavity, and cliff nesters. Human-constructed nest boxes mimic tree cavities and the development of this resource may result in the proliferation of cavity-nesting species in a given area. For example, Bittner (1988) (for Saskatchewan) and Piel (1980) (for Alberta) reported that the introduction of nesting boxes in a region significantly increased the breeding populations of mountain bluebirds. This increase also has been shown for house sparrows, tree swallows, and flycatchers (Smith, 1996). Similarly, buildings, bridges, and overpasses are surrogates for cliffs by swallows (Knapton, 1988; Belanger, 1989), doves, vultures (Beaulieu, 1985; Wapple, 1985), and phoebes (Friesen, 1983; Desment, 1987).

Since the early 1900s, the control of fire and a massive reduction in unmanaged ungulate grazing, coupled with the planting of farm shelterbelts, have all increased the area of woodland and shrub habitats (Figure 117.4). As the woodland habitats increased, the species that use them have become more abundant, including northern flicker, least flycatcher, western kingbird, tree swallow, rock wren, veery, American robin, brown thrasher, European starling, lark sparrow, and Baltimore oriole. Further, the woodland and shrubland predators such as red-tailed hawk, American kestrel, merlin, and great horned owl have increased while the once-common prairie raptors such as the ferruginous and Swainson's hawks have experienced large population declines.

Human-made structures such as utility lines, communication towers, and fence posts are used by birds as they would use tall trees or snags, providing additional nesting and perching habitat that has been historically limited (Houston, 1996; Curtis, 1997). Further, breeding birds are increasingly incorporating human-made materials in nest construction (Bancroft, 1978), perhaps showing adaptable behavior in response to a changing resource base.

The relative changes illustrated in habitat guilds (foraging habitat in Figure 117.5B and nesting habitat in Figure 117.5C) closely parallel the overall habitat trends observed in vegetation (Table 117.5) and nesting sites as described previously. Table 117.11 matches these habitat trends with the habitat guilds, with each habitat having the same negative or positive trend as the habitat guild's relative change value.

Table 117.11 Correlation between Bird Habitat Guilds and Overall Habitat Trend in the Mixed Grassland Ecoregion of Saskatchewan from Approximately 1900 to the 1990s

Guild Type	Guild	Habitat Trend	Guild Trend
Foraging Habitat	Brush/woodland	+	0.58
	Grassland	-	-0.28
	Wetland	-	-0.18
	Other	+	1.57
Nesting Habitat	Cavity	+	0.73
	Cliff	+	0.45
	Ground	-	-0.19
	Floating mat	-	-0.18
	Vegetation	+	0.38

Note: + = increasing habitat trend; - = decreasing habitat trend.

CONCLUSION

For the abundance of breeding bird populations in the Mixed Grassland Ecoregion of Saskatchewan, agricultural development has been both a positive and negative force by both created and reduced specific habitats and food supplies. For example, there has been a consistent decrease in native grassland and aquatic related guilds, while those related to woodland vegetation have increased. The areas converted to croplands not only reduced native species diversity but also the energy available to birds, because much of the biomass is harvested and transported from the field (Matson et al., 1997). Therefore, agricultural settlement has altered not only local plant communities but also the regional structure and energy flow of the ecoregion.

Studies on northern prairies at spatial scales of species assemblages have shown losses in species diversity (Leach and Givnish, 1996; Lesica and DeLuca, 1996; Bakker and Berendse, 1999; Davis and Duncan, 1999; Pepper, 1999). Thus, at the level of species associations, the prairie is becoming more homogeneous with many species becoming locally extinct. This is especially evident in agricultural fields and tame pastures (Peltzer, 2000) that together, by the mid-1990s, have expanded to cover over 70% of the prairie landscape. However, the relationship between habitat loss and diversity is not so clear because local habitats do not necessarily constrain regional diversity (Simberloff and Gotelli, 1984). In the Mixed Grassland Ecoregion since 1900, an increase in regional breeding bird diversity has occurred despite major changes in vegetation cover. Therefore, at the broader ecosystem levels (i.e., Mixed Grassland Ecoregion), agricultural practices and the development of human living spaces have added landscape heterogeneity and species diversity to the region. The changes in breeding bird guilds suggest that human land-use practices have modified the available regional habitats, altering the broad functional diversity and species composition at both the species assemblage and ecosystem levels.

The importance of society in shaping the present northern prairie environment has been primarily explored in terms of human disturbance to individual species living in conspicuous habitats (e.g., wetlands). Perhaps this is because the most visible agricultural impact is the replacement of native prairie cover with other vegetation types, and the resulting decline of individual "endangered" or "threatened" species that once lived there. However, human interactions are influencing more than a few fragmented districts or declining species. Society has carved out an ecological role within the prairie ecosystem, the effects of which may be measured by changes and responses in functional roles of key species.

Persson and co-workers (1996) examined food web structure in species associations and identified four factors which, when modified, alter the dynamics of ecological systems:

1. Habitat structure
2. Disturbance fluctuations

3. Population size and structure
4. Animal behavior and defenses

Within species assemblages in the Mixed Grassland Ecoregion of Saskatchewan, agricultural development can be linked directly to the alteration of each of these factors. Over 60% of the native plant assemblages has been significantly modified through tilling, drainage, and pesticide use. Further, it may be argued that much of the remaining 40% has been altered by secondary effects such as chemical and fertilizer runoff, air pollution, or introduced species. These impacts reduce functional diversity by excluding all but a few species in these areas. On the other hand, the introduction of woody vegetation through the expansion of brushland and aspen groves, along with the construction of shelterbelts, parks, and urban areas have added species and perhaps functional diversity. Disturbance fluctuations and population size and structure have been changed through the introduction of annual tillage, pest control, fencing, game management, and irrigation.

Since agricultural systems impact the Mixed Grassland Ecoregion at both fine and broad hierarchical levels, there are major ecological repercussions. The greatest immediate repercussion may be that modern agriculture represents an innovation that is constantly affecting prairie biota by altering food web interactions and abiotic resource distribution. Because the temporal pace of ecosystem level processes is very slow, it generally takes hundreds of years to measure the full response to a perturbation. Thus, if modern society is significantly altering the functional components of the prairie ecosystem, then it is changing the ways in which resources are partitioned for other species and diversifying selection pressures. The mechanisms that are altering prairie landscapes include human innovations that reallocate energy, space, and resources away from native to new, human-dominated systems that partition resources in new and innovative ways. Therefore, by changing the ways resources are used and divided among species, society has created new ecological space that is being exploited by many species. This new ecological space may be allowing more species and individuals to inhabit a landscape (as seen by the invasion breeding birds and the increases in regional bird richness and diversity). This suggests that measurements of an ecosystem's integrity should not rely heavily on biodiversity measurements alone.

The important changes to the Mixed Grassland Ecoregion of Saskatchewan that have occurred over the past 100 years are primarily due to recent human interactions. Thus, society has converted this prairie system into an agroecosystem. If we are to understand fully the implications of this, an integrated approach must be taken that investigates ecosystems as broad dynamic units in which society is a dominant player. Thus, in addition to lower-level mechanistic studies of species interactions, future studies must investigate ecosystems in terms of spatiotemporal scales and include societal components. In doing this, we should enhance our understanding of all ecosystem functions and how they are structured.

ACKNOWLEDGMENTS

I wish to thank Dave Gauthier and Brian Mlazgar at the Canadian Plains Research Center for their helpful input and suggestions. This manuscript was greatly improved by suggestions of three anonymous reviewers. Also thanks to Alan R. Smith of the Canadian Wildlife Service (CWS) for his suggestions in developing the bird database. This study was supported by grants from the Prairie Ecosystem Study (PECOS), an interdisciplinary research endeavor funded by the Tri-Council Natural Sciences and Engineering Research Council (NSERC), the Social Science and Humanities Research Council (SSHRC), the Medical Research Council (MRC), and the University of Regina.

Evaluating Agroecosystem Sustainability Using an Integrated Model

Ken W. Belcher and M. Boehm

INTRODUCTION

The increasing intensity of agricultural production in recent years has resulted in a degradation of natural ecosystems at a range of scales. Soil degradation, groundwater and surface water pollution, destruction of wildlife habitat and biodiversity loss have prompted questions about the sustainability of agroecosystems in recent years (Brown, 1997; World Commission on Environment and Development, 1987). The importance of agroecosystems to social and economic health has driven a demand for policy development and analysis focusing on the long-term sustainability of these systems. Agricultural ecosystems (agroecosystems), distinguished from natural ecosystems by the dominant role of human management for specific marketable products, are an important component of global land use and resource appropriation. Agroecosystems, like natural ecosystems, depend on the fundamental processes, primary production, consumption, and decomposition in combination with abiotic energy flows and nutrient cycling. Within an agroecosystem these processes are inextricably linked with economic and social components through the role of human management. These natural and social processes can be characterized as the flow of goods and services coming from the capital stock of the agroecosystem. The capital stock of an agroecosystem includes man-made, human, and natural capital corresponding to the factors of production, capital, labor, and land (Costanza and Daly, 1992; Prugh, 1995). Man-made capital is the manufactured means of production including machinery, equipment, buildings, technology, etc. (Prugh, 1995). Human capital is the collective knowledge, skills, and culture of the human population. Natural capital is comprised of components that are natural in origin. The maintenance of these capital stocks over time is an important condition for the preservation of the function of these agroecosystems.

While there has been ongoing debate about the characterization of sustainable development, there is some consensus that the concept is based on maintaining capital stocks for future generations (Batie, 1989). Costanza (1996) argues that sustainability is not a definitional problem, but a prediction problem and that it should be characterized as a long-term goal whereby research focuses on policies and conditions that will lead to this goal. The present study evaluates agroecosystem sustainability based on changes in components of systems' capital stock. It is assumed that natural and man-made capital are largely complements in the target system and, as such, sustainability requires that each component of the capital stock is maintained separately. This is consistent with strong sustainability as described by Daly (1994). Based on the strong sustainability framework,

the sustainability of an agroecosystem can be evaluated by monitoring changes in the capital stock to determine if the system is on a sustainable path.

To evaluate how a system develops with respect to a long-term goal of sustainability, researchers usually adopt some form of predictive model. To better understand system dynamics, models have traditionally been developed using spatial and temporal boundaries that minimize the interactions between the target system and the rest of the universe. Although this simplification facilitates the development of tractable models, an assumption of insignificant or linear interactions between the target system and its surroundings is necessary. Complex systems are characterized by strong, often nonlinear, interactions between the components, complex feedback loops that obscure the distinction between cause and effect, and significant time and space lags, discontinuities, thresholds, and limits (Costanza et al., 1993). An effective modeling framework for complex systems, therefore, cannot isolate the target system from its context.

The present study integrates economic and environmental components of an agroecosystem within a simulation modeling framework to assess the sustainability of the complex system. The Sustainable Agroecosystem Model (SAM) identifies an agroecosystem as a system that can be represented by economic and environmental subsystems. By integrating these component models, SAM can make explicit the effect that economic development has on the natural capital and, in turn, how changes in the natural capital stock affect man-made capital and future economic decisions. The integrated structure of the SAM model facilitates the simulation of system dynamics whereby land-use decisions in period t will influence land-use decisions in period $t + n$ through changes in components of the production systems' environmental context.

This chapter concentrates on describing the structure of SAM. The following sections provide details of the relationships used to construct the economic and soils and crop components of the modeling framework. The later sections of the chapter present results from SAM simulation runs to illustrate how the model can be used to evaluate agroecosystem sustainability.

THE SUSTAINABLE AGROECOSYSTEM MODEL

SAM is comprised of an economic model that simulates constrained profit maximizing production decisions, and a soils-and-crop-growth model that simulates changes in soil quality and the ability of the soil to provide nutrients and water for crop growth. The dynamic interdependence of the economic and environmental functions of an agroecosystem is made explicit in SAM by linking these component models. An important goal in developing SAM was to create a relatively simple model that would provide information on general system dynamics. Generality comes at the expense of precision (Costanza et al., 1993) but it was felt that models already exist that can provide high levels of precision simulating economic and environmental systems. The structure of the component models and the linkages used to integrate the models are represented in Figure 118.1.

An important characteristic of SAM is the treatment of temporal linkages in the economic and soils submodels. Although production decisions in one time period affect future soil quality – and thus future land-use decisions – the model assumes that farmers are myopic with respect to the effect of their land-use decisions. Although this unequal treatment of the temporal linkages in the soil and economic submodels appears to be inconsistent, there are good reasons to believe that this inconsistency is empirically valid.

From an economic perspective, the assumption that farmers are myopic is introduced by setting the user cost to zero. User cost is defined as the change in the future stream of profits that could be expected due to the changes in soil quality and soil function. Excluding user cost obviously simplifies the modeling process and makes solutions easier to simulate. However, the main reason for leaving out the user cost is because the requirements for its inclusion are quite stringent and unlikely to be fulfilled. For user cost to be included in land-allocation decisions, it must be assumed that (1) farmers are fully aware of the effect of soil quality on current and future production, (2)

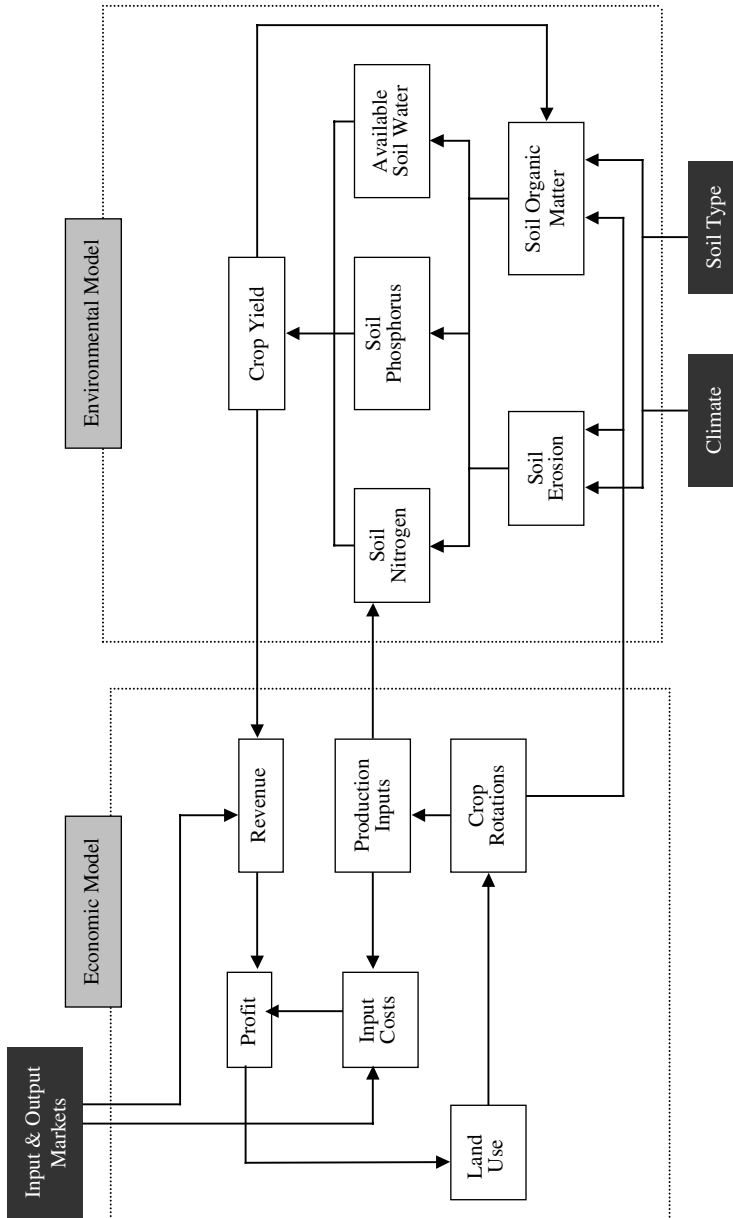

Figure 118.1 Schematic of agroecosystem modeling structure highlighting the important system linkages. Black shaded cells identify exogenous parameters.

land prices effectively reflect the capitalization of future rents, which are dependent on soil quality, and (3) land tenure enables farmers to realize the benefits of maintaining soil quality.

Research has shown that the assumptions required for user cost to be included in land-use decisions are often violated. Van Kooten and Furtan (1987) reported that farmers do not or are not often able to recognize the effect of soil quality on current and future production due to such factors as:

- A lack of knowledge regarding the relationship between soil quality and management practices.
- Technological advances that compensate for soil degradation such that yields are nondecreasing with lower soil quality.
- Fluctuations in interest rates and output prices causing an increase in the producer's discount rate such that the soil resource is allocated to the current generation.
- A nonlinear relationship between soil quality and crop yield.

With respect to the length of planning horizons and land tenure, McConnell (1983) suggests that family-owned land, and particularly rented land, are land tenure arrangements that generally do not have infinite planning horizons. Family-owned farms and rented family farms are the dominant tenure arrangements in Saskatchewan agriculture. In the absence of infinite planning horizons, the recognition of user cost requires that land prices reflect land quality. Clark and co-workers (1993) showed that land price and land rent are not highly correlated, implying that land prices do not reflect the discounted sum of the expected value of future rents. Based on these findings, the assumption of myopic decision making is more likely to reflect the actual behavior of farmers.

Many farm-scale economic models assume that farmers make production decisions using simple profit-maximizing criteria. The economic component of SAM assumes that short-run profit maximizing management decisions are constrained, with inadequate soil water conditions or low previous year profits leading to suboptimal provision of nitrogen fertilizer (see soils-and-crop-growth model, discussed later).

The spatial scale of SAM is an ecodistrict, an area defined by landform, vegetation, and soil that is relatively homogeneous in these characteristics as compared to the surrounding landscape (Acton et al., 1998). It is assumed that the farms within an ecodistrict are also relatively homogeneous in terms of their economic characteristics. An agroecosystem is the agricultural production system and its ecosystem context within a single ecodistrict.

SAM was constructed using the STELLA[®] modeling software, which facilitates the construction of models using stocks and flows. As such, the model was comprised of stocks such as organic matter, plant residue, and topsoil depth in the soils, and crop growth component and land allocation stocks in the economic component. The simulations are based on a 1-year time step; each simulation comprises 50 years. The results of the simulation are presented as mean and standard deviation values for 50 separate runs of the model. The framework used to construct the economic and soils-and-crop-growth models are now described in detail.

THE ECONOMIC MODEL

The economic component of SAM simulates the allocation of the land input by farms to four annual crop rotations and a perennial tame forage crop. The modeled rotations include summer fallow, a common management practice in southwestern Saskatchewan. In a summer fallow year, the land is idled from crop production to store water and control weeds with tillage or chemicals. The four annual crop rotations are (1) wheat–fallow (WF), (2) wheat–wheat–fallow (WWF), (3) wheat–canola–peas (WCP), and (4) wheat–fallow–peas (WFP). Native land (native grass, shrub, bush, and wetlands) is included in the model as a separate stock that provides no economic returns to the farm. However, native land may be converted to cultivated land when it is profitable to do so.

The central part of the economic model focuses on the allocation of land to the four annual crop rotations. Mathematically, the economic model incorporates the following production function:

$$x_j^t = f(g_j^t, l_j^t) \quad (118.1)$$

where x_j^t represents the output quantity from rotation j in time period t ; g_j^t denotes a vector of variable inputs (nitrogen fertilizer, soil nutrients, soil water, etc.) for rotation j in time period t ; and l_j^t denotes the land input for rotation j in time period t . In each time period, the stock of land available for cultivation is allocated to the rotations, based on their relative profitability.

The land input, in turn, is assumed to be used in fixed proportions with chemical inputs, phosphorus (P) fertilizer input, and “other inputs.” The model is calibrated such that one unit of land is 1 ha, one unit of output is the quantity produced on 1 ha, and one unit of the chemical, phosphorus, and other inputs is the quantity required to produce one unit of output on 1 ha of land. The per-hectare cost of the chemical, phosphorus, and other inputs are distinct for each rotation.

Farmers are assumed to be price takers in both the output and input markets, and output and input prices are fixed throughout the simulations. Farmers are also assumed to allocate land among rotations so as to maximize constrained short-run profits. The profit for each rotation is the difference between rotation revenue and rotation costs. Rotation revenue is calculated at each time step using fixed output prices and crop yield. Crop yields are calculated by the soils-and-crop-growth model and is discussed later. Rotation revenue is represented by average revenue per hectare. For example, gross revenue for the WFP rotation at time t (R_{wfp}^t) is calculated:

$$R_{wfp}^t = \frac{(p_w \times y_{wfp}^t) + (p_p \times y_{pfp}^t) + 0}{3} \quad (118.2)$$

where p_w and p_p are the output prices for wheat and peas, respectively; and y_{wfp}^t and y_{pfp}^t represent the yield at time t for wheat and peas, respectively. Note that revenue during the fallow year is zero.

Rotation costs include the cost of chemicals, fertilizer, and other inputs. The chemical input includes herbicides, insecticides, and fungicides. Chemical costs in the model reflect the average cost per hectare in each rotation with chemical quantities based on recommended rates for the specific crops in the specific region. For example, the chemical input cost for the WFP rotation (C_{chwfp}) is calculated:

$$C_{chwfp} = \frac{c_{chsw} + c_{chf} + c_{chfp}}{3} \quad (118.3)$$

where c_{chsw} , c_{chf} , c_{chfp} are, respectively, the per hectare chemical costs for wheat seeded into land that was cropped the previous year (stubble wheat), fallow, and peas seeded into land that was fallow the previous year (fallow peas).

The cost of fertilizer for an average hectare in each rotation (C_{ff}^t) is calculated as the sum of phosphorus and nitrogen costs. Phosphorus input cost represents the cost for an average hectare in the rotation and is calculated using the same format as described for the chemical input (Equation 118.3). Phosphorus cost is fixed in the simulation based on recommended application rates for the modeled crops. The quantity of nitrogen fertilizer used in each time step is determined endogenously in the model and is a function of soil water and soil nitrogen stocks and the previous year's profit. Therefore, the quantity of nitrogen fertilizer applied is not necessarily the profit maximizing rate. This procedure is described in detail in a later section.

The other inputs category captures those inputs not represented by the land, fertilizer, and chemical input markets. Other inputs is an index for machinery, fuel, buildings, and management skill. The price of other inputs is determined endogenously using a separate supply curve for each rotation. The development of a separate supply curve for each rotation means that other inputs are assumed to be rotation specific. These supply curves are upward sloping to reflect the increasing marginal costs associated with these inputs, particularly management.

The supply relationships for other inputs were assumed to be linear:

$$Q_{oj}^t = \alpha_{oj} + \beta_{oj}P_{oj}^t \quad (118.4)$$

where P_{oj}^t denotes the per hectare price of other inputs for rotation j at time t ; Q_{oj}^t is the quantity of other inputs for output j at time t ; $\beta_{oj} = E_{oj}(Q_{oj}^t/P_{oj}^t)$, where E_{oj} is the elasticity of supply of input j ; and $\alpha_{oj} = Q_{oj}^t - \beta_{oj}P_{oj}^t$.

To derive the other input supply functions, the initial other-input price, initial quantity, and elasticity values are used to derive the parameters β_{oj} and α_{oj} . Some important assumptions were made about the target agroecosystem to derive these values. The initial ($t = 0$) quantity of land assigned to each of the rotations (Q_{lj}^0) in the target agroecosystem is based on recent land-use statistics. Assuming that other inputs are used in fixed proportions with the land input, the initial quantity of other inputs is derived ($Q_{oj}^0 = Q_{lj}^0$).

It is further assumed that the initial land allocation represents an economic equilibrium so that total costs equal total revenue:

$$P_{oj}^0 = R_j^0 - (P_l^0 + C_{chj} + C_{fl}^0) \quad (118.5)$$

where P_{oj}^0 represents the initial other-input price; P_l^0 represents the initial input cost of land or land rent; and C_{fl}^0 represents the cost of fertilizer. The assumption of zero profits in Equation 118.5 implies that there are no excess profits in farming. The return to land is determined by land rent, while the return to management is included in the price of other inputs.

The other input supply elasticities were derived by noting that the own-price and cross-price area response elasticities for wheat, peas, and canola can be written as functions of the other, input supply elasticities, which were selected to provide a wheat own-price supply elasticity of 0.5, a value consistent with literature value estimates (see Clark and Klein, 1992; Schmitz, 1968; for estimates of supply elasticities). Given the absence of own-price elasticities estimates for peas and canola in the literature, these elasticities were simply constrained to be positive. The cross-price elasticities were not constrained to be negative (as would normally be the case), because individual crops in the model are tied to specific rotations. For example, an increase in the price of peas may not result in a decrease in the area of canola because canola and pea areas are linked within the WCP rotation. Using this procedure the other input supply elasticities were derived (E_{oj}) (Table 118.1).

The economic model requires the inverse form of the other input supply function. The inverse function is written as follows:

$$P_{oj}^t = \delta_{oj} + \omega_{oj}Q_{oj}^t \quad (118.6)$$

where $\delta_{oj} = -\alpha_{oj}/\beta_{oj}$ and $\omega_{oj} = 1/\beta_{oj}$.

The revenues and costs outlined previously can be used to derive the inverse demand for land for each rotation. The demand for land for each rotation is a derived demand that reflects the amount a farmer is willing to pay for a hectare of land, given the revenues received and the total costs of nonland inputs required to produce the output on that hectare of land. The assumption is that if

Table 118.1 Simulated “Other Input” Supply Elasticities for Modeled Rotations in the Brown Soil Zone

Crop Rotation	Other Input Supply Elasticity
Wheat–fallow	1.5
Wheat–wheat–fallow	3.0
Wheat–canola–peas	5.0
Wheat–fallow–peas	17.0

revenues exceed costs for a particular rotation, farmers will shift land into that rotation. Similarly, if costs exceed revenues in a rotation, farmers will shift land out of that rotation. This shifting land use captures farmers’ desire to increase their profits. Land use will be in economic equilibrium when gross revenues for a rotation equal the costs associated with that rotation.

The inverse demand for land is determined by equating gross revenues in period t (R_j^t) with total costs in period t ($P_l^t + P_{oj}^t + C_{chj}^t + C_{fl}^t$), substituting Equation 118.6 for P_{oj}^t and solving for the common land rent (P_l^t) as a function of the quantity of land (recall that with fixed proportions, the quantity of land equals the quantity of other inputs, $Q_{oj}^t = Q_{lj}^t$). The linear inverse demand curve for land for rotation j is

$$P_l^t = \eta_{ij}^t - \omega_{ij} Q_{lj}^t \quad (118.7)$$

where $\eta_{ij}^t = R_j^t - (\delta_{oj}^t + C_{chj}^t + C_{fl}^t)$ and $\omega_{ij} = \omega_{oj}$.

Inverting Equation 118.7 gives the standard demand curve for land for each rotation:

$$Q_{lj}^t = \rho_{ij}^t - \theta_{ij} P_l^t \quad (118.8)$$

where $\rho_{ij}^t = \eta_{ij}^t / \omega_{ij}$ and $\theta_{ij} = 1 / \lambda_{ij}$.

The total demand for all land dedicated to annual crop production is obtained by summing the demand for land for each rotation:

$$Q_l^t = \sum_j Q_{lj}^t = \rho_l^t - \theta_l P_l^t \quad (118.9)$$

where $\rho_l^t = \sum_j \rho_{lj}^t$ and $\theta_l = \sum_j \theta_{lj}$.

Within SAM, it is assumed that all land in annual cultivation is allocated to the four annual crop rotations represented in the model. This assumption implies that the supply of annually cultivated land (\bar{Q}_l^t) at any given point in time is fixed. The quantity parameter is expressed with a time superscript to indicate that the stock of annually cultivated land will increase with conversion of perennially vegetated land (tame forage and native land) to annual cultivation, or decrease with conversion of annual cultivation to perennial tame forage.

The market clearing land rent, is derived by setting Equation 118.9 equal to \bar{Q}_l^t and solving for P_l^t :

$$P_l^t = \frac{\rho_l^t - \bar{Q}_l^t}{\theta_l} \quad (118.10)$$

Substituting P_l^t into the derived land demand functions (Equation 118.7) provides the constrained profit-maximizing equilibrium quantity of land allocated to each of the rotations at a point in time.

Agroecosystems are generally comprised of a variety of land uses including annually cultivated land, land dedicated to some form of tame perennial vegetation, and native land (including native range, native grassland, shrubs, bush, and wetlands). The stock of annually cultivated land (\bar{Q}_i^t) is altered by the conversion of land from perennial cover to annual cultivation, or from annual cultivation to perennial forage.

Within SAM, land is allocated to the use (annual cultivation or perennial forage) that provides the highest potential economic returns to that land at each point in time. Land rent (P_i^t), as calculated in Equation 118.6, represents the opportunity cost of allocating land to perennial crops. Tame forage net revenue (NR_f^t) is calculated by the model, at each time step, using a fixed hay price, forage conversion costs, forage production costs, and hay yield. Hay yield is a function of precipitation based on the following relationship:

$$y_h^t = \phi + \mu(gs^t) + \tau(ws^t) \quad (118.11)$$

where y_h^t denotes tame hay yield; gs^t , ws^t denote growing season and nongrowing season precipitation, respectively; and ϕ , μ , and τ denote empirically derived coefficients. The coefficients in Equation 118.11 were statistically derived using the GRASSGRO[®] pasture growth model (Cohen et al., 1995) (Table 118.2). Coefficients were derived for different climatic and soil conditions to reflect the specific biophysical conditions of the target landscapes.

The process used by SAM to simulate the dynamics of land conversion between tame forage and annual crop is depicted in Figure 118.2. The economic threshold for converting land from forage to annual crop or breakup threshold, and the threshold for converting annual crop to perennial forage or set-aside threshold, are labeled, BUT and SAT, respectively. The line labeled D^t represents the difference between land rent (P_i^t) and forage net revenue in a given year (NR_f^t), i.e., $D^t = P_i^t - NR_f^t$. The zero line is where annual crop and forage net revenues are equal. If it is assumed that initially ($t = 0$) land is allocated to forage production, when D^t crosses the BUT ($t = X$), land is converted to annual crop production. This land remains in annual crop production until D^t crosses the SAT ($t = Y$), at which time the land is converted to forage production. Figure 118.2 shows how conversion costs buffer land-use shifts. Land remains in either annual crop production or forage production for a number of periods despite significant decreases in relative profitability.

The BUT and SAT values discussed above were calculated using Saskatchewan hay and grain net income data, and provincial grain and tame forage areas for the period 1971 to 1996 (Saskatchewan Agriculture and Food, 1996) and the conversion threshold calculation procedure described by Gray and co-workers (1993). The BUT and SAT are distinct due to the large costs associated with converting land from annual crops to forage.

Within SAM, it is assumed that cultivated land cannot be converted to native land. Thus, the stock of native land is nonincreasing during the simulations. Native land is converted to annual crop production when the opportunity cost of land, represented by land rent in the model, is greater than the cost of converting native land. The procedure used to describe the native land supply function

Table 118.2 Empirically Derived Hay Yield Coefficients for Brown Clay (Eston Plain), Loam (Gull Lake Plain), and Sandy Loam (Beechy Hills and Antelope Creek Plain) Soil Textures in the Study Area

Coefficient	Brown Clay	Brown Loam	Brown Sandy Loam
ϕ	1.16 (2.71) ^a	1.31 (2.38)	0.48 (1.20)
μ	0.04 (2.50)	0.03 (1.53)	0.08 (5.05)
τ	0.05 (2.94)	0.06 (3.01)	0.04 (2.40)
R-squared	0.29	0.24	0.46

^a Values in parentheses are the t statistics for the coefficients.

Figure 118.2 Economic thresholds for conversion of land between perennial forage and annual crop production. D^t represents the difference between annual crop and forage net revenue at a point in time (annual crop net revenue^t – forage net revenue^t = D^t).

was informed by a framework developed by Van Kooten (1993). It was assumed that native land conversion costs are a function of the stock of native land. The native land supply function reflects the condition that as native land is converted to cultivation — e.g., the stock of native land decreases — the average quality of the native land stock decreases and marginal conversion cost increases.

SOILS-AND-CROP-GROWTH MODEL

The soils-and-crop-growth component of SAM is based on the SIMPLE model developed by Greer and co-workers (1992). This part of SAM simulates crop production as a function of climate and soil quality, with soil quality being influenced in turn by management in previous years. The model simulates wheat, canola, peas, and summer fallow management in context of the WF, WWF, WFP, and WCP rotations.

The model was parameterized using ecodistrict-specific biophysical data: (1) soil type — texture, thickness, initial organic matter content; (2) climate — growing season precipitation, nongrowing season precipitation, growing degree days, mean daily temperature; and (3) initial soil stocks — surface residue, organic matter carbon, nitrogen, phosphorus. The sectors that comprise the soils-and-crop-growth model are now presented in detail.

Crop yields are simulated in the model based on the law of the minimum, whereby the maximum potential yield is achieved only if all plant growth requirements are optimal. It was assumed that annual crop yields are limited by available water, nitrogen, and phosphorus, such that one of these factors will be the binding constraint:

$$y_{crj}^t = y_{cr\ max} \times y_{s_{rcrj}^t} \times y_{s_{ncrj}^t} \times y_{s_{pcrj}^t} \tag{118.12}$$

where y_{crj}^t denotes the yield for crop cr in rotation j at time t ; $y_{cr\ max}$ denotes the maximum potential yield for crop cr ; and $y_{s_{rcrj}^t}$, $y_{s_{ncrj}^t}$, $y_{s_{pcrj}^t}$ represent crop input sufficiencies, or the proportion of maximum yield ($y_{j\ max}$) possible, given available water, nitrogen, and phosphorus, respectively. These sufficiency values fall between zero and one, with a value of one reflecting conditions where

available water, nitrogen, and phosphorus are nonconstraining. The yield equation was parameterized using empirically derived boundary conditions of scatter plot relationships between annual crop yield and water, nitrogen, and phosphorus availability. The remainder of this section discusses how SAM simulates the provision of the crop growth parameters by the soil.

Growing season precipitation and snow melt equivalent precipitation (nongrowing season precipitation) provide the soil water that will potentially be available for crop growth. The proportion of total precipitation that is available to the crop in each time step is determined by the infiltration rate, recharge rate, and the water storage capacity of the soil. It is assumed that approximately 50% of the overwinter water enters cropland soil. Soil water storage capacity determines the water available for crop growth. The water storage capacity of the soil is a function of soil texture (percent clay) and the organic carbon content of the soil and is consistent with the universal soil loss equation (Wischmeier and Smith, 1978).

Soil organic matter carbon (SOMC) dynamics reflect the difference between the rate of organic matter addition to the soil as crop residues and the rate of organic matter loss as CO_2 through microbial decomposition. Additions of crop residue are modeled as a function of grain yield and the type of residue (Douglas and Rickman, 1992). More specifically, crop residues are determined as follows:

$$CR_{cr}^t = y_{cr}^t \times CA_{cr} \times HI_{cr} \quad (118.13)$$

where CR_{cr}^t denotes the quantity of crop residue added by crop cr in time period t ; y_{cr}^t is the yield of crop cr ; CA_{cr} is the carbon content of the residue for crop cr (%); and HI_{cr} is the harvest index ratio of grain to total biomass for crop cr .

The rate of crop residue decomposition (Decomp^t) is a function of the nitrogen content of the residue, soil water, and growing degree days (Douglas and Rickman, 1992). Decomposition is calculated using the following relationship:

$$\text{Decomp}^t = Rd^t \times (\exp(NC_{cr} \times W \times k \times \text{GDD})) \quad (118.14)$$

where Rd^t is the stock of crop residue at time t ; NC_{cr} represents the nitrogen content of plant residue from crop cr ; W is a scalar tillage factor (summer fallow = 0.3, crop = 0.2); k is a constant (-0.0004); and GDD is growing degree days, a measure of solar energy input. Increasing the frequency of tillage increases the rate of decomposition by increasing soil temperature, soil aeration, and available nitrogen (Hendrix et al., 1988). Soil organic matter carbon stocks will also decrease under summerfallow management primarily due to the lack of crop residues being added during the fallow year (Tiessen et al., 1982).

The amount of nitrogen available to a crop is soil N plus fertilizer N. Soil N is mineralized from soil organic matter through microbial decomposition. It is assumed that SOMC has a carbon to nitrogen ratio of ~10:1. Based on this assumption, available nitrogen (Avail.N) is calculated:

$$\text{Avail.N}^t = N_{\min} \times \left(\frac{\text{SOMC}^t}{10} \right) \quad (118.15)$$

where N_{\min} is the rate of nitrogen mineralization; and SOMC^t is the stock of soil organic matter carbon at time t . The nitrogen mineralization rate varies with soil thickness, soil temperature, and soil moisture. For example, processes that decrease soil thickness (e.g., erosion) cause a loss of soil organic matter and a decrease in soil nitrogen. In contrast, production practices that increase the SOMC stock, soil temperature, or soil moisture will increase the rate of nitrogen release from the soil organic matter. In SAM, soil nitrogen is made available through the production of nitrogen fixing crops such as peas.

It is assumed that nitrogen fertilizer is available to the crop only in the year of application. An upper limit on the quantity of nitrogen fertilizer permitted at each time step is imposed by assuming that soil N plus fertilizer N cannot exceed 100% sufficiency for each crop. Nitrogen fertilizer rates are further adjusted based on previous year profits for the particular rotation, and available soil water at the beginning of the growing season. For example, the quantity of nitrogen applied would be scaled back from optimum rates if spring soil moisture conditions were less than 50% of average or the previous year revenues less than average. These relationships were developed based on the assumption that low net revenue or poor soil moisture conditions will cause farmers to be less willing to invest in fertilizer inputs.

The quantity of available soil phosphorus (Pa_j^t) is determined by the rate of phosphorus release from mineral, organic, and fertilizer sources. Mathematically, available soil phosphorus is calculated:

$$Pa_j^t = (Po^t + Pi^t + (Pf_{cr} \times 0.25)) \times Pu_{cr} \quad (118.16)$$

where Po^t represents the mineralization rate of organic phosphorus; Pi^t is the mineralization rate of inorganic phosphorus; Pf_{cr} represents the quantity of phosphorus fertilizer provided for crop cr in the economic model; and Pu_{cr} represents the rate of phosphorus uptake by the crop. Organic P occurs in soil organic matter with a C:N:P ratio of 100:10:1. Inorganic phosphorus is determined by soil clay content and, as such, is influenced in the model by the soil texture. The proportion of fertilizer phosphorus that becomes available is based on the assumption that only 25% of fertilizer phosphorus is available for plant growth (Greer et al., 1992).

Erosion of soil by wind, water, and tillage is assumed to remove a fixed quantity of top soil in each time step: (1) WF, 10 t/ha/year; (2) WWF, 5 t/ha/year; (3) WCP, 0 t/ha/year; (4) WFP, 5 t/ha/year (Monreal et al., 1995). These erosion rates provide an estimate of the level of background erosion associated with management regimes (tillage intensity and frequency) and biophysical properties (soil type and climate).

SUSTAINABILITY INDICATORS

The sustainability of a complex system can be evaluated effectively only by monitoring changes across the system, including the economic and biophysical components. SAM produces a range of output parameters that reflect the condition of the agroecosystem under examination. The following parameters are the sustainability indicators used in this chapter:

1. SOMC: SOMC is an important indicator of soil quality and soil function due to its role in soil nutrient availability, soil structure, water-holding capacity, and soil microbial ecology (Karlen et al., 1997). SOMC is responsive to tillage, residue management, cropping intensity, and nitrogen and phosphorus fertilization.
2. Carbon dioxide emissions: CO₂ is an important greenhouse gas. CO₂ emissions in SAM originate primarily from decomposition of soil organic matter, with smaller contributions from direct and indirect fossil fuel use (e.g., input embodied carbon).
3. Crop yield: Annual crop yield is an integrative indicator reflecting the ability of the soil to provide water and nutrients for crop growth. The ability of the economic component of the agroecosystem to maintain or improve soil function through nitrogen fertilizer application, soil management, and rotation choice is revealed through crop yield.
4. Land rent: Economic returns to land indicate whether the farming system is economically viable. Lower land rent values generally imply a lower probability of economic sustainability. The standard deviation of land rent provides insight into the economic risk of the farming systems.
5. Land use: The allocation of land to annual and perennial cropping strategies provides a landscape-scale sustainability indicator. An agroecosystem that is dominated by a single crop is assumed to be less economically and environmentally sustainable than one that has a more diverse landscape.

SIMULATING AGROECOSYSTEMS

The target area of the present research lies within the 15,700 km² crop district 3BN in the Mixed Grassland Ecoregion of southwestern Saskatchewan. Crop district 3BN was the primary study area of the Prairie Ecosystem Study (PECOS). This semiarid region has a severe moisture limitation to annual crop production with evapotranspiration rates double the total annual precipitation received.

Four ecodistricts within crop district 3BN are the focus of this research: Eston Plain, Beechy Hills, Antelope Creek Plain, and Gull Lake. Soils in the study area range from predominantly Brown or Vertisol soils of clay texture in the Eston Plain ecodistrict, to a mixture of Brown loam and sandy loam in the Gull Lake Plain ecodistrict. Other biophysical characteristics of the four target ecodistricts are presented in Table 118.3.

The wheat–summer fallow production system is dominant in this area, with wheat being produced on approximately 45% of the annual cropland, and summer fallow comprising another 40% of this land (Statistics Canada, 1997) (Table 118.4). The data presented in Tables 118.3 and 118.4 are used to parameterize the soils and crop growth and economic component models. Growing season and nongrowing season precipitation at each time step is randomly selected from gamma distributions that were developed based on the statistical characteristics of the appropriate precipitation data. It should be noted that it was assumed that precipitation patterns were unaffected by climate change.

Table 118.3 Biophysical and Climatic Characteristics of Target Ecodistricts

Parameter	Antelope Creek			
	Eston Plain	Beechy Hills	Plain	Gull Lake Plain
Soil texture	Brown clay	Brown loam	Brown loam	Brown loam/ sandy loam
Growing season precipitation (cm) ^a	19	18	19	19
Nongrowing season precipitation (cm) ^b	15	14	17	18
Growing degree days	1,479	1,507	1,459	1,397
Initial solum (cm) ^c	60	60	60	60
Initial SOMC (t/ha) ^d	50,000	50,000	50,000	50,000
Initial surface trash (kg/ha) ^e	4,200	4,200	4,200	4,200

^a Total precipitation received between May and July.

^b Total snowmelt equivalent precipitation received between August and April.

^c Total depth of the A and B horizons of the soil, specific to soil zone.

^d Organic matter carbon content of the soil to depth of solum, specific to soil zone.

^e Quantity of residue carbon on the surface of the soil, specific to soil zone.

Table 118.4 Initial Land-Use Statistics (ha) for the Four Target Ecodistricts

Land Use	Antelope Creek			
	Eston Plain	Beechy Hills	Plain	Gull Lake Plain
Annual crop	370,604	91,104	101,481	42,291
Summerfallow	272,442	46,039	70,168	26,095
Tame hay	4,379	4,295	6,496	5,005
Improved pasture	11,714	13,383	11,998	13,339
Native pasture	108,822	58,453	35,444	41,181
Other land ^a	15,614	4,726	4,973	4,002
Total farmland	783,575	218,000	230,560	131,913

^a Other land includes farm yards including buildings, shelterbelts, fencerows, ditches, wetlands, shrubland, and woodland.

Source: Statistics Canada, 1996.

Production cost data for an average 660-ha farm in the Brown soil zone of southwestern Saskatchewan (Saskatchewan Agriculture and Food, 1998) and 1998 output prices were used to parameterize the supply-and-demand relationships of the economic component of SAM. An important assumption required to set up these relationships, as discussed earlier, is that the most-recent ecodistrict land-use statistics (Statistics Canada, 1996) represent an equilibrium position with respect to land allocation.

AGROECOSYSTEM SIMULATIONS

The results discussed in this chapter represent two categories of simulations of the target agroecosystems by SAM: (1) baseline scenario, 50-year simulations for the four target ecodistricts to highlight the responsiveness of the model to a range of climatic and physical characteristics; and (2) carbon emissions policy scenarios, 50-year simulations of a single ecodistrict under a carbon credit policy.

BASELINE SIMULATIONS

The baseline simulations provide insight into changes in the sustainability of the target agroecosystems, based on the selected indicators, in two dimensions: (1) within the ecodistrict, calibrated with current biological, physical, and social parameters; and (2) between ecodistricts, each with distinctly different biological, physical, and social parameters.

As discussed earlier, the allocation of land to different crops and management schemes is an important driver of agroecosystem change at a range of scales. The baseline simulations indicated that these management decisions are set in context of the biophysical constraints specific to the production system. Annual crop yields were higher, with lower variability, in the Eston Plain compared to the other ecodistricts. The Eston Plain has clay-textured soils, adequate precipitation, and a less-severe temperature constraint. The simulated yields of the Eston Plain result in higher and less-variable revenues for the annual crop rotations, and therefore, higher and less-variable economic returns to land (Table 118.5). In contrast, the less clayey textured soils, lower rainfall or greater temperature stress of the remaining ecodistricts resulted in lower and more-variable yields, which cause lower revenues and less-favorable economic conditions.

The economic signals simulated by SAM drove the land-allocation decisions over the course of the simulations. In the Eston Plain, the area of land allocated to each of the land-use categories was relatively stable over the course of the simulations (Figure 118.3). In contrast, land in the Beechy Hills and Gull Lake Plain generally shifted to WF and WWF with virtually no land being allocated to the WCP and WFP rotations. In addition, the area of native and tame forage declined. It should be noted that because the Eston Plain ecodistrict had the smallest initial stock of native land of the four ecodistricts, a relatively inelastic segment of the native land supply curve influenced land-allocation decisions. This resulted in smaller decreases in the native land stock than may be expected given the high opportunity cost of land in this landscape.

Table 118.5 Simulated Mean and Standard Deviation of Land Rent (\$/ha), Averaged over 50-Year Simulation

	Ecodistrict			
	Eston Plain	Beechy Hills	Antelope Creek	Gull Lake
Mean	30.96	24.13	30.60	23.39
Standard deviation	51.15	65.73	61.38	56.01

Figure 118.3 Simulated change in land allocation in the four ecodistricts over the 50-year simulations.

Within SAM, annual crop yields are a function of soil quality, as determined by physical and climatic conditions, and soil management practices. Therefore, soil quality changes, as influenced by yield and revenues, are an important factor determining land use. An important positive feedback captured by the model is as follows: higher yields result in larger additions of plant residues to the soil, which are allocated to the SOMC stock or released to the atmosphere as CO₂ through decomposition. Greater stocks of SOMC result in increases in available soil water, soil nitrogen, and soil phosphorus, thereby providing conditions for greater yields. In addition, the greater availability of organic nitrogen decreases the requirement for nitrogen fertilizer, thereby decreasing input costs.

The SOMC–yield feedback relationship resulted in a “rich get richer, poor get poorer” scenario with increasing yields and improved economic indicators in the ecodistricts with minor biophysical constraints (Eston Plain), and decreasing yields and decreasing economic parameters in the ecodistricts with greater biophysical constraints (Beechy Hills, Gull Lake Plain) (Table 118.6). In the Beechy Hills and Gull Lake Plain ecodistricts, the lower inherent crop yields resulted in smaller additions to the SOMC stock, thereby decreasing soil quality and future yield. In addition, the combination of low revenues and limited soil water, as determined by inherent soil texture and soil quality attributes, provided little incentive to increase nitrogen fertilizer inputs, further limiting future yields. The land-use effect in these ecodistricts was to allocate more land to rotations that provide more-consistent yields such as WF and WWF. These rotations facilitate higher yields under poor water conditions due to the presence of wheat, a relatively drought-tolerant crop, and summer fallow, which increases soil water stocks. This land allocation limited the increases in SOMC stocks due to greater decomposition rates and greater erosion rates associated with the more-frequent fallow management on lighter textured soils.

Based on the strong sustainability criteria, a synthesis of the indicators discussed facilitates a system-based view of the relative sustainability of the target ecodistricts. The economic indicators simulated for the Eston Plain suggest that components of the man-made capital stock of this system

Table 118.6 Simulated Changes in Soil Indicators over Initial Value for an Average, Annually Cropped Hectare

	Ecodistrict			
	Eston Plain	Beechy Hills	Antelope Creek	Gull Lake
SOMC (kg/ha)	4947.18	2799.67	3968.79	3383.16
N fertilizer (kg/ha)	1503.72	1559.46	1567.59	1569.83
Soil CO ₂ (kg/ha)	75,697.59	52,150.06	58,214.48	51,326.74

Table 118.7 Simulated Carbon Balance over the 50-Year Simulations per Average Hectare of Annual Crop Plus Tame Forage Land (Mt/50-year)

Carbon Balance	Eston	Beechy	Antelope	Gull Lake
Input-embodied C	10.27	9.41	9.08	8.61
Soil CO ₂ emissions	70.63	49.15	52.57	44.86
Total CO ₂ emissions	80.90	58.56	61.65	53.47
Total C stored	6.44	4.98	6.73	7.01
Net CO ₂ /ha emissions	74.46	53.58	54.92	46.46

would be maintained. In addition, the soil natural capital would be maintained or improved. However, simulation results also indicate that relatively large levels of CO₂ are being emitted from the Eston Plain agroecosystem, primarily due to decomposition of large SOMC stocks in annually cropped land, and greater levels of input-embodied carbon. This result may be interpreted as indicating an unsustainable path with respect to climate change contributions (Table 118.7).

In contrast to the Eston Plain results, the biophysical characteristics of the Beechy Hills and Gull Lake Plain restricted the viable annual crop production options to WF and WWF. As a result, SOMC stocks were smaller and land rent values were approximately 25% lower than the other two ecodistricts. These indicators suggest a lower probability of maintaining the man-made and soil natural capital stocks. The Antelope Creek Plain ecodistrict produced indicators that fell between the extremes presented in the other ecodistricts.

In general, the simulations indicated that the WF and WWF rotations were the only economically viable rotations in all of the ecodistricts, with 61 to 74% of the landscapes being allocated to these rotations. These low diversity landscapes, created by the dominance of wheat and summer fallow, will likely have lower levels of economic and ecological resilience, and, therefore, a lower probability of agroecosystem sustainability. One of the important policy implications of these simulation results is that any menu of incentives or disincentives aimed at moving these ecosystems toward sustainability must take into account the production options available to the farmers, as influenced by the specific biophysical constraints. For example, a set of policies forcing farmers to adopt management practices that disturb the soil less (i.e., continuous cropping, perennial crops) may result in a very different set of incentives to farmers in Eston Plain compared to the Gull Lake Plain.

CARBON POLICY SCENARIOS

Increases in atmospheric greenhouse gas concentrations and the associated concerns about global climate change have stimulated such global initiatives as the United Nations Framework Convention on Climate Change in 1992, and the Kyoto Protocol in 1997. These agreements focus on “stabilizing atmospheric concentrations of greenhouse gases at a level that will prevent dangerous anthropogenic interference with the climate system” (Bruce et al., 1998). Agriculture has been identified as both an important source of greenhouse gases and potential sink for atmospheric carbon. As a result, policy tools, such as government or industry paying landowners for soil carbon sequestration services, may be an important strategy in initiatives addressing climate change.

The relative sustainability of the Antelope Creek ecodistrict under the influence of a carbon credit policy is evaluated using a series of simulations. A carbon credit serves as a subsidy to those land-use practices that sequester carbon in the soil. In this analysis, it was assumed that a carbon credit applies only to the incremental carbon sequestered in annual cropland and tame forage land, while native vegetated soils are assumed to be in equilibrium with respect to organic carbon. Simulations were carried out using carbon credit levels of 25, 75, and \$125 per tonne (Mg) of carbon to discern the effect of varying incentive levels on the capital stock indicators.

The SAM simulation results indicated that a carbon credit increased the quantity of land allocated to those land uses that sequester more carbon. Tame forage has a greater rate of carbon sequestration

Table 118.8 Simulated Percentage Change in Land Use with Different Levels of Carbon Credit

Scenario	Land-Use Category (% change)					
	WCP	WFP	WF	WWF	Hay	Native
Baseline (ha)	3479.00	1083.00	93,161.00	78,429.00	15,875.00	39,139.00
\$25 credit	53.39	-62.10	-8.52	-7.60	87.91	-2.33
\$75 credit	-32.82	-99.77	-30.35	-22.00	340.50	-5.07
\$125 credit	-47.02	-100.00	-49.24	-33.48	525.38	-8.73

than any of the modeled annual crop rotations. As a result, the implementation of a carbon credit resulted in land being allocated from annual crop to tame forage (Table 118.8). In addition, there was a relative shift in annual crop land allocation toward the WWF rotation as carbon credit levels increased. At higher carbon credit levels, the marginal productivity of the nitrogen fertilizer input, in terms of soil carbon increments, was greater with WF and WWF, which are less constrained by water than the WCP or WFP rotations. As a result, revenues for WF and WWF increased at a relatively greater rate than the other annual crop rotations with carbon credit. Nitrogen fertilizer inputs in these rotations increased the marginal change in soil carbon which translates into a revenue-optimizing strategy in this scenario. In general, the WWF rotation was more positively influenced by the SOMC yield feedback process, with larger SOMC stocks providing greater levels of organic soil nitrogen, less demand for nitrogen fertilizer, and more-stable yields leading to larger decreases in economic risk. The economic conditions created by a carbon credit resulted in WWF being the most economically attractive annual crop rotation in this ecodistrict.

Increased revenues, coupled with constant nonland input costs under a carbon credit, translated into an upward shift in the overall demand for annual cropland. This increased demand for annual cropland put upward pressure on land rent. This upward pressure on land rent was complemented by an increase in tame forage land, which decreased the stock of annual cropland. The relatively large increases in land rent (19% increase at \$25/Mg carbon credit; 70% increase at \$75/Mg carbon credit; and 93% increase at \$125/Mg carbon credit) increased the opportunity cost of native land, resulting in an increase in the rate of conversion of native lands to annual crop and tame forage production (Table 118.8). The decrease in native land has negative consequences for the ecological sustainability (i.e., biodiversity) of the agroecosystem.

Simulated carbon dioxide emissions decreased with increasing carbon credit levels primarily due to the shift in land allocation toward tame forage production (Table 118.9). The cost of decreased carbon dioxide emissions was calculated as the total payments made for sequestered carbon divided by the change in net emissions over the simulations. The \$25/Mg credit was the most economically efficient due to the moderate decreases in total input embodied carbon emissions (with decreased annual cropland) and a moderate increase in sequestration simulated at this credit level. At credit rates above \$25/t, the shift in annual crop land to WF and WWF, which increased organic matter decomposition and greater levels of input-embodied carbon associated with greater nitrogen fertilizer use, increased CO₂ emissions from annual cropland. At these higher credit levels, decreases in net emissions were realized primarily through greater sequestration in tame forage land which must be paid for under a carbon credit policy, thereby increasing its cost. It should be noted that total emission calculations did not include the mineralization of soil carbon associated with the

Table 118.9 Simulated Carbon Dioxide Balance with Carbon Credit and Carbon Tax Policies (Mt/50-year)

Policy Scenario	Total Emission	Total Soil Sequestered C	Net Emission	Emission Change	Emission Decrease Cost (\$/t)
Baseline	11.81	1.29	10.51	—	—
\$25 credit	11.13	1.65	9.48	-1.04	\$39.77
\$75 credit	9.98	2.43	7.55	-2.96	\$61.43
\$125 credit	8.91	2.95	5.96	-4.55	\$80.85

conversion of native land to annual cultivation. This may be an important source of CO₂ considering the increased rate of native land conversion caused by a carbon credit.

These results reveal an interesting implication for policy development. A carbon credit increases the economic returns to land and therefore implies maintenance of the man-made capital stock of the agroecosystem. The carbon credit also provides an incentive to adopt management practices that have a higher marginal productivity of nitrogen fertilizer in terms of incremental soil carbon. However, in this moisture-constrained ecodistrict, those rotations that include fallow management are more productive. Therefore, the carbon credit policy encourages greater frequency of fallow, causing an increase in soil CO₂ emissions on annually cultivated land. The carbon credit also encourages greater additions of nitrogen fertilizer, which contains high levels of embodied carbon. In addition, the higher opportunity cost of land increases the incentive to convert native land to annual crop production that decreases the environmental sustainability of the system. As a result, the carbon credit policy results in a land-use pattern that may be less sustainable.

CONCLUSION

Agroecosystems, as complex systems, are characterized by multiple feedback and linkages between environmental and social components. These characteristics make it difficult to meaningfully assess the sustainability of these systems. The integrated, interdisciplinary model used in this study facilitates the simulation of dynamic system effects within a biophysical context, and provides insight into the agroecosystem changes over time. While the results obtained should be evaluated considering the assumptions and structure of the SAM, insight into the sustainability trends are revealed using appropriate indicators within the strong sustainability framework.

The baseline and carbon policy simulations presented in this chapter reveal the importance of feedback processes in the dynamics of agroecosystem structure and function over time. In addition, the biophysical constraints had a strong influence on the management options available to farmers and, therefore, on the sustainability of the agroecosystem. These results highlight the importance of recognizing the biophysical characteristics of a target system when designing policy.

None of the simulated landscapes showed systemwide improvement or degradation of all components of the capital stock. This result suggests the difficulty in developing a policy, or set of policies, that will engender a sustainable system without assigning relative societal or environmental system values to the capital stock components. Identifying those capital stock components in which degradation will not be tolerated or accepted is a process requiring knowledge of societal preferences, ethical responsibilities, degradation thresholds, and system coevolution.

Prediction of Soil Salinity Risk by Digital Terrain Modeling in the Canadian Prairies*

Igor V. Florinsky, Robert G. Eilers, and Glenn W. Lelyk

INTRODUCTION

Soil salinization is a typical process for steppe, semiarid, and desert landscapes. Saline soils have increased content (more than 0.25% of dry weight of a soil sample) of soluble salts, such as chlorides and sulfates of sodium, magnesium, and calcium. These soils are observed commonly in flat, closed, and poorly drained areas with nonpercolative water regimes, in territories with saline surface deposits and discharges of saline groundwater. There are primary and secondary salinizations. Primary salinization is caused by integration of natural phenomena, such as climatic, geological, and geomorphic factors; secondary salinization is a result of human activities, such as land-use and water management, which may lead to vertical and lateral redistribution of salts in the landscape. Salinization is one of the main factors of soil cover degradation (Kovda, 1946, 1971, 1973; Mordkovich, 1982; Lobo and Khabarov, 1983).

Topography is one of the major natural factors determining spatial distribution and dynamics of soil salinization. Different manifestations of topographic control of soil salinization can be seen at different scales. At macro-topographic scale (typical sizes reach several hundreds and thousands of meters), build up of salts occurs in closed and partly drained macro-depressions, which are natural accumulators of substances moved by gravity from macro-crests and macro-slopes. At meso-topographic scale (typical sizes range between several tens and hundreds of meters), meso-depressions have additional moisture due to overland runoff, and so they are marked by more leached soils than meso-slopes and meso-crests. Bands of solonchaks and solonchaks are typical for meso-slopes around meso-depressions through redistribution and secondary accumulation of leached substances. At micro-topographic scale (typical sizes are several meters), build up of salts is typical for micro-crests marked by low moisture and high evaporation (Kovda, 1946, 1971, 1973). So, topography determines a spatial mosaic of soil salinization, all other factors being equal.

One of the essential steps in studies of soil salinity is compilation of maps of soil salinization (Khakimov et al., 1983). A map allows one to conveniently represent regularities of spatial distribution of an object, a phenomenon or a process studied corresponding to the given scale (Aslanikashvili, 1974). Among these scale-dependent regularities are relationships between the relief and soil salinization indicated earlier. In other words, small- and middle-scale maps should represent relations

* This chapter appeared in the *Canadian Journal of Soil Science*, Volume 80, No. 3, pp. 455–463, 2000. It is reprinted here with permission.

Table 119.1 Definitions and Physical Interpretations of Some Topographic Variables

Variable	Definition	Interpretation
$G, ^\circ$	An angle between a tangent plane and a horizontal one at a given point on the land surface (Shary, 1991)	Velocity of substance flows
k_v, m^{-1}	A curvature of a normal section of the land surface by a plane, including gravity acceleration vector at a given point (Shary, 1991)	Relative deceleration of substance flows
k_h, m^{-1}	A curvature of a normal section of the land surface; this section is orthogonal to the section of vertical curvature at a given point on the land surface (Shary, 1991)	Convergence of substance flows
H, m^{-1}	A half-sum of k_h and k_v (Shary, 1991)	Flow convergence and relative deceleration with equal weights
k_a, m^{-2}	A product of k_h by k_v (Shary, 1995)	Degree of flow accumulation

Data from Florinsky and Kuryakova, 1996; Florinsky, 1998a.

between soil salinity and macro-depressions; salinization of meso-slopes should be shown on large-scale maps, while salinization of micro-crests should be indicated on detailed maps.

However, existing approaches for compilation of soil salinity maps, as a rule, cannot allow one to display these regularities (Khakimov et al., 1983). On these maps, polygons characterizing type and extent of soil salinization include depressions, slopes, and crests (Kondorskaya, 1967; Novikova, 1975; Eilers et al., 1995, 1997). As this takes place, authors of these maps mean that actual salinization can be observed within landforms corresponding to the given scale rather than within all polygons. However, since these relationships are not graphically displayed, users of such types of maps insert corresponding corrections to the best of their ability. This is because (1) there are no rigorous quantitative definitions of depressions, slopes, and crests and (2) there are no methods for reproducible delineation of these landform types using topographic maps and digital terrain models (DTMs).

To compile small-scale maps of soil salinization of great areas of Middle Asia, Stepanov (1979) and Khakimov and co-workers (1983) tried to solve this problem using data on horizontal land-surface curvature (k_h) (Table 119.1). For depressions, they considered areas of flow convergence described by negative values of k_h . However, k_h data are not sufficient to recognize depressions because, from the geomorphic point of view, values $k_h < 0$ correspond to valley spurs rather than depressions (Evans, 1980; Shary, 1995).

Metternicht and Zinck (1997) used a qualitative geomorphic map to compile small-scale predictive maps of secondary soil salinization for a mountainous valley in Bolivia. Lack of this technique is connected to a subjectivity of landform presentation on a traditional geomorphic map transferred to a salinization map.

To improve small-scale predictive maps of secondary soil salinization for the Crimean steppe, Florinsky (2000) used DTMs and a concept of accumulation, transit, and dissipation zones of the land surface (Shary et al., 1991; Shary, 1995). Applying this approach, one can partition a landscape into polygons marked by relative accumulation, transit, and dissipation of flow. These quantitative terms have the qualitative geomorphic analogues of depression, midslope, and crest, respectively.

In this chapter, we present some results of compilation of a small-scale map of salinity risk index for the Canadian prairies and adjacent territories using DTMs and the concept of accumulation, transit, and dissipation zones.

STUDY AREA

Soil salinization is a typical process for the Prairie Ecozone within the Canadian provinces of Manitoba, Saskatchewan, and Alberta, and some adjacent territories of the Boreal Plains ecozone (Figure 119.1) (Eilers et al., 1995, 1997).

Figure 119.1 Geographical position of the study area.

The Canadian prairies are the northern extension of open grasslands in the Great Plains of North America. The area has a continental climate; subhumid to semiarid with long, cold winter and short, hot summer; low levels of precipitation; and high evaporation. Mean winter temperature is -10°C , and mean summer temperature is 15°C . Mean annual precipitation ranges from 250 mm in the arid grassland areas in southwest Saskatchewan and southeast Alberta, to 700 mm in Manitoba. The boreal plains are situated to the north of the prairies. Mean winter temperature is -14°C , and mean summer temperature is 14°C . Mean annual precipitation ranges from 300 mm in Alberta to 625 mm in Manitoba (Ecological Stratification Working Group, 1995).

The prairies and the boreal plains are underlain mostly by Cretaceous shales. These are nearly level to rolling landscapes consisting of hummocky glacial moraine and undulating to nearly level lacustrine deposits. Most rivers flow in an easterly direction across these territories. The soils are Black Chernozems with groves of trembling aspen, balsam poplar, and intermittent grassland in the northern edge of the prairies. The driest shortgrass prairie section with Brown Chernozems occurs in southwestern Saskatchewan and southeastern Alberta. The moist mixed grasslands and Dark Brown Chernozems can be observed in other parts of the prairies as a transition zone between these two zones. Dark Grey Chernozems Luvisols occur within the boreal plains. White birch, trembling aspen, and balsam poplar are typical in areas of the boreal plains adjacent to the prairies, while white and black spruce, jack pine, and tamarack are typical in the north of the boreal plains (Ecological Stratification Working Group, 1995).

Agriculture is the dominant land use in the prairie ecozone and in the southern and northwestern parts of the boreal plains. Saline soils are present in many areas throughout these regions (Figure 119.2). Sulfate salinization dominates there; 62% of the farmland in the prairies has a low extent of salinity (less than 1% of lands affected). Low-salinity areas usually have well-drained soils and are found generally on major uplands, over rapidly drained sandy soils, next to deep river channels that help to drain the soil, and in northern areas with soils formed under forest vegetation in moist conditions. About 36% of agricultural soils on the prairies are moderately affected by salinity (1 to 15% of lands affected). These are mainly medium-textured soils that occur next to small wetlands

Figure 119.2 Map of salinity risk.

and in depressions. Areas with a greater extent of saline soils are fairly small and scattered throughout southern regions. These areas often receive regional groundwater discharge, such as those found on nearly level plains at the base of prominent uplands, nearly level plains where the discharge is from major aquifers, and where drainage is limited (Figure 119.2) (Eilers et al., 1995).

MATERIALS AND METHODS

The following initial data were used in this analysis:

- A map of salinity risk for Manitoba, Saskatchewan, and Alberta (Eilers et al., 1995, 1997) (Figure 119.2).
- A digital elevation model (DEM) of an area between 48°55' and 60°05' N, and 88°55' and 120°05' W. The DEM was given by a spheroidal trapezoidal grid with the grid size of 5' (NOAA, 1988). This DEM included 50,625 points.

Salinity risk index (Figure 119.2) is used to rank individual land areas according to the chance that the salinity level will change with changing conditions. Evaluation of salinity risk is based on the concept that salinity is a dynamic condition of the soil cover, and on the premise that functional relationships exist among components affecting the salinization, that these components can be given a relative numerical weighting for their influences, and that each of these weightings can be combined resulting in a dimensionless index. The following factors are used to assess salinity risk:

1. Current extent of salinity derived from existing salinity maps at a scale of 1:1,000,000 indicating presence, extent, and position of moderate or greater salinity levels in each soil landscape (the electrical conductivity of a saturated-paste extract of a soil sample is more than 8 dS/m)
2. Slope gradient (G) (Table 119.1)
3. Soil drainage class
4. Aridity (the difference between precipitation and potential evapotranspiration)
5. Surface cover representing land-use and land management practices (Eilers et al., 1995, 1997)

The notion that soil salinization is typical for macro-depressions, meso-slopes, and micro-crests was not used in estimation of salinity risk index.

The concept of topographically expressed accumulation, transit, and dissipation zones is based on the following assumptions. Gravity-driven overland and intrasoil transport can be interpreted in terms of divergence or convergence, and deceleration or acceleration of flows (Shary, 1995). Flow tends to accelerate when vertical land-surface curvature (k_v) is positive, and to decelerate when k_v is negative (Table 119.1) (Speight, 1974; Shary, 1991). Flow diverges when $k_h > 0$, and converges when $k_h < 0$ (Table 119.1) (Kirkby and Chorley, 1967; Shary, 1991). Flow convergence and deceleration result in accumulation of substances in soils. At different scales, the spatial distribution of accumulated substances can depend on the distribution of the following landforms (Shary et al., 1991):

1. Landforms marked both by convergence and deceleration of flow; i.e., both by $k_h < 0$ and by $k_v < 0$ (accumulation zones)
2. Landforms offering both divergence and acceleration of flow; i.e., both $k_h > 0$ and $k_v > 0$ (dissipation zones)
3. Landforms that are free of a concurrent action of flow convergence and deceleration as well as divergence and acceleration; i.e., values of k_h and k_v have different signs or are zero (transit zones)

Recognition of accumulation, transit, and dissipation zones can be realized by simple registration of k_h and k_v maps (Koshkarev, 1982; Lanyon and Hall, 1983). However, in this case one can visualize only spatial distribution of these zones without quantitative estimation of a probable degree of flow accumulation. To solve this problem, Shary (1995) proposed use of data on accumulation (K_a) and mean (H) land surface curvatures (Table 119.1). Negative values of K_a correspond to transit zones, while positive values of K_a correspond to both accumulation and dissipation zones. Accumulation and dissipation zones can be distinguished using values of H . Positive values of K_a with negative values of H correspond to accumulation zones, whereas positive values of K_a with positive values of H correspond to dissipation zones (Shary, 1995).

We derived digital models of H and K_a from the DEM by the method of Florinsky (1998b). These were calculated using a grid spacing of 5' because it is best matched to the regional scale and readability of maps to be obtained. H and K_a digital models include 49,609 points. Derivation of H and K_a digital models was carried out with LandLord software (Florinsky et al., 1995). A map of accumulation zones (Figure 119.3) was obtained by combination of H and K_a data.

To produce an improved map of salinity risk index taking into consideration typical occurrence of soil salinization in macro-depressions, we linked the map of salinity risk index for Manitoba, Saskatchewan, and Alberta (Figure 119.2) and the map of accumulation zones for this area (Figure 119.3). The resulting map (Figure 119.4) represents only those landscape polygons marked by different rates of soil salinization that are located within accumulation zones.

RESULTS AND DISCUSSION

A comparative analysis of the old and the improved maps of salinity risk index (Figures 119.2 and 119.4) demonstrates that once data on macro-depressions have been taken into account, areas marked by different levels of salinity risk decrease significantly. Therefore, the method proposed can prevent an overestimation in predictions of soil cover degradation due to salinization. This is not to say that soil salinization cannot occur within areas marked by nil salinity risk. However, this possible salinization relates to other scale levels and should be indicated on more-detailed maps.

The method applied can be used to compile maps of soil salinization at other scales. To produce middle-scale maps of soil salinization, one must consider data on accumulation zones; to compile large-scale maps, one should use information on transit zones; and to produce detailed maps, one

Figure 119.3 Map of accumulation zones.

Figure 119.4 Improved map of salinity risk.

should apply data on dissipation zones. In all these cases, data on spatial distribution of accumulation, transit, and dissipation zones of the land surface can be derived from DEMs characterized by an appropriate resolution.

The method proposed can extend the use of DTMs in landscape investigations (Moore et al., 1991; Shary et al., 1991; Florinsky, 1998).

CONCLUSION

1. The following main principles should be taken into consideration in compilation of soil salinization maps: small- and middle-scale maps should represent relations between soil salinity and macro-depressions; salinization of meso-slopes should be shown on large-scale maps; salinization of micro-crests should be indicated on detailed maps.
2. The concept of accumulation, transit, and dissipation zones of the land surface can be applied to recognize depression, slope, and crest of different scales. Maps of accumulation, transit, and dissipation zones can be produced by linking K_a and H digital models derived from DEMs.
3. The small-scale map of the salinity risk index for the Canadian prairies and adjacent territories was compiled using existing data on soil salinity, DTMs, and the concept of accumulation, transit, and dissipation zones.

SECTION III.3

Aquatic Ecosystems: Lake Tahoe and Clear Lake, California

Overview: Aquatic Ecosystems: Lake Tahoe and Clear Lake, California

Dennis E. Rolston

Lake Tahoe and Clear Lake are two very important lakes in California, and each have very different characteristics from which lessons can be learned to aid in understanding and managing complex, multiple-stressed ecosystems. Clear Lake is an ancient, shallow, highly productive lake at an elevation of 395 m in an oak woodland–dominated northern Coast Range mountain watershed with rich habitats for breeding and migrating waterfowl, fish-eating birds, and mammals. The lake has a mean depth of about 7 m. Lake Tahoe lies in the crest of the Sierra Nevada mountains at an elevation of 1898 m and is located in a montane-subalpine watershed dominated by coniferous vegetation and nutrient-poor soils. It is a deep lake with a mean depth of 313 m. Each of these lakes has been studied extensively for a number of years.

This section consists of three chapters. The chapter by Suchanek et al. gives the history of various natural and anthropogenic stressors to the Clear Lake ecosystem and describes a holistic approach to understanding and managing the ecological health of this lake. It is one of the most comprehensive studies of the effects of multiple stressors on a well-defined ecosystem, and has contributed greatly to fundamental understanding of ecosystem function and dynamics. It represents an example of an interdisciplinary approach to studying ecosystem health.

The chapter by Cech, Choi, and Houck describes a specific study of the uptake of methyl mercury by one species of Clear Lake fish. Since mercury is one of the major contaminants in the lake, this study is important in understanding possible exposure pathways to birds and humans.

The chapter by Reuter et al. summarizes the history of various natural and anthropogenic stressors to the Lake Tahoe ecosystem and describes an integrated approach to studying the watershed. The decreasing transparency of the lake has been well documented by more than 30 years of data, and the chapter points out the need for long-term data sets to study complex systems. It also describes the necessary role that monitoring and fundamental research play in adaptive watershed management.

Evaluating and Managing a Multiply Stressed Ecosystem at Clear Lake, California: A Holistic Ecosystem Approach

INTRODUCTION

Clear Lake (Figure 121.1) and its watershed in Northern California constitute a serene and beautiful environment that has been used extensively by inhabitants of the surrounding basin for millennia. It has one of the oldest documented North American “early man” sites, with paleo-indian occupation of the Clear Lake Basin about 10,000 years before present (ybp) at Borax Lake, immediately adjacent to Clear Lake (Heizer, 1963). Native American settlement was relatively dense during European contact in the early 1800s, with about 3000 people scattered among 30 or so villages within the basin (Baumhoff, 1963). These people utilized the lake’s abundant fish, as well as tens of thousands of waterfowl and runs of native fishes in adjacent streams (Simoons, 1952) to supplement their staple acorn diet. Various named *Lupiyoma*, *Hok-has-ha*, or *Ka-ba-tin* by early Native Americans (Mauldin, 1960); *Big Waters* by some of the early European pioneers in the 1820s; *Laguna* for a short time by Spanish Californians in the 1830s; and finally, Clear Lake in the 1840s, this lake has had a long and fascinating history. European or American trappers first started visiting the lake seasonally in 1833, but more permanent agricultural settlers did not arrive until the 1850s (Simoons, 1952).

Volcanic activity in the area of the lake provided heat to drive hydrothermal systems that created rich mineral deposits. Almost immediately, settlers began to extract these minerals from the landscape. The first commercial mines were small-scale operations that exploited borax in 1864 and sulfur in 1865. Mercury mining became a significant industry with the development of the Sulphur Bank Mercury Mine in 1872. Beginning in the mid-1870s, abundant mineral springs attracted thousands of health-conscious citizens to the region (Simoons, 1952).

The population of Lake County has grown from approximately 3000 in 1860 to more than 55,000 in 1999 (Table 121.1). Associated with that population growth have come dramatic land-use changes, altering the watershed and limnological and ecological dynamics of Clear Lake. Today, the Clear Lake watershed basin includes a high proportion of forested land, oak woodlands, orchards and vineyards, other croplands, and little remaining original wetlands (Figure 121.2). Clear Lake is used for storage of agricultural irrigation water for downstream Yolo County. The Yolo County

Flood and Water Conservation District owns the rights to use the water in the lake and regulates the flow of releases from the single outlet dam to Cache Creek. The lake's rimlands and surrounding watershed also support extensive agricultural production, including pears, walnuts, grapes, and wild rice. The area supports breeding populations of several important bird species associated with the lake itself, including the western grebe (*Aechmophorus occidentalis*), Clark's grebe (*A. clarkii*), double-crested cormorant (*Phalacrocorax auritus*), great blue heron (*Ardea herodias*), osprey (*Pandion haliaetus*), and bald eagle (*Haliaeetus leucocephalus*). In addition, this aquatic setting supports many other species of birds associated with surrounding wetlands and uplands. It supports the only commercial fishery on a lake in California and extensive sport fisheries, especially for bass and catfish. Clear Lake is used heavily for water sports (swimming, boating, water skiing, jet skiing); thus, it attracts significant recreational tourism, especially during summer months.

This aquatic ecosystem has also been subject to multiple stresses, both natural and anthropogenic. It has experienced periodic flooding and fires and has lost over 85% of its original natural wetlands habitat. However, dam construction in Lake County has added approximately 6500 acres of impoundment water. The lake experienced increased nutrient loading and decreased water clarity between 1925 and 1938, likely due to the introduction of more-efficient heavy earth-moving equipment in the basin and the loss of original wetlands on the major tributaries (Richerson et al., 2000). By 1938, the lake had become too turbid for rooted aquatic vegetation to flourish and noxious cyanobacterial scums became a perennial problem (Lindquist and Deonier, 1943; Murphy, 1951). The lake also has elevated concentrations of mercury, among other contaminants; a U.S. EPA Superfund site is located on the eastern shore of Clear Lake at the former Sulphur Bank Mercury Mine. Clear Lake was also the first site at which the deleterious effects of large concentrations of organochlorine pesticides on bird populations were documented (original research reported by Hunt

and Bischoff [1960] and Rudd [1964], and popularized in Rachel Carson's *Silent Spring* [1962]). The lake contains a fish fauna comprised of over 75% introduced species. Clear Lake has been designated by the State of California as an "impaired water body" under Section 303d of the Clean Water Act, which mandates the state to identify water bodies or stream segments that currently are not meeting, or are not expected to meet, designated beneficial uses.

Managing multiple, frequently conflicting, uses of the lake and watershed is challenging; it involves ecological, economic, and political balances. Before rational management can be successful, however, managers must understand, to a useful approximation, the complex processes that drive the ecosystem's behavior. Our goal is to document the historical and modern-day multiple uses and multiple stresses associated with the Clear Lake aquatic ecosystem, including the lake proper and the surrounding watershed, in an attempt to demonstrate what rational management of this and similar valuable, multiply stressed ecosystems demands of applied science programs.

This chapter provides a prehistoric and historic background from which to evaluate the importance and impacts of a multitude of natural and anthropogenic stresses imposed upon Clear Lake and its watershed. Specifically, we identify major geological, climatological, ecological, political, and economic factors that influence the outcome of management and policy-level decisions on the health and well-being of the entire ecosystem, especially the lake proper. Natural stressors include geologic and tectonic events, regional and global climate change, fires, droughts, and floods. Anthropogenic stressors include:

1. Modifications to the landscape, including fires, logging and deforestation, dam construction, and other creek modifications
2. Contaminants, including pesticides, mining, sewage and septic overflows
3. Land-use changes, including original wetland losses (and some wet habitat increases, see previous) dredging, filling, and creek bed alterations, water table and shoreline modifications, road building, agriculture, soil exposure and transport, and livestock grazing
4. Intentional and accidental species introductions

Finally, we illustrate how scientific research has contributed significantly to addressing multiple management objectives in this extremely complex ecosystem.

NATURAL SETTING

Clear Lake (Figure 121.1) is located at 39°00' N, 122°45' W within Lake County in the Coast Range of California at an elevation of 402 m with surrounding ridges rising up to 1500 m. Through evidence from a series of cores to ~177 m maximum sediment depth, collected by the U.S. Geological Survey in the 1970s and 1980s, Clear Lake is believed to be the oldest lake in North America with continuous lake sediments of about 480,000 years (Sims, 1988; Sims et al., 1988). It also is possible that Clear Lake is a remnant of an ancestral lake represented by deposits of the Cache Formation, dating back to the early Pleistocene, making it 1.8 to 3.0 million years old (Casteel and Rymer, 1981; Hearn et al., 1988). The Clear Lake Basin represents a fault-bounded subsiding graben related to movement along the San Andreas Fault. The lake is set within an active volcanic region. Abundant geothermal springs release both fluids and gases (primarily CO₂, H₂S, and methane) from the lake bottom. Clear Lake is polymictic (typically well mixed), alkaline (pH 8), shallow (average depth about 6.5 m), and highly productive (eutrophic). Subsidence (caused by block faulting beneath the lake) has kept up with natural sedimentation. Thus, Clear Lake has been a relatively shallow lake since its initial formation, but at least parts of the current basin have been an open water system since the middle Pleistocene. Although early reports claim that "it derives its name from the clearness of its waters" (Menefee, 1873), and it may have been clearer in the 19th century than it is today, it was almost certainly a eutrophic system during the course of its entire existence (Bradbury, 1988). However, many recent land-use changes (described later) likely

have exacerbated sediment and nutrient loading to the lake, enhancing noxious cyanobacterial (blue-green “algae”) blooms (Richerson et al., 1994). In modern times, the lake supports populations of ~100 species of green and yellow-green algae and cyanobacteria, about 115 species of diatoms, 23 species of aquatic macrophytes, 94 species of invertebrates, and 34 species of fishes, plus numerous lake-associated or lake-dependent mammals such as otter, mink, raccoon, and numerous species of birds such as osprey, bald eagle, and grebes (Horne, 1975; Macedo, 1991; Richerson et al., 1994; Meillier et al., 1997; Moyle, 2002; Lake County Vector Control, unpublished).

NATURAL STRESSORS

Geologic and Tectonic Events

Two different hypotheses have been proposed for the origin of Clear Lake’s drainage route. Davis (1933) proposed that Clear Lake was originally two lakes separated by an isthmus at the Narrows: one lake essentially comprising the Upper Arm (which drained westward into the Russian River system via Cold Creek), and another lake comprising the present-day Oaks Arm and Lower Arm (which drained eastward via Cache Creek into California’s Central Valley and the Sacramento River) (Figure 121.1). A lava flow in the eastern drainage was believed responsible for forming a dike high enough to build up the water level in the eastern lake allowing water to overflow and cut through the narrow isthmus, thereby connecting the two lakes. The drainage flowed from the eastern lake to the Upper Arm and out Cold Creek into the Russian River system (Mauldin, 1968). Later, perhaps 10,000 ybp, an earthquake likely initiated a landslide in the Cold Creek drainage which blocked the westward flow, forcing the entire lake (both halves) to drain again into the Central Valley through Cache Creek. Alternatively, Becker (1888) and Brice (1953) argue that Clear Lake occupies the lowest part of a shallow fault depression. Hodges (1966) later concurred with this hypothesis and proposed that Scotts Creek formed a fan delta and clogged the western outlet valley of Cold Creek with fluvial debris; thus Cache Creek remained the only outlet. In either case, fish from the Central Valley colonized the Russian River system and there was some speculation that the reverse might have occurred as well (Hopkirk, 1973, 1988).

Regional and Global Climate Change

California’s climate has been undergoing dramatic and continuous change over the past 100 years. This change is coincident with documented global climate change over the same time period (Mann et al., 1999; Hileman, 1999); yet it is uncertain how changes in regional climate are linked to more global processes. In California, the coefficient of variation in rainfall and the frequency of 1000-year storm events has been increasing dramatically over the past century (Goodridge, 1998; Figure 121.3). In addition, the frequency of El Niño events has become unusually common in recent years (Trenberth and Hoar, 1997) and this likely is linked with much of the fluctuation in regional and global climatological events at Clear Lake. Furthermore, if global warming enhances El Niño events, for which there is growing evidence (Meehl and Washington, 1996), then California’s climate over the next several decades may look like an amplified version of the extreme events that have taken place over the past several decades (Field et al., 1999).

Fires

The Mediterranean climate and vegetation of this region are naturally conducive to fire. The change in regional weather described above also may contribute to an increase in large fires. Lightning is a common cause of fires in this region and although we do not have documentation of fire origins, especially before European contact, we do have moderately accurate records on the

Figure 121.3 Regional California climate changes over the past century showing dramatic increases in the coefficient of variation in rainfall and increase in the frequency of 1000-year storms. (Adapted from Goodridge, J., The impact of climate change on drainage engineering in California, Report to the Alert Users Group Conference in Palm Springs, CA, 26–29 May, 1998.)

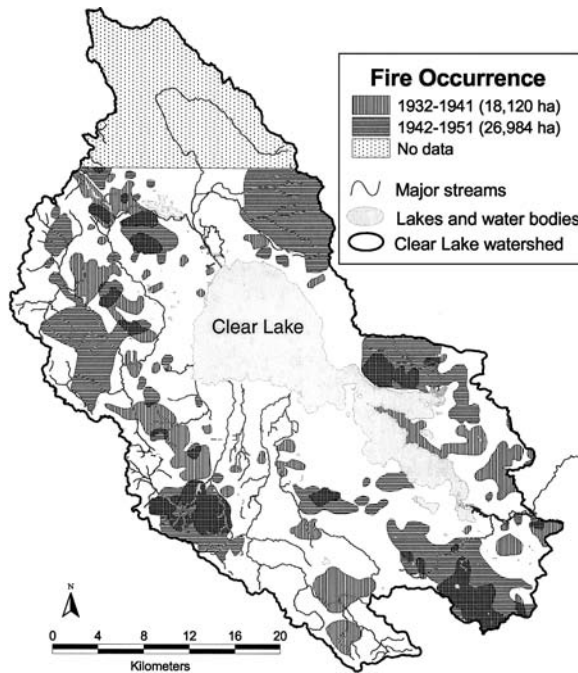

Figure 121.4 Location of fires in the Clear Lake Basin from 1932 to 1951. (Adapted from Simoons, F.J., The Settlement of the Clear Lake Upland of California, Master’s thesis, University of California, Berkeley, 1952.)

extent of fires in these watersheds since the turn of the century (see Figure 121.4). It has been estimated that in more modern times (1960s to 1980s) lightning accounted for only about one third of all forest fires (West, 1989).

Droughts and Floods

Short- to medium-length droughts have been documented in the historical record of California. A significant 3-year drought (1975 to 1977), and 6- to 7-year droughts during recent (1987 to 1992) and historical (1928 to 1934) periods lowered the lake level substantially (see Figure 121.5). Tree ring data from California back to the 1500s suggest decade-scale droughts (Earle, 1993). More substantial 46- to 140-year-long droughts (before A.D. ~1350) and >200-year-long droughts (before A.D. ~1112) also have been documented in California by dating submerged tree stumps (Stine, 1994). The most comprehensive understanding we have on how such droughts can impact ecological and limnological processes in and around Clear Lake comes from a 24-year Department of Water Resources water quality data set (1969 to 1992) that includes the 1975 to 1977 and 1987 to 1992 droughts. An analysis of those data by Richerson and co-workers (1994) shows that the drought period correlated strongly with some moderate increases in pH and Secchi disk readings (water clarity) during the longer drought in the Oaks Arm and Lower Arm of Clear Lake (but not necessarily the Upper Arm or during the shorter drought) (Figure 121.6A). In addition, dramatic increases in water column phosphorus (especially dissolved phosphorus) and electrical conductivity have been observed in all three arms (Figure 121.6B), especially during the longer 1985 to 1992 drought. Interestingly, during the past 3 years (1998 to 2000) Clear Lake has exhibited exceptional water clarity (high Secchi disk readings) during nondrought conditions. Clear Lake also has experienced one of the most severe seasons of cyanobacteria (blue-green “algae”) blooms in recorded history toward the end of these documented drought periods (Figure 121.7), likely because of increased sediment phosphorus releases.

With increasing frequency of 1000-year storm events resulting from regional climate change (see previous), there also is increased risk from natural flooding to lakeside real estate and public utilities, and additional risk of increased sedimentation, nutrient inputs, and acid mine drainage from the local Sulphur Bank Mercury Mine (discussed later). Figure 121.5 provides documented water levels (high and low water) for Clear Lake relative to a baseline depth of “0 ft Rumsey” (which is equivalent to 1318.256’ 1929 National Geodetic Vertical Datum, NGVD) originally established in 1872. Flooding also has increased recently, and the winter of 1997 to 1998 produced the highest recorded lake levels since the emplacement of the Cache Creek dam in 1914 (Figure 121.5).

Figure 121.5 Clear Lake water levels (annual minimum and maximum) relative to the Rumsey scale.

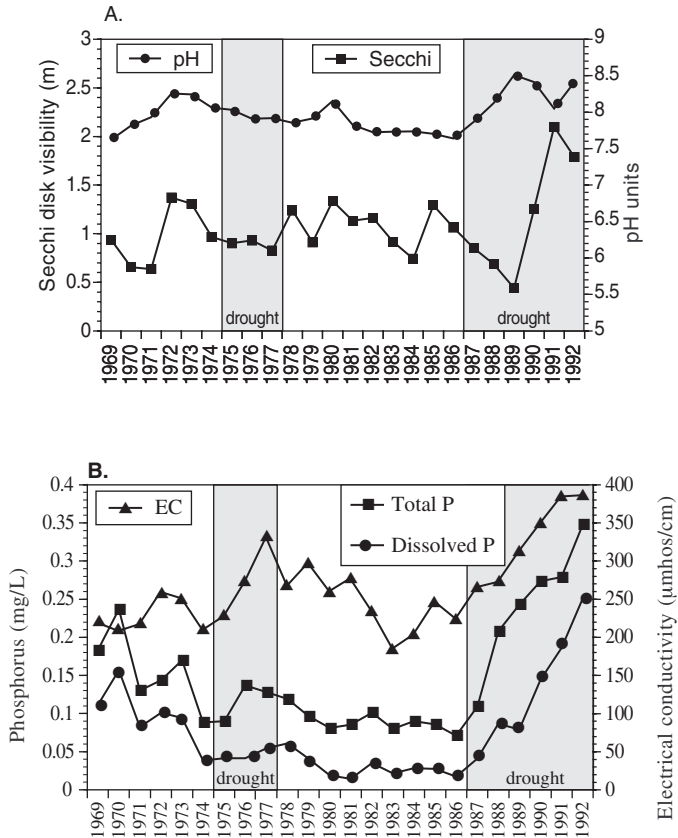

Figure 121.6 A 24-year data set (1969 to 1992) of limnological conditions within the Lower Arm of Clear Lake showing dramatic changes associated with the drought from 1987 to 1992 (A) Water quality as quantified by Secchi disk values and pH readings (B) Phosphorus and electrical conductivity values. (Adapted from Richerson, P.J., T.H. Suchanek, and S.J. Why, *The Causes and Control of Algal Blooms in Clear Lake*, Clean Lakes Diagnostic/Feasibility Study for Clear Lake, California, prepared for EPA Region IX, 1994.)

ANTHROPOGENIC STRESSORS

Modifications of the Landscape

Fires

Often it is difficult to discriminate between natural and anthropogenic causality for fires. Humans set fires, but also attempt to control them; yet, both processes impact natural ecosystem dynamics. It is likely that pre-Spanish fires in the Coast Range were relatively frequent (10 years or less) (West, 1989). When Europeans first settled the basin during the mid-1800s, widespread intentional burning was common. Herdsmen intentionally burned brush on such a large scale to graze sheep, goats, and cattle that California state legislation was passed in 1872 making fire-setting in wooded or forested lands illegal; yet, this had little impact on burning (Simoons, 1952). These activities were many more times as destructive as lumbering (discussed later). Early European settlers set fires primarily for three reasons: (1) to encourage grass growth for spring feed, (2) to burn needles in coniferous forests to prevent accumulations that would cause unplanned catastrophic fires, and (3) to improve deer feed. While lightning is often the cause of modern fires, anthropogenically

Figure 121.7 Volume of three species of scum-forming cyanobacteria (blue-green “algae”) over a 24-year period (1969 to 1992) in the Lower Arm of Clear Lake. Note especially the abundance of *Microcystis* at the end of the drought period, a particularly buoyant species that drifts into shore and accumulates in large windrows, then dies, lyses, and creates noxious odors which affect shoreline aesthetics. (Adapted from Richerson, P.J., T.H. Suchanek, and S.J. Why, *The Causes and Control of Algal Blooms in Clear Lake*, Clean Lakes Diagnostic/Feasibility Study for Clear Lake, California, prepared for U.S. EPA Region IX, 1994.)

mediated fires are now more likely caused by accident or by arson rather than as a deliberate attempt to manage the landscape using fire. The two main watersheds that provide over 50% of the inflow to Clear Lake (Scotts Creek and Middle Creek) have experienced numerous natural and anthropogenically influenced fires. An example of fires documented during the periods from 1932 to 1941 and from 1942 to 1951 (adapted from Simoons, 1952), as well as more-recent fires within the Scotts Creek and Middle Creek watershed, are shown in Figure 121.4 and Table 121.2. As elsewhere in California, control practices probably make fires fewer and less frequent, but more devastating when they do occur because of increased fuel accumulation. For example, the “Forks Fire” decimated over 86,000 acres just north of Clear Lake in 1996, including about 12,600 acres in the Middle Creek watershed that drains into Clear Lake.

Logging and Deforestation

Major modifications of the forested landscape by Mexican and American ranchers began as early as the 1840s. In the 1850s some of the landscape was cleared for orchards, vineyards, and especially for timber harvest. The most significant timber harvest was Douglas fir (used for mine timbering), sugar pine, and Ponderosa pine (used mostly for lumber) and oak for fuel (Simoons, 1952). Much of this wood was used as fuel for the borax and mercury mining operations (see below). By 1870, no fewer than five commercial sawmills were operating on the lake; by 1905, there were 11 mills that processed over 1.5×10^6 board feet of lumber annually, and in 1946 more

Table 121.2 Acres Burned by Fires in the Middle Creek Watershed during the 20th Century

than 11×10^6 board feet was processed (Simoons, 1952). As a result of forest removal and soil exposure, sediment transport probably increased into Clear Lake, depositing additional entrained nutrients into the system. Nevertheless, this exploitation was not severe enough to be apparent in the pollen record of Clear Lake as deduced from sediment cores (Richerson et al., 2000).

Dam Construction

The Clear Lake dam along Cache Creek was completed in 1914 for the purpose of regulating agricultural irrigation waters to downstream Yolo County, which owns the rights to Clear Lake water (discussed in Richerson et al., 1994). An earlier dam at Clear Lake’s outlet (about 2.5 km upstream of the present dam) was first constructed in 1867 to increase water levels to operate a mill at that end of the lake, but was destroyed in 1868 by about 300 angry rimlander property owners who were getting flooded during periods of heavy rain. This is one of the most colorful accounts of Clear Lake history, when a vigilante group took into custody several individuals (including the sheriff, his deputies, the county judge, the superintendent of the mill works, and other prominent citizens) who appeared sympathetic to the dam’s owners and operators (Anon.,

1881). A pumping station was installed in this same location around 1910 to increase water flow to irrigate rice crops in downstream Capay Valley, but that station also was intentionally destroyed about 1912. Numerous other dams have been erected within the Clear Lake watershed from 1955 to 1980, primarily for irrigation or recreation purposes (see Figure 121.1 for locations). All of these dams have slowed and altered natural flow of waters from the watershed to Clear Lake and may have prevented some species of Clear Lake fishes (such as the Clear Lake splittail, *Pogonichthys ciscooides*) from migrating upstream to spawn (Moyle, 2002). While there was the potential for increased flooding as the result of the construction of the Clear Lake dam, ironically lake levels have been significantly lower (see Figure 121.5) since the construction of the Cache Creek dam in 1914. Other dams higher up in the watershed have water-holding capacity that lowers flooding risks, and they likely have contributed to the lowered lake levels mentioned previously. They also retain sediments and nutrients that have the potential to become deposited into Clear Lake and thus help to limit eutrophication in the lake.

Other Creek Modifications

Lowering of Cache Creek

The Clear Lake outlet through Cache Creek was deepened in 1938 to accommodate more efficient agricultural irrigation, although further work was halted by a suit filed by a citizen's group.

Kelsey Creek Downtcut

In 1965, the delta of Kelsey Creek was dredged to accommodate the installation of a marina. This caused destabilization of the creek bed, providing increased erosional products to be transported into Clear Lake. This increased deposition appears to be recorded in sediment cores from the region of the lake immediately offshore from Kelsey Creek and is represented as apparent increased sedimentation rate during the period starting ca. 1965 (see Suchanek et al., 1997; Richerson et al., 2000).

Contaminants

Aquatic Pesticides

Pesticide applications in Clear Lake have been used primarily to eradicate insects (the Clear Lake gnat *Chaoborus astictopus*) and emergent macrophytes (the exotic and prolific aquatic weed *Hydrilla verticillata*).

In the 1940s, the Clear Lake gnat (at larval densities of 640 larvae per square foot of lake bottom) was creating a serious aesthetic nuisance; while the adult gnats are nonbiting, they would aggregate in huge clouds around the lake's rimlands (Dolphin, 1959). University of California researchers had studied the gnat biology and possible control from 1916 to 1936, and in 1938 Congress appropriated funds to the Department of Agriculture (USDA) for further study of the gnat and its control. The USDA and the California Department of Fish and Game began lab treatment studies in 1945 to 1946 and field trials in 1947. The Lake County Mosquito Abatement District (which became the Lake County Vector Control District in 1995) was created in 1948 to deal with this problem. To reduce populations of the gnat, the California Department of Health Services contributed to funding three large applications of dichloro diphenyl dichloroethane (DDD), about 4×10^4 gal of 30% DDD per treatment in Clear Lake: in 1949, 1954, and 1957 (Dolphin, 1959; Hunt and Bischoff, 1960; Rudd, 1964; Cooke, 1981). DDD was added in extremely high concentrations (Clear Lake water contained ~0.02 ppm DDD) and resulted initially in 99% kill of the gnat larvae in sediments, although the effectiveness of this kill rate declined in future years (Hunt and Bischoff, 1960). Additional treatments of DDD also were applied to 20 other small lakes and reservoirs within about 25 km of Clear Lake.

Unfortunately, it also killed many other benthic invertebrates and had a devastating impact on the resident breeding populations of the western grebe (*Aechmophorus occidentalis*) (Herman et al., 1969). Five years after the initial DDD applications (in 1954), over 100 grebes were found dead in one survey season; in 1957, another 75 dead grebes were documented. No disease was identified, but in 1957 analyses of grebe fat tissues revealed extremely high concentrations of DDD (1600 ppm). In 1958, Clear Lake fishes finally were collected and also found to have excessively high DDD concentrations (40 to 2500 ppm); the largest concentrations were found in brown bullhead (*Ameiurus nebulosus*), largemouth bass (*Micropterus salmoides*), and black crappie (*Pomoxis nigromaculatus*). In addition, there was a substantial crash of the breeding grebe populations. Prior to 1949, over 1000 nesting pairs were estimated at Clear Lake. In the period 1958 to 1959, there were fewer than 25 pairs observed, but none was nesting; and at the end of that season no fledglings were found (Hunt and Bischoff, 1960). Concentrations of DDD in plankton were about 265-fold higher than the water in which they were found, about 500-fold higher in small fishes and ~80,000- to 85,000-fold higher in predaceous birds (grebes) (Lindquist and Roth, 1950; Rudd, 1964). This was the first identification of the process of pesticide bioaccumulation in food webs and the phenomenon of delayed expression of toxic symptoms among biological concentrators of pesticides (Carson, 1962; Rudd, 1964). Interestingly, the period when the western grebe populations were declining (1950s) was the same period during which the last major mercury mining was taking place at the Sulphur Bank Mercury Mine. Yet no one has investigated the possibility that mercury also played a significant role (additively or synergistically) in the decline of the western grebe populations. We (DWA and THS) are in the process of evaluating museum specimens of western grebes collected from Clear Lake during this era to determine whether mercury levels also were elevated. The signal of residual DDD within Clear Lake sediments from this period is so prominent that it also has been used as a dating tool (Chamberlin et al., 1990; Suchanek et al., 1993, 1997).

Within a few years, DDD applications were ineffective in reducing gnat populations, likely because the insects became resistant to the pesticide (Apperson et al., 1978). As a result, a series of other insecticide compounds (including EPN, parathion, dicapthion, methyl trithion, methyl parathion, 2,4-dimethyl menzyl ester of chrysanthemumic acid, barthrin, trithion, Co-ral, DDVP, delnav, diazinon, dylox, ethion, guthion, korlan, malathion, phosphamidon, phostex, and sevin) were used in laboratory tests for their efficacy in killing the *Chaoborus* gnat, but most were never used in Clear Lake proper (Dolphin and Peterson, 1960). Because of the strong resurgence of the gnat populations, two stop-gap measures were implemented in 1959 (Dolphin and Peterson, 1960). The first involved spraying a petroleum product (Richfield Larvicide™) on gnat eggs located on 5500 acres of rafts of drifting debris material along the shorelines of Clear Lake. The other stop-gap measure involved the spraying of malathion to tree and shrub resting areas of adult gnats. In 1962, three applications of methyl parathion were made to Clear Lake (at a concentration of 3.3 ppb), which effectively controlled *C. astictopus*. Methyl parathion was subsequently applied each summer from 1962 to 1975, at which point the treatments failed to control the gnat which had, once again, developed a resistance.

Hydrilla verticillata (see more documentation under introduced species) has become an aggressively growing nuisance macrophyte since about 1994. Beginning in the summer of 1996, annual efforts to control and eliminate this weed have been undertaken primarily using two aquatic herbicides, Komeen™ (copper sulfate), which acts on the emergent vegetation, and SONAR™ (fluridone), which acts on the tubers and is intended to stop production of propagules. Because copper is applied in relatively high concentrations locally, and because mercury is an ongoing contaminant in Clear Lake, it is valuable to understand the interaction of copper and mercury on aquatic biota. Only one formal study has undertaken the task of evaluating the impacts of the multiple contaminants mercury and copper on Clear Lake zooplankton (Gilmartin, 1998; Gilmartin et al., 1998). These preliminary results indicate that copper and mercury act independently (i.e., additively) with respect to their effects on zooplankton behavior and reproduction.

Finally, there are many private (i.e., homeowner) uses of pesticides that are not subject to pesticide use reporting. Several over-the-counter pesticide products are available without a permit (defined as

an operator identification number in pesticide use law) and are not regulated by California Pesticide Use Reporting requirements. These pesticides have the potential to enter Clear Lake waters, but no studies have quantified their importance, either from a loading or impacts perspective.

Terrestrial Pesticides

While the human population in the Clear Lake Basin has increased over the past century, so too has the conversion of the landscape to agricultural production (discussed later). The widespread use of highly toxic organophosphate and organochlorine pesticides (OPs), mostly in the lake (e.g., DDD, see previous) has been reduced dramatically over the past 50 years. However, intimately associated with high agricultural production, and particularly with some of the high value crops, has been an increase in the use of pesticides to increase crop yield and ensure crop quality. Since many of the orchards and vineyards surround the lake or eventually drain into the lake, it is important to evaluate whether the use of such xenobiotics may affect the ecology of the watershed. Figure 121.8 illustrates trends of the ten highest use categories of pesticide application, and Figure 121.9 provides trends on the application of the top 10 of the approximately 165 most-heavily used pesticides in Lake County between 1990 and 1998 (California Department of Pesticide Regulation, 1990 to 1999).

Nearly 1 million pounds annually of various petroleum and mineral oils are used primarily on pears (to delay or discourage egg laying by psylla or to smother mite eggs and in some cases codling moth eggs). On rare occasions, oils are used on grapes. During the application of dormant and emergent sprays, these oils often are used simultaneously with some organophosphate pesticides (usually during summer). Currently, alternative approaches to control codling moth involve the use of pheromone mating disrupters, especially when the density of moths is relatively low (Elkins and Shorey, 1998; Bentley et al., 1999). The second most heavily used product, which is not acutely toxic to humans or wildlife at low doses, is sulfur and lime-sulfur. The primary use of these compounds has been as

Figure 121.8 Annual cumulative pesticide applications for the top ten crops and uses in Lake County from 1990 to 1998 (by weight). (A) Total pesticide applications for the top five crops (by weight). (B) Total pesticide applications for the second five crops with the heaviest pesticide applications (by weight).

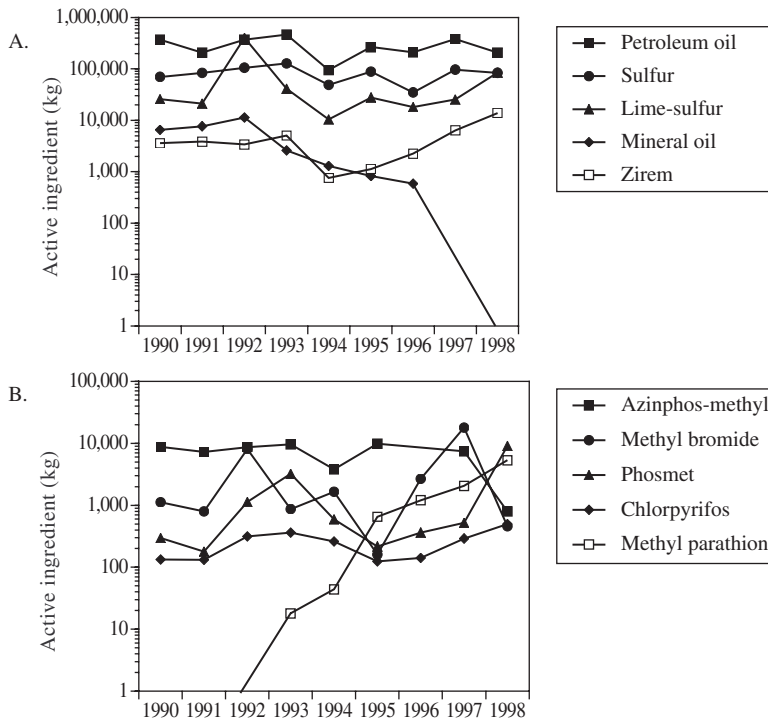

Figure 121.9 Annual pesticide applications for the ten most heavily used pesticides in Lake County from 1990 to 1998 (by weight). (A) Total applications for the top five pesticides. (B) Total applications for the second five most heavily applied pesticides.

fungicides on vineyards for protection against powdery mildew. While not highly toxic, the high application rates have the potential to increase sulfur loading into the lake, which also may interact with sulfate-reducing bacteria in the conversion of inorganic mercury to methyl mercury. However, no studies have been conducted to determine the origin of sulfur compounds in Clear Lake.

Although the four most widely used pesticides have a low environmental risk (both acute and chronic), the use of more-toxic compounds is still widespread. Examples of this have been the two most heavily applied broad-spectrum OPs, methyl parathion and azinphos-methyl (Guthion) (see Figure 121.9). Methyl parathion increased dramatically from approximately 30 lbs in 1993 to nearly 12,000 lbs in 1998, mostly for use against codling moth. Guthion, on the other hand, has seen nearly constant usage from 1990 to 1998, when usage dropped significantly, mostly because codling moth began to show signs of resistance. Due to the U.S. EPA's recent restrictions on methyl parathion residues, and a ban against its use after 1999, we expect to see a rise in Guthion rates in response, although recent restrictions on Guthion will likely keep its use low as well. Although the use of these insecticides is high, their potential ecological impact is somewhat offset by the fact that they have relatively short environmental persistence. Both compounds have terrestrial half-lives from 3 to 16 days, and aquatic half-lives of 1 to 6 days. This significantly reduces their risk to wildlife, unless large amounts are used near the lake as fish and aquatic invertebrates are particularly sensitive to these compounds. Nevertheless, additional research is needed to determine whether terrestrial pesticides are being transported into Clear Lake and, if so, what their potential impacts to the aquatic community might be.

MTBE

Methyl tertiary butyl ether (MTBE), a synthetic chemical *oxygenate* added to gasoline to improve air quality as required by the Clean Water Act, had been used in gasoline in limited

quantities since the 1970s. It is considered a possible human carcinogen. It is highly soluble in water and does not readily degrade in the environment; most public water systems are not equipped to remove it completely from drinking water. It has a turpentine-like taste and smell, and initial studies show that some people can detect it in drinking water at concentrations as low as 2.5 ppb. In 1992, oil companies began using it extensively, and in recent years it has been detected in Clear Lake water. A 1998 University of California study indicated that there are significant risks and costs associated with water contamination due to the use of MTBE. In addition, it found that the use of gasoline containing MTBE in motor boats and crafts, in particular those with older two-stroke engines, results in the contamination of surface water reservoirs. In January 1999, the California Department of Health Services established a secondary (taste and odor-based) maximum contaminant level (MCL) allowable standard of 5 ppb, and a primary human health-based MCL of 13 ppb in May 2000. In March 1999, Governor Gray Davis issued an Executive Order for California to phase out the use of MTBE by 2003, and legislation to ratify the order (Senate Bill 989) was passed during the 1999 session. In March 2000, the federal government announced it would ban the use of MTBE under the Toxic Substances Control Act.

Some water samples collected from various locations within Clear Lake have detectable levels of MTBE, but those levels were always lower than the MCL for taste and odor. Nine of 53 Lake County water samples collected from January 1984 to December 1999 showed detectable MTBE concentrations. Of those 53 samples, 23 were collected within Clear Lake proper and 8 of those 23 showed a range of MTBE concentrations of 1.1 to 4.5 ppb. These values are below the taste and odor MCL standard of 5 ppb and significantly below the human health-based standard of 13 ppb, now in effect.

Mining

Clear Lake has contributed significantly to mining operations within the U.S. In 1864, this region was the first location to be mined for borax within the U.S. (Bailey, 1902), and a year later California's first sulfur was extracted from a surface deposit of elemental sulfur called the Sulphur Bank Mine (California Division of Mines, 1950). The deeper deposits of sulfur from this site were contaminated with cinnabar (mercury sulfide), and in 1872 the site was converted to mercury mining as the Sulphur Bank Mercury Mine. At that time California accounted for 89% of the nation's mercury production and the Sulphur Bank Mercury Mine produced about 10% of California's total mercury output (Simoons, 1952). Because of elevated concentrations of mercury in fishes first documented during the 1970s (Curtis, 1977), the Sulphur Bank Mercury Mine was placed on the U.S. EPA's National Priority List as a Superfund site in 1990 (Suchanek et al., 1993).

Mining at the Sulphur Bank Mercury Mine is believed to have contaminated the lake with both mercury and arsenic (Sims and White, 1981; Chamberlin et al., 1990; Suchanek et al., 1993, 1997). Inorganic mercury concentrations in lake bed sediments are significantly elevated (over 400 ppm) close to the mine and decline exponentially with distance from the mine (Suchanek et al., 1997, 1998a, 2000b). Arsenic is only slightly elevated close to the mine, but also exhibits a recognizable background signal throughout the lake, likely as a result of outflow from numerous lakebed springs (Suchanek et al., 1993). Since 1992 detailed studies have been conducted on mercury contamination from the Sulphur Bank Mercury Mine (Suchanek et al., 1993, 1995, 1997, 1998a,b, 2000a,b; Anderson et al., 1997; Mack et al., 1997; Slotton et al., 1997; Webber and Suchanek, 1998; Wolfe and Norman, 1998). Research at this site has identified acid mine drainage, which is low in pH and high in sulfate, as the most likely point source for methyl mercury contamination in Clear Lake (Suchanek et al., 1993, 1997, 2000b; Nelson et al., unpublished). Remediation of the mine is expected to begin around 2003.

Other mining operations have been widespread throughout the Clear Lake Basin. Figure 121.10 provides a location map for the diverse array of mining operations that have existed within this watershed over the past 150 years. With the advent of home and especially road

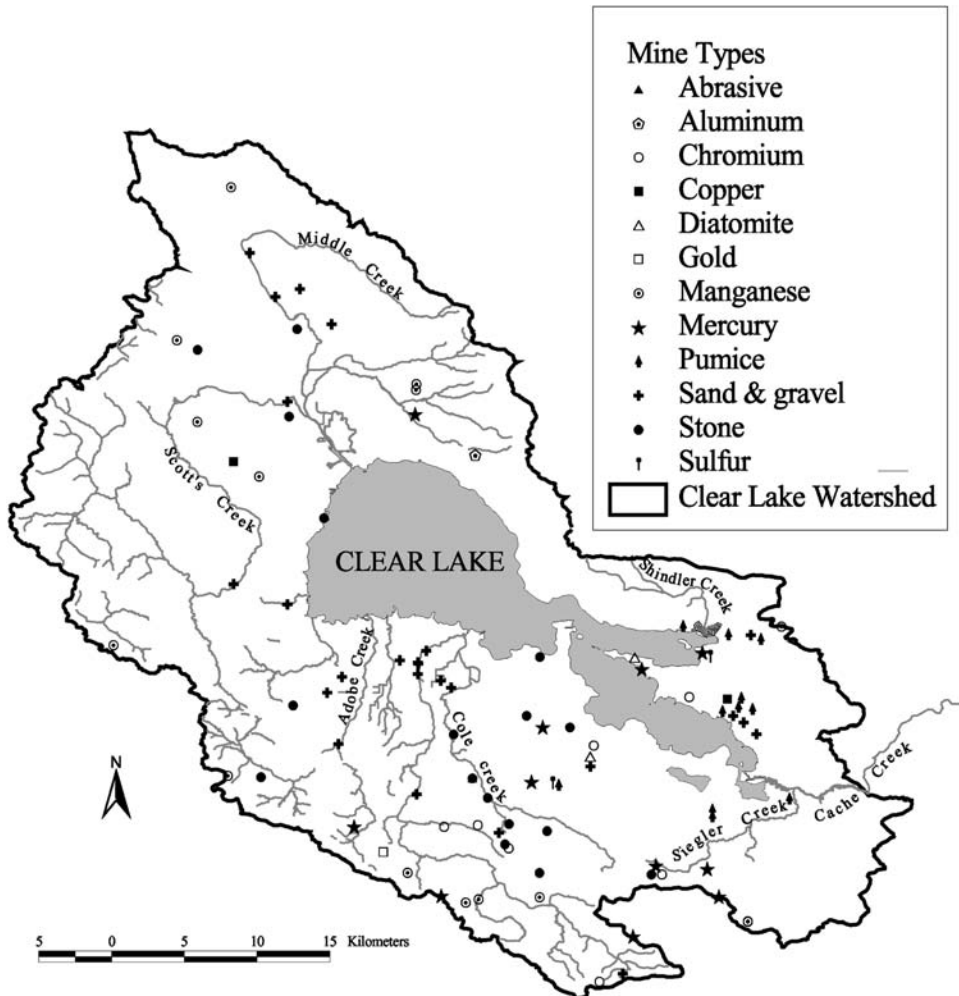

Figure 121.10 Map of mining operations within the Clear Lake watershed over the past 150 years.

construction in the early 1970s, Lake County needed an easily accessible source of gravel as road base. Creek beds provided this resource; thus large volumes of gravel were extracted from Scotts Creek, Middle Creek, Kelsey Creek, Adobe Creek, Forbes Creek, Cole Creek, and Burns Valley Creek (see Figure 121.10). Gravel mining, which was common until 1987 (Zalusky, 1992), changed the level of stream beds as much as 15 ft and caused destabilization and increased erosion during the next flooding season, carrying higher loads of sediments and associated nutrients into the lake. Additionally, roads now block upstream areas that once were used for spawning (e.g., hitch). Volcanic cinder cones also have been mined as a source of aggregate and decorative rock, but the environmental impacts have been relatively small compared with mining in active stream beds. Mining operations that are still active include primarily sand and gravel, cinders, and decorative stone and rock.

Sewage and Septic Overflows

Although there have been many sewage overflows, especially during major flooding periods, this probably does not represent a significant nutrient loading to Clear Lake (see Richerson et al., 1994, for discussion).

Land-Use Changes

Wetland Losses and Gains

Original natural wetland acreage around the rimland of Clear Lake declined by nearly 85% from about 9000 acres in 1840 to about 1500 acres in 1977 (Table 121.3). One of the most dramatic land-use changes experienced within the Clear Lake watershed has been the process of wetland conversion to agriculture. Beginning in the 1890s, a large area of natural wetlands from the Robinson Lake and Tule Lake region in the northwest side of Clear Lake was reclaimed primarily for agricultural production of string beans and lima beans (Simoons, 1952). This was followed by another reclamation project in 1927 in the Middle Creek watershed for agricultural production, and the 1959 Rodman wetland reclamation by the Army Corps of Engineers. These projects collectively increased agricultural production, but also altered the transport of sediments and associated nutrients into Clear Lake, with the likely result that noxious cyanobacteria (blue-green “algae”) blooms significantly increased beyond previous levels (Richerson et al., 1994). Wetland reclamation is not unique to Clear Lake; it is a process that was similarly initiated in the late 1800s throughout the country, and especially in the San Francisco Bay–Delta system where 79% of the marshlands have been lost in the last 200 years, and over 538,000 acres were converted to agricultural land (Monroe et al., 1999).

There are several categories of newly created water bodies or wetland habitats, including sewage treatment ponds, agricultural ponds, irrigated crops (such as rice), or pastures and reservoirs, which can have both positive or negative feedbacks to the Clear Lake ecosystem. For example, several tracts of original wetland habitat, such as Tule Lake, are now in rice production. These habitats are managed by flooded irrigation practices, so for much of the year they are functional wetlands and enhance populations of some invertebrates, which in turn provide food resources for some wildlife. These practices can both enhance wildlife and produce potential problems for disease vector agents such as mosquitoes. Some of the more recently created reservoirs can also be beneficial in trapping sediments with associated nutrients before they enter Clear Lake, which would also help to limit nutrient loading. However, we are not aware of any studies that have compared the functionality of original vs. newly created wetlands for any of these categories.

The intrinsic ecological values, in terms of biodiversity and natural filtering capacity of wetlands, have now become more recognized, and a trend to restore and rehabilitate previously reclaimed wetlands has been popular in recent years. At present, reclaimed former wetlands in both the San Francisco Bay–Delta system and the Clear Lake system are being considered for wetland restoration and rehabilitation. In the case of Clear Lake, the Army Corps of Engineers has completed a Reconnaissance Phase and is currently in the Feasibility Phase of a plan to restore up to 1200 acres of wetlands in the Robinson Lake/Middle Creek region of Clear Lake (Jones and Stokes, 1997; Smythe, 1997; Van Nieuwenhuysse, 1997).

Table 121.3 Wetland Loss in the Region Surrounding Clear Lake

Year	Acres	% of 1840 Acreage
1840	9000	100
1920	5400	60
1952	5300	59
1958	5200	58
1966	3400	38
1968	1900	21
1977	1500	17

Dredging and Filling

Over the past 150 years, vast areas around the rimland of Clear Lake that previously were wetlands have been filled or converted to either private, commercial, or public use (for homes, businesses, or roads), especially in response to the population increase after about 1925. These projects also tended to deliver large volumes of sediment and nutrients to Clear Lake (Richerson et al., 1994). The residential subdivision of Clearlake Oaks (known as the Keys) resulted in the extensive dredging of wetlands during the 1960s, and in the generation of about 6.5 miles of navigable channels. Other similar developments include Corinthian Bay and Lands End. For other smaller projects, these sometimes subtle yet continuous changes have been the most difficult to document, for there are few records that quantify conversion of small- to medium-sized areas of wetlands, especially before the turn of the 20th century.

Within the past 5 years there has been a movement by one citizens' group to dredge Clear Lake to a depth of about 60 ft (about 18 m) or more, with the stated purpose of generally "improving water quality," but without any documented specifics. Because the average depth of Clear Lake in most locations is 8 to 10 m, this would involve dredging another 9 m deeper. This concept is fraught with problems, not only economic, but ecological as well. Because relatively high concentrations of mercury and pesticides (DDD) are buried in the sediments of Clear Lake (especially within the top 60 to 70 cm) (Suchanek et al., 1993, 1997; Richerson et al., 2000), these materials would have a high probability of becoming remobilized into the water column and bioaccumulated into the trophic web in the course of dredging. Another problem with increasing the depth of Clear Lake to 60 ft is related to the issue of summer water column stratification. Most deep lake systems undergo temperature and oxygen stratification during the summer, whereby a temperature discontinuity (thermocline) is formed in the water column with an associated water mass at the bottom (hypolimnion) that has dramatically different physical and chemical characteristics from the surface water mass. This hypolimnion is typically cooler and is much more likely to be anoxic than surface waters. Clear Lake's present depth creates a situation in which bottom waters (near the sediment–water interface) occasionally become anoxic, but this condition does not typically last long because of wind-driven mixing. If the lake were significantly deeper, this anoxic condition would persist for long periods of time, perhaps months. This is exactly the condition under which sulfate-reducing bacteria flourish. As this microbial group has been implicated in the conversion of inorganic mercury into toxic methyl mercury, a deeper lake would most likely promote a higher production of toxic methyl mercury in the bottom waters. Winter turnover of the water column would allow this methyl mercury to be remobilized and potentially bioaccumulated by organisms in the lake. Because mercury is already an issue of great concern in Clear Lake, any changes that would promote further methyl mercury production would be undesirable. Nevertheless, such proposals point to the need for ongoing studies and monitoring to understand how natural and anthropogenically mediated processes may influence the complex dynamics imposed by multiple stresses on this ecosystem.

Creek Bed, Water Table, and Shoreline Modifications

The lower reaches of Clear Lake hitch (*Lavinia exilicauda*) spawning streams have usually dried up naturally, but due to groundwater extraction, these areas dry up earlier, resulting in spawning failures; additionally, the loss of marshy wetland areas surrounding the lake limits the habitat available to larval hitch.

Agriculture

Private fruit and nut orchards were planted early (around 1860) within the Clear Lake Basin with the production of pears, plums, prunes, apples, almonds, peaches, nectarines, and grapes, and commercial orchards started in the 1880s (Simoons, 1952). Figure 121.11 provides estimates

Figure 121.11 Trends in conversion of landscape to agriculture in the Clear Lake Basin. *Note:* No data available for hay, corn, wheat, and barley after 1910; no data on walnuts and grapes before 1920; no data on grapes before 1880.

of acreage planted in the top five crops and orchards since the early 1900s, when reasonably accurate records were first kept. Much of the increase in wetland reclamation was driven by a desire to convert rich, easily irrigatable soils into profit-making tracts of land. The types of crops grown were driven, to a large degree, by market value. At present, wine has made a significant resurgence in the marketplace and a large movement to convert existing orchards (especially walnut orchards) into grape production is under way. Over the past 10 years, the land area committed to growing grapes has increased dramatically from about 2500 acres in 1989 to 7000 in 1999, with no immediate end of the surge in sight (see Figure 121.11). During at least the first 2 years of the establishment of a vineyard (before any ground cover can be established), there is the potential for sheet wash erosion to transport large volumes of sediment and associated nutrients into Clear Lake. This potential problem can be reduced by the early establishment of a ground cover crop that will help stabilize the soil. While this is a topic of considerable debate within the agricultural and environmental community in Lake County, to date we are unaware of any specific studies that have quantitatively addressed the impacts of vineyards or orchards on erosion within the Clear Lake Basin.

Cattle and Sheep Grazing

The first cattle (initially Longhorn, then many other breeds including Shorthorn, Hereford, Polled Hereford, Angus, and Scotch Highland) were brought to the Clear Lake area in 1839, and their grazing impacts on the landscape increased thereafter (Mauldin, 1968). Richerson and co-workers (2000) discuss some of the early farming and ranching practices. Sheep herds were abundant and peaked sharply in the late 1870s at about 50,000 head; declined dramatically thereafter due to declining pasture quality; increased again to nearly 40,000 head around the 1930s; and then steadily declined to today's low levels. Goats and hogs peaked around the turn of the 20th century at about 10,000 each, yet cattle numbers were more stable with about 10,000 head from 1861 through the 1980s. Even in early days, there was a problem with overgrazing, which resulted in the eventual closing of most of the local forest to cattle ranchers in 1947 (Mauldin, 1968). Overgrazing causes decreased soil stability and increased erosion, and results in greater nutrient input to the lake. Recently, grazing has become a problem in regions of emergent vegetation, especially in low water years when cattle have access to tule beds (as happened in 1999), because it can impact grebe nesting colonies.

Soil Exposure and Transport

Construction of residential and commercial facilities along the rimlands and on the upper slopes of the Clear Lake watershed have the continual effect of transporting sediments and associated nutrients into Clear Lake during the rainy season. Nonpaved roads also contribute significant loading of erosional materials to Clear Lake. During the summer, large numbers of off-road vehicles traverse back country roads (e.g., about 20 miles along Cow Mountain), loosening soil from the roadbed. At the end of the summer season, there is often a 5- to 10-cm layer of fine-grained soil (and associated nutrients) on the surface of the roadbed, which is flushed into drainage pathways and the lake with the first major rainstorm.

Species Introductions

Due in large part to its high productivity, Clear Lake has continually supported a very rich fish fauna. The structure of the fish community has changed a great deal over the past 100 years in response to numerous alien fish introductions. Prior to European settlement, there were 13 naturally occurring fish species in the lake, 4 of which were endemic (Hopkirk, 1973). The current fish community consists of 21 species, only 5 (24%) of which are native to the lake (see Table 121.4). The introductions began in the late 1800s with the establishment of three species, the white catfish (*Ameiurus catus*), brown bullhead (*A. nebulosus*), and common carp (*Cyprinus carpio*) (Murphy, 1951) and all three species continue to flourish in the lake.

The introduction with perhaps the greatest impact on the Clear Lake fish community in recent years was the inland silverside in 1967 (Li et al., 1976). Like the western mosquitofish (*Gambusia affinis*), the inland silverside was introduced primarily for control of the Clear Lake gnat. Within 1 year, they established themselves as one of the most abundant fish in the lake and now are the dominant planktivore of the littoral zone (Moyle, 2002). This niche dominance likely acted as a catalyst for sweeping changes throughout the lake. Upon its introduction, the inland silverside reduced zooplankton populations in the nearshore regions of Clear Lake, outcompeting other planktivorous fishes in that region (Moyle, 2002). Moyle also credits the introduction of the inland silverside as a major factor in the final demise of the planktivorous Clear Lake splittail (*Pogonichthys ciscooides*), a species already in serious decline. One example of the inland silverside's effects on other fish is provided by the black crappie (*Pomoxis nigromaculatus*) and white crappie (*P. annularis*). After the introduction of the inland silverside, the mean standard length of young crappie (also planktivores) decreased and that of adult crappie increased from pre-introduction levels (Li et al., 1976). This suggests that the inland silverside may have competed with young crappie, and that adult crappie were likely preying on silversides. The silversides also have become the primary forage fish for other predatory species and undoubtedly have helped the already booming sport-fishing industry in Clear Lake.

Other introductions that have had dramatic impacts on the structure of the aquatic community are the myriad sportfishes such as several species of catfish (e.g., *Ameiurus catus*, *Ictalurus punctatus*), the largemouth bass (*Micropterus salmoides*), and other centrarchids. Moyle (2002) notes that the success of the white catfish (*A. catus*) was associated with a decline of the native cyprinids. He additionally credits the elimination of the pikeminnow (*Ptychocheilus grandis*, previously called squawfish) and the extinction of the thicketail chub (*Gila crassicauda*) to the presence of the largemouth bass and other exotic predators.

The most-recent fish introduction is that of the threadfin shad (*Dorosoma petenense*) in 1985 (Anderson et al., 1986). The impacts of the shad introduction have not been thoroughly quantified; however, it is generally assumed that they compete heavily with the silversides for food, leading to greatly fluctuating zooplankton populations. It also has been observed that the shad themselves go through very large population fluctuations, as evidenced by numerous die-offs that have occurred since their introduction. These generally occur in winter (as occurred during the winters of 1990

Table 121.4 Past and Present Fishes in Clear Lake, including Dates of Introduction for Alien Species

Species	Family	Native/ Introduced	Trophic Position (Juvenile/Adult)	Current Status	Reason for Introduction
Thicktail chub (<i>Gila crassicauda</i>)	Cyprinidae	Native	Omnivorous piscivore and invertivore assumed trophic position ^a	Extinct (1941–1950)	—
California roach (<i>Lavinia symmetricus</i>)	Cyprinidae	Native ^b	Benthic browser	Extinct (<1963)	—
Clear Lake splittail (<i>Pogonichthys ciscooides</i>)	Cyprinidae	Native	Littoral planktivore/pelagic planktivore	Extinct (1972)	—
Hitch (<i>Lavinia exilicauda</i>)	Cyprinidae	Native	Littoral planktivore/pelagic planktivore	Abundant	—
Sacramento blackfish (<i>Orthodon microlepidotus</i>)	Cyprinidae	Native	Pelagic planktivore/benthic detritivore	Abundant	—
Sacramento pikeminnow (<i>Ptychocheilus grandis</i>) ^c	Cyprinidae	Native ^b	Pelagic invertivore/pelagic piscivore	Unknown	—
Threespine stickleback (<i>Gasterosteus aculeatus</i>)	Gasterosteidae	Native	Benthivore	Extinct (<1894)	—
Rainbow trout (<i>Oncorhynchus mykiss</i>)	Salmonidae	Native	Pelagic and benthic invertivore	Extinct (<1963)	—
Pacific lamprey (<i>Lempetra tridentata</i>)	Petromyzontidae	Native ^b	Parasite	Unknown	—
Sacramento sucker (<i>Catostomus occidentalis</i>)	Catostomidae	Native ^b	Benthic detritivore and invertivore	Unknown	—
Sacramento perch (<i>Archoplites interruptus</i>)	Centrarchidae	Native	Littoral planktivore/benthic invertivore and piscivore	Rare	—
Tule perch (<i>Hysterothorax traski</i>)	Embiotichidae	Native	Planktivore and invertivore	Common	—
Prickly sculpin (<i>Leptocottus armatus</i>)	Cottidae	Native	Benthic invertivore	Abundant	—
Lake whitefish (<i>Coregonus clupeaformis</i>)	Salmonidae	Introduced (1873) ^d	Planktivore/benthic invertivore	Unsuccessful introduction	Sportfishery
Common carp (<i>Cyprinus carpio</i>)	Cyprinidae	Introduced (1880) ^d	Benthic omnivore	Abundant	Accidental
Brown bullhead (<i>Ameiurus nebulosus</i>)	Ictaluridae	Introduced (1880) ^d	Benthic littoral omnivore	Abundant	Sportfishery
Largemouth bass (<i>Micropterus salmoides</i>)	Centrarchidae	Introduced (1888) ^d	Top predator	Abundant	Sportfishery
Golden shiner (<i>Notemigonus crysoleucas</i>)	Cyprinidae	Introduced (1896) ^d	Littoral and pelagic planktivore	Rare	Forage fish
Bluegill (<i>Lepomis macrochirus</i>)	Centrarchidae	Introduced (1910) ^d	Planktivore/omnivore	Abundant	Sportfishery
Black crappie (<i>Pomoxis nigromaculatus</i>)	Centrarchidae	Introduced (1910) ^d	Pelagic planktivore/omnivore	Common	Sportfishery

^e From Li and Moyle, 1979.

to 1991 and 1998 to 1999 when tens of thousands of threadfin shad died and floated to shore), and likely is due to their poor tolerance of cold water, because they have great difficulty feeding below 9°C (Griffith, 1978). The introduction of the threadfin shad resulted in a significant decline in *Daphnia* populations that serve as the primary food source for young-of-year largemouth bass. Thus, a cascade effect that reduced the numbers of largemouth bass was correlated with the introduction of shad. Furthermore, when the shad population crashed in 1990, the largemouth bass population made a significant rebound, which most likely was due to the resurgence in the number of *Daphnia* found in the lake (Colwell et al., 1997). One study suggests that *Daphnia* consume primarily planktonic diatoms, but typically leave the less-palatable blue-green “algae” (Elser et al., 1990). Additionally, Colwell and co-workers (1997) have shown a strong positive correlation between threadfin shad abundance and that of various piscivorous birds such as Clark’s grebes (*Aechmophorus clarkii*) and western grebes (*A. occidentalis*), double-crested cormorants (*Phalacrocorax auritus*), and California gulls (*Larus californicus*). This may be because the shad prefer well-lighted surface waters, making them easy prey for the birds. After the 1990 population crash, the populations of the aforementioned birds returned to pre-introduction levels. This combination of top-down and bottom-up strong interactions suggests that if this species ever establishes permanently high densities, its introduction may result in dramatic changes throughout the ecosystem, perhaps greater than the changes caused by any previous introduction.

Over the past decade, there typically have been three to four commercial fishing licenses on Clear Lake, mostly focused on the Sacramento blackfish (*Orthodon microlepidotus*) and common carp (*Cyprinus carpio*), which typically are sold live to Asian markets in the San Francisco Bay region. In the 1960s and 1970s, there were years when more than 317,000 kg of carp were taken from the lake and sold mostly to processing plants for cat food. A single haul of carp in about 1990, toward the end of the 6-year drought, yielded about 45,400 kg; yet in recent years carp and blackfish have been in relatively low abundance (Meadows, personal communication, 2000).

Today, there still exist numerous threats to the survival of many Clear Lake fishes. For example, threats to hitch (*Lavinia exilicauda*) involve loss of spawning habitat and nursery areas. The establishment of the threadfin shad (*Dorosoma petenense*) tended to greatly reduce populations of the zooplankton *Daphnia*, a principal food of hitch.

Hydrilla (*Hydrilla verticillata*), indigenous to Southeast Asia (Langeland, 1996), is a noxious, nonnative, submerged aquatic weed that is spreading rapidly throughout the U.S. It was first discovered in Florida in the 1960s and for the first time in Clear Lake in August 1994 (O’Connell and Dechoretz, 1997; Dechoretz, 1998). Where it occurs it causes substantial economic hardships, interferes with various water uses, displaces native aquatic plant communities, and adversely affects freshwater habitats (Langeland, 1996). In 1994, about 175 to 200 surface acres in Clear Lake experienced infestation. This area increased to 648 acres by 1998 (Dechoretz, 1998), and in 1999 the affected area expanded to 845 acres* (Lockhart, personal communication, 2000). This weed is adapted to grow at low light levels, competes effectively for sunlight, and has a rapid growth rate (up to 1 in. per day). It has four different modes of reproduction and the potential to spread with enormous speed to clog enclosed and open waterways, including water bodies as large as Clear Lake (Langeland, 1996).

Ecosystem Complexity

The aquatic ecosystem of Clear Lake and its supporting basin and watershed are extremely productive and complex. The trophic structure of the lake’s biota is complicated and dynamic. Figure 121.12 represents a simplified version of an elaborate, multitiered trophic network for some of the more common species in Clear Lake. Richerson and co-workers (1994; Table 121.3.3) also provide documentation of a preliminary food web for Clear Lake, including known predator-prey

* In addition to regions actively infested, this figure for 1999 also includes all areas that still are being treated in which *Hydrilla* has ever been found, and may not represent current infestation.

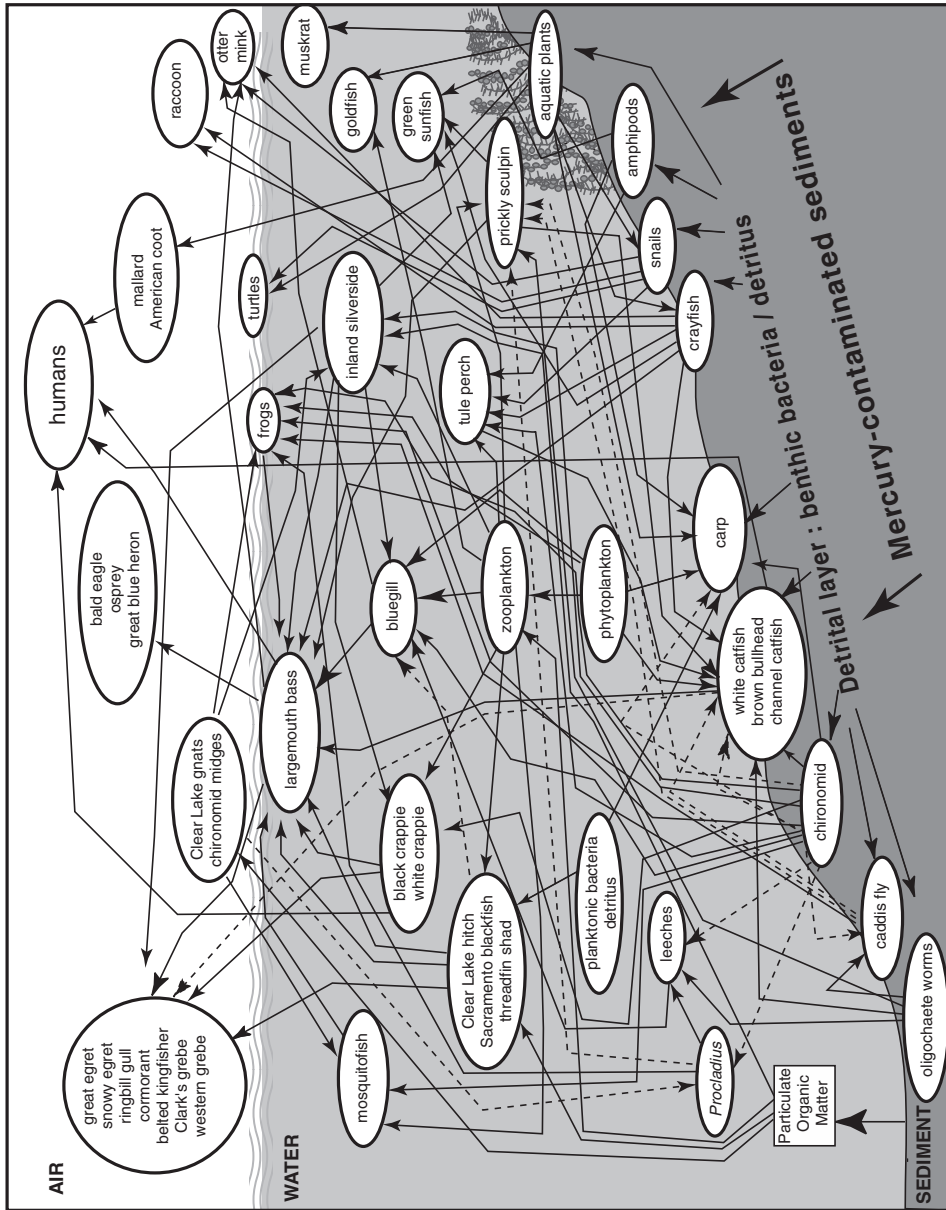

Figure 121.12 Simplified food web for Clear Lake.

relationships. Many of the factors identified above are dynamic, affecting the ecological relationships between species, and present significant challenges to resolving systemwide ecological problems. While considerable research has been conducted on the Clear Lake aquatic ecosystem, there exists a large degree of uncertainty about our knowledge of the impacts from the multiple stresses outlined previously.

Multiple Management Objectives

The previous discussion highlights many multiple stresses that affect the aquatic ecosystem of Clear Lake proper and the surrounding watershed and basin. These impacts affect not only the natural ecology of the system, but interact with aesthetic and economic dimensions as well. The Clear Lake Basin is an aesthetically beautiful setting and, as it has for over a century, attracts many thousands of tourists each year. Tourist visitation revenues for Lake County were estimated at \$162 million in 1992 and increased on average about 7.9% per year to \$237.5 million in 1998 (Dean Runyan Associates, 1999). It is estimated that \$7 to 10 million of tourist revenue is lost annually due to the influence of poor water quality associated with cyanobacterial blooms alone (Goldstein and Tolsdorf, 1994). Given the complexities of managing a productive and multiuse watershed, many conflicts exist. For example, what is the best solution for maintaining the lake level? Downstream farmers in Yolo County would like to accumulate as much water as possible in Clear Lake during periods of winter precipitation for use the following summer; yet, the higher the lake levels rise, the greater risk of flooding to citizens living along the rimlands, as occurred when the first Clear Lake dam was erected in 1867 (see above). Another example relates to the use of pesticides and fertilizers for agricultural crops. Farmers typically use pesticides and fertilizers to maximize production; yet, the health of the aquatic ecosystem (especially its resources for sport and commercial fisheries) may be negatively affected by these practices. Some Lake County residents strive to enact regulations or change land-use patterns to reduce the free-floating cyanobacterial blooms and the noxious odors associated with their stranding on shore. During years when the blooms are minimal, water clarity is improved but shallow-rooted aquatic macrophytes proliferate and clog boat propellers. Yet, macrophytes are desirable as refuges and habitats for increased biodiversity and often act as nursery grounds for young fishes. Trade-offs will always exist, but it is the responsibility of science to provide informed decision-making options (and their inherent consequences) before exploiting multiple-use resources found within Clear Lake and its watershed.

Lake County has been one of the most progressive counties in the state in developing a Coordinated Resource Management and Planning (CRMP) process (Follansbee, 1996). Simply put, using a consensus model, the CRMP process brings together citizen interest groups and representatives from local, state, and federal agencies to develop integrated approaches to complex resource management issues. The first use of the CRMP process in 1949 to address grazing for an allotment in Oregon was documented by Anderson and Baum (1988). Over 200 such CRMPs are in existence within California and several have been started within Lake County. One of the first Clear Lake CRMPs dealt with the problems associated with the cyanobacterial blooms. A committee initially established as the Algae Abatement Committee in 1984 (and now operating under a broader mandate as the Clear Lake Advisory Subcommittee [CLAS]) has met regularly since its inception to address problems and potential solutions to eutrophication and other issues related to water use and quality within Clear Lake and its surrounding watershed. It has since evolved into an entity that addresses county-wide resource issues in an integrated manner while attempting to maintain and enhance the ecosystems and economy of Lake County (Follansbee, 1996). This group has been folded into a more-structured Lake County Resource Management Committee (RMC), which began in 1989 and now includes representatives from county-level resource agencies, agricultural interests, Native Americans, fishing and hunting groups, environmental special interest groups, realtors, Chambers of Commerce, and the University of California. The structure of the RMC includes four subcommittees: Clear Lake Advisory, Biological Resources, Land and Water Resources, and Database and

Information Outreach. These subcommittees seek out information from each of the representative participants and draw heavily upon past and ongoing scientific research that is conducted on Clear Lake and its surrounding watershed. In general, the RMC seeks to improve coordination of planning, research, and land and resource management by obtaining input from all interested parties, sharing information, collecting data, conducting research, and developing policies and regulations that will maximize benefits for the citizenry of the county (Follansbee, 1996). In addition to the Clear Lake (Upper Cache Creek) Watershed CRMP, there are several other local and regional CRMPs that interact closely to resolve environmental issues. These include High Valley and Schindler Creek CRMP, Lake Pillsbury Watershed CRMP, Middle Creek CRMP, and the Scott's Creek CRMP.

Recommendations from the RMC, which receives input from the various CRMPs, are passed to the county Board of Supervisors, who then vote on whether to adopt or modify them. One example of a process initiated and mediated by the Clear Lake CRMP has been an investigation of "The Causes and Control of Algal Blooms in Clear Lake" (see Richerson et al., 1994). University of California, Davis (UCD), scientists conducted a study (funded by the U.S. EPA Clean Lakes Program) to evaluate possible remediation options to reduce blue-green "algal" blooms in Clear Lake. A series of recommendations from this study were provided to the RMC and voted on by the Board of Supervisors. As a result, Lake County has been engaged in several remediation strategies to reduce nutrient inputs to Clear Lake. Two examples include (1) stabilization of creek bed channels (disrupted by gravel mining) by replanting willows and cottonwoods, and (2) initiation of a process to restore and rehabilitate up to 1200 acres of wetlands in the northwest region of Clear Lake (formerly Robinson Lake) that were converted to agricultural production over the past 100 years. The CRMP process is holistic and appears to be working well, yet is always dependent on accurate scientific data for proper strategic planning.

Research

Some of the earliest environmental and ecological research at Clear Lake was a series of observations dealing with fish biology that were initiated shortly after Europeans arrived in the basin (Stone, 1874), and a more broadly based biological survey of the lake in the 1920s (Coleman, 1930). Unfortunately, we have found no documented history of the ecology of the lake before 1870, which would have provided a true aboriginal baseline, especially regarding the level of eutrophication in Clear Lake. The most productive periods of scientific research in Clear Lake have been associated with:

1. Application of DDD to control the Clear Lake gnat (Lindquist and Deonier, 1943; Dolphin, 1959; Hunt and Bischoff, 1960).
2. Early water quality investigations (Goldman and Wetzel, 1963; Lallatin, 1966; Kaiser Engineers, 1968).
3. Cyanobacterial bloom research undertaken by the Clear Lake Algal Research Unit (CLARU) during the period from 1969 to 1972 (Wrigley and Horne, 1974; Horne and Commins, 1987; Horne and Goldman, 1972, 1974; Horne, Javornicky, and Goldman, 1971; Horne et al., 1972; see Richerson, Suchanek, and Why, 1994, for a more complete list).
4. A multidisciplinary investigation of the tectonic, stratigraphic, and paleoclimatic history of the Clear Lake Basin, especially as evidenced by deep (168-m depth) sediment cores collected in the 1970s and early 1980s (Sims, 1988; Sims and White, 1981; Sims, Adam, and Rymer, 1981; Sims, Rimer, and Perkins, 1988; West, 1988).
5. Studies on mercury and arsenic contamination from the Sulphur Bank Mercury Mine that are still ongoing (Columbia Geosciences, 1988; Chamberlin et al., 1990; Suchanek et al., 1993, 1995, 1997, 1998a,b, 2000a,b).
6. An ongoing monitoring program by the Lake County Vector Control District that encompasses water quality, plankton, benthic invertebrates and fishes.
7. A series of ongoing integrated studies by UCD researchers since the early 1990s on the impacts of multiple stresses on the Clear Lake aquatic ecosystem.

The earliest studies (e.g., water quality work, Clear Lake gnat research, cyanobacterial bloom studies), especially in the 1940s and 1950s, were typically "special purpose" programs designed to address specific problems. There was little integration and little continuity; the science was relatively unsophisticated, even though the scientific teams were utilizing the most modern standards of the day. Initially, DDD treatments of the lake were effective in cutting back the populations of the Clear Lake gnat, but some deleterious side effects did occur. Later observations, however, suggested failure of the large pesticide applications and fish predator introductions to reduce and eliminate populations of the Clear Lake gnat, and indicated secondary consequences of population crashes of the western grebe, presumably from DDD contamination. However, western grebes have rebounded in recent years, and exhibited the largest population size ever recorded at Clear Lake (about 210,000 individuals) in the year 2000. The 1970s spawned an era of more-consistent data-collection efforts, with the California Department of Water Resources (DWR) launching a water-quality monitoring program begun in 1969 and continuing to the present day. These data collection efforts provided continuity, but still lacked directed investigation or integration with lake-wide environmental issues. As addressed previously, results of Goldstein and Tolsdorf's (1994) study suggested that compromised water quality in Clear Lake likely is diminishing tourism by \$7 to 10M per year. The economic impact suggests that there has been far too little investment in acquiring management-relevant data. Unfortunately, Lake County's responsibilities to support these efforts far outstrips its financial resources to do so.

The U.S. EPA has supported much of the recent work (since 1990) that has been conducted at Clear Lake, both on hypereutrophication and associated cyanobacterial blooms (Clean Lakes Program, about \$100,000) and studies on multiple stresses affecting Clear Lake and its watershed (U.S. EPA Office of Research and Development, UCD Center for Ecological Health Research, about \$100,000 per year from 1992 to 2001). The U.S. EPA also has funded studies on the impacts of mercury from the Sulphur Bank Mercury Mine on the lake's aquatic ecosystem (U.S. EPA Superfund Program, about \$500,000 per year from 1994 to 1998). As a cumulative effort since 1990, funding has supported about five master's theses and seven Ph.D. dissertations (the result of about 42 graduate student study-years) to date.

The U.S. EPA-funded Center for Ecological Health Research (CEHR) at UCD, operating at the watershed scale, is utilizing Clear Lake as one of three model ecosystems (the other two are the Sierra Nevada Ecosystem, including Lake Tahoe, and the Sacramento River Watershed) to evaluate the impacts of multiple stresses on ecosystem health. Another U.S. EPA watershed project (funded by the National Center for Environmental Research Quality Assurance [NCERQA] program) involves policy and management issues associated with assessing water management options. The CEHR program at Clear Lake involves numerous subprojects that are focused on many interrelated questions associated with the dynamics of this system subjected to diverse natural and anthropogenic stresses and how these relate to more regionally based water-quality issues. The intimate relationship between the various disciplines and projects being undertaken by this program is diagrammed in Figure 121.13. Virtually every project has its own set of ongoing investigations (with a rich publication record too extensive to list here), but is well coordinated and integrated with the other projects. The CEHR work is interdisciplinary, reviewed semiannually through scoping and evaluation meetings with a CEHR national Scientific Advisory Committee, and is in the process of producing a synthetic publication summarizing nearly 10 years of research on this ecosystem.

To date, we have made significant progress in understanding the complex dynamics of natural and anthropogenic stressors on the Clear Lake aquatic ecosystem from first principles. For example, the ecological assessment of the impacts of the Sulphur Bank Mercury Mine on Clear Lake was nearing completion in 1995 when we discovered a significant amount of ongoing acid mine drainage (AMD) from the mine site entering Clear Lake through underground seepage, not just as surface runoff. This shifted the entire emphasis of the investigations from the lake bed sediments (which previously were believed to be the point source for the lake's mercury contamination) to ongoing

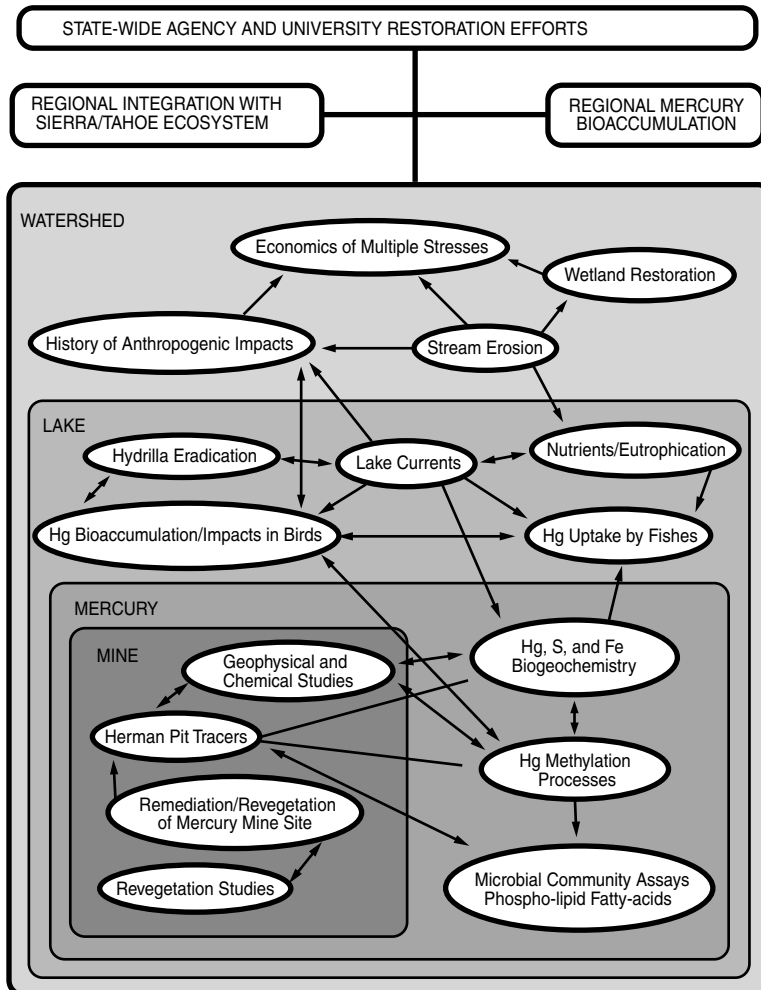

Figure 121.13 Relationship between Clear Lake research projects within the EPA-funded Center for Ecological Health Research.

investigations of AMD. This discovery was made possible only through an active and ongoing monitoring program (Suchanek et al., 2000b). It is possible that our current understanding of the dynamics and influence of sediment and nutrient loading on Clear Lake's productivity also may be incomplete. No "silver bullets" have been found to resolve the complexities of the many natural and anthropogenic stresses imposed on Clear Lake and its surrounding watershed, nor are they likely to be. However, as our work demonstrates, although uncertainties about ecosystem processes remain, we continue to improve our abilities to predict the effects of anthropogenic impacts and manage this productive resource. With unpredictable changes associated with global and regional climate change, new species introductions (purposeful or accidental), and other as-yet-undefined stressors, this system will need continued and sophisticated adaptive management. In a complex ecosystem such as Clear Lake, research can (1) make steady progress in understanding the complexities of the system, (2) guard against indefensible plans such as the deep dredging of Clear Lake, and (3) offer recommendations for future actions based in the spirit of adaptive management.

If society wants to manage complex ecosystems like Clear Lake at a state-of-the-art level, it must be prepared to make substantial investments in monitoring, research, and modeling on an ongoing basis. Because these investments involve contributions to understanding ecosystems at

a fairly fundamental level that will be applicable to many other similarly stressed systems, a substantial federal contribution is warranted. However, a healthy and meaningful program requires more state and local investment than has been forthcoming thus far. A strong commitment from federal, state, and local funding agencies will be needed to provide a reliable technical basis for science-based decision making and management. Lake Tahoe, with its much higher profile nationally, has a relatively well-funded research and monitoring program. However, even this program is weakly institutionalized, has periodic funding crises, and has a funding base that is none too generous considering the scope of its problems. Multiply stressed ecosystems require a sustained and rather costly investment of scientific and technical resources. Recent requests by the National Science Foundation for a major increase in environmental science funding are a step in the right direction, but the more applied and management-oriented part of the investment portfolio still will be neglected unless other agencies step forward.

ACKNOWLEDGMENTS

We would like to thank the County of Lake and specifically Supervisor Karan Mackey for continued support throughout the past decade. In addition, Art Colwell and Norm Anderson of the Lake County Vector Control District, Bob Reynolds of the Lake County Air Quality Management District, Bob Lossius and Tom Smythe of the Lake County Public Works Department, and Marty Winston of the Lake County Department of Public Health have given generously of their time and data to help evaluate and understand many of the stresses affecting Clear Lake. Art Colwell significantly improved the manuscript by providing historical accuracy. Peter Moyle helped us correct the simplified food web diagram. Many other people too numerous to mention have contributed in many ways to this effort. This work has been supported by the following grants or contracts: U.S. EPA Clean Lakes Program (contract 0-166-250-0 to the California State Water Resources Control Board), U.S. EPA Center for Ecological Health Research (R819658 and R825433), U.S. EPA-NSF Watershed Grant (R-825285-01-0), U.S. EPA Region IX SuperFund Program (68-S2-9005), and a UCD Jastro Shields grant to E.J. Gilmartin. Although the information in this document has been funded in part by the United States Environmental Protection Agency, it may not necessarily reflect the views of the agency and no official endorsement should be inferred.

Trans-Gill and Dietary Uptake of Methyl Mercury by the Sacramento Blackfish, a Planktivorous Freshwater Fish

Joseph J. Cech, Jr., Monica Heekyoung Choi, and Ann G. Houck

INTRODUCTION

Clear Lake, CA, is a focus ecosystem of the EPA-supported University of California, Davis (UCD), Center for Ecological Health Research. Several Clear Lake fish species carry high levels of methyl mercury (MeHg) in their flesh (Stratton et al., 1987). Mercury (Hg) leaches into the lake from naturally occurring cinnabar ores and from anthropogenic sources such as the Sulphur Bank Mercury Mine, an EPA Superfund site. Hg-contaminated sediments near the abandoned mine from the lake's Oaks Arm are classified as hazardous waste by the California Department of Health Services. By contact or ingestion, Hg is taken up by aquatic organisms and, presumably, biomagnifies up the lake food web (Watras et al., 1994; Suchanek et al., 1997). The abundant Clear Lake fishes are important components of the food web (Moyle, 1976), but little is known about the fishes' Hg uptake routes and rates in the ecosystem.

Heavy metals in the environment and their effects on living organisms have received increasing attention in recent years (Heath, 1995). Mercury, especially in the methyl (MeHg) form, has received much of this attention (Watras and Huckabee, 1994). Inorganic mercury has low water solubility, is readily complexed or adsorbed to particulates, and precipitates to sediments (Benes and Havlik, 1979). Jensen and Jernelöv (1969) showed that inorganic mercury could be methylated in the aquatic environment to the highly toxic MeHg. In freshwater systems, the majority of MeHg appears to be generated by bacteria in the surface sediments and transferred by biota (Beijer and Jernelöv, 1979). Environmental pH, temperature, redox potential, alkalinity, and concentrations of dissolved organic carbon (DOC), oxygen, sulfate, and calcium can affect the Hg methylation rate and MeHg's bioavailability (Benes and Havlik, 1979; Carty and Malone, 1979; Fitzgerald and Clarkson, 1991; Matilinen and Verta, 1995; Choi et al., 1998). When methylated, mercury becomes less water soluble and more lipid soluble. MeHg is extremely mobile, very stable, and can easily penetrate membranes in living organisms (Beijer and Jernelöv, 1979; Hodson, 1988). The high mobility facilitates rapid MeHg uptake and penetration of sensitive tissues, particularly the lipid membranes of neurons, where its toxicity is well known (Wiener and Spry, 1996). Importantly, MeHg then preferentially forms bonds with thiol-containing molecules, such as proteins and enzymes, moving it into the water-soluble cytosolic fraction, slowing depuration.

Although the Clean Water Act of 1972 effectively ended intentional discharges into most U.S. waters, anthropogenic sources of mercury such as old mine tailings and new impoundments continue to contaminate aquatic systems. Much data on human health and MeHg intoxication have accumulated since the outbreak of MeHg poisoning in Minamata, Japan (1956), but less is known about the actual effects of intoxication on wildlife. The effects of mercury toxicity can occur at all levels of the food chain from reduced photosynthesis of phytoplankton to neurotoxic effects on vertebrates including subtle effects on the rates of population reproduction, growth, and mortality (Peterle, 1991). However, the greatest hazards remain in the aquatic food chain where bioaccumulation and bioconcentration occur. Fish species that are shorter lived, those that feed low on the food chain, or those that grow very fast accumulate less mercury than long-lived piscivorous fish (Armstrong, 1979).

In fish, free MeHg is rapidly and efficiently absorbed through the gut and across the gills (Armstrong, 1979). Its high affinity for sulfhydryl groups in proteins dramatically increases its biological half-life (Grieb et al., 1990; Bloom, 1992). These factors account for its very high bioaccumulation and biomagnification factors in aquatic food chains (e.g., concentrated in fish muscle tissue (Huckabee et al., 1974) and in terrestrial animals feeding on aquatic organisms. Methyl mercury is one of the most toxic forms of Hg, causing irreversible and likely cumulative damage to the central nervous system (Choi, 1990). Several studies have demonstrated that DOC is an important factor affecting fish Hg bioaccumulation that also includes pH, temperature, sulfide concentration, redox potential, fish age, and growth rate (Driscoll et al., 1995). The ubiquitous DOC in lakes and other freshwater systems originates from the decomposition and degradation of organic detritus, and generally ranges from 0.5 to 4.0 mg C/l in lakes and rivers to 10 to 50 mg C/l in wetlands and marshes (MacCarthy, 1989). It has been well established that because of their polyelectrolytic nature, DOC complexes with or chelates heavy metal ions in natural waters (Mantoura et al., 1978). This metal complexation capacity of DOC therefore plays an important role in natural systems, influencing the environmental fate, bioavailability, toxicity, and mobility of heavy metals by controlling their speciation in natural waters (MacCarthy, 1989) and their uptake by living organisms. For example, complexation of inorganic Hg with organic carbon has been shown to reduce bioavailability to fish (Ramamoorthy and Blumhagen, 1984).

Clear Lake, in the Coastal Range of northern California, is the largest natural lake wholly within California's borders. This shallow, naturally eutrophic lake is located 100 km north of San Francisco and is surrounded by the many communities and parks that dot its shores. While the lake supports a productive commercial and sportfishery, it is also a highly disturbed ecosystem subject to many environmental stressors: chlorinated hydrocarbon residues from an early 1960s attempt to control a nuisance midge, arsenic from natural sources, and mercury from the abandoned Sulfur Bank Mine (Suchanek et al., 1997). Fish are additionally stressed by seasonal extremes in temperature, low dissolved oxygen, and heavy parasite loads (Murphy, 1950; Goldman and Wetzel, 1963). Clear Lake presents a unique opportunity to model the routes and rates of Hg movement through an ecosystem, including its complex food web. Unfortunately, the available data on the fishes' roles in moving Hg through the ecosystem, especially through the food web, are simply inadequate. Our objective was to quantify trans-gill and dietary MeHg dietary uptake rates in Sacramento blackfish (*Orthodon microtepidotus*), a planktivorous, commercially fished species.

MATERIALS AND METHODS

Trans-Gill MeHg Uptake Studies

Sacramento blackfish (900 to 1200 g wet weight) were seined from Clear Lake and held in 600-l fiberglass tanks at the UCD under natural photoperiod for about 1 year before experiments. Tanks were aerated and received a continuous flow of air-equilibrated well water (mean total

hardness: 456 mg/l as CaCO_3 , total alkalinity: 485.1 mg/l as CaCl_2 , and pH: 8.1), and blackfish were fed Silver Cup trout pellets (Nelson and Nelson, Murray, UT) up to 48 h before surgery. Fish were anesthetized (100 mg/l, 3-aminobenzoic acid, ethyl ester [MS-222]; Sigma Chemical, St. Louis, MO, buffered with NaHCO_3 and NaCl), weighed (electronic balance), measured for total length (linear rule), cannulated (PE-50, dorsal aorta) for blood sampling, immobilized by spinal transection (McKim and Goeden, 1982; Schmieder and Weber, 1992), fitted with an oral latex membrane to separate inspired and expired water, and recovered in the respirometer in aerated UCD well water at least 20 h before MeHg exposure.

The water-jacketed respirometer (20 × 20 × 66 cm, 1-cm thick acrylic plastic) incorporated three compartments: A (pre-gill), B (post-gill), and C (posterior body) were separated by latex membranes (Choi et al., 1998). The water containing Me^{203}Hg was pumped from reservoir 1 by a metering pump (Alidos, Marietta, GA) to compartment A, and the water in compartment A was pumped to compartment B by the fish's gill ventilation. Ventilation volume (V_g) was the volume of water displaced from the compartment B drain by the fish's gill ventilation (Choi et al., 1998). Water was simultaneously sampled from compartments A and B by a peristaltic pump (Minipuls, Gilson, Middleton, WI) for dissolved O_2 samples (calibrated O_2 meters, Model 113, Instrumentation Laboratories, Lexington, MA) and for MeHg samples (discussed later). Oxygen consumption rate (MO_2 , mg O_2 /h/kg) was calculated by multiplying V_g by the inspired–expired O_2 content difference. Whereas O_2 extraction efficiency (UO_2) was calculated from $100 \times$ the inspired–expired O_2 content difference/inspired O_2 content, Hg extraction efficiency (UHg) was calculated from $100 \times$ the inspired–expired MeHg content difference/inspired MeHg content. Finally, trans-gill Hg uptake rate (RHg) was calculated by multiplying the Hg concentration in the water by the product of V_g and $\text{UHg}/100$. Equal water levels in all compartments eliminated pressure head–induced leakages (checked after each experiment with food dye) between compartments. The whole system was closed, except for the vents connected to the In-Line Gas Purifier (400 ml, Ailtech, Deerfield, IL) in the fume hood, to prevent the release of volatilized MeHg to the atmosphere. Volatilized MeHg levels in the Gas Purifier were measured by Geiger–Mueller counter, and water temperature was maintained by a thermoregulator (CFT-75, Neslab, Portsmouth, NH) circulating water through the water jackets of the chamber and reservoirs. The supply water in reservoir 1 was carefully aerated (to minimize volatilization) by using chemically inert porous PTFE tubing (IMPRA, Tempe, AZ).

Blackfish were exposed to aqueous solutions of the MeHg (1.4 ± 0.25 ng/l, reference treatments) or to MeHg (1.4 ± 0.25 ng/l) with 2 and 5 mg DOC/l treatments in the respirometer at 20°C for 1 h (Choi et al., 1998). The Me^{203}Hg or DOC-equilibrated Me^{203}Hg stock solution was added to reservoir 1 and allowed to mix with water via aeration for 1 h before starting Me^{203}Hg exposure. Radiolabeled MeHg was chosen for this experiment due to the simple and sensitive analysis at low concentrations. During the experiment, three, 1-ml water samples from reservoir 1, compartment A, and compartment B were taken and placed in 20-ml liquid scintillation (LS) vials for Me^{203}Hg concentration measurements. Heavy-walled, Teflon (PFA) tubing was used (except viton tubing in peristaltic pump head) for the water samples to minimize losses of Me^{203}Hg and O_2 ; 1 ml of water containing Me^{203}Hg was mixed with 10 ml of LS cocktail (Universol, ICN Biomedicals, Costa Mesa, CA) in a 20-ml borosilicate LS vial. The ^{203}Hg activity was measured using the LS counter, and quenching effects were corrected. MeHg concentrations were calculated from the specific activities of the stock solution and corrected for radioactive decay. To minimize stress, the chamber was partially covered with black plastic sheet during experiments. After each experiment, wastewater was decontaminated by pumping through a series of water purification filters (Adsorber/Universal System, Cole-Parmer, Niles, IL), and its radioactivity was checked using a Wallac 1410 LS counter (Pharmacia, Turim, Finland) before disposal.

Humic acid (Aldrich, Milwaukee, WI) was dissolved in deionized water and filtered through binder-free glass fiber filters (TCLP, 0.7 μm ; Gelman Sciences, Ann Arbor, MI) to remove particulate material to make our DOC stock solution (1100 mg C/l; Choi et al., 1998). The carbon content of

the DOC stock solution was measured using a total carbon analyzer (Shimadzu TOC 500, Tokyo, Japan). Initial trace metal concentrations (mg/l) of the DOC stock solution were determined by inductively coupled plasma-mass spectrometry (ICP-MS): As (<0.2), Cd (<0.03), Cu (0.02), Fe (28.2), Pb (<0.1); Mn (0.59), Mo (<0.04), and Zn (0.25). The DOC stock solution was refrigerated (4°C) until diluted with UCD well water to 2 or 5 mg C/l for the experiments. The Hg (<0.001 ng/l) and DOC (<1 µg C/l) concentrations of UCD well water were not detectable. The DOC stock solution was equilibrated with our Me²⁰³HgCl stock solution for 48 h before DOC and Me²⁰³Hg exposure experiments started (Hintelmann et al., 1995). Immediately after the 1-h exposure and sampling period, each fish was over-anesthetized with MS-222 and dissected for tissue Me²⁰³Hg concentrations (Choi et al., 1998).

SuperANOVA (Abacus Concepts, Berkeley, CA) was used for one-factor analyses of variance to compare the DOC effects on the different treatment means. Multiple comparisons for proportions were used to compare the DOC effects on the ratio between blood and water (Zar, 1984). The statistical significance of the differences in variables among the three treatments were determined by Student–Newman–Keuls test.

Dietary MeHg Uptake Studies

Sacramento blackfish broodstock were purchased from commercial fishers at Clear Lake, and spawned in a UCD campus pond (Cech et al., 1982). Juvenile fish were distributed among 24 aquaria (six replicate aquaria of each of four MeHg-exposure treatment groups) for two, sequential 35-day MeHg dietary exposure periods (70-day total exposure). Weighed (Mettler electronic balance) fish epaxial muscle samples were taken for total Hg analysis. Because previous work has shown that >95% of the Hg in fish is in the form of MeHg (Bloom, 1992), the less expensive (compared with MeHg) total Hg assays (cold vapor atomic absorption spectrometry, developed by Slotton et al., 1995) were used. Similarly, we measured fish food samples (total of 8) from all treatment groups and aquarial water samples (total of 8) using cold vapor atomic fluorescence. Dietary Hg uptake rates were calculated following Rodgers and Beamish's (1982) methods. Concentration of Hg (in tissues, food, water) and uptake rates treatment means were compared using ANOVA, Kruskal–Wallis, and *post-hoc* tests (Sokal and Rohlf, 1981), using Systat and SigmaStat software.

Food consumption rates were measured simultaneously in the dietary MeHg exposure blackfish. Experimental diets were prepared from a complete, commercial trout chow (Silver Cup Trout Chow) mash and mixed with an aqueous methyl mercuric chloride solution to reach the target concentration. Wet diets were extruded to the correct diameter, dried at 37°C, cut into pellets of the correct size, and frozen until use. Calculated treatment concentrations of MeHg were 0 mg/kg dry weight of feed (control), 0.45 mg/kg (mean concentration of these species' prey in Clear Lake; Suchanek et al., 1997), 20 mg/kg, and 50 mg/kg (two "threshold" concentrations for comparisons with other studies; Phillips and Buhler, 1978; Rodgers and Beamish, 1982). Fish were situated in groups of 35 in each of six replicate 38-l aquaria per treatment. Each aquarium was considered an experimental unit to avoid pseudoreplication. At the start of the experiment, fish were weighed in water (calibrated, self-taring electronic balance), measured (standard length: tip of snout to caudal peduncle; fork length: tip of snout to end of fin rays in the center of the caudal fin; and total length: tip of snout to end of rays in the longest lobe of the caudal fin), and distributed among the aquaria. Each aquarium was partially immersed in a temperature-controlled (24°C) fiberglass water bath and supplied with a continuous flow of (nonchlorinated) air-equilibrated well water. Pilot experiments showed that water flows of 0.5 l/min were adequate to maintain high dissolved oxygen concentrations (7 to 8 mg/l, Corning O₂ meter) and low dissolved ammonia (<0.2 mg/l, Hach colorimetric kit) with aquarial aeration. Fish were fed *ad libitum* (indicated by excess food on bottom of aquaria after the feeding bout has ceased) twice daily, and tanks were siphoned twice daily to remove uneaten pellets and feces.

Siphoned pellets were filtered (individual, tared paper filters) from siphon water and dried at <37°C to a constant weight immediately prior to weighing. Food consumption rates (g dry weight feed/tank/day) were calculated by subtracting the amounts not eaten from those provided. Treatment means were compared using ANOVA (Sokal and Rohlf, 1981).

RESULTS

Adult Sacramento blackfish take up about 36% of waterborne MeHg (at Clear Lake concentrations of 1.4 ng/l) with one ventilatory pass over their gills. Interestingly, the addition of 2 to 5 mg DOC/l decreased the MeHg uptake rate by about 80% (Table 122.1). In contrast, Sacramento blackfish respiratory variables were not affected by DOC addition. Mean Vg, MO₂, and UO₂ of blackfish exposed to Me²⁰³Hg were not influenced by the presence of DOC (*p* > 0.05; Table 122.1). In contrast, mean UHg and RHg significantly (*p* < 0.05) decreased by 78 and 74%, respectively, with 2 mg C/l of DOC, and 85 and 82% with 5 mg C/l of DOC (Table 122.1). Decreased RHg indicates slower Me²⁰³Hg bioaccumulation in organs as Me²⁰³Hg become less available to fish, presumably due to binding with DOC. The whole blood to inspired water ratio of mean Me²⁰³Hg concentrations significantly (*p* < 0.05) decreased by 63 and 70%, respectively, with 2 mg C/l and 5 mg C/l of DOC from the MeHg reference treatment. There were no significant differences (*p* < 0.05) in this ratio, UHg, or RHg means between the 2 mg C/l and the 5 mg C/l DOC treatments.

Although body burdens of dietary-exposed blackfish have not yet been completed, preliminary food consumption rates (overall mean: 24.0 ± 0.47 SE g dry weight of food consumed per tank of 35 fish, after 35 day) showed no effect of dietary MeHg concentrations (Table 122.2).

Table 122.1 Mean (± SE) Values of Respiratory and Methyl Mercury (1.4 ± 0.3 ng/l in inspired water) Uptake Variables in Sacramento Blackfish as a Function of DOC Additions^a

Variable	Treatment Group		
	Reference Group (no DOC)	With 2 mg DOC/L	With 5 mg DOC/L
Ventilation volume (l/h/kg)	21.53 ± 2.87	22.38 ± 3.07	18.34 ± 1.27
O ₂ consumption rate (mg O ₂ /h/kg)	55.85 ± 6.64	71.93 ± 7.25	70.05 ± 5.53
O ₂ extraction efficiency (%)	33.34 ± 5.92	40.30 ± 3.62	43.05 ± 4.13
MeHg extraction efficiency (%)	35.65 ± 3.51	7.69* ± 0.73	5.33* ± 0.60
MeHg uptake rate (ng/h/kg)	8.96 ± 1.56	2.35* ± 0.22	1.57* ± 0.23

Note: Asterisk indicates significantly different (*p* < 0.05) from reference group.

^a N = 5 in each treatment group.

Table 122.2 Mean (± SE) Preliminary (35-day Exposure) Food Consumption Rates of Juvenile Sacramento Blackfish Exposed to Dietary MeHg^a

Dietary MeHg Concentration (mg MeHg/kg dry weight of feed)	Food Consumption Rate (g dry weight of feed eaten/aquarium)
0 (control)	24.46 ± 0.27
0.45	23.83 ± 0.48
20	24.13 ± 0.43
50	23.58 ± 0.71

^a N = 35 fish per aquarium.

DISCUSSION

Clear Lake, located in Lake County, is one of California's outstanding recreational areas, and Hg pollution is a very important problem (EPA, 1997). Lake County relies on recreational fishing to support a large segment of the economy. The area surrounding the lake has a sizable population of fixed-income retirees who depend heavily on fish from the lake as a dietary supplement; there is, therefore, a potentially important human health benefit from the Clear Lake studies on fishes. The Sulphur Bank Mine, an EPA Superfund site, is a primary source of Hg pollution, especially in the Oaks Arm of the lake. Hg levels in edible fish (including largemouth bass) muscle tissue have exceeded the maximum limits set for safe human consumption (Suchanek et al., 1997). Little is known about how the mercury accumulates to these high levels in fish and what their physiological ramifications are for the fish. Our study will make a significant contribution to a more-complete understanding of the movement of mercury through the Clear Lake food web and its physiological effects on Clear Lake fishes.

To best manage a mercury-polluted site, we must first have a sufficient understanding of how mercury moves through the system, including the aquatic and terrestrial food webs. The roles of fishes in the pathways of mercury movement in Clear Lake, from mine-contaminated sediments through the water and through the Clear Lake aquatic and surrounding terrestrial food webs are unknown. Several fishes (19 species), including Sacramento blackfish, are preyed upon by a variety of birds and terrestrial aquatic mammals.

To quantify trans-gill MeHg uptake, we directly measured MeHg uptake across the gills of Sacramento blackfish, emphasizing DOC effects on the MeHg bioavailability, using the fish metabolic chamber (McKim and Goeden, 1982; Choi et al., 1998). Direct measurements of Hg uptake rate eliminate potential kinetic analyses errors of bioaccumulation due to rapid biotransformation of the compound, pharmacodynamics within the organism, or statistical interdependence (co-correlation) of fitted parameters in the iterative program used to estimate uptake rate coefficients (Black and McCarthy, 1988),

The presence of DOC significantly decreased Me²⁰³Hg uptake by blackfish, but did not influence the fish respiratory variables (Table 122.1). DOC additions also generally decreased Me²⁰³Hg accumulations in Sacramento blackfish organs depending on tissue-specific blood flow (Choi et al., 1998). Decreased Me²⁰³Hg uptake can be accounted for by Me²⁰³Hg binding to DOC in solution, thereby inhibiting its ability to pass across gill membranes due to both the DOC's polar nature and the large size of the macromolecule (Kerndorff and Schnitzer, 1980). These results support the contention that in an alkaline aquatic environment DOC could be an important factor to reduce Me²⁰³Hg bioaccumulation in aquatic organisms (Choi et al., 1998). Mantoura and co-workers (1978) reported that in pH 8.0 freshwater 90% of the Hg is complexed by humic substances, especially the strong complexation between inorganic Hg and fulvic acids. Methyl mercury and inorganic Hg complexes of humic substances are very stable due to binding to sulfhydryl functional groups (Hintelmann et al., 1995). Ramamoorthy and Blumhagen (1984) demonstrated that chelation of inorganic Hg to DOC reduces uptake by rainbow trout, *Oncorhynchus mykiss* (pH 8.5 water). Thus, it is crucial to include the physicochemical interactions of Hg when predicting toxic effects on organisms in the natural environments due to DOC-associated decreases in MeHg uptake resulting in reduced bioavailability and toxicity. For example, it is important to look at environmental factors such as eutrophy that would influence DOC and MeHg complexation. Clear Lake (pH 8.3) is naturally eutrophic and algal blooms are frequent during summer (Goldman and Wetzel, 1963). Lake eutrophication and nuisance growth of blue-green algae may be linked with the presence of aquatic humus. In spite of high Hg-contaminated sediments from the mine tailings, Clear Lake fish may have lower than expected MeHg uptake from the waters due to decreased DOC-linked bioavailability. Mercury concentrations are typically lower in fish from eutrophic lakes due to the DOC complexation (Huckabee et al., 1974; McKnight et al., 1983).

Concentrations of MeHg in water are very low. Partly because of this, Spry and Wiener (1991) concluded that direct uptake of aqueous Hg probably accounted for little (perhaps <10%) of the Hg accumulated by fish. More recently, Post and co-workers (1996) modeled Hg uptake in juvenile yellow perch and concluded that uptake from water was much more important, and that the relative contributions of water and diet varied seasonally (due to temperature, food availability, and metabolism) and with ontogenetic diet changes. Post and co-workers (1996) suggested that the rate of Hg uptake and the relative contribution of the two uptake pathways are seasonally dynamic because temperature, body size, and diet often vary substantially with season. They also argued that the pathways depend on the food habits and their relative intake of algae or aquatic plants with low Hg concentrations or of animal prey already highly contaminated with Hg (Post et al., 1996).

DOC plays complicated roles in bioavailability and speciation of Hg in lake ecosystems. It may enhance or retard methylation, serve as a carrier to transport Hg into waters, or compete with other binding sites (e.g., gills or sediments) for inorganic and organic Hg species. Driscoll and co-workers (1995) reported that in acidic lakes, DOC controlled the solubility and watershed export of total Hg and MeHg deposited in precipitation or bound to MeHg, limiting its availability to aquatic organisms. Results from Choi and co-workers (1998) showed that gill MeHg uptake is inhibited in the presence of DOC, yet a number of other studies show that in natural systems, fish from colored waters have higher Hg concentrations. This might imply that dietary uptake is more important in high DOC waters. Therefore, DOC effects on MeHg bioavailability at fish gills are only important if branchial uptake represents a significant route of uptake. Because nonoligotrophic lakes typically contain at least 2 mg/l DOC (McKnight et al., 1983), MeHg dietary uptake may be the principal route for the resident fishes in these systems.

These MeHg uptake studies contributed significantly to our understanding of the Clear Lake ecosystem and associated modeling effort. They also address important questions of applied science that have implications beyond the specific problems of the Clear Lake system, toward ecosystem health improvements (Cech et al., 1998).

An Integrated Watershed Approach to Studying Ecosystem Health at Lake Tahoe, CA–NV

John E. Reuter, Thomas A. Cahill, Steven S. Cliff, Charles R. Goldman, Alan C. Heyvaert, Alan D. Jassby, Susan Lindstrom, and David M. Rizzo

INTRODUCTION: CAUSE FOR CONCERN

Lake Tahoe lies in the crest of the Sierra Nevada mountains at an elevation of 1898 m within both California and Nevada. The drainage area is 812 km² with a lake surface of 501 km², producing a ratio of only 1.6:1 (Figure 123.1). This ratio is much smaller than the 10:1 ratio found for typical watersheds. The lake is located in a montane-subalpine watershed dominated by coniferous vegetation and nutrient-poor soils. It is the world's 11th deepest lake at approximately 505 m with a mean depth of 313 m. Its volume is 156 km³, with a hydraulic residence time of about 650 to 700 years, and is ice-free.

Continuous, long-term evaluation of water quality in Lake Tahoe since the early 1960s has shown that algal growth is increasing at a rate > 5% per year (Goldman, 1988). Correspondingly, there has been a decline of clarity at an alarming rate of 0.25 m per year (Jassby et al., 1999) (Figure 123.2). This long-term trend is both statistically significant and visually noticeable. If the rate of clarity loss continues, the lake could lose a total of 15 m of transparency by the year 2030. The resulting Secchi depth will most likely be accompanied by a change of color and a permanent change in trophic status. Lake Tahoe was once classified as ultraoligotrophic (Goldman, 1974), i.e., low nutrient content, low plant productivity, and high transparency. However, because of the ongoing decline in clarity and rise in algal growth rate, its trophic status (level of fertility) has been moving away from this extraordinary condition.

Research on the spatial distribution of phytoplankton (free-floating algae) indicates a marked correspondence between the highest algal growth rates and the most extensive shoreline development. Synoptic studies have shown that the central portion of the lake has historically been characterized by relatively less algae, with areas near shoreline development exhibiting enhanced production (Goldman, 1974). Similar studies of the attached algae or periphyton also demonstrate this pattern. The dramatic differences in algal growth on rocks at various shoreline locations is linked to nearby development (Loeb and Reuter, 1984).

Ironically, some of the same features that maintained the exceptional historical water quality in Lake Tahoe now threaten its health under current conditions of increased nutrient and sediment loading. Tahoe's large depth and volume once acted to dilute pollutants to a level of no significant effect; however, this is no longer the case. We now know that after nutrients enter the lake, they

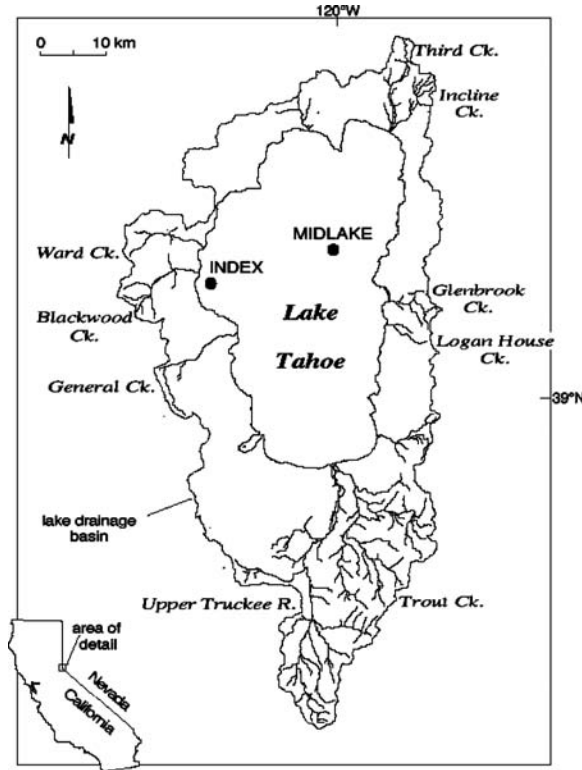

Figure 123.1 Location of Lake Tahoe and its watershed, showing some of the most important tributaries.

Figure 123.2 Mean annual Secchi depth based on long-term data collected by the Tahoe Research Group, showing the significant decline in lake clarity as measured by Secchi depth transparency. Each annual point represents the mean of 30 to 35 individual observations taken on a regular 7- to 10-day schedule.

remain in the water and can be recycled for periods of more than 10 years (Jassby et al., 1995). As a consequence, these pollutants accumulate from year to year.

Research has shown a fundamental shift from frequent stimulation of algal growth by nitrogen additions to primarily phosphorus stimulation (Goldman et al., 1993). The response of Lake Tahoe algae to nutrient enrichment has been measured since the 1960s, with the observed shift occurring in the early 1980s. Since phosphorus is typically transported along with sediment, these findings underscore the importance of sediment control and erosion mitigation. Atmospheric deposition of nitrogen from both in-basin and out-of-basin sources is now considered a significant factor contributing to the observed shift in nutrient stimulation (Jassby et al., 1994). Because much of the phosphorus input to the lake is still derived from the watershed, erosion control, acquisition of sensitive lands, and other watershed restoration practices remain appropriate courses of action.

LINKAGE BETWEEN SCIENCE AND POLICY FOR THE BENEFIT OF ECOSYSTEM MANAGEMENT

One of the cornerstones of integrated watershed management is a comprehensive understanding of (1) hydrologic, atmospheric, and ecological processes and their interactions; (2) real-time assessment of environmental conditions (e.g., air quality, water quality, forest health, etc.); (3) response to anthropogenic and natural disturbance; and (4) the ability to predict environmental improvement based on various management strategies. Indeed, serious concerns regarding ecological condition and long-term environmental protection underscore the need to provide the highest quality science to aid in problem resolution. Ecosystem health, sustainable environment, and watershed management are interrelated and part of the growing view that the fabric of the natural landscape is a complex weave of interacting influences that include physical, chemical, and biological factors. Without a sound scientific foundation, critical discussions are too easily misdirected toward narrowly focused interests.

The watershed approach taken at Lake Tahoe for many decades recognizes that lake water quality is linked to upland watershed processes and air quality. Disruption of natural ecosystem processes that naturally treat runoff (e.g., wetlands, groundwater infiltration, vegetation) and a changed landscape, which alters hydrology and promotes the accelerated loading of nutrients and sediment (e.g., impervious cover, road network, habitat disruption, land disturbance), have affected natural watershed processes. Successful implementation of land, air, and water quality restoration projects is considered the only likely avenue to arrest further decline in lake clarity. Scientific efforts must be focused toward restoration objectives and coordinated so that information needed for adaptive management can be obtained.

OBJECTIVES

In this chapter, we provide an initial look at integrating a number of disciplines, all important to ecosystem health and management at Lake Tahoe. These include air quality, water quality, and forest health, all of which are affected by human development. The following discussions come from individual presentations given at the International Congress on Ecosystem Health held in Sacramento, California, in August 1999. The theme of the Congress was "Managing for Ecosystem Health," and the session was entitled, "Moving Beyond the Conflict at Lake Tahoe." Participants agreed that a multidisciplinary approach for developing effective water management strategies was critical in the Tahoe Basin, and that a marriage between policy and science was essential. This type of approach was the focus of the recently completed Lake Tahoe Watershed Assessment (USFS, 2000), which was funded through the U.S. Forest Service (Lake Tahoe Basin Management Unit) and included contributions by academic and agency scientists.

PAST HUMAN LAND-USE AND ENVIRONMENTAL CONDITIONS

The past is part of the living present. The Lake Tahoe basin embodies the consequences of a long legacy of human and environmental history. Humans have been a component of the Lake Tahoe ecosystem for at least 8000 years, and land disturbances were initiated here with low-intensity land management by the Washoe Indians and their prehistoric predecessors. Within a century's time, indigenous practices were replaced by profound resource exploitation by incoming Euroamerican populations (beginning in the late 1800s). Within the last few decades, agency regulation has struggled to control explosive community growth induced by millions of people who visit the Tahoe Basin each year.

Contemporary land management attempts to restore the Lake Tahoe ecosystem benefit from an understanding of the long-term ecological role of aboriginal people and historic Euroamericans in the dynamics of wild plant and animal populations and their physical environments. Past land management practices engendered environmental impacts that varied in space, time, scale, intensity, and consequence. At Lake Tahoe, human disturbances range widely in scale, from pruning a patch of native shrubs to clear-cutting thousands of acres of timberland. Some resources were targeted in a single brief event, while others were affected for decades or generations. Furthermore, prehistoric and historic impacts may not have extended basin-wide, and some areas may have been relatively unaffected.

Changing attitudes and assumptions about Tahoe's environment have both enshrined and desecrated its landscape. Native Americans considered themselves stewards of the land and sustained a balanced relationship between human society and the environment. The 19th century arrivals viewed the Tahoe Basin as a natural setting for capital investment and profit associated with the silver mining activities of Nevada's Comstock era. Devastating practices, such as clear-cutting forests, were acclaimed by a society that celebrated human conquest of nature as progress. During the 20th century, the emerging dominance of the tourism industry was accompanied by a growing awareness of resource protection rather than resource extraction. However, the environmental pressure of large numbers of tourists and the growing residential population that exists to serve them has transformed the Tahoe Basin into a landscape that is, paradoxically, increasingly imperiled by its own attractiveness (Raymond, 1992). Tahoe's future well-being directly depends on a healthy physical and socioeconomic environment, not only the public's perception of one. With this latest shift in land-use paradigms, the direction of progress for 21st century users of the Tahoe Basin is less clear. In this fragile context, the Lake Tahoe environment is becoming intensively managed. This action has been partly prompted by research findings developed over the last few decades, which show that the ecosystem is a victim of multiple stresses and is now degrading at a pace observable to the largely shore-bound populace.

To shape an approach to ecosystem planning and resource management in the Tahoe Basin, we pose a number of key questions regarding the physical and cultural conditions that existed in the past, and the scope and scale of anthropogenic or human-induced disturbances that have altered conditions.

- How have climate changes affected changes in Tahoe's overall physical and cultural environment? Under varying climatic regimes, what sustainable environmental conditions are possible in the future and what type and scale of management treatments would be required to achieve them?
- What did presettlement terrestrial and aquatic ecosystems look like, and how have prehistoric and historic anthropogenic disturbances affected changes in plant and animal communities?
- What were the prehistoric and historic fire regimes in the Tahoe Basin?
- What are the past and present sources of sediment and nutrients in Tahoe's watershed that affect water quality?
- How has air quality and atmospheric visibility changed from prehistoric to present times?
- What are the historic underpinnings of causal relationships among the many socioeconomic and environmental factors in the Tahoe Basin?
- What are the culturally important locales and biotic species in the basin, and what threatens these resources?

To answer these and other questions, historical data sources that are uniquely tied to the human dimension of the ecosystem must be explored, in concert with past, present, and future biological, hydrological, and atmospheric sciences studies. In this way, we hope to establish standards by which environmental and socioeconomic health can be measured. History directs future decision making by setting a baseline of reference conditions to determine (1) how present conditions differ from past conditions, (2) the reasons for those differences, and (3) what sustainable conditions may be possible in the future. With a knowledge of how peoples have interacted with their landscape in the past, scientists and land managers not only reconstruct and interpret how people shaped past ecosystems, but link this information to the restoration and maintenance of future ecosystems. Archaeological, ethnographic, and historic documentation offer great time depth and are used as independent and corroborative tools to achieve a nexus between historic conditions and contemporary research, monitoring, and adaptive management (see discussion of paleolimnological reconstruction). Within this context of interplay among multiple sources of information, it may be possible to achieve an understanding that would not be possible using any single source of information.

THE STATE OF AIR QUALITY AND MODELING, AND ITS ROLE IN ECOSYSTEM MANAGEMENT

Lake Tahoe's unique geographical setting is marked by a cold, deep lake surrounded by an air basin defined by high mountains with dramatic vertical relief. The presence of the cold lake at the bottom of this basin defines an atmospheric regime that, in the absence of strong synoptic weather systems, develops very strong (to 10°C), shallow (30 m) subsidence and radiation inversions at all times throughout the year. In addition, the rapid radiation cooling at night generates gentle (1 m/s) but predictable downslope winds each evening, moving from the ridge tops over the developed areas at the edge of the lake and out over the lake itself. Local pollutant sources within this bowl are trapped by inversions that greatly limit the volume of air into which they can be mixed; as a result, pollutants build up to elevated concentrations. Further, the downslope winds each night move local pollutants from developed areas around the periphery of the lake out over the lake, thereby increasing the opportunity for these pollutants to deposit into the lake itself. This meteorological regime, weak or calm winds and a strong inversion, is the most common pattern throughout the year (Cahill et al., 1996).

The location of Lake Tahoe in the crest of the Sierra Nevada creates the second most common meteorological regime, that of atmospheric transport from the Sacramento Valley into the basin by mountain upslope winds. This pattern develops when the western slopes of the Sierra Nevada are heated, causing the air to rise in a chimney effect and move upslope and over the Sierra crest. The strength of this pattern depends on the amount of heating, and thus is strongest in summer, beginning in April and essentially ceasing in late October (Cahill et al., 1997). This upslope transport pattern is strengthened and made even more frequent by the alignment of the Sierra Nevada range across the prevailing westerlies common at this latitude, which combine with the terrain winds to force air up and over the Sierra Nevada from upwind sources in the Sacramento Valley.

Both the proximity of the basin to upwind urban areas and the preponderance of automobiles, which provide access to Tahoe's tourism-based economy, contribute to air pollution in the basin. Due to topography and location, the simplified Lake Tahoe air basin is defined by three major meteorological regimes: the summer daytime westerly winds, the summer nighttime inversion, and a persistent wintertime stagnant inversion. These meteorological regimes transport and then trap pollutants near the lake surface. Recently, measurements at Lake Tahoe indicate a loss of lake clarity which is significantly coupled to an atmospheric source of both nutrients and fine particles (Jassby et al., 1994, 1999; Cliff and Cahill, 2000). An air-quality model specific to this region was developed as part of the Lake Tahoe Watershed Assessment program to aid in management decisions with respect to air quality and ecosystem health.

The Lake Tahoe Airshed Model (LTAM) is a heuristic eulerian model designed to provide predictive capabilities for management of the basin. It also allows us to gather the disparate sources of air quality data at Lake Tahoe into a consistent framework. Pollution sources including automobiles and forest fires (both wildfires and prescribed fires) are put into the model; transport and a factor for deposition across the basin are predicted. The LTAM is an array of 1248 individual 2.56 km² cells across the basin encoded on a Microsoft® Excel spreadsheet. The domain is 72 km north to south (Truckee to Echo Summit) and 42 km west to east (Ward Peak to Spooner Summit). All but the southernmost end of the watershed is taken into account by the model. The LTAM is semiempirical in design, and incorporates all available air quality measurements at Lake Tahoe, plus aspects of meteorological and aerometric theory. Free variables (traffic flow, acres burned in the forest, population density, etc.) are assumed to be linear with pollutant emissions. Additional research is proposed to test these and other model assumptions.

LTAM is designed to provide information on the role of the atmosphere in the health and welfare concerns of the Lake Tahoe basin. It has two major immediate goals: (1) to predict the concentration of air quality pollutants in the Tahoe Basin at spatially diverse locations where no data exist and (2) to predict the potential for atmospheric deposition of nutrients and fine particles to the watershed and lake by determining spatial concentration of pollutants within the basin. A thorough description of the LTAM, inputs to the model, and several output scenarios is given in Cliff and Cahill (2000).

Scenarios used as examples for the Lake Tahoe Watershed Assessment modeling integration were developed to present the type of results that are possible with single medium (in this case air quality) models designed specifically for the Tahoe Basin. We evaluated prescribed burns within the Ward Creek watershed, in October, on 40-year (50 ha) and 20-year (100 ha) return cycles, as well as a wildfire (occurring in August) that burned approximately 75% of the forested part of the Ward Creek watershed (1500 ha). From the calculated emission parameters for the wildfire and prescribed fire scenarios, the LTAM calculates the falloff in smoke PM_{2.5} (particulate matter captured on a 2.5- μ m filter) across the basin. The resultant values from the LTAM are graphed as a concentration vs. location and then plotted over a map of the area represented by the model. A comparison of the 20- and 40-year return cycle scenarios is shown in Figure 123.3.

Contrasted to the historical wildfire comparison (Figure 123.3A), it is seen that the LTAM predicts massive violations of federal and state PM_{2.5} standards for the 20-year return scenario (Figure 123.3C). The historical wildfire is an analysis of past conditions based on a 40-year return in the basin divided among the total burn season, equaling about 12 ha burned per day in three small (4 ha) wildfires (Figure 123.3A). The 40-year return scenario predicts localized violations for the October period (Figure 123.3B). A model run for the same scenario for a typical summer period (not shown) predicts lesser violation, mostly due to the increased ventilation of the basin during that period. The hypothetical wildfire during August (1500 ha) is predicted to completely fill the basin and beyond with smoke (Cliff and Cahill, 2000). Although the wildfire burns an order of magnitude more land than the prescribed fires, the number of resultant violation days is predicted by LTAM to be roughly equivalent. That is about 2 to 3 violation days for the 40-year fire, 3 days for the 20-year fire, and 4 to 5 days for the wildfire. This apparent discrepancy is due mostly to the increased ventilation of the basin during the late spring and summer months. Furthermore, increased lofting of smoke in a wildfire results in impact at greater downwind distance than in a prescribed fire situation. It should be noted that the LTAM is capable of only limited predictions at this time. Further study of the impact of fire on the Lake Tahoe ecosystem, especially the impact of smoke on lake clarity, visibility, and human health, is necessary to better define parameters for integrated management models in general, and the LTAM in particular.

Air quality modeling at Lake Tahoe, although at the nadir of development, is capable of aiding in ecosystem health management. The most significant finding from the construction and use of

Figure 123.3 $PM_{2.5}$ concentration ($mg\ m^{-3}$) predictions from LTAM, based on a 24-h average superimposed on the basin map. Comparison of three fire scenarios in the Lake Tahoe basin. (A) The historical wildfire (12 to 16 ha). (B and C) Hypothetical prescribed fire scenarios located in the Ward Creek watershed; (B) a 50-ha prescribed fire; and (C) a 100-ha prescribed fire representing a 40- and 20-year total fire return time to the basin, respectively. The black isopleth is set at $65\ mg\ m^{-3}$, which is the (proposed) federal 24-h standard for $PM_{2.5}$. The peak concentrations for A, B, and C are 29, 165, and $500\ mg\ m^{-3}$, respectively.

LTAM is that pollutants associated with dry deposition are most likely to deposit to the lake surface and hence potentially degrade lake clarity at times of intense inversion; this provides support to direct measurements of deposition (Jassby et al., 1994). Atmospheric inversion at Lake Tahoe is the most predominant meteorological condition in the evening during the summer months, and all day throughout the interstorm winter period. An evaluation of $PM_{2.5}$ for hypothetical wildfire and prescribed fires in the Ward Creek watershed has been performed. The result of this evaluation indicates that, for the prescribed fires, a fall burn is particularly troublesome from the standpoint of air quality. The atmospheric inversions that tend to be present during the fall inhibit ventilation and hence allow buildup of the concentration of $PM_{2.5}$. Currently, not enough is known about the chemical composition and speciation of prescribed fire smoke to evaluate the impact of these prescribed fires on the clarity of Lake Tahoe. It is known, however, that $PM_{2.5}$ is a pollutant from the perspective of human health. The potential for violations of federal, state, and basin air quality standards based on visibility is also expected from prescribed fires. In general, to better evaluate the impact of air quality and ecosystem health at Lake Tahoe requires further study. It is imperative to understand the link between emission, transport, and deposition of air constituents throughout the basin to better design integrated modeling tools for management use.

LAKE TAHOE NUTRIENT BUDGETS

For decades, planning, regulatory, and implementation actions in the Tahoe Basin have focused on controlling nutrient and sediment inputs to the lake. Examples include, but are not limited to, acquisition of environmentally sensitive lands, building restrictions, BMP retrofitting, erosion control, installation of BMPs for treatment of surface runoff, permits, and education. However, these have largely been done on a project-by-project basis rather than as part of a unified, comprehensive plan. Now that the public and private sectors are working in cooperation to achieve environmental restoration activities in the basin, it is more important than ever that budgets quantify the critical sources of nutrients and sediment. Setting priorities for restoration projects depends on identifying the critical sources of these materials.

Five major categories of nutrient loading to Lake Tahoe have been identified: (1) direct atmospheric deposition and precipitation, (2) stream discharge, (3) overland runoff directly to the lake, (4) groundwater, and (5) shoreline erosion. The major losses include settling of material from the water column to the bottom and discharge to the Truckee River, the sole tributary outflow. We provide preliminary estimates for total phosphorus (TP), dissolved P, and total nitrogen (TN) loading (Table 123.1).

Atmospheric Deposition

In 1994, the first estimate was made of the contribution by atmospheric deposition of N and P to the annual nutrient load of Lake Tahoe (Jassby et al., 1994). This study analyzed both wet (rain and snow) and dry fallout. It was concluded that atmospheric deposition provides most of the dissolved inorganic nitrogen and total nitrogen to the loading budget of Lake Tahoe. It was further concluded that deposition also contributes significant amounts of soluble reactive P and total P loading, but to a lesser extent than for nitrogen. Comparisons of atmospheric loading at the Ward Lake level, located along the west shore, showed that (1) deposition of nitrate and ammonium were similar, regardless of whether the wet or dry forms were being considered; (2) wet deposition of nitrate and ammonium in the form of snow and rain had approximately twice the loading rate as deposition from dry fallout; (3) conversely, the loading of dry soluble reactive P was 2.4 times that for wet; (4) the ratio of total N to dissolved inorganic N (i.e., nitrate plus ammonium) was 2:1 with dry fallout comprising 64% of TN deposition; and (5) the ratio of total P to soluble reactive P was also just over 2:1, with dry fallout comprising 70% of TP deposition.

Using data contained in Jassby et al. (1994), combined with other portions of the historic deposition monitoring database, and the existing isohyetal map for Lake Tahoe, which shows the spatial distribution of precipitation over the entire lake and watershed, loading values for N and P, which fall directly on the lake surface were calculated. Nutrients deposited on the watershed and

Table 123.1 Budget of Total Nitrogen, Total Phosphorus, and Dissolved Phosphorus Inputs to Lake Tahoe

	Total N	Total P	Soluble P
Atmospheric deposition	234	12.4	5.6
Stream loading	82	13.3	2.4
Direct runoff	23	12.3	2.4
Groundwater	60	4	4
Shoreline erosion	1	1.6	—
Total	400	43.6	14.4

Note: Values were obtained from direct measurements of concentration and discharge, and scaled to the whole lake. They represent an average during the period 1980–1993. Data are presented as metric tons (MT) per year.

which are subsequently transported to the lake are included in the calculations of stream discharge, direct runoff to the lake, and groundwater. For the entire lake surface area, the contribution of P was 12.4 metric tons (MT; where 1 MT = 1000 kg or 2205 lbs). Direct N loading to the lake surface was estimated at 234 MT. This accounts for 28 and 59% of the annual TP and TN budgets, respectively. At this time, we hypothesize that P present in precipitation and dry fallout results from wood smoke, road dust, and aeolian (wind) transport from disturbed land. Sources of N come from within and outside the Tahoe Basin, and include automobile emissions, agrochemical residues, wood smoke, etc.

Stream Loading

A total of 63 streams drain into Lake Tahoe. These streams are characterized by different levels of urban development and disturbance. The Lake Tahoe Interagency Monitoring Program (LTIMP) has been sampling up to ten of these streams since 1980. Because of variation in watershed characteristics around the basin and the significant “rain shadow” effect along the west-to-east direction across the lake (i.e., decline on total precipitation from west to east), no single location is representative of all watersheds. Flow from these monitored streams comprises 50 to 55% of the total discharge from all tributaries. Each stream is monitored on at least 30 to 35 dates each year. N and P loading calculations were done using the LTIMP flow and nutrient concentration database.

Using data from the early 1980s to 1993, the Tahoe Research Group has calculated stream loads for N and P as part of two separate studies. The results for annual N loading were 81 and 55 MT for the beginning and end of this period, respectively. Comparable loading values for total P were 13 and 11 MT (Marjanovic, 1989; Jassby et al., 1994). Differences from period to period reflect the variation in precipitation and runoff. Contributions for N and P in our budget were taken as the mean, or 68 and 12 MT, respectively. Thodal (1997) also provided a very preliminary estimate of nutrient loading to Lake Tahoe during the period 1990 to 1993. Annual nutrient load associated with stream flow was estimated by multiplying the mean annual volume of surface water runoff by the mean annual nutrient concentration. Using this simple approach, loading was reported as 70 MT for total N and 20 MT for total P (Thodal, 1997). A very early estimate of stream flow nutrient load by Dugan and McGauhey (1974) estimated 120 MT of total N and 9 MT for total P. Taking the mean of these four values, which represent different time periods and consequently different precipitation conditions, loading estimates of 82 and 13.3 MT were obtained for total N and total P, respectively. These account for 21 and 31% of the N and P budgets.

Direct Runoff

The Tahoe Basin has 52 intervening zones which drain directly into the lake without first entering the streams. These intervening zones are generally found between the individual watersheds and as such are distributed around the entire lake. These zones range in size from 0.1 km² to 10.5 km². The range for covered or otherwise disturbed land within these intervening zones ranges from 0 to 63%. The overall ratio of disturbed to total area is 27% with runoff from the intervening zones accounting for 10% of the entire drainage.

Calculations of loading from direct runoff requires quantification of flow and concentration. Flow from each of the intervening areas was estimated by Marjanovic (1989). Data on N and P concentrations are not extensive since this type of study has not received priority funding in the basin. However, based on a limited database presented and reviewed by Reuter et al. (2001), we estimated concentration data for this preliminary nutrient budget. For the purpose of calculation, an intervening area was considered urban if 25% or more of its areas was classified as covered or disturbed. Concentrations representative of urban and rural conditions were taken from the

field studies cited previously and used in the quantification of loads (for urban conditions, total Kjeldahl N [TKN] = 0.48 mg l⁻¹, nitrate = 0.08 mg N l⁻¹, total P = 0.31 mg l⁻¹, and soluble reactive P = 0.05 mg l⁻¹, for rural conditions, TKN = 0.19 mg l⁻¹, nitrate = 0.01 mg N l⁻¹, total P = 0.10 mg l⁻¹, and soluble reactive P = 0.01 mg l⁻¹).

N loading was calculated at 23 MT or 6% of the total N budget while P loading was 12.3 MT or 28% of the total P budget. The observation regarding the high contribution of P loading from direct runoff is particularly important because a significant portion of the urbanization at Tahoe is found in the intervening zones. It provides project planners with the understanding that control and treatment of urban and direct runoff to the lake is critical and should be a high priority.

Groundwater

The most comprehensive, basin-wide effort to date comes from Thodal (1997) as part of a hydrogeology study of the Tahoe Basin. Data on the results of a groundwater quality monitoring study done from 1990 through 1992 are presented. By multiplying mean nutrient concentrations from their groundwater survey (N = 1.0 mg l⁻¹, P = 0.074 mg l⁻¹) and estimates of total annual groundwater discharge to the lake (5.15×10^7 m³), Thodal calculated "rounded estimates" of 60 MT for N loading and a 4 MT for P loading. This accounted for 15% of the TN budget and 9% of the TP budget.

Shoreline Erosion

The process of shoreline erosion and its quantitative importance to the nutrient and sediment budgets of Lake Tahoe have received very little attention. However, the importance of shoreline erosion has been highlighted in recent years when the combination of high lake levels and strong and sustained winds altered some of the west shoreline by many feet. Recently, Adams and Minor (2000) estimated shoreline changes in Lake Tahoe by analyzing historical photographs and combined this evaluation with measurements of the nutrient content of shoreline sediments. They estimated an annual loading of only about 1 MT for nitrogen and 1.6 MT for phosphorus.

Budget Review

This budget clearly suggests the importance of direct runoff as an important P source from urban areas and highlights the need for additional study of loading from this source. At the same time, the contribution of atmospheric deposition to the N budget clearly dominates other sources. Heyvaert (unpublished data) has found that nutrient sedimentation losses to the bottom of Lake Tahoe are 402 MT for total N and 53 MT for total P. These data agree remarkably well with the independent loading estimates given previously. This close agreement gives us increased confidence that the loading rates are representative.

Phosphorus reduction strategies at Lake Tahoe will have to address multiple sources including direct runoff, atmospheric deposition, and stream loading. Using the estimated loading of dissolved P as a first approximation of biologically available P (BAP), this budget further shows that BAP is on the order of 33% of TP. This value is not uncommon (Rechow and Chapra, 1983); however, the 14.4 MT value may underestimate true BAP to the extent that bioavailable P is released from particulate P entering the lake's water column. Research to investigate this further has been proposed. Looking at dissolved P alone, the relative importance of the groundwater contribution increases.

As restoration projects are being targeted and adaptive management proceeds, it will be very helpful to have more detailed data on the specific sources of nutrients within each of the major categories discussed previously. Restoration should give priority to those areas that make the greatest contribution to the nutrient loading budget.

PALEOLIMNOLOGICAL RECONSTRUCTION OF BASELINE CONDITIONS AND ECOSYSTEM RESPONSE TO ANTHROPOGENIC DISTURBANCE

Lake sediments constantly accumulate material derived from the watershed and from the overlying water column and, over time, a physical record accrues. Biogeochemical analysis of this record can provide useful information about lake response to changing conditions, whether from natural causes or from anthropogenic disturbance in the watershed. The analysis of lake sediment cores allows us to examine ecosystem processes at a longer and more-relevant time scale than is usually attained from available monitoring data. When used in conjunction with process-oriented research that includes both modeling and the analysis of long-term data, this approach can also significantly improve our efforts to forecast ecosystem response to contemporary watershed disturbance.

In the Tahoe Basin, there have been two major episodes of watershed disturbance since it was located and described by Lt. John Fremont in 1844. The first event was extensive clear-cut logging associated with the Comstock era that began in the 1860s and continued into the 1890s. Timber from the Tahoe Basin was exported to adjacent communities for construction of railroads, mines, and towns. It is estimated that over 60% of the watershed was clear-cut during this period, with much of the remaining land either alpine, barren, or inaccessible. The second period of disturbance began with rapid urbanization in the late 1950s. To this day, development continues within the Lake Tahoe watershed. Among other significant disturbances, an extensive road network now surrounds the lake, located mainly in lower reaches of individual watersheds, but extending a considerable distance up accessible slopes in many areas. Of particular interest are the effects on lake function from logging into the late 1800s, and the system response after that disturbance ended. Such information could be instructive for evaluating modern environmental impacts from urbanization and the potential response from mitigation and restoration.

Over the years, several sediment cores have been extracted from various points within the lake to determine spatial and long-term patterns of sediment composition and accumulation (Heyvaert, 1998). These cores have been analyzed for many chemical and biological constituents and for characterization of their physical attributes. The specific goals of this project were to (1) identify biogeochemical markers that indicate lake and watershed responses to ecological stress; (2) establish the baseline predisturbance condition of these markers and its natural background variability; (3) assess watershed response to historical periods of fire, drought, and timber harvest; (4) determine lake responses to urbanization since the late 1950s; and (5) establish a database for the calibration and verification of watershed–lake models in the Tahoe Basin.

The most important preliminary step in this study was to establish an accurate sediment chronology. We now have a relatively reliable geochronology for the Tahoe sediments, constructed from ^{210}Pb and ^{14}C data. These data indicate significant basin-wide changes in mass sedimentation rates over the last 150 years. Specifically, high sedimentation rates were associated with clear-cut logging in the Tahoe Basin from 1860 through 1900. That period was followed by a three- to five-fold decrease in mass sedimentation rates during the early 20th century. These lower sedimentation rates persisted until urbanization began in the Tahoe Basin after World War II.

From ^{210}Pb data, the average mass sedimentation rate (90% confidence interval) during the Comstock logging era from 1860 to 1900 was $0.043 (\pm 0.011)$ g cm^{-2} per year. By comparison, the average mass sedimentation rate for the recent period from 1970 to 1990 was $0.027 (\pm 0.006)$ g cm^{-2} per year. Notably, both of these rates are significantly higher than the average mass sedimentation rate of $0.009 (\pm 0.004)$ g cm^{-2} per year determined for the intervening period from 1900 to 1970.

Predisturbance sedimentation rates were estimated from ^{14}C measurements in several deep sections of two cores. The long-term average rate was $0.006 (\pm 0.002)$ g cm^{-2} per year, which is just slightly less than the sedimentation rate that was estimated for the period intervening between Comstock logging and urbanization. Since these rates are comparable, it would suggest that

landscape recovery was rapid after clear-cut logging ended and that lake sedimentation rates dropped back almost to predisturbance levels.

Diagenesis and organic decomposition preclude a quantitative reconstruction of historical algal primary productivity (PPr) from the carbon record. However, diatoms represent greater than 80% of the phytoplankton biomass in Lake Tahoe, so biogenic silica accumulation rates were used as a proxy for historical algal productivity. The PPr reconstructed for that interval from 1900 to 1970 was on average 28 g cm⁻² per year, which is about 25% less than the earliest ¹⁴C PPr measurements conducted at Lake Tahoe in 1959 (39 g cm⁻² per year). Primary productivity reconstructed for the historic period of Comstock logging gave an average annual rate of about 176 g cm⁻² per year, which is comparable to annual average PPr measured in 1993 (183 g cm⁻² per year). Our estimate of baseline, predisturbance PPr in Lake Tahoe before 1850, was 27 g cm⁻² per year. Apparently the lake nearly returned to its baseline PPr during the intervening period, soon after logging ended, despite a 650- to 700-year hydraulic retention.

The fact that mass sedimentation rates and biogenic silica flux decreased shortly after the logging disturbance ended is testimony to rapid landscape stabilization and recovery with second-growth forest. It also indicates that Comstock logging produced a pulse disturbance. By contrast, the disturbance from urbanization could persist as a chronic perturbation for a considerable time. These data also suggest, however, that effective mitigation of the watershed erosion caused by urbanization could directly improve water quality on a decadal timescale. This corresponds to the 50% response times calculated independently from sediment trap data for nitrogen and phosphorus settling velocities.

At this time we continue to refine the Tahoe Basin sediment chronology and our estimates of mass and nutrient sedimentation rates. Work has also begun on the interpretation of additional sediment markers for understanding other disturbance patterns, including drought and forest fires. Recently, piston cores representing several thousand years of lake and watershed history were recovered from the lake. These data will yield, among other factors, long-term profiles of natural variation in sedimentation rates and historical PPr at Lake Tahoe.

FOREST HEALTH IN THE TAHOE BASIN

As in many areas of the western U.S., periodic fire in the coniferous forests of the Tahoe Basin is considered to be a defining influence on ecosystem function and health, altering fundamental plant, soil, and microclimate conditions. Historically, frequent low-intensity fire has been the main disturbance driving ecosystem structure, function, and composition. Within the last century, however, fire suppression and logging at Lake Tahoe (both clear-cutting and selective harvests) have significantly altered stand conditions by increasing stem densities of shade-tolerant species, soil litter depth and understory shading. Both understory and overstory tree densities have increased dramatically throughout basin forests; in particular, there has been a doubling in the importance of white fir and incense cedar and a decline in the importance of Jeffrey pine and sugar pine by 50% (Barbour et al., 2002). Sites that have been previously logged currently exhibit the highest stem densities for both overstory and understory trees. In association with a recent drought, highly visible levels of tree mortality in the Tahoe Basin began in the mid-1980s (Smith et al., 1994; Elliot-Fisk et al., 1996). Based on 1997 and 1998 ground surveys of 31 stands in the basin, overall cumulative tree mortality in the lower montane forests ranges from 9 to 33% in 31 sampled stands with mean mortality of 25% for previously logged stands (seral stands) and 21% for old growth stands that have never been logged (Maloney and Rizzo, unpublished data).

In many stands these conditions are outside the forest's historic range of variability, fundamentally altering ecosystem processes. It has become apparent that in fire-dependent ecosystems, the absence of fire will lead to pests (often in conjunction with drought) and mechanical thinning, which become the primary drivers of both mortality and recruitment. Epidemic levels of bark

beetles are clearly the most important cause of tree death in the past 10 years in the Tahoe Basin. A number of reports show increased mortality of Jeffrey pine due to the Jeffrey pine beetle (*Dendroctonus jeffreyi*) and white fir due to the fir beetle (*Scolytus ventralis*) during the drought years of 1987 to 1993 (Ferrell et al., 1994; Smith et al., 1994; Dale, 1996). Bark beetles are known to build to epidemic levels by attacking trees under stress from strong competition for available resources (Ferrell et al., 1994; Smith et al., 1994). Such conditions were readily apparent in the Tahoe Basin during the drought. In addition, a number of pathogens (e.g., root disease and dwarf mistletoe) play a role in tree mortality in the basin, with diseased trees often serving as susceptible hosts for resident populations of bark beetles during interdrought periods (Maloney and Rizzo, unpublished data).

The condition of Lake Tahoe forests has become an important concern for residents and forest managers of the basin. The presence of increased fuel loads, due to many years of fire suppression and the recent tree mortality event, and current high densities of living trees has led to fears of a catastrophic fire. Such a fire can threaten human life and property, as well as potentially upset historical ecological processes. Current fire models suggest that the probability of a large-scale fire (i.e., >4 ha) in the Tahoe Basin is relatively low because of the high elevation climate, basin topography, and quick response times of local fire officials (Manley et al., 2000). However, when such a fire does occur, it most likely will be a crown fire that will cause significant tree mortality.

In light of the current state of Lake Tahoe forests, how should these lands be managed? The most critical need for Lake Tahoe forests is to set the goals that will be used to determine the direction of forest management. Scientific studies of the ecology of coniferous forests are an important part of this process. Research to determine reference conditions to serve as points of comparison and experiments into forest ecosystem processes are ongoing in the basin (e.g., Manley et al., 2000; Barbour et al., 2002). While such information is important, science cannot set societal goals; the major role scientists will have is to offer a series of alternative management schemes and potential outcomes from an initial set of objectives. A number of citizen groups (e.g., Tahoe Forest Health Consensus Group) and government agencies have taken the initiative of setting these goals. In California, Lake Tahoe forests, along with the National Parks, are unique in that there is little pressure for a sustained timber harvest to maintain traditional logging communities. In an urbanized environment dependent on tourism, prevention of catastrophic fire and aesthetics are likely to be the main concerns. However, goals such as prevention of catastrophic fire to protect property may not necessarily be compatible with goals that call for old growth restoration. There are many definitions of forest health; these range from commodity-based utilitarian views to ecosystem-based ideas that do not include humans as part of the definition (Kolb et al., 1994). The ability to partition the needs of an urbanized population from needs of natural ecosystem functioning will require much discussion among interested parties.

A number of proposals have been put forth as ways to improve forest health at Lake Tahoe. Restoration of basin forests could potentially focus on both stand thinning and prescribed fire. In theory, restoring forests to their natural densities should mitigate most serious pest outbreaks (e.g., reduced bark beetle epidemics during drought periods) (Ferrell, 1996). As we gain a better understanding of precontact forest, the temptation will be to use these data to return forests to previous stand densities. Moving seral stands toward conditions found in old-growth stands may prevent catastrophic fire, as well as maintain or increase biological diversity. But restoring ecosystem process is more than just restoring patterns and historical tree densities. The long-term impacts of procedures such as thinning dense understories and prescribed burns on ecosystem processes are not explicitly known. For example, thinning may potentially reduce pest problems by lowering stand densities and relieving the potential for drought and competition-induced stress, but such treatments also have the potential to increase pest incidence in some instances. Logging operations often damage residual trees and can increase the buildup of root disease inoculum due to saprobic survival in stumps. Scorched trees, due to hot-burning prescribed fires, may be more susceptible to bark beetle attack. Studies to elucidate the relative roles of mechanical thinning and fire on

various organisms and ecosystem processes are currently under way at several locations in California. However, none of these studies is currently being conducted in the Tahoe Basin.

Because of urbanization and population growth in the basin, letting “nature run its course” is clearly not an option in managing Lake Tahoe forests. It is thought that 3500 ha per year historically were burned in the basin; currently less than 400 ha are underburned (Manley et al., 2000). Current air quality regulations will continue to influence the amount of forestland that can be burned. Even if large-scale prescribed burns can be implemented, it is not clear what intensities of prescribed burns should be used to effectively mimic natural wildfires (Manley et al., 2000). Due to uncertainties with the long-term consequences of current management options, scientifically based monitoring will be critical for evaluating the efficacy of these large-scale experiments. If true ecosystem-based management is to take place in Lake Tahoe forests, managers must design any forest treatment with the collection of scientific data in mind. Otherwise, the ability of managers in the future to adapt to changing conditions will be compromised.

CONCLUSION

By its special status as an Outstanding National Resource Water under the federal Clean Water Act (within the state of California), Lake Tahoe is recognized as unique and must be protected. As presented in this chapter, water quality, air quality, forest condition, along with past, current, and future socioeconomic conditions are all integrated under the heading of ecosystem health. They must be considered in concert and not as individual issues. The agency approach for decades at Lake Tahoe has focused on watershed management for the purpose of water quality protection. This is clearly stated in the many planning documents produced over the years for the Lake Tahoe Basin, and is central to the mission of nearly all the participating local, state, and federal resource agencies. Now a wide array of public and private institutions form an extensive foundation for linking policy to scientific research and monitoring.

For effective lake management, we need to know:

1. The specific sources of sediment and nutrients to the lake (within each of the major categories) and their respective contributions
2. The amount of reduction in loading is necessary to achieve the desired water quality standards and total daily maximum loads for Lake Tahoe (i.e., lake response)
3. How the necessary reduction can be achieved

Continued scientific efforts at Lake Tahoe must address these questions.

ACKNOWLEDGMENTS

A special thank you is given to Dennis Rolston (Director) and Cheryl Smith (Manager) of the Center for Ecological Health Research (CEHR), located at the University of California, Davis. For many years, the CEHR has promoted and encouraged interdisciplinary environmental research, and has provided the intellectual climate for productive, integrated studies. The Tahoe story, as we know it today, represents the combined effort of literally hundreds of faculty colleagues, staff, graduate students, undergraduates, and volunteers. We thank Charles Soderquist and Dennis Rolston for their helpful reviews. Major sources of funding for the research described in this chapter come from the EPA through the CEHR (R819658), an EPA/NSF-sponsored Water and Watersheds grant through the National Center for Environmental Research and Quality Assurance (R826282), and support from the U.S. Forest Service, Lake Tahoe Watershed Assessment. The views in this document do not necessarily reflect those of the federal funding agencies, and no official endorsement should be inferred.

SECTION III.4

Aquatic Ecosystems: New York, Maryland, and Florida

Overview: Aquatic Ecosystems: New York, Maryland, and Florida

Dennis E. Rolston

This section contains chapters describing three case studies dealing with aquatic ecosystems in three states. Each of the three studies used a different approach to evaluate the effects of various human activities or stresses on the aquatic ecosystems of the study area.

Weisskoff used economic analysis to measure the implications of different restoration scenarios for the Florida Everglades within affected counties of South Florida. Two commonly used regional economic models were compared to the predicted impacts. The investigator advocates use of an economic analysis because it may help citizens and policy makers to gain a deeper appreciation of the restoration challenge and the need for imaginative collaboration among the stakeholders.

The objective of the study by Mehaffey and co-workers was to evaluate the relationships between land use and surface-water quality in New York watersheds, and to evaluate the risk for New York City's drinking-water supply system. A traditional stepwise regression analysis was used to relate human use of the land to water-quality parameters of the streams in the watersheds.

The chapter by Yuan describes the results of a pilot study in which a knowledge base (expert system) was used to relate human activities to stream ecological conditions. The indicator of stream ecological condition was benthic macroinvertebrates in a Maryland watershed. Fuzzy logic was used to analyze situations for which absolute rules in the expert system that weighs and chooses different options are difficult or impossible to define.

A Tale of Two Models: IMPLAN and REMI on the Economics of Everglades Restoration

Richard Weisskoff

INTRODUCTION AND BACKGROUND

The restoration of the Everglades ecosystem in South Florida is the largest of its type in the world today. The Central and South Florida (C&SF) Comprehensive Review Study (known as the Restudy) was sent to the Congress on July 1, 1999, and passed as the Comprehensive Everglades Restoration Plan (CERP) in December 2000. The total project is expected to cost \$8 billion over the next decades, with funding split half from the federal government and half from the state of Florida. If fully implemented, the Everglades Plan is expected to revitalize the ecosystem by improving the quantity, quality, distribution, and timing of the natural water flows, while assuring more-reliable flood protection for the cities, and a more-regular supply of water for agriculture. The Everglades Plan thus promises the best of all worlds to the major stakeholders of the region. This is ironic indeed, given the long-term litigation concerning the finding that upstream agriculture has been responsible for polluting the Everglades in the first place.*

The hypothesis of this chapter is that the major investments required to save the Everglades may inadvertently accelerate its destruction for the following three reasons. First, by assuring an adequate, low-cost supply of water and more extensive flood protection, the plan will allow the high levels of economic growth of the region to continue. Second, the very magnitude of the construction and operation of the rescue mission itself, together with its economic linkages, might cause a significant increase in jobs and income. Third, enhanced amenities that restoration will bring to the region will encourage new activities, such as ecotourism, further home construction, and greater levels of in-migration. All these will create even greater pressures on the ecosystem, especially higher demands for water and land.

The effects of all of these factors will be evaluated in this chapter through the application of two different regional economic models which will measure the impacts of alternative economies. First, the models will be used to project the current trends without restoration (the baseline projection). Then, the regional economy will be altered to include the restoration spending plus other “missing pieces” of economic activity omitted from the baseline projections, namely, large-

* Litigation began with the seminal 1988 case, *U.S. v. South Florida Water Management District, et al.*, in the U.S. District, So. Dist. of FL, Case No. 88-1886-CIV-HOEVELER, in which the federal government sued the state of Florida for failing to protect its waters and named the sugar growers as the primary polluters of the Everglades. A complete collection of Everglades litigation can be viewed at www.law.miami.edu/library/everglades. For background to the history of land and water in the region, see McCluney, 1969; Derr, 1989; Douglas, 1988; Light and Dineen, 1994; and Watercourse, 1996.

scale restructuring of agricultural activity, plus higher levels of tourism, new construction, and in-migration.

An approach similar to the present study was taken by Duchin and Lange (1994) for the world economy. Using the world model developed by Leontief and co-workers (1977), Duchin and Lange found no quantitative support for the optimistic vision of the 1987 Brundtland Report that an expanding economy was compatible with an improved environment unless a major change in consumption and production patterns were to occur. Our analysis carries a similar urgency, because plans regarding the future of the Everglades are now being formalized and implemented.

There may also be a parallel between the circumstances in South Florida today and the conditions that led to the Latin American debt crisis of the 1980s. Prior to that crisis, international banks lent money to many autonomous government entities throughout the continent, and these loans were guaranteed by each respective national government in the event of default.* As the individual entities began to fail in the worldwide stagflation of the early 1980s, national governments were apparently caught off-guard by the magnitude of the accumulated debts for which they had become responsible. Beginning with Mexico in 1982, nation after nation defaulted, initiating an era that was to undo much of the economic progress of the previous decades.

So, too, in South Florida, the ecosystem is under enormous pressure to accept the ambitious projects of many donors. But there is a growing awareness that environmental degradation has resulted from rapid economic growth, which, until recently, had been viewed almost universally as the solution to, rather than the cause of urban problems.

Unfortunately, the analysis of the economic impact of Everglades restoration comes as an afterthought, rather than as an integral part of the plan.** The Restudy, after all, was conceived as an attempt to solve a huge and complex hydrological–ecological problem. What could possibly have been gained by connecting computer models that simulate the water flows to computer models that simulate the economic growth of the region?

The answer, of course, is simple: Everglades restoration is primarily an economic problem, as well as a scientific one, for it is the very success of the regional economy that has doomed the natural system. Furthermore, if the goal of policy makers is to prepare the ecological setting for “what will be” rather than for “what is,” then we must know how the economy is growing and how the economy and the environment are interrelated.

There is perhaps another factor that makes models of economic growth even more alien to the ecological modelers, and that is the manner in which the two professions view the influence of time. Models of the environment rely on the historical records of the past: how are we to restore the natural system, given the historic rainfall patterns and the current needs for flood protection of the farmlands and cities. Models of the economy are just the opposite: what was will never again be repeated; historical trends and interrelationships are used only to forecast the new economic levels which may be expected in future years. The economy of the year 2002 will never be seen again, and the economy of the year 2030 will surely differ, quantitatively and qualitatively, from the present one. To the extent that the demands of this new economy can be anticipated, we are forced to repeat the basic question of this chapter: Is a restored Everglades of the future compatible with the expected economy of the future?

This chapter offers a broader framework for researchers facing this question by extending my earlier study, “Missing Pieces in Ecosystem Restoration: The Case of the Florida Everglades” (Weisskoff, 2000). In that paper, I attempted to measure the impact of restoration spending plus other simultaneous investments on the present and future regional economy. The present work improves on the earlier work by comparing the results of two very different regional economic models.

In the first section of this chapter, I review the characteristics of the South Florida economy, the historical record of its growth, and the overall projections for the region. I then apply the

** See U.S. Army Corps of Engineers, 1998, Appendix E, “Socio-Economics.”

IMPLAN and REMI models, which have been tailored to the region by the author in several innovative ways, in order to trace out the impacts of the new projects. Then the projects are combined into different superscenarios and the results of the two models compared.

It is hoped that the conclusions will encourage economists to work hand in hand with ecologists to interpret and anticipate the consequences of the full array of activities occurring in the region. Just as the original 1948 C&SF Comprehensive Project opened the region to massive new investments, which had the effect of transforming the environment and setting the stage for the present crisis, so, too, the current Everglades restoration may trigger another prolonged spiral of spectacular growth by enhancing the region's amenities.*

Is there an alternative? The failure to restore will simply permit the present trend to continue, a trend in which economic growth has gone hand in hand with the demise of the natural wetlands, saltwater intrusion into the coastal wells, destruction of estuarine breeding grounds, and the disintegration of the coral reefs. Perhaps by looking closely at the economic picture, all citizens of the region, as well as the Everglades' supporters throughout the nation, may gain a broader picture of the restoration challenge and the need for more imaginative collaboration and compromise among all the stakeholders.

THE REGION AND ITS GROWTH

The South Florida region, which comprises the Everglades and its headwaters, covers almost 40,000 km² (15,000 mi²) and 13 full counties, accounting for 28.1% of Florida's land area, 39.2% of the state's residents, and almost half the state's consumption of fresh water (Table 125.1, lines A.1, A.2, A.4, cols. 1, 4). The region is home to nearly 6 million people, 6.5 million motor vehicles, and over 600,000 cattle and calves (Table 125.1, lines A.2, A.5, B.6). If we consider the time spent by the 18.8 million visitors in the region, the full-year population would be increased by 7.1% on an annual basis (lines A.6–A.8). The region accounted for 3.6% of all new housing permits in the U.S. in 1997, although it contains but 2.2% of the total population. These figures underscore the relative magnitude of the regional housing boom (Table 125.1, lines A.2, A.3, col. 6).

Forty-one percent of the region's land is in agriculture. These farms represent 62% of the state's irrigated farmland, 46% of the nation's sugarcane land, and 38% of the nation's citrus trees. Included also are extensive livestock, sod, and vegetable plantations, as well as many small farms and nurseries (Table 125.1, lines B.3, B.6–B.9, cols. 1, 4, 6).

In terms of environmental heritage, nearly two thirds of the threatened and endangered species in Florida can be found in these counties (Table 125.1, lines C.1, C.2, col. 4). The region is characterized by low elevation and a semitropical climate. Its average temperatures and rainfall are higher than the rest of Florida and much higher than the rest of the U.S. (Table 125.1, lines C.3, C.4, cols. 4–6).

South Florida is one of North America's last frontiers. Large-scale settlement began only in the first decades of the 20th century once the Florida coastal railroad was extended to Miami and drainage of interior swampland for farms began. A series of violent hurricanes in the late 1920s and the Great Depression suspended the frenzy of land speculation until the 1950s, when the improvements in infrastructure brought by the C&SF Project provided better flood protection for the cities and superior drainage for new farmland.

From 1970 to 1990, regional population nearly doubled, while employment and real income have grown much faster (Table 125.2, lines 1–3). Although growth rates have slowed in the most recent decade and are expected to fall further, population surpassed 6 million by the year 2000 and is expected to reach almost 10 million by 2045. The population boom is reflected in the remarkably

Note: All data refer to 1997 unless otherwise noted; n.a. = not applicable; n.c. = data not comparable.

^a In columns 4–6, refers to share of farmland in the smaller unit to farmland in the larger unit of column heading. Methods and Sources: All county, state, and some national-level data are from Bureau of Economic and Business Research 1998b, cited below as “fsa” (Florida Statistical Abstract), unless otherwise noted. County data were summed for the region and compared to state and national totals. Other national data are from U.S. Census Bureau, 1998.

Section A

- Line 1 fsa, t. 8.01 and 8.03.
- Line 2 Smith and Nogle, 1999. Florida ranks fourth after California, New York, and Texas.
- Line 3 fsa, t. 11.05.
- Line 4 fsa, t. 8.39 (refers to all freshwater withdrawals, including irrigation).
- Line 5 fsa, t. 13.21 (includes out of state registrations).
- Line 6–8 Office of Tourist Research, 1998, table, p.i, gives numbers and destinations; table, p. 39 gives number and length of stay of auto and air visitors.
- Lines 1–2 National list of species is available for each Florida county from EnviroTools, Inc., 1998. These species were compared to those appearing on the lists for the state and the nation, which are posted on the Web site of the U.S. Fish and Wildlife Service, www.fws.gov/, dated April 30, 1999.
- Lines 3 fsa, t. 8.01.
- Line 4 fsa, t. 8.74. Data for selected cities are taken to represent the regions: column 1 (Miami); column 2 (Jacksonville); column 3 (average of Los Angeles, Atlanta, Chicago, New York).

Section B

- All data from U.S. Department of Agriculture, 1999. The region is summed from county data given in the state files.
- Line 8 includes land in sugarcane for both seed and sugar production.
- Line 9 refers to land in vegetables harvested for sale.

Section C

- The 13 full counties included in the Greater Everglades region are Broward, Collier, Miami-Dade, Glades, Hendry, Highlands, Lee, Martin, Monroe, Okeechobee, Osceola, Palm Beach, and St. Lucie.

Table 125.2 South Florida Growth, Performance, and Projections, 1970–2045

	Historical				Projections			Annual Growth Rate for Period				
	1970	1980	1990	2000	2010	2045	1970–1980	1980–1990	1990–2000	2000–2010	2010–2045

b. Services	24.2	26.8	32.5	35.3	38.0	39.8						
7. South Florida in state (%)												
a. Population	38.2	39.8	39.5	39.1	39.1	39.1						
b. Employment	40.1	41.6	40.1	39.2	39.3	39.3						
c. Income	44.3	44.8	44.4	43.7	43.6	43.6						
d. Housing starts:												
1. Multifamily	53.5	49.0	53.6	53.6	54.0	n.a.						
2. Single family	36.8	34.3	36.2	36.9	36.6	n.a.						
3. All	45.6	40.4	40.4	41.6	42.7	n.a.						
8. Farm employment (%) ^b	2.8	2.2	1.5	1.6	1.3	0.8						

Notes: Data for 1970–2010 are derived from Bureau of Economic and Business Research (1998a) and for 2045 from U.S. Department of Commerce (1999). Lines 1–5 are aggregated from the county estimates given Bureau of Economic and Business Research (1998a, Vol. 1), and figures for 2000–2020 from Smith and Nogle (1999) for “medium” projections for the 13 counties which fall entirely or almost entirely within the South Florida Water Management District. Excluded are three “partial” counties. Line 6 is constructed from Bureau of Economic and Business Research (1998a, Vol. 2), by summing and averaging data for the six metropolitan statistical areas (MSAs) that fall in the region, plus Monroe County and the South Central nonmetropolitan area (which includes four of the rural counties in the Everglades region), for the years 1970–1996. For lines 4–6, average shares were computed for 1970–1979, 1980–1989, and 1990–1996.

Projections for 2045 for South Florida were made for lines 1–3 by applying the BEA annual growth rates computed for the state to the latest available BEBR region projection for each corresponding concept. The BEA benchmark years are 2010, 2015, 2020, 2025, and 2045. BEA growth rates for total personal income in constant 1987 dollars were applied to the BEBR real income projections. The age distribution of the population (line 5) for 2045 was estimated by applying BEBR’s 2010 shares for South Florida in the state for each age cohort to the BEA forecasts for the absolute number of people in each of the statewide age cohorts for 2045. Shares were then recomputed. The employment distribution (line 6) for 2045 was estimated by applying BEBR’s 2010 sector shares of South Florida in the state to BEA’s estimates of statewide sectoral employment for 2045 and then converting these numbers into shares.

Line 8, farm employment for South Florida for 1970–2045 was computed by applying the region’s share of farmland in the state to BEA’s estimates of statewide agricultural employment. Farm area for the 13 counties was computed from the U.S. Census of Agriculture for the years 1974, 1982, 1992, and 1997, corresponding to the years in columns 1–4 above, and the 1997 shares were applied to the years 2010 and 2045. The region’s agricultural employment was then added to BEBR’s total nonagricultural employment (line 2 above) and the share of A to total employment computed for the corresponding years.

^a Refers to nonagricultural jobs.

^b Share agricultural (A) to total A plus non-A employment (BEA).

high number of multifamily housing starts during the 1970s and the subsequent rise in the number of single-family units in later decades* (Table 125.2, lines 4a, 4b). The state’s forecast of a strong upward trend in both single- and multifamily housing will have great implications for continuing land pressures in these counties.

The age distribution of the residents (Table 125.2, lines 5a to 5c) indicates an inverting of the age pyramid by 2045. The share of young (≤ 19 years), which was 29% of the population in 1970, is expected to fall to 20% by 2045. The oldest cohort (>65 years), which accounted for 17.5% of the total in 1970, is expected to rise to 28%. Even these trends understate the importance of the older population due to the exclusion of seasonal residents (“snow birds”) from the permanent population.

A summary of the distribution of nonfarm employment (Table 125.2, line 6a) highlights the decline in the share of the combined construction–manufacturing–utilities sectors from 30.6% of the labor force in 1970 to 15.1% by 2045. It is the rise of employment in the services sector (Table 125.2, line 6b) from 69.4 to 80.5% between 1970 and 1990, and its expected increase to nearly 85% by 2045, that is determining the general character of the region.

In summary, South Florida’s strong economy compounds its environmental problems: an expanding agricultural and commercial society serving a large tourist, retiree, and transient population. All this surrounds North America’s only semitropical and largest remaining wetland, the Florida Everglades.

The struggle between the economic growth and Everglades restoration is today occurring on all four fronts of South Florida (see right-hand map in Figure 125.1). In the northern and central stretches of the ecosystem, the growth of Orlando’s suburbs, cattle and dairy lands of the Kissimmee River Valley, diking of Lake Okeechobee, and drainage of the Everglades Agricultural Area (EAA) have altered the downstream flow to the remaining Everglades. To the southwest of Lake

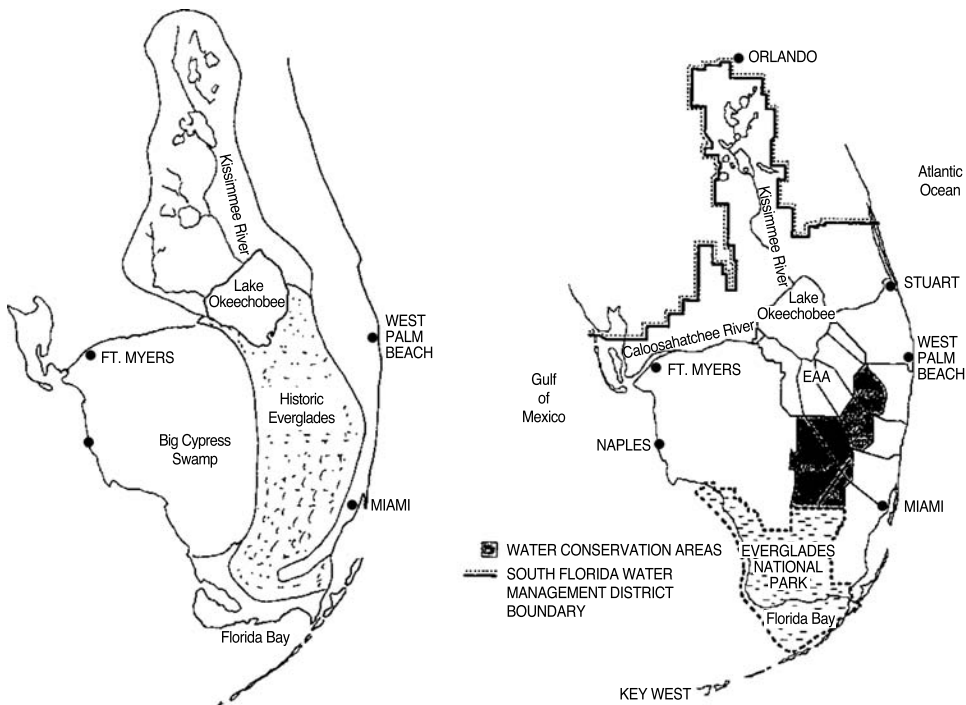

Figure 125.1 Comparison of the Greater Everglades Region in 1890 and the geographical features today.

* The number of housing starts has been averaged for each decade due to the wide annual fluctuations. South Florida has accounted for more than half of the state’s multifamily starts since the 1970s, a share considerably greater than the region’s population share.

Okeechobee, new areas are drained for expanded cattle, citrus, and vegetable production. To the east, only the 100-mile-long protective levee restrains the expansion of the Miami–Ft. Lauderdale metropolitan areas into the Everglades, and three large water conservation areas, actually vast holding tanks, compartmentalize what once was the “River of Grass.” To the south, Florida Bay and the Keys receive nutrient-rich runoff from canals that drain the southeastern counties. The cities sprawl and agriculture thrives as the Everglades die, despite the \$1.1 billion already spent.*

MODELS

A model of the regional economy that would be useful to policy makers, stakeholders, and taxpayers in general must be detailed enough to pinpoint specific activities, flexible enough to replicate a wide range of alternatives, and clear enough to be comprehensible to layperson and expert alike. But the design and calibration of a new regional economic model requires major investments of time and money. Fortunately, the economic researcher may choose from among three ready-made, off-the-shelf models, designed for any “generic” region in the U.S. Each of these models can then be “fitted” with actual data gathered by different federal and state agencies for any configuration of Florida counties.

The Regional Industrial Multiplier System (RIMS-II)

RIMS-II was first developed in the early 1970s by the Bureau of Economic Analysis of the Department of Commerce. It currently adapts the national BEA input–output table to local conditions on the basis of location quotients (LQs), adjusts for regional household leakages, and estimates regional multipliers for detailed industries (U.S. Department of Commerce, 1992).

Impact Analysis for Planning (IMPLAN)

In contrast to RIMS-II, IMPLAN is a package of flexible software and county-level databases that permits researchers to estimate their own regional model for any configuration of counties and for any level of aggregation of sectors. IMPLAN was developed by the Forest Service of the Department of Agriculture in the late 1970s and has been improved and maintained since 1993 by the Minnesota IMPLAN Group (MIG). The IMPLAN system regionalizes the national BEA input–output table by applying regional purchase coefficients (RPCs) after adding more detail to agriculture. The IMPLAN software then constructs a complete social accounting matrix (SAM) for 528 sectors and 21 economic and demographic variables, as outlined in Figure 125.2, and also computes the regional impact multipliers (see Minnesota IMPLAN Group, 1997).**

While the IMPLAN coefficients provide an up-to-date x-ray of a regional economy in great detail, they measure the impact of new spending on output, employment, and several types of income for only a single year. IMPLAN thus assumes that all the economic effects of the spending are played out in the single time period and that there are no dynamic effects or “carry-overs” of this year’s spending into the future. It is up to the user to adapt the model to trace out patterns if the initial spending is spread over many years.

Regional Economic Models, Inc. (REMI)

REMI provides a dynamic modeling capability that allows the user to simulate scenarios involving a much larger number of economic and demographic variables for a set region or group

* See South Florida Ecosystem Task Force (1998) for detailed expenditures.

** IMPLAN was extended to Puerto Rico by Ruiz and co-workers (1994). For a detailed discussion of the IMPLAN model, see Weisskoff, 2000.

Payments:		Industries	Factors	Households	Other Institutions & Trade	Total
Receipts:						
Industries	A_{11} Direct Requirements Coefficients			A_{13} Household Consumption Coefficients	y_1 Institutional Consumption & Exports	x Industry Output
Factors	A_{21} Value Added				y_2	x_2 Value Added
Households	A_{31} Direct Requirements from households	A_{32} Factor Disbursement Coefficients	A_{33} Inter- Household Transfers	y_3 Inter-instit. Transfers, Instit. Factor Serv., Exports	x_3 Institutional Receipts	

note: indicates matrices used in computation of impact multipliers

Figure 125.2 Social accounting framework, IMPLAN Type II formulation.

of regions (Treyz, 1993). The historical coefficients are based on time series from the previous 15 years. The modeling horizon extends 35 years into the future, and the blocks of variables include output, population, labor, market shares, and prices.

REMI is actually a massive system of demographic and economic equations set up automatically in a dynamic, multiperiod framework. Unlike IMPLAN in which Spending A causes Impact A in the same year, REMI allows Spending A to be spread over many years and its impacts to be played out on all the dynamic features and feedbacks in the coming decades. It is thus better suited for a long-term project such as Everglades restoration, in which construction occurs in the early years and maintenance expenses are incurred in the later years.

Each model has its own strengths. RIMS-II is a convenient tool for regional agencies that require computed multipliers to assist in project evaluation for a preset region at a modest price. IMPLAN gives the researcher the software and data, and hence the ability to change the model and counties comprising the region. Both RIMS and IMPLAN are relatively low-cost tools and provide detail for 471 and 528 sectors, respectively. REMI, on the other hand, uses historical data as well as input-output data for fewer sectors (14, 53, or 172, depending on cost), allowing the model to play out over a future up to 35 years. The researcher, therefore, is also able to simulate different policy interventions or new projects over time. The effects of these projects and their trajectories are then compared to the “base” or “control” forecast for the same time period.

In one sense, REMI is an agile or fleet-footed runner for any future course, allowing the researcher access to a great many variables applied to fewer, but still an adequate number of sectors. IMPLAN, by contrast, is an old-fashioned clunker, a disaggregated input-output model, augmented with only a few other variables and made, in this chapter, to move slowly over time, like an awkward robot climbing steps.

Several recent articles have compared the performance of the three models by collapsing the dynamic framework of REMI and imposing a uniform way of “closing” the consumption-income link.* Our approach is to use both IMPLAN and REMI to examine the hypothesis that the spending on Everglades restoration could contribute to greater growth of the region. First, we compare both models in terms of their reactions to impacts on single sectors and on simple combinations of sectors. Then we scale up the combined sectors into more realistic scenarios to replicate ongoing and future projects, for example, Everglades restoration and tourist promotion. We apply annual projections of these expenditures to an annual IMPLAN model and to the REMI model. The scenarios are then

* See Rickman and Schwer (1995) and Crihfield and Campbell (1991).

further combined into Summary Scenarios and the increases in output and employment compared to the growth of the “base region” in the absence of the new projects. Both models are applied to the South Florida region constructed of 13 South Florida counties. For data, see Appendix 125.I.

RESULTS: SECTORAL ANALYSIS

Understanding the sectoral characteristics of the model is essential to evaluating the complex scenarios. By adding an additional \$10 million of final demand to each sector, we compare the total output and total number of jobs generated within each of the models (Table 125.3). Of the agricultural sectors in Panel A, rice (No. 11), vegetables (No. 18), and sugar crops (No. 19) compete for the organic soils of the EAA, but each has its own drainage needs and creates different runoff characteristics. Citrus (i.e., fruit trees, No. 16) requires good drainage and is grown on a wider range of sandy soils. Greenhouses (No. 23) are concentrated closer to the cities and compete for land needed by new residential housing (No. 48). The future of commercial fishing (No. 25) on both Atlantic and Gulf Coasts is threatened by the periodic discharges of fresh water drained from the interior farmlands and coastal cities. The selected manufacturing sectors (Nos. 70–97) process the region’s agricultural products. The selected transport and service sectors (Nos. 437–488) are all components of tourist spending.

In the IMPLAN model, the sectors generate between \$13.9 (fish processing) and \$19.0 million (fruit trees, agricultural services) in total output (Table 125.3, col. 1), but new employment ranges from 90 jobs in rice milling to 867 jobs for agricultural services (col. 2). In general, the service and agricultural sectors generate the most employment, while manufacturing generates the least. The profiles of car rentals and airlines are more similar to manufacturing than to services, and commercial fishing is more similar to services than to agriculture.

In the REMI model, new output ranges from \$10 million in greenhouses to \$23 million in recreation services. New jobs range from 109 in rice milling and 463 in recreational services. REMI’s agricultural sectors generate less output but more jobs than IMPLAN, and REMI’s service sectors generate more output and less employment than IMPLAN’s. The similarity in the averages of new output and employment between the two models for the 16 comparable sectors is striking: \$16.8 million and 284 jobs for IMPLAN vs. \$15.6 million and 274 jobs for REMI.

The impacts of \$10 million of new demand on the composite scenarios (Table 125.3, Panel B) are based on actual engineering data and on projects in progress which affect combinations of sectors. For IMPLAN, the scenarios yield about the same output (Table 125.3, col. 1, lines B1 to B4), except for the Operation and Maintenance Program of the current Everglades Protection Project (EPP), due to the higher proportion of direct wages in this program. The tourist package (Table 125.3, col. 2, line B.3), which is based on several different statewide and regional visitor spending surveys, yields the highest employment of the four scenarios. For REMI, the EPP construction generates the most output and employment, and other scenarios yield remarkably similar employment totals.

The consumption patterns of the three income classes available with IMPLAN but not REMI (Panel C) suggest the contradiction between the slightly higher output generated by the \$10 million spending by the lowest class (col. 1) and the slightly higher employment generated by the same level of spending of the highest class (col. 2). A growth pattern that results in higher incomes to the top classes, therefore, stimulates more jobs, due to the service-intensive component of that expenditure bundle, while the same increase in spending of the lower class generates greater output.

RESULTS: COMPONENTS OF THE SCENARIOS

In the following sections, we review the components and their combination into scenarios (Table 125.4).

Table 125.3 IMPLAN and REMI: Economic Impacts of \$10 Million New Demand for Sectors, Programs, and Income Classes, South Florida

	REMI	154	169	191	2389	2545	2697	2677

Agricultural Restructuring

- Sugar/rice rotation (3 years sugar/1 year rice) replaces the uninterrupted monoculture of sugarcane and may lead to higher sugar yields and reduced soil subsidence and pesticide use.* In the fourth year, two rice crops are harvested under this plan prior to the replanting of sugarcane in the fifth year. In any single year, one quarter of the EAA sugar lands would be growing rice.
- Organic rice could become the most profitable crop for the EAA as soil subsidence lowers sugar yields, environmental standards regarding downstream runoff are tightened, and low-priced foreign sugar is given a larger share of the U.S. market.
- Water storage only in the EAA removes all agricultural activity and converts the sugarcane lands into reservoirs and marshes. The loss is calculated as the reduction of all current sugarcane production and milling.

Everglades Restoration

- EPP. The ongoing Everglades Protection Project, which is comprised of 14 projects, will be completed by 2005, with Operation and Maintenance (O&M) costs continuing into the future.
- Restudy, completed by the Army Corps of Engineers and now known as the Everglades Plan, will be under construction by 2005 and may end by 2025, with full annual O&M costs continuing thereafter. The project includes 287 conventional water control structures (pumping stations, spillways, culvert, canals, and levees) as well as several untried technologies, such as 345 aquifer storage-and-recovery wells (ASRs) and 47 miles of underground seepage barriers, 10 to 28 ft in depth. The impacts measured here result from construction expenditure only and exclude land acquisition costs.

Tourist Promotion

- Auto and air tourism is based on continuing the 4-year trend in expenditure of visitors who report South Florida as their primary destination.
- Everglades Region nature tourism assumes a doubling of the historical rate of increase in the number of visitors to the major national parks, wildlife preserves, and waterways in the region, but for a fixed expenditure per visitor (U.S. Army Corps of Engineers, 1998, Appendix E, pp. 209–213).**
- New construction. The historical statewide rate for all new construction activity was extended to the region for the entire period.
- Consumption of new residents reflects the expenditure of new retirees and in-migrants at twice their historical numbers in the region.

Summary Scenarios

The sectors and their combinations shown in Table 125.3 comprise the scenarios of Table 125.4. All represent additional pieces to the base projections of output and employment and assume steady growth of the existing economy. In a regional economy where tourism is a key sector, the state's growth model (BEBR in Table 125.2) excludes a tourists sector per se. Rather, elements of tourism, such as spending on food, hotels, and amusements, are absorbed into the spending patterns of local residents, making it virtually an endogenous sector. In our model, however, new spending on tourism is treated as an array of exogenous demands, despite the fact that these demands themselves are promoted by the state through extensive advertising. A restored Everglades, the flagship of the U.S. environmentalist movement, will also add to the region as an important destination for ecotourism and recreation.

* On the compatibility of profitable agriculture and improved environment, see Glaz (1995). On subsidence, see Shih and co-workers (1997).

** The historical rate of increase in nature tourism (3.4%) is also similar to the average annual growth rate of the number of visitors (3.61%) to all the state parks in the region from 1993–1997.

Figure 125.3 South Florida employment, 1970–2030.

In each of the following summary scenarios, the output and employment generated by each model is compared to its respective base, which is the future of the region if present trends continue and no Everglades restoration occurs. We use county and statewide forecasts from Florida’s Bureau of Economic and Business Research (BEBR) and the Department of Commerce to estimate the base for the IMPLAN projections. The REMI model generates its own base or regional control on the basis of the regional model with no intervention and the national macro-model which it also generates. The basic employment series from 1970 through the forecast year 2030 for BEBR and REMI are shown in Figure 125.3.

- The “Growth as Usual” Scenario (Table 125.5, line A.1) sums up the projects already underway and ongoing trends: finishing the EPP projects; continuing the greater shares of air visitors but a reduced share of auto visitors to the region; continuing the rate of overall construction activity and the rate of in-migration.* During the projected years, increases due to tourism and construction dominate the output and job impacts. The “Growth as Usual” scenario, according to IMPLAN, results in 0.65% increase in output and 1.43% increase in employment over the total output and total employment, respectively, for 2030 (Table 125.5, line B1, cols. 4 and 8). The REMI model gives the increase in output as 0.95% and the increase in employment as 1.02%.
- But when compared to the annual increase in output and employment of the 2030 economy, the output and employment newly generated by the “Growth as Usual” scenario is quite significant, i.e., 36.0 and 233.6% over the respective annual increases for the basic economy in 2030 (Table 125.5, line C1, cols. 4 and 8), according to IMPLAN, and 60.2 and 129.5%, respectively, according to REMI. These scenarios highlight the degree to which the official projections understate the effects summed here.
- The “New Projects” Scenario adds the rice rotation, the full Everglades Restoration, and additional regional nature tourism (Table 125.4, lines 1a, 2b, and 3b). The sum of the elements in the “New

* This is a conservative scenario, as it excludes the growth of other leading sectors, such as greenhouses and commercial fishing. The recent introduction of best management practices (BMPs) in sugar growing has led to dramatic declines in nutrient runoff and a surprising rise in sugarcane output, perhaps a hint of the potential impact that further changes in cropping patterns and growing practices might have on the environment.

Panel A: Annual IMPLAN impacts refer to sum of direct, indirect, and induced impacts of scenarios in each of the benchmark years at col. head. Annual REMI impacts refer to the absolute differences in output and employment between the scenario generated by the complete dynamic model and the REMI base control.

Base 1: The first line (I) is the base line used for IMPLAN comparisons. It refers to the joint BEBR-BEA forecast for each year estimated by applying growth rates to the most recent published base year estimate. Base year output is for 1995 (\$225 billion in 1995 dollars) from IMPLAN data for the countries in the study area. Base year total employment is from Bureau of Economic and Business Research (1998a) for 2010. Different growth rates for output and employment were then derived from Bureau of Economic and Business Research (1998a) for 1995–2000, 2000–2010, and from U.S. Department of Commerce (1999) for 2010–2015, 2015–2025, 2025–2045, and applied to forecast “normal” output and employment from the base to the benchmark years. The second line (R) is the base for the REMI comparisons and refers to output and employment given in the REMI database.

Panel B: Compares the IMPLAN and REMI figures for annual increases in output and employment to their respective total bases.

Base 2: The annual changes in output and employment in each of the bases between the preceding year and the benchmark year in the heading. These figures are also used in Figures 125.4A and 125.4B, where annual changes are also shown for 1969–1970, 1980–1981, and 1989–1990, for both IMPLAN and REMI base series.

Panel C: Compares the IMPLAN and REMI figures for annual increases in output and employment to their respective annual bases.

Projects” adds 27.9% to the annual increases in new jobs according to IMPLAN in the peak years 2010 to 2020 and 97.2% more jobs in 2020 according to REMI (Table 125.5, line C.2, col. 7).

- The “Full Speed Ahead!” Scenario sums “Growth as Usual” and “New Projects.” By 2030, annual increases in output and employment will be 38.0 and 246.3%, respectively, above IMPLAN’s forecast annual increase and 71.7 and 154.9%, respectively, above REMI’s annual increase in 2030 (Table 125.5, line C.3, cols. 4, 8).
- The “Naturalist Moderation” Scenario would substitute rice for sugarcane, the latter a more labor-intensive crop, and reduce the levels of the activities that make up “Growth as Usual” and “New Projects.” This scenario generates an annual increase in output and employment of 13 and 81%, respectively, above the annual increases for 2030, according to IMPLAN, and 40 and 63%, respectively, according to REMI (Table 125.5, line C.4).
- Naturalist Moderation minus the EAA cuts out all sugarcane growing and milling in the EAA, further reducing output and employment below the levels of “Naturalist Moderation.” This allows some of all the new projects to be undertaken, but replaces the agricultural zone with water storage. The results for both IMPLAN and REMI are remarkably similar: by 2030, the increase in jobs would be 22 to 24% of the annual increase, a fraction of the “Full Speed Ahead!” scenario discussed previously.

The annual number of jobs generated for each of the summary scenarios is compared to the annual increase in jobs in the control base for the IMPLAN in Figure 125.4A and for REMI in Figure 125.4B. Both sketches show similar trends. The annual number of new jobs generated in both bases continues to decline from its peak growth in the 1980 period; the expected increase in new jobs due to Full Speed Ahead! and the reduction in these annual numbers through Naturalist Moderation.

CONCLUSIONS AND CAVEATS

The apparent coincidence of IMPLAN and REMI results for the scenarios presented here is somewhat surprising. IMPLAN is an extremely disaggregated, static input–output model. In this exercise, it has been made to leap into the future by providing it with forecasts of exogenous demands, and its impacts have then been compared to the state–federal forecasts of future employment without the new projects. REMI, by comparison, is a quick-footed, dynamic econometric model with a more aggregated input–output model within it, as well as the mechanism to grow on its own, once the future exogenous demands are provided. REMI also generates its own control base as the model runs into the future with no exogenous demands.

Both models clearly warn us of the high and unanticipated impacts of continued growth. The path of “Natural Moderation” and its variant suggests one way of modifying the magnitude of those impacts.

While the magnitudes of the exogenous demands reflect many judgments by the author, the general procedure developed here is intended to capture the forces that are currently at work in the region. The current trends may change, but if they do not, the results here reflect the probable impact of the current course on the economy of the region.

We have found that the annual increases in output and employment due to the major new trends “missing” from the basic forecast are relatively small compared to the large base. Even in the “Full Speed Ahead!” scenario, the IMPLAN and REMI models suggest annual increases of \$3.4 to 3.8 billion in output and from 47,000 to 57,000 new jobs by 2030. The former would add 0.69 to 0.95% to the region’s total output and the latter would add from 1.2 to 1.5% to total employment (base 1) for 2030.

The annual increases in output and employment, however, are very large numbers, when compared to the annual increase in the base, especially in the later years. The two models indicate that the Full Speed Ahead! scenario generates from 38 to 72% more output and from 155 to 246%

Figure 125.4 (a) IMPLAN: Annual jobs generated by base and scenario; (b) REMI: Annual jobs generated by base and scenario.

more employment than the annual increase generated by the base in 2030. This finding has important implications for those lumpy public investments, such as water and sewage treatment plants for which the annual increase in demand is critical for determining the need for new capacity. The notion of relative annual increases is also important in determining spending on education, police, and other services.

Our findings take issue with the findings of the Restudy’s regional economic impact study (Appendix E of the Restudy, pp. E-304 to E-308) which the present author had also computed. I compared the impacts of new construction expenditures, as modeled by IMPLAN, to the total

number of jobs and output in the region. All other growth trends were deliberately ignored, because they did not technically fall within the domain of the project. But when the task of the economist is expanded to include the evaluation of other major growth trends that are, in fact, facilitated by the Everglades restoration and are progressing in the region, then we are compelled to reach quite opposite conclusions. It is, after all, not only the contribution that Everglades restoration will make to new output or to new employment that should be of concern, but rather the contribution that all new projects make to the growth of the basic economy. The \$8 billion for Everglades restoration may be indeed crucial in that it will permit the basic economy to reach, or as we are suggesting, to overshoot its forecast levels.

Our application of two independent growth models suggests that, in the absence of any intervening natural or social calamities, large numbers of jobs are being created in the region on an annual basis. It is urgent that the implications of this development on land use and water consumption now be evaluated.

Everglades restoration will allow the region to continue its current expansion by providing more water and, in effect, more usable land through better flood protection of the outlying areas. But it is not the only force that contributes to the supercharged economy. Other state and local policies also work to encourage growth, urban sprawl, and agricultural expansion. Tax exemptions, wage subsidies, low impact fees, and low utility rates all attract new manufacturing, commercial, and tourist facilities and promote new housing. Generally low energy rates encourage the construction of larger air-conditioned homes, and low water rates promote green lawns all year round.

Is all this growth desirable? Slower growth itself need not lead to reduced consumption. In the absence of extremely aggressive policies of conservation, the present trend is to encourage greater, not lesser, resource use in urban areas. In the countryside, the water-intensive and land-extensive technologies borrowed from temperate agriculture for the region's crops, dairies, and fishponds are also proving highly inappropriate for the semitropical Everglades ecosystem. Continuing on the current path will surely accelerate ecological pressures. But the total costs of these pressures cannot alone be computed by the complicated but narrow economic models applied here. The restoration effort, designed by engineers from outside the region, needs to be complemented by efforts at smart production and consumption, designed and imposed by taxpayers inside the region, as the broad population comes to recognize the true social and environmental costs of living within a fragile ecosystem.

Hurricanes and rising sea levels may be nature's way of imposing limits on growth. Hurricane Andrew caused \$425 billion in damage in just a few days in August 1992, and two powerful hurricanes in the late 1920s helped shut down South Florida land speculation for two decades. New hurricanes could put a stop to the current building frenzy, or simply shift it northward to less densely populated counties. Rising sea levels may also be part of a violent rather than a gradual process, with major storms resulting in changes that irrevocably alter the shoreline.* If the present trend continues, much of South Florida could be under water by the middle of the 21st century.

The economy may exert brakes of its own, for the South Florida engines of growth, such as tourism and construction, are sensitive to the national business cycle. The opening of Cuba and access to its sugarcane lands could result in the reduction of Everglades agriculture, especially as the peat soils of the EAA subsidy and productivity falls in much of the area. But putting this type of speculation aside, it may be only the intentional redesign of South Florida's urban sprawl and changes in farm practices that together will enable the Everglades to survive the 21st century.

APPENDIX 125.I

Data Sources and the Scenarios

SCENARIOS AND INCOME PATTERNS (FOLLOWING THE ROWS OF TABLE 125.4)

1. Agricultural data: Details on sugarcane and rice are found in Snyder et al., 1978; Alvarez et al., 1994; U.S. Department of Agriculture, 1997, 1998; and Izuno et al., 1999.
2. Everglades restoration: Line items for the detailed construction costs and also operation and maintenance costs for each of the projects within the Everglades Protection Project are specified in the appendices of Burns and McDonnell (1994). Details on the Restudy are in U.S. Army Corps (1998), Appendix E.11, computed by the present author on the basis of seven prototypical structures.
3. Tourist expenditures are constructed from the Office of Tourist Research (1996 to 1998) for statewide spending patterns; Strategy Research Corps (1997 to 1999) for urban Miami; English and Kriesel (1996) for detailed regional recreation in the Keys; and Visitor Services Project (1989, 1996) for Everglades National Park visitor spending. The growth of spending for auto and air visitors were averaged for 1994 to 1998 for each mode and then deflated by the travel price index for the state. Total spending level was computed from per-day expenditures and total number of person-nights reported for each mode and for the regional destinations by quarter. Almost half the air visitors but only 13 to 16% of auto visitors reported South Florida as their regional destination.
4. The “new development” package was estimated on the basis of the 1996 sector profiles for new construction, given in Bureau of Economic and Business Research (1998b).
5. Expenditure patterns are given by IMPLAN for three levels of spending over the full range of BLS commodities. New residents are assumed to be attracted at twice the present rate of 43 thousand middle-income households per year.

Analysis of Land Cover and Water Quality in the New York Catskill–Delaware Basins

Megan H. Mehaffey, Timothy G. Wade, Maliha S. Nash, and Curtis M. Edmonds

INTRODUCTION

Prior to 1776, New York City's drinking water was supplied by public wells, but demands for water eventually resulted in construction of the city's first reservoirs. The Croton Reservoir (1842) supplied over 90 million gal/day to the city, but eventually even this amount could not meet the city's needs. To ensure the water supply into the future, the Catskill and Delaware systems were developed (Hecker, 1991; Weidner, 1974). The construction of the impoundments, aqueducts, and tunnels needed to supply water to New York City spanned a total of six decades (1905 to 1965). The six reservoirs are the Cannonsville, Pepacton, Schoharie, Neversink, Rondout, and Ashokan (Figure 126.1). Together, these reservoirs provide 90% of the 1.4 billion gallons of drinking water consumed by New York City residents. With the development of the Catskill–Delaware systems, New York City's drinking water remains one of the cleanest in the nation. Currently, New York City is trying to maintain the high quality of the drinking water supply through the development and implementation of a long-range watershed protection program. The watershed protection plan was signed in 1997 and unites efforts by local communities, the City and State of New York, environmental groups, and the EPA (Ashendorff et al., 1997; Okun et al., 1997). The plan includes upgrading current sewage treatment plants, implementing new watershed regulations, designing and constructing a filtration system for the 10% of water supplied by the Croton system, and acquiring land deemed critical to the preservation of high water quality in the Catskill–Delaware system. Land acquisition was selected, partly to protect the environment, but also to save the taxpayers of New York State billions of dollars. Installing a filtration system for the city's water supply would cost an estimated \$2 to 8 billion, while land purchase is estimated to cost \$250 to 300 million (Featherstone, 1996; MOA, 1997). The majority (90%) of money spent for land acquisition will be used in the Catskill–Delaware basins. The city has set as its goal the solicitation of 350,000 acres of land (MOA, 1997). Under the agreement, the New York Department of Environmental Conservation issued a permit to acquire land through outright purchase and conservation easement. Priority is given to the purchase of nonresidential land around reservoirs, streams, and wetland areas. Secondary land acquisition will focus on the purchase of sensitive lands surrounding streams and rivers. The expected result of land acquisition and conservation practices is the protection of more than 165 stream miles, the preservation of thousands of acres of natural areas, and continued high water quality without the cost of a multibillion dollar filtration system (Murphy et al., 1995; Featherstone, 1996; MOA, 1997).

Figure 126.1 The Catskill–Delaware basins and location within New York State.

As a result of topographic constraints, both agricultural and residential land use is concentrated close (250 m) to river and stream riparian zones. Forested riparian zones act as a buffer, and diminish excessive runoff of water and pollutants such as fertilizer, pesticides, and other chemicals (Finlayson, 1991; Manlanson, 1993). When forests are removed, the potential for flow of pollutants into streams is greatly increased. Fertilizers, pesticides, and other pollutants can be transported into streams flowing through or very close to agricultural or residential land more easily than streams that flow through forest (Lowrance et al., 1986; Osborne and Wiley, 1988). Agriculture has the potential to increase soil erosion. When cropping takes place on soils with a 3% or greater slope there is increased likelihood of erosion (Lowrance, 1984). The human population in the Catskill–Delaware basins has increased only 17% in the past 30 years, resulting in approximately 12 people/km² (U.S. Census, 1990; FGEIS, 1993). However, the continued effluent inputs from waste treatment plants, nonpoint agricultural

sources, and residential runoff increase the potential risk of contamination above acceptable water quality standards for drinking, and survival of freshwater fish and macroinvertebrates. The economy of the area depends largely on seasonal tourism and dairy farming (Stave, 1995), the latter making fecal coliforms, nutrients, and sediment load a particular concern (Hansan, 1996; Wall et al., 1998).

The objective of this study was to explore the relationship between land-cover metrics and surface water quality measurements at the scale of the basin, subbasin, and riparian zone in the Catskill–Delaware basins. Results will be used to evaluate potential risk to New York City’s drinking water supply system. Data generated from this study can be used to target basin, subbasin, and riparian zones in need of protection within the basins.

METHODS

Site Characteristics

The 4104-km² Catskill–Delaware basins are located in the southeast corner of New York State, 160 km northwest of New York City (Figure 126.1). Average monthly precipitation ranges from 50 to 150 mm. The highest precipitation events occur during the spring and fall months. Temperature ranges from –10 to 27°C; July and August are the hottest months. The topography of the area is diverse and, except for the Adirondacks to the north, has the highest elevation in the state. The bedrock geology of the area is sedimentary and consists of sandstone, shale, and conglomerates formed during the Devonian time period (Miller, 1970). The bedrock is exposed or within 1 m of the surface in about 30% of the basin area. Of the remaining surface geology, almost 60% is glacial till. The basins are bisected by numerous streams including the Delaware, Schoharie, and the Neversink. The alluvial deposition and outwash from these streams and their tributaries account for the remaining 10% of the basin surficial geology.

Historically, the Catskill–Delaware basins were dominated by northern hardwood trees, including maple, birch, and beech. Other species present in smaller numbers were white and red pine, hemlock, elm, and ash (van Valkenburg, 1996). Much of the area was logged prior to the mid-1800s. However, due to the need to eliminate a substantial debt owed by Ulster County, lands owned by the county were conveyed back to New York State in 1884. With the transfer of ownership, 13,759 ha of forest were brought under state protection and the Catskill Park and Forest Preserve was born. In the decades since the Park and Forest Preserve’s inception, the forest has rebounded from its previous losses and is once again made up of a mixture of hardwoods and other deciduous and evergreen trees, encompassing over 250,000 ha of land (van Valkenburg, 1996).

Land-Cover Data

Land-cover data are required to calculate most land cover metrics, and for regional and larger areas is generally derived from satellite imagery. The New York City Department of Environmental Protection (NYCDEP) supplied the following Arc View coverages for the study area: basin and subbasin boundaries, topography, soils, roads, streams (including lake shorelines), and water-sampling site locations. Land-cover data from the National Land Cover Database (NLCD) were acquired from the EROS Data Center, a consortium of four federal agencies. The land cover data were derived from a composite of two Landsat thematic mapper (TM) images, an early spring (leaf off) and summer scenes (leaf on) (April 28, 1989 and June 21, 1991). The land-cover data set was generated using an unsupervised classification technique. Clusters of spectrally similar areas were grouped and assigned a land-cover class using National High Aerial Photography program (NHAP) aerial photos. Areas that contained more than one land-cover class were labeled with the aid of ancillary data such as population or elevation (EROS Data Center, 1998). For the purposes of this study, the NLCD classes were aggregated into six categories: water, forest, barren, row crop, pasture, and residential (Table 126.1).

Table 126.1 Aggregation of the National Land-Cover Database (NLCD) Land-Use Classes

NLCD Class	Aggregated Class
Open water	Water
Low intensity residential	
High intensity residential	
High intensity commercial	Residential
Corn, alfalfa, specialty crops	Row crop
Pasture/hay	
Other grasses (e.g., parks, lawns, golf courses)	Pasture
Evergreen forest	
Deciduous forest	
Mixed forest	
Woody wetlands	
Emergent herbaceous wetlands	Forest
Quarries/strip mines/gravel pits	
Transitional	Barren

Land-Cover Metrics

Land-cover metrics of characteristics believed to have a relationship to drinking-water quality were calculated for six basins (average area 700 km²) and 79 subbasins (average area 50 km²) in the Catskill–Delaware basins. Four metrics were chosen based on results of a previous study in the Mid-Atlantic region (Jones et al., 1997). These metrics are (1) percentage of the six land-cover categories listed above, (2) human use (U-index), (3) percentage of land cover in and near (100-m buffer) stream riparian zones, and (4) percentage of agriculture on steep slopes.

Because forest is the dominant vegetation cover of the Catskill–Delaware basins (Kuchler, 1964), percentages of other land cover were used as indicators of disturbance. The land-cover metrics were generated by overlaying the land cover with basin and subbasin. Water was excluded from the total area when calculating percentages. Percentages of the six land-cover categories were calculated by basin and subbasin. Total human use, or U-index (O'Neill, 1988), was calculated by summing the percentages of agriculture, residential, and nonnatural barren (e.g., mines or gravel pits) land use.

The MOA (1997) limits development within 100 m of the reservoirs and 50 m from streams. We selected the largest buffer distance (100 m) for use in our analysis. Two metrics were generated for the riparian zone: the percentage of each land cover in a 100-m distance from streams by basin and subbasin, and the percentage of each land cover 100 m upstream of 25 water quality sampling sites. The 25 sampling sites were selected based on the quantity and quality of available water quality data. The two metrics were calculated by overlaying land cover with streams and buffered area polygons. Water was again excluded when calculating percentages.

Erosion potential is related to the steepness of slopes in agricultural use and soil type (Comeleo et al., 1996; Lowrance, 1986). The threshold for increased erosion is a 3% slope (USDA, 1951). Percent slope was generated from 30-m Digital Elevation Model (DEM) data. The soil erosion potential metric was calculated by overlaying the distribution of slope with land cover. The metric was reported by subbasin as the percentage of agriculture in the subbasin on slopes greater than 3%.

Surface Water Quality

An 8-year window (1986 to 1994), enclosing the classified NLCD image of years 1989 and 1991, was used to select water quality data. Data from 243 sampling sites across the Catskill–Delaware basins were captured for this period (Figure 126.2). The main source for the chemical and physical water quality parameters was the EPA storage and retrieval database called STORET.

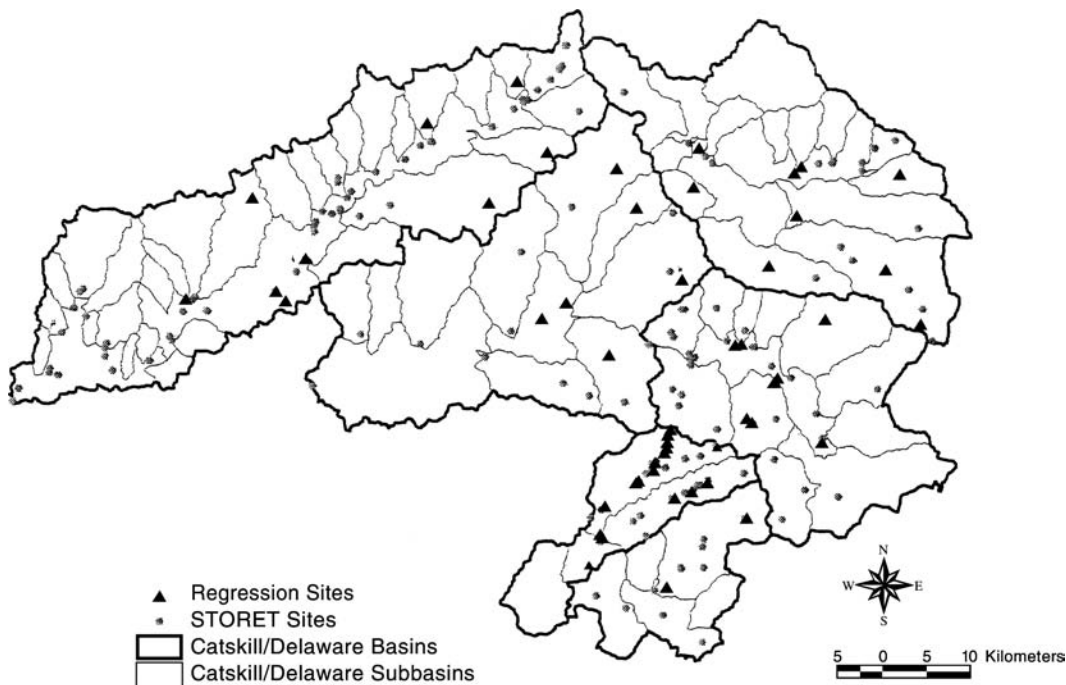

Figure 126.2 STORET sample locations in the Catskill–Delaware basins and those used in the regression analysis.

STORET is a repository for water-parameter data for the contiguous U.S. Many organizations contribute to the database including federal, state, interstate, universities, contractors, individuals, and water laboratories.

Compiling water quality data from a number of different sources gave rise to problems of inconsistency and lack of comparability due to differences in measurement and analytical methods. In the course of our data compilation we encountered the following:

1. Differences in methodologies between agencies and with time.
2. Changes in detection limits of chemicals and metals over time, making comparison with earlier samples difficult.
3. Sample sites monitored for short time spans (1 to 3 years) rather than continuously.
4. Some sites sampled more frequently than others.
5. Discontinuation of monitoring and initiation of new sites in different locations.

Data were not temporally and spatially adequate to confidently characterize the changes in many water quality parameters with time and their relationship to land-cover metrics. Therefore, attention was focused on water parameters with data collected during most of the 1986 to 1994 time period, which have a known relationship to land use. Because of differences in vegetative productivity, nutrient cycling, and climate, the influence of land cover may vary with season. Therefore, we used seasonal average for water quality data. The chemical water quality parameters included nitrate-nitrogen ($\text{NO}_3\text{-N}$), chloride, silica, conductance, and dissolved oxygen (DO); physical measures included temperature, suspended sediment, and flow rate.

Statistical Analysis

An analysis of variance (ANOVA) and Tukey's studentized range test of means were conducted to determine significant differences between basin land cover metrics (SAS, 1990). In order to

relate land use to the water quality data, we assumed minimal land-cover changes between 1986 and 1994. To examine the relationship of water quality and land cover, data from all sampling sites were used in the correlation analyses at three scales, basin ($n = 6$), subbasin ($n = 79$), and riparian zone ($n = 79$). For these analyses, independence between sampling sites was assumed. For each scale, we used a seasonal average for water quality data.

A stepwise regression ($n = 25$) was run for a subset of water sampling sites to determine the effect of nearby land cover (100-m upstream buffer) on seasonal water quality. The locations of the subset sampling sites were chosen for comprehensive spatial coverage of the basins. From the previous correlations, seasonal water quality data of four parameters (total chloride, silica, pH, and $\text{NO}_3\text{-N}$) that had a significant correlation ($P \leq 0.05$) with land cover were used in regression analysis. A new variable was introduced to the regression that represents a multiplication of two land-cover metrics. This new variable, statistically known as an interaction term, is represented in the tables by the symbol “/” set between two land-use cover metrics and in the text with “and” between the two variables combined in the interaction.

RESULTS

The Catskill–Delaware basins were dominated by evergreen and deciduous forest with an average forest cover of 92% across the basins (Table 126.2, Figure 126.3). Three of the six major basins have more than 95% forest cover. The greatest human use of the basins was agriculture (8%), of which 6% was pasture and 2% row crops. However, the majority of the agriculture was concentrated in the Cannonsville basin. Using ANOVA ($P \leq 0.05$), Cannonsville basin was found to have significantly greater percentages of crops (3%) and pasture (17%) than the other five basins. The Schoharie and Pepacton basins had the next highest concentration of agricultural land use, averaging around 10%, of which 3% was row crop, and 7% pasture. The remaining basins had 3% or less total agricultural use. All agriculture (8%) in the basins was located on slopes greater than 3%. Residential land use was minimal and averaged less than 1% of the total area. The Ashokan basin had the highest concentration of residential land use (1.12%). Cannonsville and Schoharie basins were second and third with 0.70 and 0.73% cover, respectively. Basins with the least residential cover were the Neversink, Rondout, and Pepacton, all with less than 0.40%.

The higher percentage of agriculture in the Cannonsville, Pepacton, and Schoharie basins resulted in a greater U-index in these basins (Table 126.2). Although the Ashokan basin had the highest percentage of residential use, its U-index was similar to that of both Neversink and Rondout basins. The U-index in the Neversink and Rondout basins was related to agricultural use. Within the basin riparian areas (100-m stream buffer), the percentage of forest was lower, and agriculture and residential use was higher. Higher percentages of both agricultural and residential land use were found in subbasins containing a major stream (i.e., Esopus in the Ashokan, Batavia Kill and Schoharie in Schoharie, East Branch Delaware in Pepacton, and West Branch Delaware in Cannonsville).

The Cannonsville basin had the highest mean total chloride, silica, and $\text{NO}_3\text{-N}$ (6.88, 3.88, and 0.52 mg l^{-1} , respectively) (Table 126.3). The Ashokan basin had the second highest total chloride and silica values. The Pepacton basin had similar $\text{NO}_3\text{-N}$ value as the Cannonsville basin (Figure 126.4). The lowest median total chloride, silica, and $\text{NO}_3\text{-N}$ values were found in the Neversink basin. The Neversink basin also had a relatively low pH, which ranged between 3 and 7.88 (Table 126.3). Conductance ($112.16 \mu\text{mol}$) and sediment (7 mg l^{-1}) mean values were greatest in the Cannonsville basin. However, the range of sediment values was greatest in the Ashokan (0 to 27 mg l^{-1}). Dissolved oxygen mean values were similar among all basins (8.99 to 10.95 mg l^{-1}).

Correlation analysis suggested several significant relationships ($P \leq 0.05$) between basin and subbasin land-cover percentages and seasonal water quality parameter values. Of the eight water quality parameters, total chloride, silica, pH, and $\text{NO}_3\text{-N}$ were significantly related to one or more of the land-cover metrics ($r = 0.35$ to 0.65). During all seasons, a greater percentage of forest cover

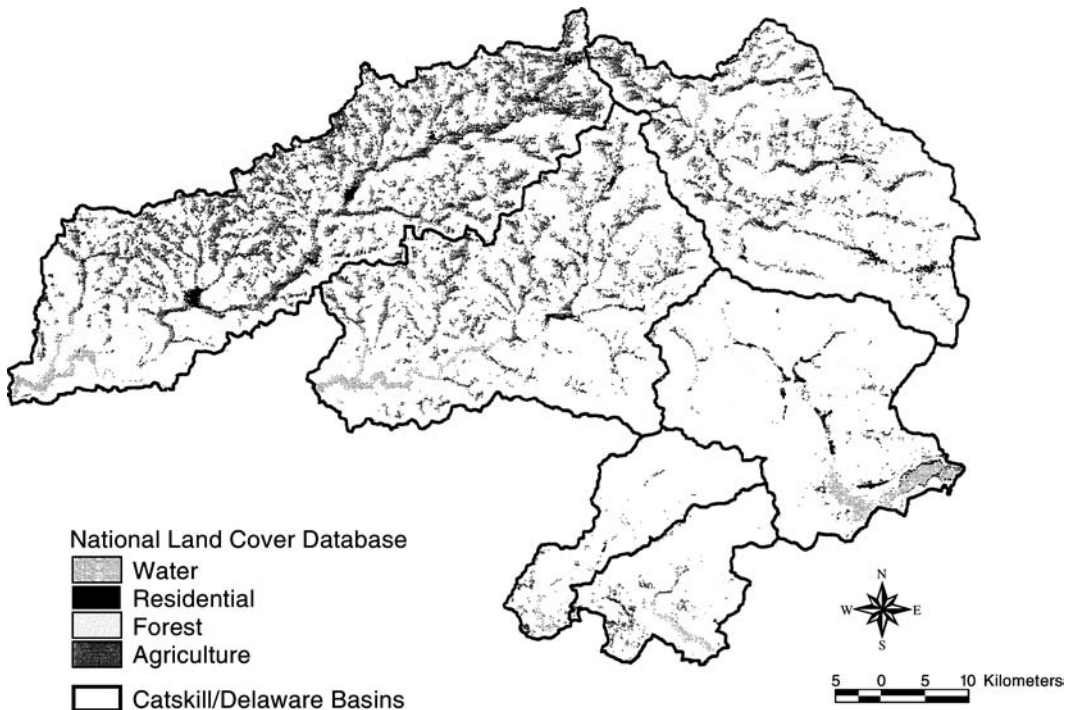

Figure 126.3 Land cover and use in the Catskill–Delaware basins. The land-cover and use categories were aggregated from the National Land Cover Database (NLCD) classification.

was related to lower values of all (total chloride, silica, pH, and $\text{NO}_3\text{-N}$) water quality parameters. In winter and fall $\text{NO}_3\text{-N}$ was higher in basins and subbasins having greater amounts of pasture, while in spring and summer $\text{NO}_3\text{-N}$ was lower. However, greater percentages of pasture were related to higher total chloride, silica, and pH values in all seasons. Greater residential land-use percentages were associated with higher total chloride in the fall and $\text{NO}_3\text{-N}$ in the winter. Greater percentages of row crops were associated with higher silica values in the fall and spring.

The inclusion of interaction variables in the regressions generally resulted in more-complex models with higher R^2 (Table 126.4). The land cover influencing total chloride values varied with season. In winter, the interaction of crop and residential land use was related to an increase in total chloride, while in spring, greater percentages of forest cover were related to decreased total chloride. In summer, approximately one half of the variation in total chloride was explained by the percentage of pasture. Greater percentages of pasture were related to higher total chloride levels. The remaining main and interaction variables of forest, crop and pasture, forest and pasture, and residential and pasture were related to lower total chloride levels, each variable accounting for 5% of the remaining variation. The interaction of residential and pasture land use was associated with higher total chloride and accounted for 40% of the variation (Table 126.4). Greater percentages of forest were related to lower silica in winter, spring, and summer and accounted for close to half the model variation. In winter, forest cover was the only variable related to silica. During spring, summer, and fall forest and pasture and crop and pasture were related to higher silica levels. Interaction between crop and pasture accounted for 40% of the variation in the summer and 16% in the fall, while forest/pasture accounted for 6% in the spring. The overriding land cover affecting pH was percentage of forest. Greater forest cover was related with lower pH and accounted for 20 to 40% of the variation. However, in spring, the interaction term of forest and pasture was included in the model accounting for 5% of the variation associated with higher pH. The $\text{NO}_3\text{-N}$ was significantly related to pasture,

forest, crop and forest, crop and pasture, and crop and residential. None of the variables accounted for more than 20% of the variation in $\text{NO}_3\text{-N}$. Crops were related to $\text{NO}_3\text{-N}$ as part of an interaction variable during all seasons, except summer. However, summer $\text{NO}_3\text{-N}$ values were not significantly related to any land-cover variable. Greater percentages of forest, pasture, and crop and forest were associated with lower $\text{NO}_3\text{-N}$ during the winter and spring months. The interaction terms of crop and pasture and crop and residential were related to higher $\text{NO}_3\text{-N}$ values during winter and fall.

DISCUSSION

With the exception of a maximum pH in the Cannonsville basin and a minimum pH in the Neversink basin, the water quality parameters during the 1986 to 1994 period of this study never exceeded the maximum contaminant levels (MCLs) set by the New York State Department of Health or the Environmental Protection Agency (NYCDEP, 1997). Considering the fairly limited human use in most of the Catskill–Delaware basins, water quality was expected to be fairly high. The low residential and agricultural land use in the basins is related not only to presence of the Park and Forest Preserve, but also to low population density. However, the concentration of human use in the riparian zones of rivers and streams remains a potential source of pollution. New York City has set as a first priority land acquisition around the reservoirs to ensure that potential sources of pollution are not located near the water supply (Murphy et al., 1995; MOA, 1997; Ashendorff et al., 1997). Second priority has been given to lands around the Esopus River that feeds the Ashokan Reservoir. Results from this study support the priority area. The Ashokan basin and subbasins intersecting Esopus Creek

were found to have the highest percentage of residential land use (Figure 126.5a). Regression analyses suggest that residential land use was associated with higher NO₃-N and total chloride values (most likely due to contributions from sewage treatment plants and leach field effluent release into the river). Third priority is land purchase or protection around the West Branch of the Delaware River. The riparian zones around the West Branch have the highest agricultural usage and the second highest residential use (Figure 126.5a,b). In our analysis, greater pasture and row crops were related to higher NO₃-N values in the fall and winter months. In spring, pasture and the interaction between crop and forest had a negative relationship with NO₃-N (most likely due to uptake during spring greenup). The relationship between human use and water quality became stronger as the scale decreased from basin to subbasin and riparian zones. Other third-priority areas for land acquisition include subbasins in the Pepacton and Schoharie basins. These selected areas coincide with our findings of subbasins having high agricultural and residential land use. Land in the Neversink and Rondout basins fall in the fourth-priority level for acquisition. These two basins had the highest forest cover, lowest human use, and, except for low pH levels, better overall water quality values. The link between greater forest cover and lower pH was evident in results from the correlation and regression analyses (Table 126.4). The pH values observed in the Neversink have been noted in other surface water studies and linked to the effects of acidic deposition and a decrease in soil and stream acid-neutralizing capacity (Stoddard, 1991; Murdoch and Stoddard, 1992).

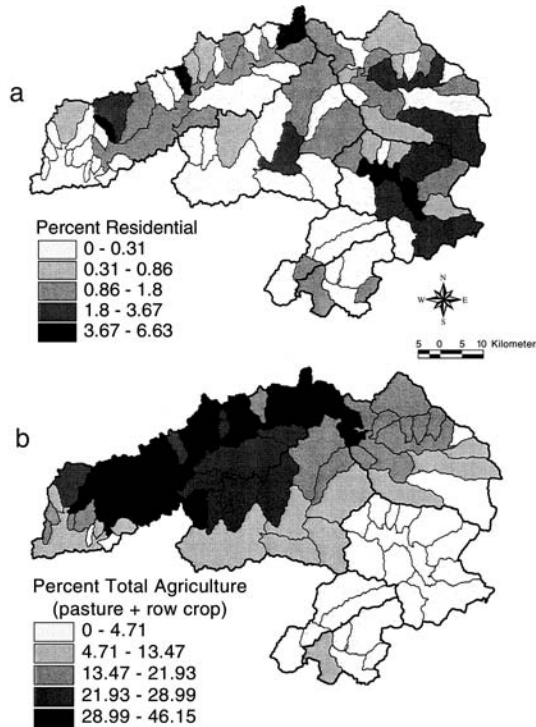

Figure 126.5 Percent of (a) residential and (b) total agriculture in a 100-m riparian buffer by subbasin in the Catskill–Delaware basins. Increased percentages of land use correspond to darker colors.

In regression analysis, land-cover metrics are often analyzed separately to determine their relationship to water quality. Results from this study suggest that combinations of land covers are important in explaining specific water quality parameter measurements. Furthermore, because of differences in vegetative productivity, nutrient cycling, and climate, the influence of upstream (100 m) land cover may vary with season. Besides spatial and seasonal influences on the relationship between land cover and water quality, other potential synergistic components are past land cover history, acid deposition, soils, and geology. In the Catskill–Delaware basins, acid deposition has been shown to contribute to low pH in the Rondout and Neversink basins. In the Schoharie and Ashokan basins, streams like Stoney Clove and Batavia Kill have a history of high sediment and turbidity. However, sediment contributions more likely come from eroding glacial clay lakes than from current agricultural practices (Rich, 1934; Miller, 1970). Analysis of different seasons and spatial scales provided a more-detailed description of the association between land cover and changes in water quality. This study was a first step in examining land-cover influences on water quality in the basins of the Catskill–Delaware basins. Future research could better defined these relationships by conducting a multiyear study.

ACKNOWLEDGMENTS

The authors would like to thank all the people who have participated in the creation of this study. Special thanks goes to the staff of the New York City Department of Environmental Protection, particularly Barbara Dibler, who willingly shared her knowledge of GIS, the Catskill–Delaware basins, and its community whenever we visited. Thanks also goes to members of the Landscape Ecology Branch, many of whom provided invaluable assistance in the production, assessment, processing, analyzing, and editing of this chapter. Without these people this study could not have been completed.

The Environmental Protection Agency, through its Office of Research and Development (ORD), funded and performed the research described. This manuscript has been subjected to the EPA's peer and administrative review and has been approved for publication. Mention of trade names or commercial products does not constitute endorsement or recommendation by the EPA for use.

Using a Knowledge Base to Assess the Effects of Stream Stressors

Lester Yuan

INTRODUCTION

Watershed management is rapidly becoming the preferred method for controlling the damage done to natural systems by human activities. This approach focuses on managing the activities of people residing and working in a given catchment through stakeholder involvement and incentive-based methods, instead of through traditional command-and-control regulations (U.S. EPA [Environmental Protection Agency], 1996; NAS, 1999). Watershed management has arisen partly in response to changes in the dominant stressors upon stream ecological integrity, as attention has shifted in recent years from controlling individual point source releases to addressing nonpoint sources of degradation. Nonpoint source stressors, such as habitat loss, invasive species, and nutrient runoff, are much more difficult to control than point sources, as they are dispersed across large areas and usually involve many different stakeholders.

Computational models that link human activities to specific stressors and to specific ecological effects have great potential as tools for facilitating watershed management. First, a robust, predictive model would allow managers to rapidly assess various management alternatives for their effects upon the ecosystem. Second, models could enhance monitoring efforts, as they could be used to extrapolate measurements from a finite number of field sites to all areas of the watershed. Managers would then be able to use these results to identify regions in a watershed that are either minimally impacted and therefore candidates for preservation, or that are highly degraded and to be targeted for restoration work. Finally, models could facilitate discussions at stakeholder meetings and focus groups by illuminating the pathways along which certain human activities eventually cause degradation in aquatic systems. To fulfill these potential applications, models must be reasonably reliable and must include most major watershed processes.

Many models for watershed processes exist, ranging from those predicting precipitation runoff to those predicting fish population dynamics. Unfortunately, current models fall short of their promise as management tools, primarily because scientists still lack a quantitative understanding of many of the processes by which human activities affect stream ecology. Much of the existing knowledge regarding the response of stream biota to different stressors remains largely qualitative. A second factor that inhibits greater adoption of models for management purposes involves a lack of holistic models that include most watershed processes, particularly those that relate physical stressors and human activities to biological end points. For example, the modeling package BASINS includes

modules for hydrology and the in-stream evolution of toxics, but lacks a component linking the hydrological and toxic calculations to biological responses (Lahlou et al., 1998). Because many states and regions are gradually moving toward using biological indicators of water quality (Karr and Chu, 1999), developing holistic models that combine physical and ecological processes seems particularly important. Intuitively though, the prospect of building a model that encompasses all human activities and all ecological end points in a given watershed is a daunting task.

In this chapter, I propose that a knowledge base may be a viable, alternative modeling approach. A knowledge base is a means of representing expert knowledge using linguistic rules. In the application discussed in this chapter, the knowledge base provides a coarse level of modeling that allows one to represent qualitative knowledge and to adopt a more holistic approach to the problem. To assess its potential for application to the field of watershed management, I have designed a demonstration knowledge base that relates some of the human activities in a watershed to stream stressors. Many relationships between human activities and stream ecological effects have been greatly simplified for this knowledge base prototype, as the main goal of this work is to demonstrate the potential of this approach.

KNOWLEDGE BASES

Knowledge bases, also commonly known as expert systems, have been used for many years in the computer science community wherein researchers have sought methods for representing expert knowledge in computer programs. Recently, they have received increasing attention as a possible alternative to traditional modeling approaches for both physical and biological systems (Silvert, 1997; Wenger et al., 1990; Mitra et al., 1998). A knowledge base has two basic components: a set of linguistic rules that defines relationships between variables in the system, and an inference engine that uses the rules to draw conclusions using input data. Each rule is structured as follows:

IF condition THEN conclusion.

Condition and *conclusion* are defined by simple logical clauses in the following form:

$$\text{IF } X \text{ is } A \text{ THEN } Y \text{ is } B \quad (127.1)$$

where X and Y are variables, and A and B are words that quantify X and Y . For example, in the clause, "urban land use is high," the phrase "urban land use" is the variable, and the word high quantifies urban land use. A complete rule using this clause might be "IF urban land use is high, THEN pollutant level is high." The word high only quantifies urban land use approximately, so to define explicitly the meaning of the word high, one uses fuzzy logic.

Fuzzy logic was developed to address situations in which defining absolute rules that decide between different options is difficult or impossible. For example, if one were to define the meaning of the word tall, a reasonable definition could be that anyone over 6' in height would be considered "tall." However, with this definition someone who is 5'11" would never be classified as tall, which is clearly a limiting situation. Fuzzy logic addresses this difficulty by capturing the approximate logic people employ in making decisions. Instead of clearly etched values of true or false, fuzzy logic permits one to specify gradations of truth. That is, if true is defined numerically as 1, and false is defined as 0, then fuzzy logic allows values that lie between.

These gradations of truth are represented by relationships known as membership functions. The term *membership function* refers to the idea that we must explicitly define the degree to which objects belong in a group. In the previous example, a person who is 5'11" is a partial member of the group of tall people. Returning now to the urban land-use example, the notion that urban land use is high is expressed as a function that relates the fraction of urban land use in a catchment to

Figure 127.1 Membership function for “urban land use is high.”

the degree of truth (Figure 127.1). In this case, a catchment with no urban land use would imply that the degree of truth for the statement “urban land is high” is 0, while a catchment entirely composed of urban land use would generate a degree of truth of 1. Intermediate values of urban land use would produce intermediate degrees of truth. In general, any functional form can be used to specify the membership function; however, in the current work membership functions have been restricted to trapezoidal shapes for simplicity.

The second component of the knowledge base, the inference engine, uses the rule base to draw conclusions from an input database. A significant amount of literature on various inference techniques exists, and the reader is referred to Zimmermann (1991) for complete coverage. Details of the inference methods employed for this work are provided in the example in Zimmermann’s Section 4.

METHODS AND MATERIALS

Study Area

The Patapsco River Basin (Figure 127.2) spans two distinct physiographic provinces. The headwaters of the Patapsco lie in the ridges of the Piedmont Province, where the soils are derived from granite rock and consist of loams and clays with rock fragments and gravel. As it flows south

Figure 127.2 Patapsco River Basin, Maryland (inset).

and east, the river enters the Northern Coastal Plain, which is characterized by sands, sandy loams, and silt loams resulting from sea deposits. Land use in the watershed is predominantly agricultural in the northwest, but changes to urban development as one approaches metropolitan Baltimore in the southeast.

Data

Because of the holistic approach employed in this study, the data requirements are large and diverse. For land-cover information, the Multi-Resolution Land Characteristics (MRLC) digital data set is used. This data set was developed by a consortium of federal agencies and is based on LandSat 1991 to 1993 Thematic Mapper images. The data classify land cover into 15 different categories and have a resolution of 30 m. Access to the data was provided by EPA Region 3 (Delaware, Maryland, Pennsylvania, Virginia, West Virginia, and the District of Columbia) and the EPA Office of Water. Delineation of the boundaries of the Patapsco River Basin was provided by the Maryland Natural Resource Conservation Service, while the delineations of catchments corresponding to individual sampling sites were computed by the author from 30-m digital elevation data obtained from the U.S. Geological Survey (USGS). Point source data were obtained from the EPA Permit Compliance System, which is now housed in the Envirofacts warehouse (http://www.epa.gov/enviro/html/ef_overview.html).

Local observations of stream biota and physical habitat were obtained from the Maryland Biological Stream Survey (Roth et al., 1997, 1998). This statewide survey is conducted by the Maryland Department of Natural Resources and employs a stratified random sampling design to assess the biological condition of the nontidal small (first through third order) streams of Maryland. Sampling teams visited the Patapsco River basin in two different years, measuring 61 sites in 1995 and 68 sites in 1996. At each site, teams sampled both fish and benthic macroinvertebrates, and conducted systematic surveys of the quality of the physical habitat (Roth et al., 1997). Indices of biotic integrity based on fish (Roth et al., 1997) and benthic communities (Stribling et al., 1998) were developed using accepted multimetric index procedures. These indices have been shown to consistently distinguish between least impacted *reference* sites and sites that show substantial human influence. Although the benthic index of biological integrity (B-IBI) measures ecological condition relative to a predetermined reference condition, in this chapter it will be used as a surrogate for ecological integrity. I adopt the definitions of Karr and Chu (1999), who define ecosystems with good ecological integrity as those systems that are pristine and whose biota are the result of natural evolutionary and biogeographic processes.

Knowledge Base Development

Because a knowledge base consists only of a set of semantic rules, developing the rules requires one to elicit the qualitative knowledge of experts in the appropriate field. In many cases the knowledge-elicitation process consists of extensive interviews with experts, whose responses are then combined to form a collective set of rules (Chang et al., 1998). Because the primary focus of this current project is only to illustrate the usefulness of knowledge bases in a new arena, it was decided that multiple expert opinions would not be solicited. Instead, the rule base was determined primarily by the qualitative knowledge of the author and by informal consultation with Versar, Inc. and EPA staff familiar with the Maryland data. The simplicity of this approach substantially reduced the time required to develop the knowledge base.

Conceptual Model and Rule Base

The conceptual model illustrated in Figure 127.3 provides a qualitative representation of the linkages between human activities and stream ecology, based on an extensive literature review (see,

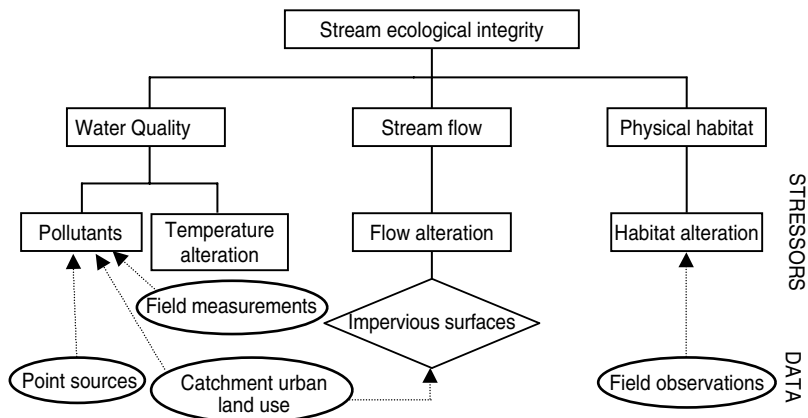

Figure 127.3 Conceptual model.

for example, Schlosser, 1991; Richards and Host, 1994; Richter et al., 1996; Allan et al., 1997). The first level of the conceptual model broadly asserts that the ecological integrity of a stream depends on three factors: water quality, physical habitat, and stream flow. Many researchers include a fourth category that includes ecological effects such as predation and migration (Karr, 1991), but this level of ecological detail is beyond the scope of this work. At the next level in the figure, different stressors are listed that fall within the main groups. This list is not exhaustive, as the stressors listed are only those that are observed to be dominant in the Patapsco basin. The list has also been shortened to reflect the coarse modeling approach of this pilot study. So, instead of listing different stressors for nutrients, toxics, and dissolved oxygen, these factors are all grouped together as *pollutants*. At the final level of the figure, data sources are shown enclosed within ovals. Arrows link these data to the appropriate stressor. One final entry in the conceptual model is *impervious surfaces*. It is enclosed in a diamond to indicate that it is an intermediate value, distinguishing it from directly measured data in ovals and final stressor levels in boxes. Again, the list is not a complete accounting of all possible sources of data, but merely represents those data that are currently available.

The qualitative rule base (listed in Table 127.1) follows directly from the conceptual model, further clarifying the linkages between data sources and stressors and between stressors and ecological condition. Each rule is composed of a condition and a conclusion. Intermediate levels in the conceptual model are represented by intermediate variables. For example, setting pollutant level is an action at the lowest level, but pollutant level then becomes one of the variables used in the conditions for determining water quality.

The knowledge base software used for this work is the Ecological Management Decision Support System (Reynolds et al., 2000). This system integrates a knowledge base inference engine with a geographical information system; thus, it allows one to use geospatial data as inputs to the knowledge base.

Calibration

Once the qualitative linguistic rules were established, the knowledge base was calibrated by adjusting the bounds of individual membership functions, using data from the 1995 Maryland Biological Stream Survey (MBSS) in the Patapsco. Calibration procedures differed depending on whether a given membership function was used in the condition clause or in the conclusion clause in the rule base. For those that were used in the condition clause, calibration procedures depended on the spatial scale at which the variable is relevant, i.e., catchment scale stressors affect all sites, while local stressors affect only a small fraction of the sites, so the calibration techniques applied

Table 127.1 Rule Base

Stream Ecological Integrity

If water quality is good and flow flashiness is low, then ecological integrity is good.
 If physical habitat is poor or water quality is poor or flow flashiness is high, then ecological integrity is poor.

Physical Habitat

If minimum score is poor and mean score is poor, then habitat is poor.
 If minimum score is good and mean score is good, then habitat is good.
 If minimum score is fair or mean score is fair, then habitat is fair.

Stream flow

If impervious surfaces are high, then flow flashiness is high.
 If impervious surfaces are low, then flow flashiness is low.

Water Quality

If pollutant level is low, then water quality is good.
 If pollutant level is high or measurements are poor, then water quality is poor.

Pollutants

If point source is near and urban land use is high, then pollutant level is very high.
 If point source is near or urban land use is high, then pollutant level is high.
 If urban land use is low, then pollutant level is low.

Measurements

If DO is low or NO₃ is high, then measurements are poor.
 If DO is high and NO₃ is low, then measurements are good.

to each were quite different. For the membership functions used in conclusion clauses, additional constraints existed which limited the types of functions that could be used.

Catchment Scale Stressors

Urbanization is the main human activity affecting stream ecological integrity in the Patapsco. Its effects can be seen in Figure 127.4, in which B-IBI decreases with increased catchment urban land fraction. The amount of urbanization in a catchment can affect stream biota in many ways, and two main mechanisms are represented in the conceptual model. First, urban catchments are

Figure 127.4 Fraction of urban land use vs. B-IBI. Regression relation shown on graph.

Figure 127.5 Membership function for “fraction impervious surface is low.”

covered by more impervious surfaces; therefore, they alter runoff volumes and change flow patterns in the stream. Second, the precipitation runoff from urban areas can carry significantly higher concentrations of pollutants than runoff from forested catchments. So, urban land cover links directly to stream flow alteration and to pollutant level in the rule base and in the conceptual model. To determine appropriate bounds for the membership function expressing “high urban land use,” the regression line relating urban land use to B-IBI was used, but only to identify the general trend in the data, as the membership function does not translate directly to a regression line. The final version of the membership function for urban land use takes the form of a straight line, varying smoothly from no urban land use to 100% land use (Figure 127.1). This illustrates the basic approach employed in establishing the membership functions, in which the simplest relation was initially assumed. Substantial evidence of deviations from the simple linear relationship had to be observed before the basic form was altered.

The fraction of impervious surface can be computed from land-cover data using estimates for impervious surfaces (Roth et al., 1998). As mentioned previously, urban land use correlates strongly with the amount of impervious surfaces in the catchment, which impacts runoff patterns and can lead to substantial flow alteration. Here again, regression lines relating the fraction of impervious surface to B-IBI were examined and used as guidance in determining membership functions. The range of values for the fraction of impervious surface in a catchment was 0.20 to 0.65 and the membership function (Figure 127.5) reflects the reduced range.

Local Stressors

Local scale stressors presented difficulties for calibration, as they generally affected only a small fraction of sites within the study area. Only 4 sites of the 61 sampled in 1995, for example, have at least one point source within 1000 m upstream. A similarly small number have low habitat assessment ratings or poor water quality measurements. Because of these small sample sizes, calibrating the membership functions was, by necessity, somewhat *ad hoc*. However, the model itself retains its validity because the rule base remains grounded in a qualitative understanding of the relationships. The three local stressors considered in this work were habitat quality, local water quality measurements, and the presence of point source releases.

Habitat quality was assessed by the MBSS in nine different categories (in-stream habitat; epifaunal substrate; velocity and depth diversity; quality of pools, glides, and eddies; riffle quality; channel alteration; bank stability; aesthetic rating; and remoteness), each on a 20-point scale (Roth et al., 1997). To aggregate the habitat scores into a smaller number of ecologically meaningful statistics, the minimum and mean value for the nine observations were calculated for each site. This combination of statistics captures situations in which one category is rated particularly poorly, as well as situations in which the overall habitat quality of the site is poor. To determine membership functions, the aggregated habitat scores were plotted vs.

Figure 127.6 Membership functions for mean and minimum habitat scores.

B-IBI, and the trends noted. In contrast to the catchment scale stressors, ecological integrity does not increase consistently with increasing values of habitat quality. Instead, threshold values exist, below which B-IBI values are depressed. These threshold values are reflected in the steep changes in the membership functions shown in Figure 127.6. Other habitat variables, which are not rated on a 20-point scale (e.g., percent embeddedness), were also measured in the MBSS, but these observations have not been included in the knowledge base.

Limited water chemistry measurements were also available from the MBSS data, including dissolved oxygen (DO) and nitrate measurements. Membership functions were initially specified for concentrations of these compounds based upon published water quality criteria (U.S. EPA, 1986, 1999). These values were then slightly adjusted to reflect observations from the Patapsco data. The threshold value for DO was set at 6 ppm, below which a significant drop in B-IBI values was observed. Similarly, the threshold value for nitrate was set at 10 mg/L, above which B-IBI scores were depressed. Membership functions that use these threshold values, representing agreement with the statements “nitrates are high” and “DO is low” are depicted in Figure 127.7.

Point sources, as mentioned earlier, were close to only a small number of sites within the study area. As with other factors, the treatment of point sources is very simplistic for this prototype knowledge base. The knowledge base tests only for the presence or absence of a single point source within a fixed distance upstream from the sampling site. Other relevant factors, such as the composition and quantity of released effluents and the status of compliance with release permits, are not included. To define the membership function for “point source is near” B-IBI scores were again examined at all sites for which any point sources lay upstream. Of these sites, only those with point sources within 1000 m showed significant degradation. This threshold distance was then used to define a membership function, in which the degree of truth decreases linearly with increasing distance (Figure 127.8).

Figure 127.7 Membership functions for “nitrates are high” and “dissolved oxygen is low.”

Figure 127.8 Membership function for “point source is near.”

Intermediate Variable Membership Functions

As alluded to earlier, intermediate membership functions are constrained by two factors. First, limitations in the capabilities of the current knowledge base software restrict the range of possibilities for the membership functions located in the conclusion part of the rule; all membership functions must be the same rectangular shape (as shown in Figure 127.9). The only variation allowed is in the location of the function along the horizontal axis. Second, all intermediate level variables represent abstract concepts, rather than measurable quantities. In theory, one could devise a way of measuring a variable such as pollutant level as some aggregated index of individual toxics and nutrients. However, in the present knowledge base, pollutant level refers more to an assessment of the various human activities that give rise to waterborne pollutants, rather than an actual value. Because of these two constraints, all membership functions for conclusion variables are defined as ordinal numbers. For example, pollutant levels can be either low or high, so these are assigned ordinal values of 1 and 5, respectively. Evaluating the pollutant level portion of the rule base then leads to values that lie between 1 and 5 and that characterize the relative amount of pollutants produced by activities in the catchment. Because the final result of the knowledge base is itself an ordinal value, using ordinal values in the intermediate stages does not reduce the effectiveness of the model.

EXAMPLE EVALUATION OF A FUZZY RULE

The max-min compositional rule (Zimmermann, 1991) has been chosen as the method for evaluating fuzzy rules in this study. To illustrate this method consider the following example. Suppose we would like to evaluate the rule “IF urban land use is high OR point source is near

Figure 127.9 Membership functions for “pollutant level is low” and “pollutant level is high.”

Figure 127.10 Graphical illustration of rule evaluation.

THEN pollutant level is high.” Data sources provide numerical values for the fraction of urban land use in the catchment and for the distance to the nearest point source. For this example, take these values to be 72% and 400 m, respectively. To evaluate the rule, we use the appropriate membership functions to determine the degree of truth (DT) for each of the two antecedent conditions. To account for the OR conjunction, we then take the maximum degree of truth of all antecedent conditions (Zimmermann, 1991). In this case, “urban land use is high” has a DT equal to 0.72, while “point source is near” has a DT equal to 0.6, so the DT of the antecedent conditions is 0.72. The rule therefore produces a conclusion that the DT of the statement “pollutant level is high” is also 0.72. We represent this conclusion in terms of membership functions by truncating the membership function for “pollutant level is high” at DT = 0.72. This entire process is shown graphically in Figure 127.10.

Overall pollutant level is represented by a group of different rules, each with a different truncated membership function. In the rule base listed in Table 127.1, three different rules predict pollutant level. With the max-min compositional technique, the union of the results of the three rules determines the membership function for overall pollutant level. Thus, the resulting membership function for pollutant level can be a collection of irregular shapes (Figure 127.11). A single value for pollutant level is required for subsequent computations in the knowledge base, and so we must reduce the irregularly shaped membership function to one number. A variety of techniques exist for this process, more details of which can be found in Zimmermann (1991). For this study, the center of mass method is used, which reduces the membership function to a single value by computing the location of the center of mass. In Figure 127.11, two distinct parts of the membership function are evident, a rectangle with pollutant level of 1 and DT = 0.30, and a rectangle with pollutant level of 5 and DT = 0.72. The center of mass ($1 * 0.30 + 5 * 0.72$) of this membership function is then 3.9.

Figure 127.11 Union of all rules predicting pollutant level.

Table 127.2 Narrative Descriptions for Knowledge Output

KB Output	Narrative Description
1-2	Poor
2-3	Marginal
3-4	Suboptimal
4-5	Optimal

Because pollutant level is an intermediate value, the numerical value for pollutant level is then used as an antecedent condition in subsequent rules. In this way, the effects of widely disparate data sources can be combined to draw a single conclusion. The final result from the knowledge base provides a value ranging from 1 to 5 that characterizes the degree to which human activities stress the stream biota at that site. Narrative ratings are assigned to whole number intervals (Table 127.2). The assessment values span the same range as B-IBI scores to facilitate comparison.

RESULTS

Calibration

The ability of the knowledge base to distinguish between four different levels of human influence is illustrated in Figure 127.12 for the data collected in 1995. Ideally, one would want a perfect separation, in which sites classified by the knowledge base as poor would have B-IBI ranging only between 1.0 and 2.0; sites classified as optimal would have B-IBI between 4.0 and 5.0; and sites classified as marginal or suboptimal would also only have B-IBI between 2 and 4. However, classification by the knowledge base is not perfect, despite the fact that the knowledge base was calibrated using this data set. Nevertheless, several aspects of the results are encouraging; at the extreme ends of the spectrum (poor and optimal), the distribution of B-IBI values is quite narrow, so it appears that the knowledge base is correctly identifying sites that also lie at the extreme upper and lower ends of the range of possible B-IBI. Classification at the intermediate ranges (marginal

Figure 127.12 Box plot showing knowledge base results compared to B-IBI values for 1995. The horizontal boundaries of each box indicate the locations of the 25th percentile, the median, and 75th percentile, respectively. The bars below and above each box indicate the locations of the minimum and maximum values.

and suboptimal) are encouraging as well. Here, the spread of the data is noticeably higher, but the median values in the intermediate range increase monotonically and lie between median values for poor and optimal sites. This monotonic increase in median B-IBI through all four classifications indicates that, on the average, the knowledge base is identifying a gradient of human influence that is reflected by the biological indicator.

One can also evaluate the knowledge base performance at a coarser level by classifying sites into only two categories: less impacted sites with knowledge base ratings of 3.0 or greater, and degraded sites with ratings below 3.0. Under this coarse classification scheme, 78% of those sites the knowledge base classified as less impacted had B-IBI greater than 3.0, while 87% of sites classified as degraded had B-IBI less than 3.0. The difference in classification efficiencies between less impacted and degraded sites reflects the conservative approach taken in the design of the knowledge base, as it was thought that if misclassifications were to occur, it would be preferable to err on the side of classifying bad sites as good. Therefore, the knowledge base is incorrect more often in misclassifying degraded sites.

Incorrectly classified sites are present at all levels. These discrepancies can be attributed to two possible sources. First, natural systems are inherently temporally variable, so incorrectly classified sites may have had particularly high or low measurements on a given day. The magnitude of the temporal variability in the B-IBI has not yet been adequately quantified. Second, all possible human activities or stressors are not included in the knowledge base. As with any model, the knowledge base is limited by the knowledge of the modeler, so this preliminary version of the knowledge base is not a complete representation.

Validation

A validation test for the knowledge base was performed by running it with 1996 data from the Patapsco. Because of the random sampling monitoring design of the MBSS, sites sampled in 1996 were all different than 1995. In other respects (variables measured, sampling procedure, etc.), 1996 data were identical to 1995 data. A comparison between knowledge base predictions and B-IBI values computed from 1996 data is shown in Figure 127.13. Overall, the knowledge base classifications were higher than measured B-IBI. This overestimation was particularly evident in the sites classified as optimal. Of the 32 sites classified by the knowledge base as optimal, only two had B-IBI greater than

Figure 127.13 Box plot showing knowledge base results compared to B-IBI values for 1996.

4.0. The same discrepancies were present when results are aggregated into only two categories. 43% of sites classified by the knowledge base as least impacted had B-IBI less than 3.0. Conversely, 96% of sites classified as degraded by the knowledge base also had B-IBI less than 3.0.

Despite the general trend toward overestimation, several positive features in the validation results could still be observed. First, median B-IBI values again showed a monotonic increase as one moved from poor to optimal, so the knowledge base was still predicting a gradient of human influence which was mirrored in the measured biotic integrity. Second, the classification efficiencies were heavily skewed toward incorrectly classifying degraded sites as least impacted. Thus, the knowledge base predictions were conservative, as desired.

Comparison to Simple Regression Approaches

Many models relating human activity to ecological end points are based on linear regressions, so one can ask whether the knowledge base approach improves on linear regression models. For this case, in particular, much of the variance in B-IBI could be attributed to urban land use, so a regression model using urban land cover would seem to produce results that were comparable to the knowledge base. To address this question, a linear regression model was computed for 1995 data, and the model tested with 1996 data. The regression with the 1995 data yielded the following predictive equation,

$$\text{BIBI} = 3.53 - 0.268U \quad (127.2)$$

where U is the fraction of urban land use in the catchment ($r^2 = 0.58$, $p < 0.0001$). This same predictive equation was then applied to the 1996 data. To facilitate comparison to the knowledge base results, the predicted results were compared to field measurements using the same format as in Figures 127.12 and 127.13; i.e., the data were binned into four categories based on predicted B-IBI scores, and box and whisker plots presented for the distribution of actual measurements within each bin (Figure 127.14). In both years the linear regression model produced results that were less accurate than those from the knowledge base. First, a monotonic behavior was not observed in validation results from 1996. Clearly, other factors in addition to urban land use had a strong effect on ecological integrity. Second, the linear regression model classified many more sites in the optimal group than the knowledge base, and so the range of values observed in this group was quite large. This behavior was expected because a large number of sample sites had small urban land use fractions. This example, however, illuminates the limitations of using a regression approach. Both of these shortcomings may be mitigated by regressing against additional variables, but a multiple linear regression analysis was beyond the scope of this current work.

DISCUSSION

In this pilot study, the knowledge base has been shown as a viable alternative to other modeling approaches for predicting the effects of human activities on stream ecological integrity. However, much further work remains before knowledge bases can be considered for general use in watershed management. One immediate concern is the failure of the knowledge base to accurately predict ecological integrity as measured by B-IBI in both the calibration and the validation data sets used for this work. Several points are relevant to this issue. First, scientific explanations for much of the variance in the B-IBI in the Patapsco do not at present exist. The knowledge base used for this work is, admittedly, simple in design, but additional stressors that could account for the unexplained variance were not obvious from the literature. The current lack of complete scientific explanations does highlight an advantage of the knowledge base approach, which is that as new information becomes available, it can be easily incorporated into the existing knowledge base.

Figure 127.14 Box plots showing results of simple linear regression model.

A second point is that B-IBI is an indicator of a biological system; therefore, a certain amount of temporal variance in the measurements is unavoidable. A means of assessing the performance of the knowledge base relative to a background of temporal variance would be useful. The MBSS is conceived as an ongoing monitoring effort, so as additional samples are taken, an estimate of natural temporal variability may be possible.

Third, natural stressors may be responsible for some of the discrepancies between predictions and measurements in the validation data. The main discrepancy one notices in the 1996 validation plots is the overestimation of ecological condition by the knowledge base. However, part of the overestimation may be a result of lower B-IBI scores. Indeed, if we statistically compare scores in 1995 with 1996 (using only those sites with urban land uses less than 10% to reduce variance), we find that the mean B-IBI score in 1995 was 3.53, while the mean in 1996 was significantly lower, at 2.72

($p < 0.001$). The reason for this general decrease in B-IBI may be attributable to harsher weather conditions in 1996. Weather records from the National Climatic Data Center (<http://www.ncdc.noaa.gov/>) reveal that 1996 had heavier and more frequent rainfall than 1995. The effects of more frequent and energetic floods upon benthic macroinvertebrates are uncertain, but in certain situations, a decrease in B-IBI might be expected. Also, the records show that the Baltimore area was hit by a late winter storm, March 8–9, 1996, in which temperature dropped to lows of approximately 10°F (−26°C) on two consecutive days. Because most of the samples in the Patapsco were taken within 10 days after the storm, this late freeze may have contributed to a general reduction in B-IBI. The knowledge base in this study focused on anthropogenic sources of stress, so these natural stressors might explain some of the lack of agreement between knowledge base results and field measurements.

In the future, the ability of a single knowledge base to successfully predict ecological integrity across different watersheds and between different ecoregions must be demonstrated. The current version of the knowledge base has been calibrated to match data from the Patapsco River basin, so sets of stressors and human activities included in its rule base are not only abbreviated but are unique to the study area. To apply the same knowledge base to watersheds in other ecoregions, the rule base must be expanded to encompass a broader set of stressors. Expanding the rule base in this way should not affect previously established rules, so the generality of the knowledge base can be increased in a natural way. Ultimately, a knowledge base would be most useful if it could accurately predict stream ecological integrity in an arbitrary ecoregion.

The limitations imposed by the software used for this study have been quite severe. Other inference engines that allow more general definitions of membership functions in the conclusion clauses may enhance the performance of the knowledge base. Future work will include an evaluation of software alternatives for the knowledge base.

This pilot study has demonstrated that knowledge bases can be a promising approach for watershed modeling. They provide a very flexible modeling environment that can represent qualitative scientific knowledge and integrate disparate sources of data. The easily interpreted linguistic rules on which the model is based can facilitate model development, and as new information emerges, it can be readily incorporated into existing knowledge bases.

ACKNOWLEDGMENTS

This chapter was prepared while the author was an American Association for the Advancement of Science Fellow at the National Center for Environmental Assessment of the U.S. Environmental Protection Agency. The author gratefully acknowledges many useful discussions with Jeff Frithsen (U.S. EPA); also, Nancy Roth, Mark Southerland, and Ginny Mercurio (Versar, Inc.) provided valuable assistance in acquiring MBSS data and interpreting results. The Maryland Biological Stream Survey is a statewide stream sampling program conducted by Paul Kazyak and the Maryland Department of National Resources, Monitoring and Non-Tidal Assessment Division, and the author is grateful for their efforts in collecting this comprehensive set of data. The author also acknowledges Keith Reynolds (Forest Service, USDA) and Jim Andreasen (U.S. EPA) for providing the EMDS software. The views expressed herein are those of the author and do not necessarily reflect the views or policies of the U.S. Environmental Protection Agency. SECTION III.5

The Langat Basin of Malaysia

Overview: The Langat Basin of Malaysia

Nicholas W. Lerche

Ecosystem health is an evolving, integrative field that explores the interrelations among human activity, social organization, natural systems, and human health (Rapport et al., 1998). One product of such integration is the development of a holistic approach to ecosystem health assessment and environmental management (Rapport et al., 1998). This collection of five chapters focuses on several key aspects of ecosystem health assessment and environmental management of the Langat Basin, a rapidly developing region in the state of Selangor, Malaysia. The principal authors, all of whom are affiliated with the Institute of Environment and Development (LESTARI) of the University of Kebangsaan, Malaysia, present a body of research documenting historical trends and the current status of critical components of the basin's ecosystem, including land cover and biodiversity, industrial development and economic growth, and water quality, as well as a novel consideration of geohazards. The results of this research provide baseline data essential not only for assessing the current state of the ecosystem, but also for identifying useful indicators of ecosystem health or dysfunction, and for evaluating the efficacy of any preventive, palliative, or restorative interventions.

LESTARI's long-term project in the Langat Basin is a valuable case study of the application of ecosystem health concepts on a regional basis to the evaluation and management of a large-scale tropical ecosystem (Nordin and Azrina, 1998). The Langat Basin is located adjacent to the Klang Valley, the most highly developed urban center in Malaysia, and site of the nation's capital, Kuala Lumpur. Proposed development projects in the Langat Basin — including a new administrative capital and a new international airport — will undoubtedly induce a large and rapid influx of commercial and industrial development in the basin, with resultant changes in landscape, water and air quality, demography, and demand on regional resources and ecosystem services (Nordin and Azrina, 1998). To the extent that the Langat Basin is representative of other rapidly developing regions throughout Asia that are facing similar ecosystem stressors and perturbations, the research methodologies presented in this collection of chapters may contribute to a conceptual framework for ecosystem health assessment and management of other large-scale tropical ecosystems.

The main goal of LESTARI's long-term project in the Langat Basin is to establish and monitor the health of the basin's ecosystem through research, training, and policy influence, ultimately contributing to a sustainable pattern of development in the basin (Nordin and Azrina, 1998). This research represents a significant contribution toward achievement of that objective.

Ecosystem Health in Malaysia: A Case Study of the Langat Basin

M. Nordin, Joy Jacqueline Pereira, Ahmad Fariz Mohamed, Saiful Arif Abdullah, Ibrahim Komoo, Shahrudin Idrus, Pauzi Abdullah, Abdul Hadi Harman Shah, Abdullah Samat, Rospidah Ghazali, W. Mohd Muhiyuddin, and Muhammad Abu Yusuf

INTRODUCTION

Tropical ecosystems are among the most complex in the world. Defining their health is a difficult task but concepts, approaches, and methods emerging from the literature on ecosystem health increasingly provide insights on how this complexity can be properly examined and understood. This large-scale ecosystem health study in the Langat Basin of the state of Selangor, Malaysia, aims to find and provide a rational framework within which the health of a tropical ecosystem may be assessed and monitored. The work is funded by the United Nations Environment Program, Regional Office for Asia and the Pacific (UNEP/ROAP) with funds from the Danish Cooperation on Environment and Development (DANCED). It is part of UNEP/ROAP's initiative on training and research on environmental management (TREM) in Thailand and Malaysia.

The Langat Basin is situated south and adjacent to the Klang Valley, Malaysia's highly developed urban conurbation where the nation's capital, Kuala Lumpur, is located (Figure 129.1). It has an area of about 2930 km² and a population of about 962,649 in 1998. It comprises a watershed catchment area to the northeast along the ridge of Banjaran Titiwangsa (Main Range) of Peninsular Malaysia and a coastal fringe along the Straits of Malacca to the southwest. Being adjacent to Kuala Lumpur, the basin has seen rapid expansion in areas developed for housing, industrial estates, and business centers over the last decade (Nordin and Azrina, 1998). This has largely been in response to the need for urban housing as well as industrial, business, and commercial property development in the basin.

Several large federal government projects, such as the Kuala Lumpur International Airport in Sepang; the new federal government administrative capital at Putra Jaya; and Malaysia's "cyber city," Cyber Jaya, are located within the basin. These development projects have spurred an influx of commerce and industry into the basin, affecting not only the price of land, but also the pattern of human settlements, landscapes, and ecology.

With the exception of the Putra Jaya and Cyber Jaya areas, development in the Langat Basin typifies, in general, the pattern of urban and industrial development in other parts of Malaysia and Southeast Asia. Urban sprawl extends from existing urban centers, in this case Kuala Lumpur, Petaling Jaya, Shah Alam, and Puchong to the north of the basin, into areas that are less developed,

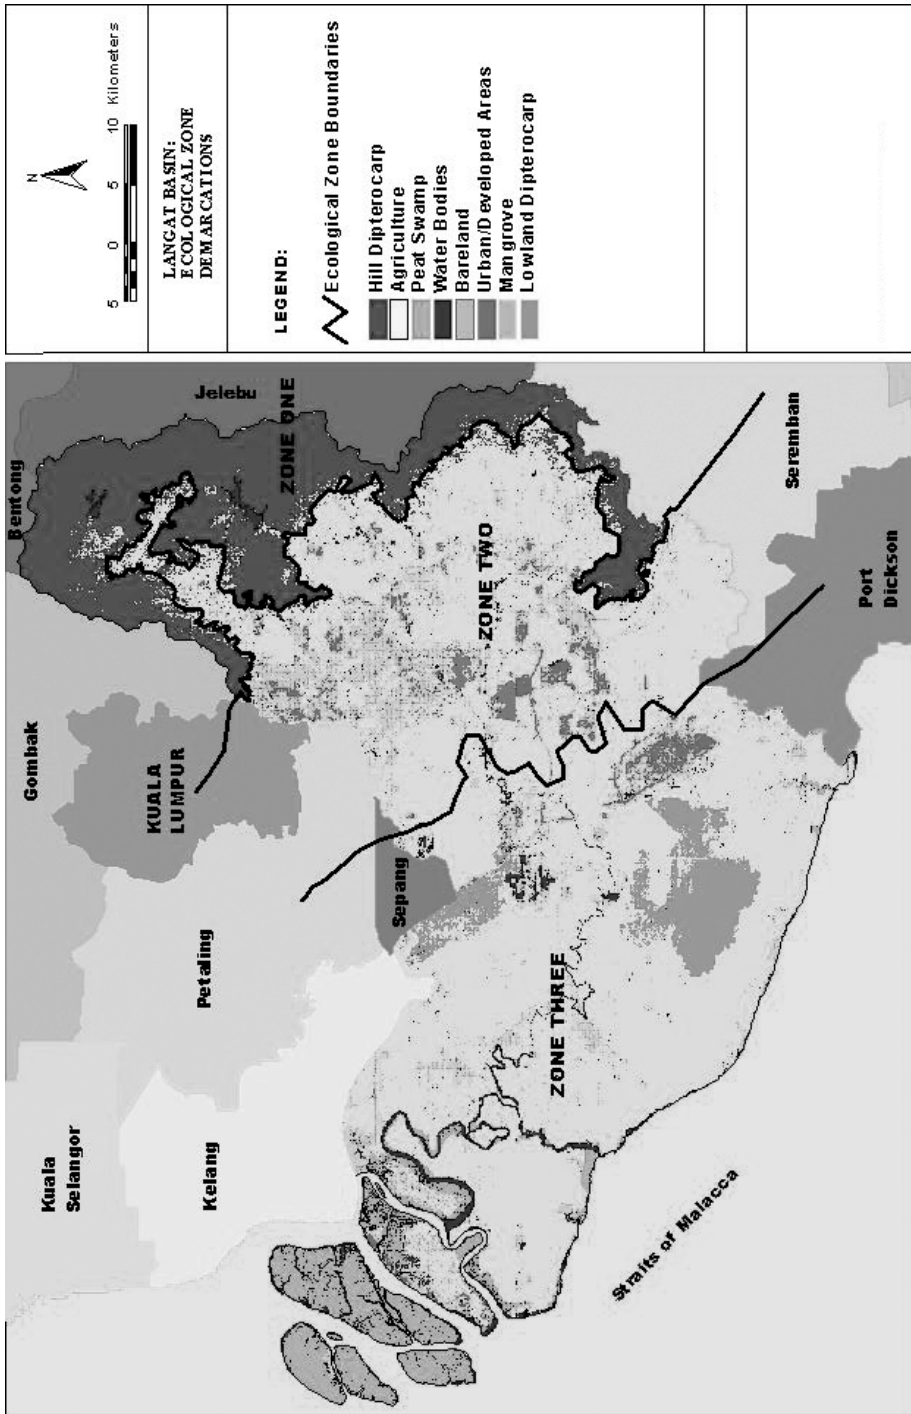

Figure 129.1 The Langkat Basin and its ecological zones.

when new infrastructure (the most important being roads, highways, and bridges) is put in place. This leads to the conversion of agricultural land and, in some instances, forest and other natural areas, into housing and industrial estates, as well as business and commercial centers. Such development leads to the establishment of new townships, which then coalesce with new growth from existing towns and villages. These areas form new urban centers that replace natural and agricultural landscapes.

The Langat Basin ecosystem is undergoing rapid change. In the 1960s and 1970s, much of its original lowland dipterocarp and peat swamp forests were lost through conversion to agricultural plantations, tin-mining areas, and human settlements (Wong, 1974). More recently, its natural areas have come under increasing pressure from urbanization and industrialization. Its rivers have become increasingly polluted from industrial, agricultural, and domestic wastes. Rivers have also been realigned and concrete lined to enable more rapid flow rates. Increases in areas of bare and developed land with increasing urban growth cause increased surface runoff. River alignment is also undertaken to minimize riverbank erosion. Large areas of its coastal zone have also been converted to ports and sites for development of industrial parks and aquaculture farms.

The purpose of this chapter is to provide an overview of the features of the Langat Basin and describe a proposed framework for assessing and monitoring the health of the basin ecosystem. Patterns of land cover, ecological zones, population, industrial sites, river water quality, agriculture, water supply and demand, geohazards, mining activities, forests, and wildlife including fish are briefly described. Criteria and indicators of ecosystem health within the methodological framework needed for assessing and monitoring the health of the Langat Basin ecosystem are still under construction. Some of these criteria and indicators are presented in this chapter.

GENERAL LAND COVER

A 1996 LANDSAT thematic mapper, seven-band satellite image was used to prepare a digital base map of the basin with land-cover calculations. Satellite data of the basin were geocoded and projected to a RSO grid using Kertau 1948 datum. The image was initially classified using unsupervised classification. In this way, 30 classes were generated and used as a guide in selecting sites for the supervised classification process. From this, eight initial land cover categories were identified using the maximum likelihood method followed by post-classification processing (Lillesand and Kiefer, 1987). Recent land-cover and land-use maps, as well as simple ground-truthing, were used to aid classification. The results of the original classification were modified during the recoding stage. The final results of the classification scheme were achieved after obtaining the consensus viewpoints from researchers conducting studies in the Langat Basin and remote-sensing experts familiar with the study area. Statistics for each land-cover category were generated from the satellite image.

Land cover in the basin is predominantly agricultural (Table 129.1) with almost 64% of the basin under this category. Large-scale rubber and oil palm plantations are found especially on the coastal plain. Small-scale farms with individual ownership and rural areas and villages where the home-garden and orchard (*kebun*) typically surround each house make up the rest of the agricultural landscape.

Only about 25% of the total area of land in the basin is covered by forests, the majority (15.7% of basin area) is hill dipterocarp forest in the eastern and northeastern parts (Figure 129.1). Mangrove forests cover 5.5% of the land area and peat-swamp forests about 4%. Lowland dipterocarp forests have been almost eliminated from the basin. Only 13.2 km² (0.5% of area) of lowland dipterocarp forest remained in 1996, mostly as small remnant fragments of what used to be extensive stretches of forests.

Built-up areas occupy 6.8% of the basin but affect the health of the ecosystem in many and disproportionate ways. Solid and industrial waste generated by industrial and urban centers cause river pollution and increased surface water runoffs that extend beyond their immediate areas.

Table 129.1 Land-Cover Categories and Their Area in the Langat Basin

Category	km ²	Total Area (%)
All Forests	739.2	25.2
Hill dipterocarp forest	461.4	15.7
Lowland dipterocarp forest	13.2	0.5
Peat-swamp forest	103.0	3.5
Mangrove forest	161.5	5.5
Agricultural	1865.6	63.6
Bareland	47.3	1.6
Developed areas	200.2	6.8
Water bodies	79.4	2.7
Total	2931.7	99.9

Bare land constituted just about 1.6% of the total land area of the basin in 1996. However, its impact on the ecosystem, especially on water quality of the rivers of the basin, is extensive and severe. Total suspended solids (TSS) values from river water in the basin frequently exceed the Department of Environment's recommended threshold value of 150 mg/l required for the maintenance of aquatic life, and can reach more than 1700 mg/l. High sediment loads are especially prevalent immediately after rain.

The total area of the basin made up of water bodies is 79.4 km², or just 2.7% of the land area. These consist of the surface area of rivers, two major reservoirs (Langat and Semenyih reservoirs) and ex-mining ponds created by open-cast tin mines.

ECOLOGICAL ZONES

The Langat Basin may be divided into three main ecological zones based on its geomorphology and physiognomy (Figure 129.1). The northeastern portion of the basin is hilly and forested, and population densities are low to nonexistent. The demarcation for this zone is the hill-foot boundary that distinguishes the forested hills from the cultivated lowlands. By definition, hill dipterocarp forests are found above the 300-m contour (Whitmore, 1984) but the hill-foot boundary starts at a lower elevation where the land rises sharply above the river floodplain. Vegetational and faunal characteristics, especially of birds, differ markedly across this boundary (Medway and Wells, 1976). The rivers in this section of the basin are relatively unpolluted and all fall within Class II (slightly polluted) of the Malaysian River Water Quality Criteria and Standards (Department of Environment, 1986, 1990, 1994). This section of the basin is designated as Ecological Zone 1 in this study.

The central section of the basin is undulating, with hills and knolls interspersed with relatively flat land. Very little natural forest cover is left and it is the most urbanized section of the basin. Population density in this section is the highest in the basin. The rivers in this section of the basin are badly polluted with chemicals and sediments (Yusuf et al., 2000). They fall within the category of Class III (polluted) and Class IV (highly polluted). It is designated as Ecological Zone 2.

The western and coastal section of the basin is almost entirely flat with the exception of Jugra Hill (232 m). Population density is relatively low and urban centers are widely scattered. Agricultural plantations occupy most of the intervening space. Two large patches of peat-swamp forests (Kuala Langat North Permanent Forest Reserve and Kuala Langat South Permanent Forest Reserve) occur inland, while the coastline is intermittently vegetated by mangrove swamp and strand forests. The Langat River in this section of the basin meanders through the alluvial plain. It falls under the river category of Class IV with high sediment and pollutant loads. It is designated as Ecological Zone 3.

POPULATION DENSITY

The estimated overall population density in the Langat Basin in 1999 was about 289 persons/km² but population distribution is uneven. Densities are highest (562 persons/km²) in the central section of the basin designated as Ecological Zone 2, especially in areas adjacent to the Federal Territory of Kuala Lumpur and the southern parts of the Klang Valley. Population density in Ecological Zone 1 is 217 persons/km², while in Zone 3 it is 143 persons/km².

MANUFACTURING INDUSTRIES

Manufacturing industries are located primarily in the central section of the basin, coinciding with the area designated as Ecological Zone 2. A total of 24 of 30 industrial estates found in the Langat Basin are located in this zone in 1997. This zone also has the highest population densities and some of the most polluted sections of the rivers and tributaries within the basin. In 1996, fewer than 10% of all factories located in the basin had installed effluent treatment systems (Fariz and Nordin, 1999). Most industrial estates are located adjacent or close to major rivers and many small- and medium-scale enterprises (SMEs) are located close to the banks of rivers. The discharge of effluent from SMEs is difficult to quantify accurately.

AGRICULTURAL ACTIVITIES

Agricultural land stretches from the coastal alluvial plain in Ecological Zone 3 to the hill-foot boundary in Ecological Zone 1. Oil palm and rubber plantations occupy the majority of the agricultural land. Agricultural smallholdings, as well as orchards and home gardens, make up the rest. Use of pesticides and inorganic fertilizers in agriculture can contribute pollution of rivers and the level of phosphates in some sections of the river in Ecological Zone 2 exceeds the minimum allowable threshold set in the Interim Water Quality Standards of Malaysia (INWQS) for the well-being of aquatic life. Livestock farms are also a major source of river pollution. Discharge of untreated animal waste from farms causes high biological oxygen demand (BOD), ammoniacal nitrogen, and TSS levels in river water. There are more than 400 livestock farms in the basin, most of which are found in Ecological Zones 2 and 3.

MINING

Tin was mined on a wide scale in the Langat Basin, and tin mining used to be a major economic activity prior to the 1980s. Production has since declined substantially and only three mines using dredges are currently in operation.

There are at present 21 granite quarries, 3 clay pits, 43 earth materials, and 1 kaolin extraction site in the basin. The majority of these are located in Ecological Zone 2. Quarrying for earth materials, clay, and granite creates bare land and accelerates soil loss. There are also 86 sand and gravel extraction sites. Sand mining from rivers increases total suspended solids and turbidity of rivers (Rozali et al., 1999).

There are no quarries in Ecological Zone 1 and only one clay pit is found in Ecological Zone 3.

RIVER WATER QUALITY

The quality of water in the rivers of the Langat Basin is variable. Estimation of overall quality is problematical as water quality monitoring stations have fixed locations and several factors

determine water quality at any one time. These include river flow, pollutant discharge rates and frequencies, type of land use in surrounding areas, and prevailing weather conditions. Thus, location and river characteristics influence detectable pollution loads and a river's ability to assimilate pollution. Based on the results of 12 monthly samplings, five stretches of the Langat River may be classified as Class II, another five Class III, and the remaining four stretches as Class IV. Only rivers categorized as Class II and less are considered healthy rivers. Although water from Class III rivers can continue to supply drinking water by treatment using conventional water treatment plants, such rivers are ecologically stressed and do not support healthy populations of aquatic life.

Rivers in Ecological Zone 1 are healthy. They are all categorized as belonging to Class II in the Malaysian river classification scheme. Rivers in Ecological Zone 2 are most unhealthy because of high inputs of chemical, biological, and other pollutants from densely populated urban and industrialized areas. Fecal coliform, *Giardia* cysts, and *Cryptosporidium* oocysts were detected at higher levels in rivers in this Ecological Zone compared to other zones (Rohani, 1999). Total suspended solids in the rivers of this zone are also high because of the prevalence of bare land from extensive ongoing infrastructure and other development projects. The river in Ecological Zone 3 are also unhealthy because of pollutants brought downstream from Ecological Zone 2, as well as from within the zone.

WATER SUPPLY AND DEMAND

Water from Langat Basin rivers is used to supply the needs of the Klang Valley as well as the Langat Basin. With further increases in population and industrial activities, water supply in the basin will go into deficit if steps are not taken to further develop its water resources and to make efficient use of water for domestic purposes, as well as for industrial and agricultural production. Loss in the form of nonrevenue water exceeds 40% at present. With further urbanization and industrialization in the basin, there will also be increasing pressure on the availability of raw water of adequate quality for extraction and processing, especially during drought months.

The estimated total demand for water in the Langat River Basin area for the year 2000 was about 468 mld (million liters per day), and this is anticipated to increase to 2141 mld by 2050 (Economic Planning Unit, 2000). The basin currently produces 1052 mld, but 65% is transferred to supply the Klang Valley areas. The estimated population in the Langat River Basin in 2005 is anticipated to be in excess of one million persons. This will double to two million by 2035. Plans are being made to ensure adequate supply to meet the demand for more water in the Langat Basin in the future through an inter-basin transfer of water resources from the adjacent state of Pahang. The Kelau Dam in Pahang, anticipated to be the main reservoir for this interstate water transfer, is planned to be operational in 2007.

GEOHAZARDS

The intensity of landslides is higher in Ecological Zone 2 of the basin, the most developed and urbanized area. The size and volume of material displaced owing to landslides are also the highest in this zone. Estimates of average annual soil loss due to erosion on a basin-wide scale is 4.2 t/km²/year. In areas being cleared for development soil loss can reach 152 t/km²/year.

WILDLIFE

Wildlife diversity in Langat Basin remains relatively high (Jasmi, 1998; Abdullah, 1999) because of the varied landscapes and habitat types found in the basin. Major natural habitats include the coastal mangroves along the coast and the peat-swamp forests in Ecological Zone 3, remnant lowland dipterocarp forests in Ecological Zone 2, and the dipterocarp forests of the basin's catchment areas

in Ecological Zone 1. Additionally, wildlife adapted to agricultural landscapes continue to survive and urban-areas continue to support viable populations of a limited number of urban adapted species.

Although the mosaic of habitats and ecotypes in the basin is conducive to the perpetuation of a wide variety of wildlife, it will only do so if the existing natural areas are preserved. Threatened species such as tiger (*Panthera tigris corbetti*), elephants (*Elephas maximus*), and Malay tapir (*Tapirus indicus*) are no longer found in Ecological Zone 2. In Ecological Zone 1, wildlife diversity remains relatively high, although logging is ongoing.

FISH DIVERSITY

A total of 41 species of fish belonging to 16 families have been recorded (Samat, 1999). The estimated number of species in Peninsular Malaysia is about 250 (Mohsin and Ambak, 1991). The basin is relatively small compared to other river basins in Malaysia, but fish diversity is moderately high for a basin of this size. Work is in progress to determine species distribution and factors affecting it. In a badly polluted section of the river in Ecological Zone 2, only nine species have so far been recorded (Samat, 1999).

CRITERIA AND INDICATORS OF ECOSYSTEM HEALTH IN LANGAT BASIN

Operationalizing the ecosystem health concept in environmental management is a major challenge. Not many examples exist where ecosystem health has been put to practical use and made the basis of environmental management, especially in tropical countries. Quantitative methods of assessment have yet to be formalized into a framework that will enable replicability across a range of environments. The assessment of ecosystem health is contextual (Rapport et al., 1999). The work undertaken by LESTARI in Langat Basin is of vital importance, as it would provide a basis for testing the applicability and functionality of the concept of ecosystem health in a tropical ecosystem.

A healthy ecosystem is said to be free from ecosystem stress syndrome, resilient, self-sustaining, does not stress neighboring areas, is relatively free of environmental risk factors, economically viable, and supports healthy communities (Rapport et al., 1995). These criteria were explored as the basis for the assessment of ecosystem health of Langat Basin. Ecosystem stress can originate from many causes. With regard to the terrestrial ecosystem in the basin, stress occurs primarily when natural areas are converted to agricultural or built-up areas causing loss of natural landscapes, biological diversity, and soil erosion. With the aquatic ecosystem, stress relates closely to high inputs of sediment, chemicals, and other pollutants into waterways and water bodies.

Two other interdependent criteria were also explored, as they relate closely to ecological well-being. They are ecological integrity and signs of ecosystem dysfunction. Ecological integrity was assessed by determining the degree of diversity of biotic communities in an area using mammal, bird, and fish species as indicators. Ecosystem dysfunction was assessed by noting the frequency of occurrence of extreme events and failure of the environment to adequately provide ecosystem services, such as providing water of adequate quality for extraction and processing as potable water. In the context of the Langat Basin, this includes the frequency with which critical chemical pollutants in the rivers of the basin exceeded IWQS threshold levels, shut down of water treatment plants, water rationing, and incidence of mudflows and slope failures.

Based on these criteria, Langat Basin ecosystems that closely approximate pristine conditions were considered to be of high ecological integrity and thus most healthy. Highly modified nonnatural areas on the other hand would be of low ecological integrity and thus of poor ecological health. They are also usually low in biological diversity and exhibit signs of dysfunction, especially under stress. To maintain a high level of environmental quality in highly modified ecosystems, such as in urban and industrial areas, requires high inputs of energy and resources.

Pristine ecological conditions can be found mostly in Ecological Zone 1 of the basin, where most of the land area is covered with hill dipterocarp forest. This area has high ecological integrity, but is environmentally highly sensitive because of steep terrain. The area around two major water supply impoundments, the Langat and Semenyih reservoirs, is legally protected as Catchment Forest to preserve the health and integrity of the forest ecosystem around the reservoirs. Additionally, some forest compartments in the area are designated as Virgin Jungle Reserves (VJR) that serve as a conservatory of the species representative of the forests in the area. These reserves are never logged and remain pristine. Rivers in this area remain relatively healthy and are categorized as only slightly polluted (Class II), mainly by sediments from soil erosion, as no industrial manufacturing or housing are located here. The area is thus ecologically healthy, as it is relatively free from ecosystem stress, does not stress neighboring areas, is relatively free of environmental risk factors, and supports healthy biotic communities. Human population density is relatively low.

An area designated as a VJR is also found within the Kuala Langat South Permanent Forest Reserve in Ecological Zone 3, a large Permanent Forest Reserve (PFR) of peat-swamp forest. However, the peat-swamp forest reserves of Ecological Zone 3 are fundamentally isolated forest islands surrounded at present mainly by oil palm plantations. In the future they are likely to be surrounded by urban and industrial areas and would come under increasing pressure to be converted to other forms of land use.

Some of the in-shore islands of the coast of Langat Basin also remain under pristine mangrove forests. These are ecologically rich environments and contain elements of terrestrial and aquatic diversity characteristic of coastal areas. They provide habitats for coastal biodiversity and function as nursery grounds for coastal fisheries. The coastal mangroves on the mainland of Ecological Zone 3 used to be sustainably harvested, as timber from them is widely used in the construction industry and the production of high-grade charcoal. They have increasingly been replaced by aquaculture farms, or reclaimed for development of industrial warehousing to serve nearby ports, and for other uses including housing estates to serve needs for housing.

The area of the basin designated as Ecological Zone 3 is not free from ecosystem stresses. Much of it has been converted to agricultural plantations growing single crops, and coastal reclamation has transformed natural areas into new housing and industrial estates. Natural resilience has been lost and the area can no longer be regarded as naturally self-sustaining. The draining of large areas of the peat swamp forest causes the peat to dry, and during drought periods it has been known to catch fire, releasing smoke that severely pollutes the air of neighboring areas. The river in this zone is badly polluted (Class IV) from materials originating upstream and from within the zone. However, the area is economically viable and supports healthy human communities. Biotic communities have been compromised, but some diversity remains, especially in the peat-swamp forest reserves and coastal mangroves.

The health of the Langat Basin ecosystem in Ecological Zone 2 is the most compromised as it is furthest from pristine ecological conditions, has low biological diversity, and high output of domestic and industrial pollution. The ecosystem in this zone is highly stressed, has lost most of its biological integrity and resilience, and is no longer naturally self-sustaining. Maintaining environmental quality and ecosystem health in this area requires high inputs of energy and resources, and it needs the most management intervention. At more than 500 persons/km², its population density is the highest in the basin. It is, at present, a major source of environmental pollution and generates the most domestic and industrial wastes compared with the other ecological zones. High outputs of sediments originating from soil erosion from bare land under development further stresses neighboring areas. Many environmental risk factors exist and the ecosystem no longer supports healthy biotic communities.

Work is in progress on the selection of indicators of ecosystem health in Langat Basin, vital for monitoring trends and managing the environment. An initial framework of indicators is outlined in Table 129.2. The indicators and benchmarks are suggested for the entire Basin rather than for the individual ecological zones. The air pollution index (API) is based on the index developed under the

Table 129.2 Initial Framework of Criteria and Indicators for Monitoring Ecosystem Health in the Langat Basin

Criteria	Indicator	Benchmarks
Ecosystem stress (pressure indicators)	1. Population density 2. Soil erosion rate 3. TME/capita	500 persons/km ² 1.6 t/km ² /yr 15 t/yr/capita
Resilience	Natural areas (%)	30%
Self-sustainability	Natural areas (%)	30%
Stress to neighboring areas	1. Air Pollution Index (API) 2. Total suspended solids in river water	80 150 mg/l
Economic viability	This indicator has not been selected; economic statistics are not available at the district level	
Health of communities		
1. Human	1. Perinatal mortality rate 2. Toddler mortality rate 3. Infant mortality rate	3/1000 0/1000 1/1000
2. Biotic	Threatened species of mammals (%)	20%
Ecological integrity	Natural areas (%)	30%
Ecological dysfunction		
1. Freshwater aquatic ecosystem	Presence of <i>Lyposarcus pardalis</i> Absence of <i>Macrobrachium rosenberghii</i>	
2. Terrestrial ecosystem	Landslides per 10 km ² per 3 years	Not yet determined

national air monitoring program. It is a composite index based on a suite of levels of air pollutants including SO_x, NO_x, and suspended particulates (PM₁₀). The presence of introduced fish species (e.g., *Lyposarcus pardalis*) and the absence of certain indigenous species (e.g., *Macrobrachium rosenberghii*) are indicative of river ecosystem dysfunction resulting from pollution and high sediment loads.

These indicators and benchmark values are tentative and much work still needs to be done to properly define and describe their construction and use. Additionally, they have to be evaluated within the context of the rapid development that the basin is undergoing and the prevailing social and cultural context of development in Malaysia.

ACKNOWLEDGMENTS

This work was supported by funding from UNEP/ROAP (Project Number CP/5220-97-02/Rev.1) with funds from DANCED. We thank ISEH for enabling our participation in the 1999 International Congress on Ecosystem Health, thus providing the opportunity to discuss and refine our ideas on operationalizing the concept of ecosystem health in environmental management. We thank Universiti Kebangsaan Malaysia for permission to attend the Congress. Numerous friends and colleagues shared ideas and provided valuable inputs that contributed to the success of this challenging initiative. We thank them all.

Manufacturing Industries and Ecosystem Health: The Case of the Langat Basin

Ahmad Fariz Mohamed and M. Nordin

INTRODUCTION

The manufacturing industry has become the main engine for Malaysia's economic growth. It plays a vital role in sustaining Malaysia's development. In 1996, it contributed RM 45.2 billion to the gross domestic product (GDP), 34.6% of overall GDP, a 13.3% increase over the previous year's value (Ministry of Finance, 1996).

The Malaysian government has identified a strategy and plan to accelerate manufacturing industries development and to assure their sustainability. According to Ministry of International Trade and Industry (MITI, 1996), during the seventh Malaysia Plan period (1996 to 2000), Malaysian manufacturers were encouraged by the federal government to adopt new growth strategies and to venture into large-scale production for the global market. New industrial estates continue to be developed as state governments respond to national plans and the need to create additional socio-economic opportunities through further development of manufacturing industries. Industrial estates' development grew at its highest rate up to 1996. Supported by well-planned strategy and policy set by federal and state governments, more investors invested in manufacturing industries.

The economic downturn in Malaysia which started in 1997 has not affected the government's long-term measures for economic growth through industrial development. New industrial parks established by the public and private sectors provide much-needed physical infrastructure for enhancing the capacity of states to increase manufacturing output. This is because manufacturing industries play a very important role in making Malaysia's economic bounce-back.

Although industrial development has accelerated the growth of the Malaysian economy, there has been a negative impact on the environment. In Malaysia, industrial development and activities contributed to water pollution, air pollution, toxic and hazardous waste, soil erosion and degradation, and affected human health (Abdullah, 1997). Current water and air pollution is directly related to industrial activity. Jamaluddin (1999) also stated that in 1982, 42 rivers were classified as heavily polluted, 16 rivers polluted, and 7 rivers as potentially polluted. In 1996, 30% of rivers monitored had been found heavily polluted with various pollutants.

Industrial activity also produced a vast amount of solid, toxic, and hazardous waste. The industries have problems in managing and disposing of this waste, thereby increasing the pollution problem. Yong (1998) stated that wastes from industrial activities are generally more hazardous and polluting, and require intensive management and treatment before they can be safely discharged.

The development of vast industrial estates would have a significant negative impact on the environment and resources if it is not planned carefully and strategically. To reduce the impact of such development and subsequent operational activities on the environment and natural resources, measures must be incorporated at the planning stage of industrial development. Therefore, encouraging the development of factories in industrial estates provides opportunities for cleaner production which will enhance future industrial environmental performances (Bateman and Tan, 1998).

OBJECTIVES

The overall aim of this substudy of the MATREM Project *Research and Training for Measuring and Monitoring Ecosystem Health in a Large-Scale Ecosystem* is to identify and create an inventory of the types of industries and their location in the Langat Basin, and examine their impact on the health of its ecosystem. Manufacturing industries in each zone within the basin were classified by type, products manufactured, number of factories, and distribution.

Available information on pollution was used to estimate the impact of manufacturing industries on every major river within the Langat Basin, especially on its water quality. Enforcement and legal issues related to the industrial activities were analyzed from case charges made by the Department of Environment between 1989 and 1995. Data obtained from other government departments were used to determine the overall level of enforcement by agencies responsible for ensuring environmental quality in the basin.

The immediate objectives of this substudy are to:

- Identify trends in the development of manufacturing industries in the Langat Basin.
- Determine the current status of industrial development and activity in the basin.
- Assess the implications of industrial development on the health of the Langat Basin ecosystem.

OVERVIEW OF THE DEVELOPMENT OF THE MANUFACTURING INDUSTRY IN MALAYSIA

The development of a modern manufacturing industry in Malaysia commenced in earnest during the early 1960s. With the introduction of the Investment Incentives Act (1968) and the establishment of Free Trade Zones in 1971, growth in the manufacturing sector accelerated. In 1970, the manufacturing sector contributed 13.4% to GDP in Malaysia; by 1990, it had doubled to 26.6%. The share of manufactured product in export by value was 11.1% in 1970, but by 1990 it had soared to 58.9% (Taylor and Ward, 1994).

The Industrial Master Plan (IMP) and its revision, the Second Industrial Master Plan (IMP2) commissioned in March 1995, guide the development of the manufacturing industry in Malaysia. During the IMP period from 1985 to 1995 manufacturing output increased significantly, surpassing most of the targets set (MITI, 1996). Export of manufactured goods increased by 28.6% (target 9.4%), and the share of manufacturing exports to total merchandise export increased from 32.8% in 1985 to 79.6% in 1995. Value added in the sector registered an average growth rate of 13.5% per annum (target 8.8%), and the share of manufacturing value added to GDP increased to 33.1% (target 23.9%). The share of manufactured exports increased considerably from 11.1% in 1970 to 79.6% in 1995 (MITI, 1996).

MANUFACTURING INDUSTRY DEVELOPMENT IN THE LANGAT BASIN

The Langat Basin Ecosystem encompasses areas in two states: Selangor and Negeri Sembilan (Figure 130.1). Policies and decisions made by both states influence the development of manufac-

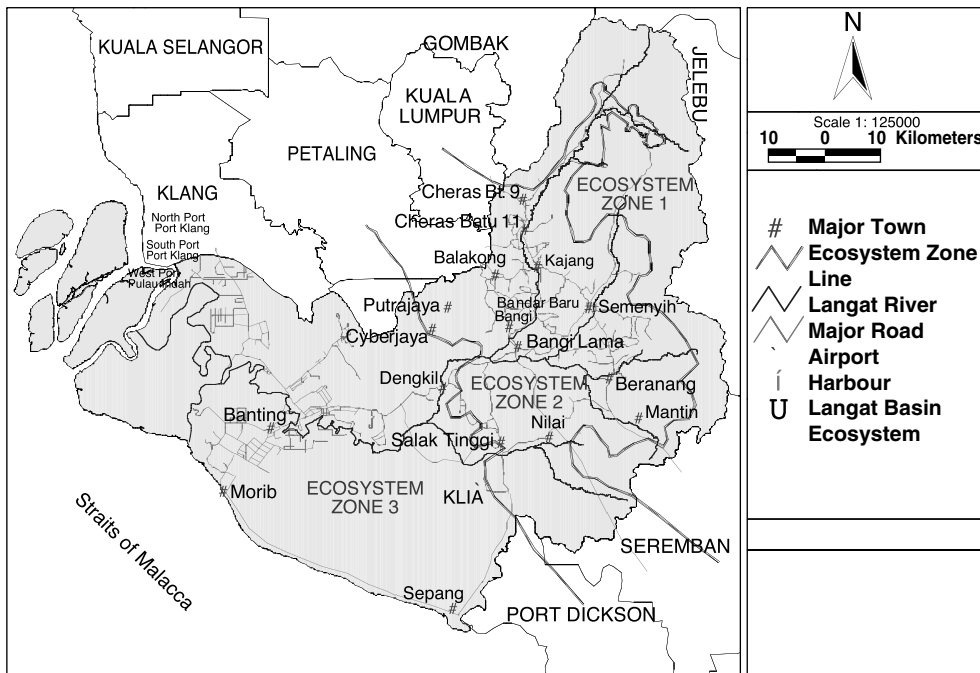

Figure 130.1 The Langat Basin ecosystem.

turing in the basin. Strategies and policies expounded in the IMP and IMP2 allowed both states to achieve considerable growth in manufacturing over the past two decades.

With the development of infrastructure in the Langat Basin and increasing congestion in the adjacent Klang Valley, new manufacturing industrial estates have increasingly moved into the Langat Basin. The federal government’s decision to develop the new Kuala Lumpur International Airport (KLIA), the new administrative capital Putra Jaya, and the Multimedia Super-Corridor (MSC) in the Langat Basin provided additional impetus for industries to congregate in the basin. Emphasis will be given to the development of high-technology information and telecommunications industries, as well as their support industries. With good infrastructure, availability of labor, and proximity to sea- and airports, industrial development in the Langat Basin will attract more local and foreign investors to the basin.

INVESTMENT PATTERNS FOR MANUFACTURING INDUSTRY IN THE LANGAT BASIN

From 1991 to September 1998, Selangor and Negeri Sembilan attracted more than RM 33 billion and RM 11 billion in local and foreign capital investments, respectively (Table 130.1). In

Table 130.1 Investment (RM) of Manufacturing Industry Projects for Selangor and Negeri Sembilan from 1991 to September 1998

State	Number of Projects	Local Investment	Foreign Investment	Total Investment

Total	300	4,602,392,555	1,723,108,975	6,325,501,531

From Selangor DoE, Investment Centre, Industrial Project and Capital Investment in Selangor, Office of the State Secretary of Selangor, Shah Alam, 1998.

Selangor, local capital exceeded that from foreign sources, but in Negeri Sembilan, the opposite was true. However, total capital investments in manufacturing in the Langat Basin during the period was RM 6.3 billion, more than one fifth of all investment in manufacturing for the state of Selangor. Local capital exceeded foreign by more than twice the amount (Table 130.2).

Well-built infrastructure in the Langat Basin enabled the basin to attract investors. Ports, services, production, and consumption centers are linked by excellent highways such as the Kuala Lumpur–Seremban Highway, North–South Link Highway, Shah Alam Highway, and Central Link Highway (connecting North–South Link with Kuala Lumpur–Seremban Highway). The newly completed South Klang Valley Highway and the Kuala Lumpur–Kajang Highway provide excellent transportation networks for manufacturers.

In addition to transport infrastructure, both states have well-developed energy and water supplies. Two power-generating stations located in Serdang and Bukit Changgang are now supplying power to the basin and some parts of the Klang Valley. In addition, each industrial estate built by the state government agency will have its own back-up power generators to ensure uninterrupted power supply.

New water processing plants and additional water intake points have been built. Eight water treatment plants are located along the Langat River. These have a combined capacity to supply more than 220 million gallon per day (mgd) to the basin and some parts of the Klang Valley. In the southern end of the basin (industrial estates around Nilai, Pajam, and Mantin) energy is generated at the Port Dickson power station on the coast, while its water supply is obtained from the Linggi River (MIDA, 1997).

Extensive investment in the Langat Basin is also influenced by the federal government's decision to locate the new administrative capital, Putra Jaya, the MSC, and KLIA in the district of Sepang, in the middle of the Langat Basin. Highways and railways linking Putra Jaya, MSC, and KLIA with Kuala Lumpur and other major cities in the Klang Valley and the existing North–South

Highway would make all industrial areas in Langat Basin highly accessible. With the increased availability of support services and transportation corridors, industries in the Langat Basin would have easy access to Port Klang and to other major towns and cities.

To ensure the development of Putra Jaya, MSC, and KLIA, as well as to facilitate their activities, plans also have been made to increase energy and water supply to these areas (PBT Kuala Langat, Sepang, Putra Jaya, JPBD S. Malaysia, 1996). These plans will also benefit industrial estates around these facilities.

The federal and state government policies and strategies, as well as the availability of well-built infrastructure and better supply of energy and water, played major role in influencing the investment pattern for manufacturing industry development in the Langat Basin.

LOCATION OF INDUSTRIAL ESTATES IN THE LANGAT BASIN

Industrial estates in Langat Basin concentrated in zone 2 of the basin are shown in Figure 130.2. In 1997, 24 industrial estates were located in zone 2, and 6 in zone 3 (Table 130.3).

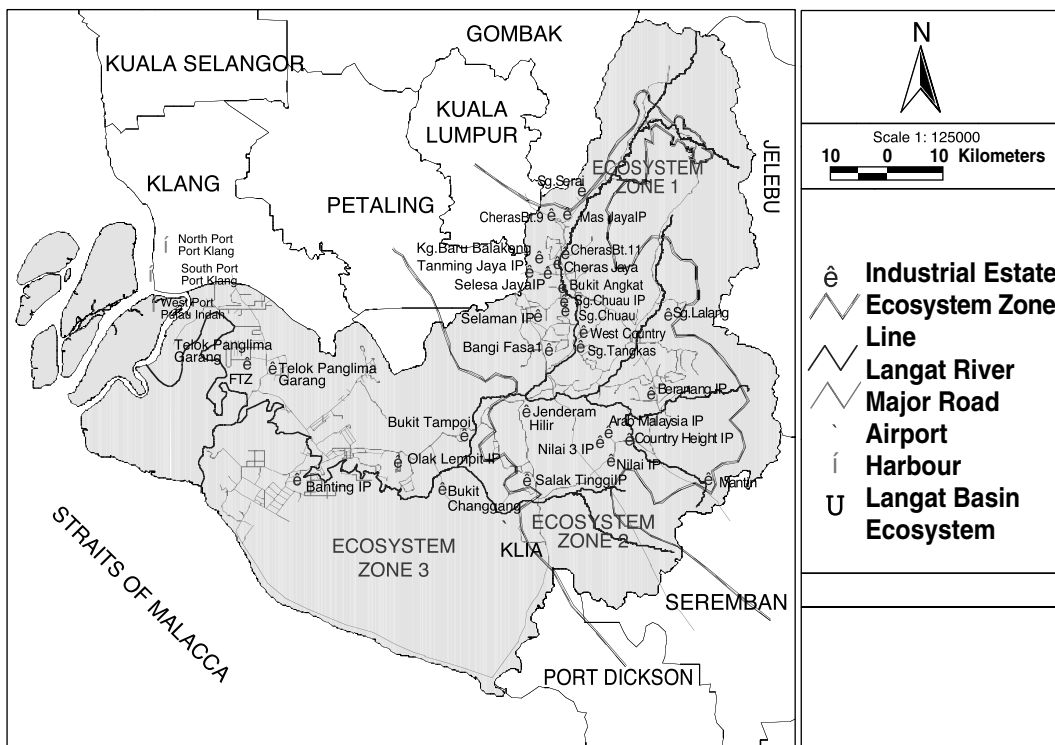

Figure 130.2 Industrial estates in the Langat Basin.

Heavy	—	147	21	168
Special industry	—	4	—	4

Modified from MIDA (1997a) and DoE (1994).

All are located within easy reach of major highways and trunk roads linking the major towns in and outside the basin.

Besides easy access to the transportation network, the ready availability of local labor, proximity to KLIA and the seaport in Klang, business centers and go-down space in the Langat Basin have influenced the location of the industrial estates. Thus, the Langat Basin has grown rapidly as the most important hub of industrial production in Selangor after the Klang Valley.

In all, 30 industrial estates housing more than 330 factories are located in the Langat Basin; 20 were developed by the private sector and the rest by state government. These engage in 22 categories of industrial production ranging from the manufacture of agricultural end products to high-tech products such as consumer electronics. Heavy industries predominate with 168 establishments, medium industry follows (Table 130.4)

Table 130.5 shows the number of factories by product category in each zone of the Langat Basin ecosystem. Electrical and electronic industries predominate with 53 factories, followed by industrial and engineering products, furniture, textiles and fabrics, building materials, and chemicals.

Most industries are concentrated in and around the urban areas such as Kajang, Nilai, Bangi, Cheras, Balakong, Banting, and Beranang (Figure 130.2). The siting of individual factories within

Modified from MIDA (1997a).

these industrial estates does not follow specific criteria. Most have mixed establishments, with the exception of the Olak Lempit industrial estate, which is restricted to factories processing wood and wood products. In mixed establishments, multinational companies (MNCs) and small and medium industries (SMIs) are located in the same estate; most of the SMIs engage in support industries for the MNC, such as in the production of parts and components. However, there are SMIs that produce their own products for the Malaysian market, for MNC outside the Langat Basin, and for export. As a whole, SMIs predominate, with many engaged in the production of industrial and engineering products.

The absence of guidelines on the possible types and scale of manufacturing industries allowed in each industrial estate means that each estate can host many types of factories, which vary in capital investment, production, and capacity to pollute.

Plans to zone industries by product type have not been successful, and to date only one industrial park for the wood and wood products industry has been established at Olak Lempit. The development of Cyberjaya in Sepang will eventually be the hub for the development of industries related to information technology and high-tech products.

In the future, state and local governments plan to identify zones for industrial estates and relocate industrial estates that have been established in unsuitable areas. This will include an unknown number of illegal factories located in the basin. In 1998, the Selangor state government estimated that there were more than 163 illegal factories along Langat and Semenyih Rivers. Measures have been taken to close these illegal factories and relocate them to industrial estates in the Langat Basin and elsewhere (*The Star*, 1998).

IMPACTS OF THE DEVELOPMENT OF MANUFACTURING INDUSTRY ON THE HEALTH OF THE LANGAT BASIN ECOSYSTEM

The health of an ecosystem is reflected in its ability to sustain a high-quality life for all its residents. Healthy ecosystems provide resources and services vital for a productive life as well as the milieu for human development. A degraded ecosystem is costly to restore, threatens human well-being, and constrains further development.

Rapid industrial development in Langat Basin has had some impacts that are detrimental to its ecosystem. Much of this has originated from factories located along the Langat and Semenyih Rivers and affects the river water quality. The following subsections examine the extent to which pollution by the manufacturing industries has affected river water quality as well as the enforcement efforts by the relevant agencies to ensure the water quality of the rivers.

RIVER WATER QUALITY

It is generally well known that the quality of the water in the Langat River has been gradually deteriorating. According to records of the Department of Environment (DoE) the river classification fell from “polluted” to the worst category, “highly polluted.” Actual values of the Water Quality Index for the river from 1985 to 1997 are given in Figure 130.3. The period of rapid decline of the river’s water quality coincided with the rapid industrial development in the basin beginning in 1991. Through spatial analysis it has been found that most of the industrial estates were located more than 500 m away from the main Langat River. Table 130.6 gives the number of industrial estates and their distance from the river system. This analysis examines only the distance of each industrial estate from the main river system and does not include the small river system; industrial estates are too close. Most of the drainage systems in the estates discharge industrial wastewater straight to the river system.

Figure 130.3 Trends of Langat River water quality, 1985 to 1997. (From Selangor DoE, Monitoring Annual Report, 1997, Department of Environment Selangor, Shah Alam, 1997a.)

200–300	—	2	—
300–400	—	1	—
400–500	—	1	1
More than 500	—	19	5

From ArcView Spatial Analysis 1.0 and MIDA (1997b).

Records also show many manufacturing facilities along the Langat River are not equipped with effluent treatment facilities. However, not all sources of pollution are from the manufacturing industry. Sources of pollution identified by the DoE are shown in Table 130.7. Oil storage facilities and sewage treatment plants predominate as potential sources of pollution. Nevertheless, 131 of the total 231 potential pollution sources along the Langat River are industrial plants. Furthermore, of 337 legal industries in Langat Basin, only 38 are equipped with an effluent processing system (EPS). Table 130.8 shows industries with EPS and their current status.

Degradation of river water quality in the Langat Basin was exacerbated by the long drought of June to August 1998. During this period, rivers were unable to “wash out” pollution produced from domestic, commercial, and industrial establishments that discharged wastes into the river. The ability of the Langat Basin Rivers to supply water for domestic and industrial use was severely

hampered and more than RM 50 million was spent to supply water from alternative sources (old mining pools, underground water) to residents in the basin and elsewhere. Water rationing was instituted in the Klang Valley and the Langat Basin for more than 2 months.

On more than three occasions during the drought, water extracted from the Langat and Semenyih Rivers could not be treated. There are eight water treatment plants with varying capacities located along the Langat and Semenyih Rivers that supply a wide range of areas (Table 130.9). Four of the treatment plants were located in zone 1 and four in zone 2.

LEGISLATION AND ENFORCEMENT ACTIVITY

Enforcement of environmental regulations to curb pollution by manufacturing industries in the Langat Basin is an ongoing process. The number of legal proceedings instituted against industrial concerns in the Langat Basin for breaches of environmental regulations from 1989 to 1996 totaled 80 cases, with the highest number of offenses recorded in 1991, 1992, and 1996 (Figure 130.4). From 1989 to 1996, 80 charges were made to industry under various environmental regulations (details are shown in Table 130.10).

The DoE has adopted strategies to enhance its efficiency in monitoring and enforcing environmental regulations. Issues of lack of manpower and technology know-how have been taken into account. Training staff to equip them with the latest information and technology is an ongoing process. Therefore, enforcement activity in the future is expected to improve.

GENERAL DISCUSSION: DEVELOPMENT OF MANUFACTURING INDUSTRIES AND ECOSYSTEM HEALTH IN THE LANGAT BASIN

The development of manufacturing industries in the Langat Basin has had many positive impacts on the economic well-being of the residents through the creation of increased job opportunities for local communities, improved infrastructure, and the increased availability of modern housing. With policy and incentives by the federal and state governments, manufacturing industries in the future will become the main engine for economic growth in the basin. With MSC development, high-tech and information technology would be the focus of industries.

Nevertheless, industrial development has had undesirable impacts related to the health of the ecosystem and the quality of the environment. Since industrial development requires changes to the physical environment, it can create ecosystem stress. Jamaluddin (1999) stated that industrial development causes habitat loss and creates disturbance and stress to natural and human-made ecosystems. This disturbance includes degradation of environmental quality through loss of aesthetic value, air and water pollution, waste, hazardous toxic waste, and other environmental problems.

Moreover, development of manufacturing industries has resulted in the clearance of large tracts of land originally under plantation crops, secondary forest, and other vegetation. This has created exposed land areas from which soil has eroded and entered river systems as sediment. High sediment loads are prevalent in areas that are rapidly developing and are the predominant cause of river pollution in Malaysia. Suspended sediments change the ecological characteristics of the river and limit its value as habitat for aquatic life. Land cleared for industrial estates is located close to river systems more often than not.

In addition to increased sediment load, the rivers in the Langat Basin have been affected by the discharge of polluting effluent from industries such that their pollution status has been upgraded from “polluted” (Class II rivers) to “highly polluted” (Class III rivers). These highly polluted rivers were found in zones 2 and 3 of the basin ecosystem. The frequent closure of water treatment plants along rivers in the basin in 1998 was a reflection of the “highly polluted” status of the river. Two plants in zone 2 were shut down due to high ammonia content. River water quality fell so much that water was no longer suitable for extraction and processing to supply potable water. The inability of the river to supply water for processing for potable water reflects poor ecosystem health.

The success of manufacturing industry development in the basin has also meant that waste generation by industries increased in type and quantity. Poor compliance by the food, textile, paper, electrical, and metal-based industries indicates that much of their wastes are discharged into the environment and threaten ecosystem health.

It is also possible that industrial estate areas may become contaminated lands. DoE of Selangor has reported that one factory located in zone 3 was found disposing of a scheduled waste into the ground behind the factories. Groundwater testing is being conducted and this case has been taken to court. Although establishing proof will take time, this example indicates that industrial estates in the basin are likely to contaminate the land and may contaminate the groundwater, too.

Inventories of individual manufacturing plants are not available in Malaysia; therefore, data on resources, chemicals used, and pollution types and loads by industries can only be estimated. With more plants becoming operational in the Langat Basin in the next few years, the health of the ecosystem and the quality of the living environment in the Langat Basin are anticipated to decline further, and we are unable to know which factory or industrial estate will be the next contaminated area. Investments in clean production by these plants are unlikely to be significant in the near future because of cost constraints and lack of market incentives. Therefore, data on individual manufacturing plants are needed to establish better management and monitoring, to reduce pollution loads, and to avoid any hazardous contamination or accidents in the future.

Local authorities are entirely dependent on DoE for enforcement of environmental regulations. Also manufacturers focus narrowly on manufacturing processes and constantly work toward optimizing profits by reducing costs of inputs and environmental care. Data on industry location, employees, chemicals and resources used, products, process and technology used are not easily available. Small- and medium-scale industries are rarely monitored for environmental performance.

Many factories are being charged in court each year for polluting the environment. There is a need to tighten enforcement, and the DoE has adopted strategies to enhance its efficiency in monitoring and enforcing environmental regulations. Issues of lack of manpower and technological know-how have been addressed, as this is an ongoing process. However, DoE cannot tackle the pollution issues alone, as some cases are very complex. There is a need to get other relevant agencies and local governments involved, especially in monitoring activities. Integrating legislative tools would enhance enforcement efficiency. Nevertheless, enforcement has not been sufficient to reduce pollution. Industries should also be proactive in reducing their waste and pollution, and local communities should participate in monitoring activities. Therefore, the command-and-control approach should include education and other incentives to minimize industrial pollution in the future.

Planners for industrial development lack adequate appreciation of ecosystem concepts. This has contributed to the unsuitable location of factories and industrial estates in the basin. Moreover,

with the absence of guidelines on the type of industry allowed, pollution has increased. Since 1976, guidelines have been developed by DoE on siting and zoning of industry; these guidelines were amended in 1994. They can be used to assist the decision maker, local governments, and developers in deciding the siting and zoning of factory and industrial estates as well as in determining buffer zones. However, DoE does not have the full power to determine location, because decision on land matters falls under the jurisdiction of the state government.

Field observation shows that existing siting and zoning of industries in the basin have created problems to ecosystem health and humans. Jamaluddin (1999) stated that 64% of heavy industry, 59% of medium industry, and 50% of light industry in zone 2 do not comply with the buffer zone guidelines. In zone 3, 100% of heavy and light industry were also found not complying with these guidelines. Buffer distance in these estates only takes into account the distance between factory zone and the nearest house, open land, or roads. Industrial estates in Cheras Batu 9, Cheras Jaya, Balakong, Bukit Angkat in zone 2, and Telok Panglima Garang in zone 3 have been found too near to river drainage systems and housing areas. There are situations where the distance between factories and housing areas is less than 20 m, while the minimum buffer distance suggested is 250 m. However, there are industrial estates that comply with the guidelines, such as Beranang, Bangi Phase I and II, and Selaman Industrial estates.

The issues raised here reflect the failure of developers and decision makers to look at the possibilities of pollution and threats to local communities by industry. At the same time, DoE industrial development guidelines, especially on the siting and zoning of factories and industrial estates, were ignored. To address this issue, state and local governments must ensure that developers comply with guidelines, and must strictly enforce the existing guidelines and standards for industrial development. The siting and zoning of industrial estates are very important. Development should ensure that pollution discharges can be easily monitored and managed, that the health of the basin ecosystem will not deteriorate, and that the safety and health of the people are protected.

On the positive side, all environmentally sensitive areas in the basin have been identified and mapped. Future planning for the development of manufacturing industries in the basin must take into account the sensitivity of these areas and their importance in maintaining ecosystem health.

Growth of the manufacturing industry is anticipated to continue, as it is the main engine of economic growth in Malaysia and contributes toward its vision as a developed country by year 2020. To ensure sustainability of industrial development while maintaining the health of the ecosystem, there is a need to develop a strategic policy and planning environment that aims to harmonize both needs. Specifically, there is the need to:

- Promote the use of clean technologies in industrial processes.
- Encourage the participation of industries, businesses, and the public in planning and decision making about the location of industries.
- Improve management and monitoring system capabilities to reduce pollution.
- Enhance legislative framework for better management and enforcement.
- Ensure SMIs use clean technologies and processes as well as optimize their use of resources by providing adequate and appropriate incentives.
- Encourage R&D by industries, local universities, and research institutions to develop clean technologies and processes as well as develop management and monitoring systems to achieve a greening of industry in the future.
- Establish data on individual industry by the state and local governments and relevant agencies for management and monitoring purposes.

Future planning would also benefit from a decision-support tool that taps into a comprehensive database on the location of industries, chemicals, and resources used, by-products produced, and processes and technologies used by all industries in the Langat Basin. Without strategic planning to incorporate an ecosystem approach for managing and monitoring by state and local governments as well as the relevant agencies, zone 2 (which is expecting a high density of urban and industrial

development) would be highly polluted. At the same time, environmental stress in zone 3 would be increasing, as pollution discharges from zone 2 will accumulate in this zone. Therefore, future planning for industrial development must balance the needs of development and economic growth with the effort to sustain the health of the basin ecosystems as well as the nation's environment. To address these issues, databases and ecosystem scenario tools are being developed at the Institute for Environment and Development (LESTARI), Universiti Kebangsaan Malaysia.

Diagnosing Ecosystem Health of the Langat Basin in the Context of Geohazards

Ibrahim Komoo, Joy Jacqueline Pereira, and W. Mohd Muhiyuddin

INTRODUCTION

The concept of ecosystem health dates back to 1788 in the writings of James Hutton, a geologist, who perceived the Earth as an integrated system (Rapport et al., 1995). It is also recorded in the 1940s composition by Aldo Leopold, a naturalist, who described unhealthy ecosystems and referred to “land sickness” (Callicott, 1992). The concept was revitalized as “ecosystem medicine” in the late 1970s and early 1980s (Rapport et al., 1979, 1981, 1985). This work formed the basis for subsequent principles and concepts of ecosystem health (Rapport, 1989; Rapport et al., 1995, 1998; Schaeffer et al., 1988). The process of assessing ecosystem health is complex and requires the establishment of indicators to differentiate healthy ecosystems from unhealthy ones, postulate the causes of sickness, and develop methods for subsequent preventive and rehabilitative measures (Rapport et al., 1995).

The concept of ecosystem is closely tied to the evolution of ecology as a discipline. Thus, it is hardly surprising that attempts to develop the methods of measuring ecosystem health are predominantly ecology based (Fausch et al., 1990; Karr and Chu, 1995; Karr et al., 1986). Indicators identified thus far emphasize the ecological aspects of ecosystem health such as loss of productivity and species diversity, nutrient loadings, acid depositions, etc. It has been argued, however, that societal values should underpin the assessment of ecosystem health, and the criteria for such evaluation require indicators for socioeconomic activity, biophysical conditions, and human health (Rapport et al., 1995).

In recent times, several topics have been studied in the context of ecosystem health, including ocean and water policy; international trade law; biological, economic, and cultural impacts of environmental contamination; integrated water catchment management; human health; vegetarianism; and gender differences (Boetzkes, 1998; Buckingham, 1998; Fox, 1999; Pellerin and Grondin, 1998; King and Hood, 1999; Yassi et al., 1999). Topics specific to physical aspects, such as mineral utilization, conservation of physical heritage, and prevention of geohazards have not been discussed within the ecosystem health framework, although aspects such as erosion and characterization of landscape patterns have been discussed (Aguilar, 1999; Johnson and Patil, 1998).

This chapter describes two major geological hazards that occur within the Langat Basin in Peninsular Malaysia, i.e., landslides and land erosion. The approach taken for their assessment, and the critical issues related to their occurrence are identified and discussed within the context of

ecosystem health. Ultimately, the status of ecosystem health is determined for the Langat Basin using a preliminary set of indicators.

GEOHAZARDS

A geological hazard or geohazard is a geological condition, process, or potential event that poses a threat to the health, safety, or welfare of human beings, or the functions or economy of a community. All processes that involve the Earth, oceans, and atmosphere, including geophysics, meteorology, climatology, and glaciology, come under the scope of geohazards (McCall, 1992). The range of geohazards is quite extensive and includes volcanic eruptions, earthquakes, tsunamis, cyclones, floods, coastal and fluvial erosion, landslides, ground subsidence, and dam failures.

Geohazards may occur due to natural or technological causes, or a combination of both (Aswathanarayana, 1995). Examples of natural hazards are earthquakes and volcanic eruptions, which cannot be controlled by humans. Technological hazards generated by human actions include subsidence near underground mines, burial of toxic waste, or a dam failure. Naturally occurring hazardous land conditions may culminate in the occurrence of a catastrophic event as a result of human intervention. Examples of these are landslides, erosion, floods, and flash floods in developed areas, and subsidence in karstic terrain. The occurrence of geohazards generally results in damage to property, disruption of normal human activities, some form of environmental degradation, or, in extreme events, loss of lives.

Currently, natural hazards are the major cause of loss of life and damage to property (McCall, 1992). Geohazards due to other causes are increasing rapidly and may eventually outnumber natural causes worldwide. In the urban areas of some rapidly developing countries, geohazards occur predominantly due to a combination of technological and natural causes (Komoo et al., 1996; Pereira et al., 1996). The main factors that contribute to the occurrence of geohazards are excessive emphasis on economic growth resulting in the forbearance of shortcuts in the development of infrastructure and other construction projects, inherent weaknesses in the planning process, as well as poor prior geological investigation in land-use planning and construction (Pereira and Komoo, 1998).

GEOHAZARDS IN THE LANGAT BASIN

The Setting

The Langat Basin, with an area of about 2938 km², is located in the central western portion of peninsular Malaysia, between the latitudes of 2°35' and 31°07' and the longitudes of 101°12' and 102°00'. The basin, defined based on the geographical concept, is drained by the Langat, Labu, and Semenyih Rivers, which flow into the Straits of Melaka. The highest peak in the basin is Nuang Mountain at a height of 1493 m.

In terms of land use, the eastern highlands in the Langat Basin are covered with primary forests and serves as the catchment for two dams, i.e., the Langat Dam and Semenyih Dam. The central portion is highly urbanized; most built-up areas in the basin are located here. The western basin is agriculture based, with tracts of oil palm and rubber plantations. Mangrove swamps are restricted to a narrow zone along the coast. The geology of the Langat Basin is relatively simple, where meta-sediments and granite, with a surficial cover of alluvium (Figure 131.1), essentially underlie the basin. The meta-sediments consist of quartzite, schist, phyllite, and shale, and are located in the central and western parts of the basin. A broad alluvial plain overlies the meta-sediments near the coast. Granitic terrain is mainly confined to the upper reaches of the basin and represents an extension of the Main Range Granite.

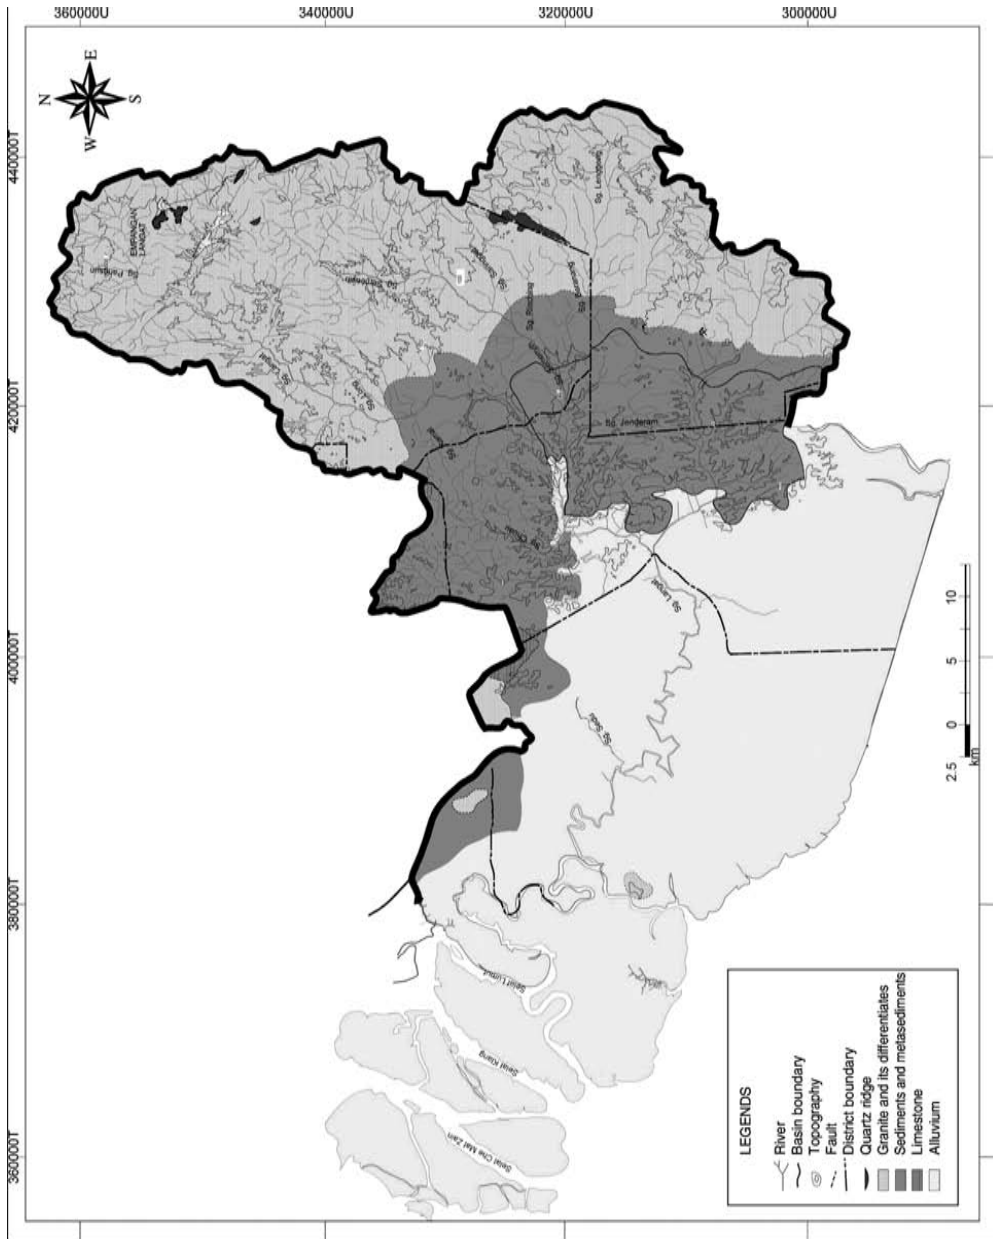

Figure 131.1 Geology of the Langat Basin.

Previous Work

Geohazard studies have been conducted in the Langat Basin only since the mid-1990s. Prior to this, geohazard investigations were conducted mainly in the adjacent northern Klang Basin, which is the focus of development activities (Komoo et al., 1996; Shu, 1986; Pereira et al., 1996; Shu and Chow, 1979). The capital city, Kuala Lumpur, is located within the Klang Basin. The Minerals and Geoscience Department of Malaysia has prepared terrain classification maps for selected parts of the Langat Basin that have been earmarked for national development projects. A macroscale study of the entire basin was initiated only recently as part of the effort to determine the overall state of ecosystem health in the Langat Basin (Wan et al., 1998, 1999).

Assessment of Geohazards

The geohazards that have been reported in the Langat Basin are landslides, land and coastal erosion, floods and flash floods, and ground settlement. Landslides and land erosion are the predominant geohazards in the Langat Basin; thus, geohazard assessment focuses on them.

Landslide is a general term employed to cover a variety of gravity-dominated processes that transport material down to lower ground, and result in slope failures with different form and behavior (Jones, 1992). There are three basic approaches to the assessment of landslides. These are direct mapping, land systems mapping, and indirect mapping (Hansen, 1984; Jones, 1992). The purpose of all three approaches is to produce landslide susceptibility maps that can be used for regional development and hazard minimization. The landslide susceptibility maps provide spatial divisions of the Earth's surface into areas of different levels of threat. It is these divisions that provide the essential framework for land-use planning, building regulation, and engineering practices.

The assessment of landslides in the Langat Basin was based on the direct mapping approach. This involved the preparation of a spatial inventory of existing landslides based on information from air-photo interpretation, field survey, and literature review. During the field survey, information was collected on the locality, type, and size of landslides; the amount of displaced material; and the geology, topography, and land use of the site. It was not possible to establish the age of the landslide from the field survey. The lack of annual systematic mapping of landslides and the limited temporal air-photo coverage made it difficult to differentiate the number of landslides that occurred annually between 1995 and 1998. The information on landslides was then used in conjunction with land cover and landform analysis to evaluate the ecosystem health of the Langat Basin. The study focused on the upper subbasin of the Langat Basin because it was representative with respect to geology and land use.

Land erosion in the tropics refers to the detachment and removal of soil and rock by the action of running water. The dominant processes are action by raindrops, running water, subsurface water, and mass wasting (Selby, 1993). This natural process transforms the surface of the Earth and contributes to the geomorphologic expression of the basin. However, human intervention has resulted in extreme soil loss and subsequent siltation of the rivers. The conventional approach to assess levels of soil loss involves mapping the factors that contribute toward soil erosion. The advent of geographical information systems (GIS) and remote sensing capabilities have led to the development of systematic and simpler mapping techniques. Assessment of soil loss can now be conducted using a combination of GIS and remote sensing techniques, based on the universal soil-loss equation model (Omakupt, 1987; Ravishankar, 1994; Saha and Pande, 1993).

The state of soil loss in the Langat Basin was established based on the TM Landsat image for three time domains — 1993, 1996, and 1998. Land cover for these images was classified into five categories: forests, agriculture, water bodies, built-up areas, and cleared land. These images were then overlaid with the erosion risk map produced by the Agriculture Department in 1996. Availability of sequential images allowed the construction process to be classified into

before, during, and after construction phases. Change of phases could be clearly identified in the images for the three time domains. Soil loss for the Langat Basin was then calculated based on appropriately weighted factors, such as land cover, level of risk, and ruggedness of the topography (Wan et al., 1999).

Landslides In The Langat Basin

The Langat Basin consists of four major subbasins: Upper Langat, Labu, Semenyih, and Lower Langat (Figure 131.2). The study on landslides focused on the Upper Langat subbasin. Ecological Zones 1, 2, and 3, as defined by Nordin and co-workers (this volume), occur within the Upper Langat subbasin; only Ecological Zones 1 and 2 occur within the Semenyih subbasin; the Labu and Lower Langat subbasins correspond to Ecological Zones 2 and 3, respectively.

The Upper Langat subbasin can be divided into four topographical categories: mountainous terrain, undulating lowlands, hilly terrain, and floodplains. Ecological Zone 1 is generally represented by mountainous terrain, Ecological Zone 2 by undulating lowlands and hilly areas, and Ecological Zone 3 by floodplains.

About 40% of the Upper Langat subbasin is covered by undulating lowlands and 30% by hilly areas, while floodplains and mountainous terrain each cover 10% of the area. The subbasin lies on granites and meta-sediments, which encompass 93 and 7% of the area, respectively. In terms of land cover, 40% of the basin is agriculture based, 28% forest, 23% built-up areas, 7% cleared area, and the balance is water bodies.

The combination of heavy rainfall and removal of vegetation has caused landslides in 70 localities within the subbasin, between the period of 1995 and 1998. So far, only two deaths from

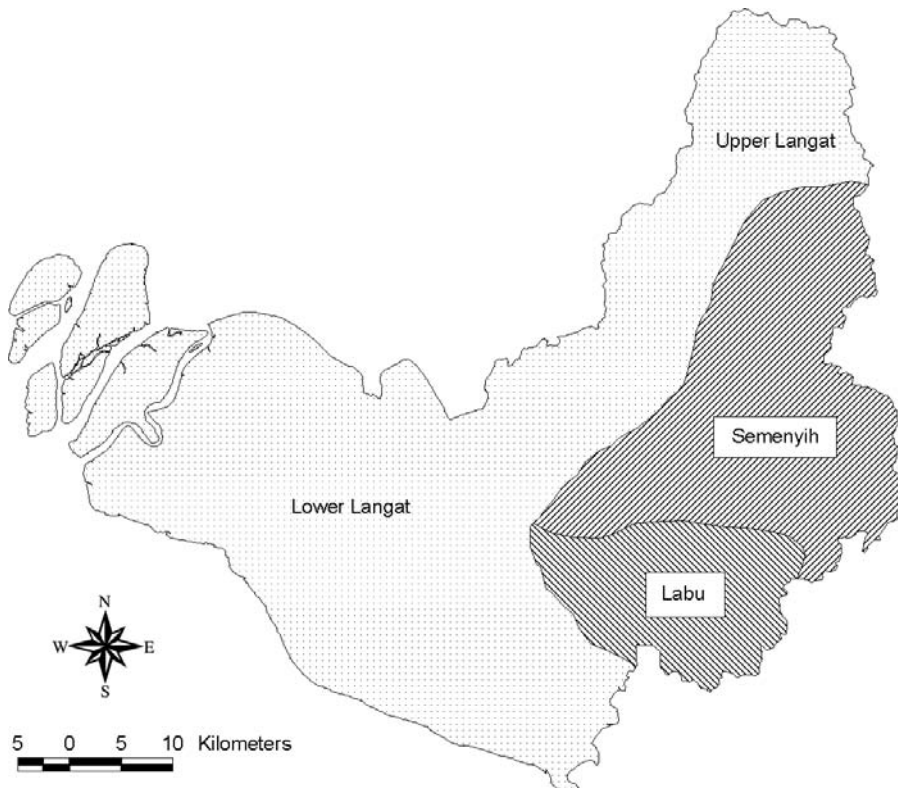

Figure 131.2 Subbasins within the Langat Basin.

Table 131.1 Landslide Intensity and Displaced Material in the Langat Basin

Landslides	No.	Volume (m³)	Area (ha)	Displaced Material per Landslide (m³)	No. per 1000 ha	Displaced Material per ha (m³/ha)
Topography						
Floodplain (<20 m)	12	1534	7255	128	1.6	0.21
Lowland (20–100 m)	49	17,315	30,000	353	1.6	0.58
Hilly (100–500 m)	9	4261	25,454	473	0.35	0.16
Mountainous (>500 m)

Forest	6	553	19,504	92	0.3	0.03
Agriculture	28	13,391	28,919	478	1.0	0.46
Built-up area	26	7921	15,835	305	1.6	0.50
Cleared area	10	1245	4590	124	2.2	0.27

landslides have been reported in the urban center of the Langat Basin. Economic losses associated with damage to infrastructure such as roads and buildings are unknown. In Malaysia, the government rarely compiles information pertaining to social costs and economic losses from geohazards.

Landslides in the Langat Basin have occurred due to a combination of natural and technological causes. Six types of slope failure are observed: earth slump, earth fall, rock fall, earth slide, complex landslide, and debris flow. The two most common types of slope failure, earth fall and earth slump, have been recorded at 26 and 25 localities, respectively, from a total of 70 incidents. Earth fall often occurs in slopes with steepness more than 60°, while earth slump is common in slopes with steepness less than 45°. The other types of failures have occurred in fewer than five localities within the subbasin.

The parameter obtained by dividing the total volume of displaced material with the number of landslides in a given area provides an indication of the average size of the slope failure. This parameter was calculated for each category of topography, geology, and land cover within the subbasin (Table 131.1). For the category of topography, the volume of displaced material per landslide is relatively smaller in the floodplains compared with the hilly areas. This indicates that the size of the slope failure increases with the ruggedness of the topography. In the case of geology, it was observed that the slope failures over granitic terrain are larger than those within meta-sediments. As the granitic terrain forms a significant proportion of the rugged areas, this result is consistent with the earlier observation for the various categories of topography. In the context of land cover, larger slope failures occur within agriculture and built-up areas compared with cleared areas and forests.

The intensity of landslides is determined from the number of landslide occurrences per unit area (per 1000 ha). The displaced material is obtained by dividing the total volume of material associated with all slope failures in a given area (Table 131.1). Generally, landslide intensity and displaced material are higher in the floodplains and undulating lowland terrain than in hilly areas. The intensity of landslides is nearly 60 times greater and displaced material six times higher within meta-sediments compared with granitic terrain. In terms of land cover, the lowest intensity of landslides and displaced material occurs in forests. The intensity of landslides is the highest in cleared area, followed by built-up and agricultural areas. However, more material is displaced per unit area within the agriculture and built-up areas compared with cleared areas. This means that cleared areas have a high number of small slope failures.

Land Erosion in the Langat Basin

The study on land erosion focused on the entire basin. The overall percentage of land cover within the Langat Basin for the time domains of 1993, 1996, and 1998 is shown in Table 131.2. Between 1993 and 1998, the forest coverage in the Langat Basin has been reduced annually by about 10% to accommodate increases in other types of land use. During the same period, cleared, built-up, and agriculture areas increased annually by 15, 10, and 3%, respectively.

Table 131.3 shows the amount of soil loss within the different types of terrain and land cover in the Langat Basin for 1993, 1996, and 1998. Generally, the highest amount of soil loss occurs in undulating lowlands and hilly terrain, followed by mountainous areas and floodplains. The average soil loss is generally very high for cleared areas (152 t/ha/year) within the Langat Basin. In comparison, soil losses in the forest and agriculture areas are not significant (less than 4 t/ha/year). Between 1993 and 1998, soil loss from cleared areas fluctuated between 4 and 13% annually, while no significant changes were observed for soil loss in forest and agriculture areas. Changes in soil loss could be attributed to the location of the cleared land, i.e., floodplains, undulating lowlands, hilly or mountainous areas. The clearing of land, particularly in hilly areas, makes it susceptible to gully, sheet, and splash erosions as a result of the heavy tropical rainfall. The eroded material generally finds its way down to nearby channels and causes siltation of rivers.

The increase in soil loss during the period between 1993 and 1998 has been correlated to increased levels of suspended sediment in the automatic monitoring stations of rivers draining the Langat Basin (Wan et al., 1999). It was also noted that the highest levels of suspended sediments were recorded during the phase construction at monitoring stations located near areas being cleared. The levels observed normally exceeded the standards for aquatic life, drinking water, and irrigation set by the Department of Environment Malaysia. Concentrations of suspended sediments usually dropped to their original levels after the construction phase.

Table 131.2 Percentage of Land Cover in the Langat Basin for 1993, 1996, and 1998

Type of Land Cover	Coverage (%)		
	1993	1996	1998

Average basin soil loss	1.65	2.2	4.2

DIAGNOSIS OF ECOSYSTEM HEALTH

The ecosystem health of the Langat Basin, with respect to landslides and land erosion, can be assessed based on spatial and temporal perspectives. For landslides, it was not possible to establish trends in annual distribution and intensity in the context of different land uses. This is because the current assessment could not differentiate the number of annual landslide occurrences between the period of 1995 and 1998. Continuous annual assessment for at least 3 to 4 years into the future is required before such trends can be established. Trends for soil erosion can be established more readily from the manipulation of remote sensing and GIS modeling.

Based on the spatial perspective, the Langat Basin can be divided into three areas according to ecosystem health: forested mountain terrain, undulating lowlands and hilly areas, and coastal and floodplains. The best state of ecosystem health is within the forested areas in the mountainous terrain, located in the eastern part of the Langat Basin. Soil loss here is below 2 t/ha/year and landslides do not exceed natural levels in size, intensity, and material displacement. The worst state of ecosystem health occurs in undulating lowland and hilly areas, in the central part of the basin where development is focused. Soil loss in this area is generally between 12 to 13 t/ha/year. In areas with land-clearing activities for major construction projects, such as the Kuala Lumpur International Airport and Putra Jaya, soil loss is about 152 t/ha/year. The highest intensity and displaced material associated with landslides occur within this area. The ecosystem health of the coastal and floodplains in the eastern part of the Langat Basin is relatively moderate. Soil losses in the mainly agriculture-based areas here generally do not exceed 3.6 t/ha/year. The intensity of landslide occurrences is quite high, but the size of slope failures and volume of displaced material are relatively low.

Overall soil loss in the Langat Basin can be attributed to increased land-clearing activity to accommodate infrastructure and other forms of physical development. The average soil loss for the basin in 1993 was 1.6 t/ha/year. In the absence of allowable limits for soil erosion within the Langat Basin, the soil erosion value for 1993 was taken as the baseline level. Compared with 1993, soil loss has increased annually by about 20% to 4.2 t/ha/year in 1998. This situation is very unhealthy for the ecosystem. Soil loss results in increased amounts of suspended sediments in rivers, particularly during the construction phase, and further deterioration of the health of the ecosystem. Thus, land-clearing should not exceed 60 km² (or 2% of the total basin) in any one year in order to retain basin soil-loss conditions similar to 1993 and maintain the overall health of the Langat Basin ecosystem. This limit of land clearing would also ensure that landslide occurrences do not exceed natural levels.

Stringent management measures should be enforced to arrest the problem of excessive soil erosion during the construction phase of development projects in the Langat Basin. Soil loss in forest and agriculture areas of the Langat Basin have not changed significantly (less than 0.2 and 3.7 t/ha/year, respectively) between 1993 and 1998. In terms of soil management, it appears that the efficiency of soil management in these sectors, particularly for agriculture, has neither improved nor deteriorated. Thus, these two areas have not contributed significantly to the deterioration of ecosystem health with respect to soil loss.

CONCLUSION

The best state of ecosystem health in the Langat Basin is within the forested areas in the mountainous terrain, located in the upper eastern part of the basin. Soil loss here is below 2 t/ha/year and landslides do not exceed natural levels in term of size, intensity, and material displacement. The worst state of ecosystem health is recorded in the undulating lowland and hilly areas, within the central part of the basin, which is the focus of development. Soil loss in this area is generally between 12 to 13 t/ha/year, attaining levels of 152 t/ha/year where there are land-clearing activities. The highest intensity and displaced material associated with landslides occur within this area. The

ecosystem health of the coastal and floodplains located in the eastern part of the Langat Basin is relatively moderate, with soil losses generally not exceeding 3.6 t/ha/year. The intensity of landslide occurrences is quite high, but the size of slope failures and volume of displaced material are relatively low.

Overall soil loss in the Langat Basin can be attributed to increased land-clearing activity to accommodate infrastructure and other forms of physical development. Since 1993, soil loss increased by 20% annually to 4.2 t/ha/year in 1998. The soil loss resulted in increased amounts of suspended sediments in rivers, particularly during the construction phase, and further deterioration of the health of the ecosystem. It is estimated that in order to improve the Langat Basin ecosystem, land clearing should not exceed 60 km² (or 2% of the total basin) in any one year. Furthermore, stringent measures should be enforced to arrest the problem of excessive soil erosion during the construction phase.

ACKNOWLEDGMENTS

This chapter is part of the research funded by MATREM CP/5220-97-02, a project of the United Nations Environment Programme's Network for Environmental Training at Tertiary Level in Asia and the Pacific (NETLAPP). The encouragement and support of Prof. Mohd Nordin Hj. Hasan, the project leader, is gratefully acknowledged.

River Water Quality Assessment and Ecosystem Health: Langat River Basin, Selangor, Malaysia

Muhammad Abu Yusuf, M. Nordin, and Pauzi Abdullah

INTRODUCTION

The Langat River Basin, which is adjacent to the Klang Valley, has an area of about 2938 km² and an estimated population of about 725,000 in 1997. Administratively it is under three whole districts — Hulu Langat, Sepang, and Kuala Langat of Selangor — as well as the southern part of the Seremban District in the state of Negeri Sembilan. The basin has been the focus of major recent development that included the new federal government administrative capital of Putrajaya, the multimedia supercorridor linking Putra Jaya with KLIA and Kuala Lumpur, Cyber Jaya, and the Kuala Lumpur International Airport (KLIA) at Sepang (Nordin and Azrina, 1998). Additionally, the development of new townships such as Bandar Baru Nilai and expansion of existing towns and villages such as Dengkil and Semenyih contribute to the growth of an increasingly dense urban sprawl with concomitant urbanization and industrialization that can potentially cause complex environmental problems.

The rivers of the Langat Basin play a significant role in the ecology of the basin, providing potable water to residents within the basin and the highly urbanized Klang Valley, and supplying industries and agricultural areas with water for manufacturing and irrigation. At present, a total of eight water treatment plants are located in the basin. Recent development activities in the basin can threaten the water quality in its rivers and disrupt its ability to meet water requirements in the basin and elsewhere. This chapter presents the findings of a 12-month study of water quality in the rivers of the Langat Basin and relates them to ecosystem health issues highly relevant to the future of the Langat Basin ecosystem. The study is a meso-scale study that examines river water quality in the entire basin.

Malaysian rivers are classified in the Interim Water Quality Standards for Malaysia (INWQS) based on water quality criteria and standards for several beneficial uses (DOE, 1986, 1990). The six river-use classifications as defined by INWQS are shown in Appendix 132.I.

MATERIALS AND METHODS

The Langat River Basin is divided into three ecological zones based on forest and soil types. Ecological Zone 1 comprises upland forest, and is located in the northern part of the basin;

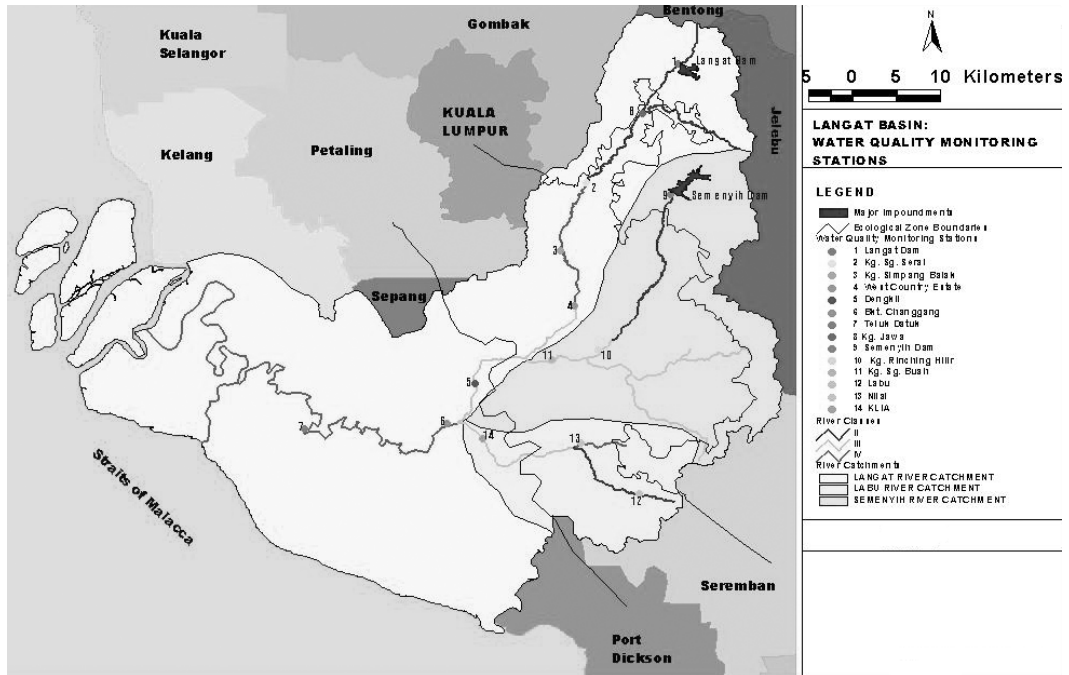

Figure 132.1 Map of the Langat River Basin and water quality monitoring stations along the rivers of the Langat Basin.

Ecological Zone 2 is comprised of lowland forest and highly urbanized areas, and is located in the middle part of the basin. Ecological Zone 3 is comprised of peat-swamp mangrove forest and agricultural land, and is located in the southern part of the basin near the Straits of Malacca.

A total of 14 monitoring stations was established along six rivers of the Langat Basin (Figure 132.1). On-site surveys were conducted prior to selection of sampling sites. Monitoring stations of the Department of Environment (DOE), the Department of Irrigation and Drainage (DID), and other study groups in the Langat Basin were reviewed and visited before selecting the monitoring stations specific to this study. Monitoring stations were selected based on accessibility and ability to sample under all weather conditions; homogeneity of the water column, i.e., the water must be fully mixed at the point of sampling so that representative samples of river water can be easily obtained at the place and time of sampling; stream characteristics so that at least one station was selected to represent subcatchment areas; water supply intake points; towns in the basin; and location of industrial sites. Stations were located a few kilometers downstream of any point source of pollution, not immediately below it.

Grab samples were collected monthly for 1 year from May 1998 to April 1999. Water sampling and analytical methods followed GEMS and Water Operations Guide (Anon., 1978), APHA Standard Methods (APHA, 1989, 1992), and HACH Quick Method (HACH, 1989). During the first 6 months, sampling commenced from the upper reaches of the river. The sampling order was reversed on the seventh month when sampling began from downstream sampling sites and proceeded upstream. All samples were collected and sent to the laboratory on the same day.

The following parameters were studied: water temperature, pH, salinity, conductivity, turbidity, total suspended solids (TSS), volatile solids, fixed solids, dissolved oxygen (DO), biochemical oxygen demand (BOD), chemical oxygen demand (COD), ammoniacal-nitrogen, nitrate-nitrogen, nitrite-nitrogen, phosphate-phosphorus, hexane extractable materials (oil and grease), total phenol, pesticides, and heavy metals (arsenic [As], aluminum [Al], cadmium [Cd], chromium [Cr], copper [Cu], cobalt [Co], iron [Fe], lead [Pb], mercury [Hg], nickel [Ni], and zinc [Zn]). Six physical

parameters (temperature, pH, DO, salinity, turbidity, and conductivity) were measured *in situ* using portable instruments (DO meter, pH meter, turbidimeter, and conductivity meter). Three other physical parameters were determined in the laboratory along with 19 chemical parameters.

APHA method 2540D (1989) and 2540E (1989) were employed for the analysis of total suspended solids, volatile solids, and fixed solids. The HACH quick method based on DR/2000 was used to analyze inorganic nutrients. Program 385 (salicylate method), program 351 (cadmium reduction method), program 371 (diazotization method), and program 490 (ascorbic acid method) were used for the analyses of ammoniacal–nitrogen, nitrate–nitrogen, nitrite–nitrogen, and phosphate–phosphorus, respectively.

APHA method 5210 (1989) was used for the analysis of BOD. HACH colorimetric method (program 430) was used for COD analysis. Oil and grease (O&G) were extracted with n-hexane according to EPA method 1664 (liquid–liquid extraction). APHA method 5530 (1989) was employed for total phenol determination.

The trace metals Cu, Cd, Cr, Co, Ni, Fe, Zn, and Pb were analyzed using atomic absorption spectrophotometry (AAS) according to APHA method 3111B (direct air–acetylene method). Arsenic was analyzed using APHA method 3114B (1989) (hydride generation method), and mercury was analyzed using APHA method 3112B (1989) (cold-vapor generation method). Aluminum was determined using HACH method 10 (aluminum method).

Strict quality assurance procedures were used for laboratory analysis. These included field and laboratory blank analysis, replicate sample spiked with known concentrations of parameters to be analyzed, and duplicate sample analysis. Analytical determinations were checked using reference materials, while instruments were routinely calibrated.

Water quality data were stored in Microsoft Excel 7.0. The data were converted to MS-DOS for statistical analysis with the aid of an SAS statistical package. Data were also converted to Microsoft Access 7.0 to prepare the map employing a geographical information system (GIS) using Arc-View 3.0 and Arc-Info 7.1.2 software.

Water quality assessment results were compared to present INWQS with respect to aquatic life, water supply, and irrigation (DOE, 1994).

Statistical tests used for examining water quality data included analysis of variance (ANOVA) and Duncan's multiple-range test with the aid of an SAS statistical package. The two-way ANOVA was conducted for each parameter to test for significant differences in means between stations, time of sampling (morning and afternoon), and interactions (Station * Time). Duncan's multiple-range test was performed to determine which ranges of means were significantly different.

The DOE-WQI index was used to identify the status of river water quality and classify stretches of the Langat Basin rivers into river classes, according to the system adopted by the DOE (DOE, 1994, 1998). Six water quality parameters (DO, pH, BOD, COD, TSS, and ammoniacal-nitrogen) were used to calculate this index (Norhayati, 1981). The index was established based on the results of an opinion poll of a panel of experts who determined the choice of parameters and weights assigned to each chosen water quality parameter (DOE, 1994). Calculations were performed not on the parameters themselves but on their subindices whose value are obtained from a series of equations. These are best-fit equations obtained from rating curves (Norhayati, 1981). The subindices for these parameters are named SIDO, SIBOD, SICOD, SIAN, SISS, and SIPH. The formula used to calculate WQI is as follows:

$$\text{WQI} = 0.22 * \text{SIDO} \pm 0.19 * \text{SIBOD} \pm 0.16 \\ * \text{SICOD} \pm 0.15 * \text{SIAN} \pm 0.16 * \text{SISS} \pm 0.12 * \text{SIPH}$$

(* indicates multiplication), where the multipliers are the weights for the corresponding parameters with a total value of 1.

The formula used to calculate subindices are shown in Appendix 132.III.

The health of the aquatic ecosystem of the Langat Basin was assessed using the Schaeffer and Cox (1992) definition of ecosystem health and by the assessment criteria for physicochemical components of ecosystems suggested by Ramade (1995).

RESULTS AND DISCUSSION

Sampling during the duration of the study proceeded successfully and no major problems were encountered. Duplicate samples were analyzed and average results are presented below for each parameter studied. All values are averages of 12 samples collected monthly throughout the duration of the study. It should be stated that the period of sampling spanned the extended period of drought that occurred in 1998.

Means of each parameter for all monitoring stations are shown in Appendix 132.III and displayed in bar charts (Figures 132.2 to 132.14). The results of ANOVA tests are shown in Tables 132.1 and 132.2.

Table 132.1 Significant and Nonsignificant Differences for Physical Parameters Determined in This Study

Parameters	Significant/Nonsignificant		
	Between Stations	Sampling Time (AM and PM)	Interaction (Station * Time)
Temperature	b	b	b
pH	NS	a	NS
Dissolved oxygen	b	b	NS
Turbidity	b	NS	NS
Conductivity	b	a	NS
Total suspended solids	b	NS	NS
Volatile solids	b	NS	NS
Fixed solids	b	NS	NS

a = significant; b = highly significant; NS = nonsignificant.

Table 132.2 Significant and Nonsignificant Differences for Chemical Parameters Determined in This Study

Parameters	Significant/Nonsignificant

Nickel	NS	NS	a
Zinc	b	NS	NS

a = significant; b = highly significant; NS = nonsignificant.

PHYSICAL PARAMETERS

Temperature

The average water temperature measured along the rivers of the Langat Basin ranged from 25.9 to 29.4°C (Figure 132.2). This is within the normal range of water temperature for Malaysian rivers (Ainon and Sukiman, 1987; Anhar et al., 1988; DOE, 1997). Water temperature in the upper reaches near the Langat and Semenyih dams averaged 25.9 and 28.4°C, respectively. Temperature gradient between the upper and lower reaches of the rivers was monitored. Water temperatures increased from Kg. Sg. Serai to Teluk Datuk along the Langat River and from Semenyih Dam to Sg. Buah along the Semenyih River. The highest average temperature measured (29.4°C) was along the Batang Nilai River.

Differences of mean temperature levels between stations, sampling time (AM and PM) and interaction (Station * Time) were highly significant ($p \leq 0.01$) (Table 132.1). Duncan's multiple-range test results grouped the range of means at different stations into four. The difference of mean temperatures at Nilai, Teluk Datuk, Dengkil, West Country Estate, and Kg. Simpang Balak were significantly higher than at other stations; Langat Dam was significantly lower ($p \leq 0.05$) than all other stations. Significant variations of mean temperatures ($p \leq 0.01$) were observed between sampling times and the interaction between sampling stations and sampling time was highly significant ($p \leq 0.01$).

Several factors influence river water temperature including location and time of sampling. Downstream areas of the river are less shaded by trees compared with the upper reaches and tend to show higher temperatures because of direct exposure to sunlight.

Salinity

Zero salinity was observed *in situ* along the rivers of the Langat Basin. Teluk Datuk and Kg. Bukit Changgang monitoring stations are near the coast, and zero salinity was also measured there as all the samples were collected during low tide. Salinity in the Langat can reach 0.15 ppt in Kg. Bukit Changgang (DOE, 1997) and 0.37 ppt in Teluk Datuk (DOE, 1998). The INWQS maximum of salinity for Malaysian rivers is 1 ppt.

pH

The average pH for measurements made at all stations ranged from 6.4 to 7.2 (Figure 132.3). This is within the INWQS range of pH for Malaysian rivers to support aquatic life. In Teluk Datuk (Station 7), low pH values of 4.9, 4.4, 4.1, and 5.0 were recorded for the months of August 1998, September 1998, January 1999, and February 1999, respectively. During the other months, pH

Figure 132.2 Temperature at different stations along the rivers of the Langat Basin.

Figure 132.3 The pH value at different stations along the rivers of the Langat Basin.

values ranged between 5.3 and 6.4. The average pH range along the rivers of the Langat Basin was within range for Malaysian rivers.

Differences in mean pH levels between stations and sampling times were highly significant ($p \leq 0.01$) and significant ($p < 0.05$), respectively. Interactions between stations and sampling times were not significant ($p < 0.05$) (Table 132.1). Duncan's multiple-range test results grouped the range of means at different stations into five. The differences in mean pH at Nilai, Langat Dam, Kg. Jawa, and Kg. Rinching Hilir were significantly higher than those of all other stations, while at Teluk Datuk the difference was significantly lower ($p \leq 0.05$) than all other stations.

Previous research records a pH range of 6.3 to 7.6 along the rivers of the Langat Basin (Ainon and Sukiman, 1987; Anhar et al., 1988; DOE, 1997, 1998). Extreme values of pH 5.6 to 8.9 have been recorded in the past (Sukiman, 1985). The pH of most natural waters ranged between 6.0 and 8.5, although lower values can occur in dilute waters high in organic content, and high values in eutrophic waters (Chapman, 1992). A pH range of 6.0 to 9.0 is suitable for supporting freshwater fish and bottom-dwelling invertebrates. The INWQS range for pH in Malaysian rivers to support aquatic life is 5 to 9.

Turbidity

The average turbidity along the rivers of the Langat Basin ranged from 20.67 to 544.17 NTU. INWQS does not propose any threshold value for turbidity of fresh waters for the support of aquatic life. The Ministry of Health has set a threshold level of raw water turbidity at 1000 NTU. The turbidity of river water in the Langat Basin is below this threshold level. Previous turbidity measurements of rivers in the Langat Basin reported values ranging from 17 to 98 NTU (DOE, 1997).

Differences in mean turbidity between stations were highly significant ($p < 0.01$), but differences between sampling time and interactions (Station * Time) were not significant ($p > 0.05$) (Table 132.1). Duncan's multiple-range test results grouped the means at different stations into four. Mean turbidities at Teluk Datuk were significantly higher ($p < 0.05$) than all other stations and at Langat Dam, Semenyah Dam, Labu, Nilai, Kg. Jawa, and Kg. Sg. Serai they were significantly lower ($p < 0.05$).

The highest turbidity and TSS values were obtained at Teluk Datuk (Station 7). Waters containing suspended solids and organic matter generally show high turbidity. Turbid water is not suitable for industrial use, can harbor pathogenic microorganisms and thus increase the risk of waterborne diseases. The rivers of the Langat Basin can still support aquatic life, as turbidity was within the acceptable range for Malaysian rivers.

Conductivity

Conductivity reflects the concentration of electrolytes in water. Average conductivity in the rivers of the Langat Basin ranged from 39.16 to 406.08 μmhos . The highest level of conductivity

was measured at Nilai (406.08 μmhos) along Batang Nilai River and the lowest at the Langat Dam (39.16 μmhos) along the Langat River. Previously reported measurements of conductivity ranged between 42.2 to 18 μmhos (DOE, 1997), 30.84 to 523.60 μmhos (DOE, 1998), and 50 to 150 μmhos (Anhar et al., 1988). These values were below the INWQS maximum threshold level (1000 NTU) for Malaysian rivers to support aquatic life.

Differences in mean conductivity between stations and sampling times were highly significant ($p < 0.01$ and $p < 0.05$, respectively); interaction between stations and time (Station * Time) was not significant ($p > 0.05$) (Table 132.1). Duncan's multiple-range test results grouped means at different stations into four. The difference of mean conductivity at stations Nilai and Teluk Datuk were significantly higher than at all other stations. The conductivity at Langat Dam, Kg. Sg. Serai, Kg. Jawa, Labu Semenyih Dam, Kg. Sg. Buah, and Kg. Rinching Hilir were significantly lower than those at all other stations.

Differences in conductivity between sampling times indicated that at some locations values were higher in the afternoon than in the morning. High temperature in the afternoon increasingly dissolves some salts in river water and can explain the higher conductivity.

Total Suspended Solids

Differences in average TSS content of the Langat Basin rivers were considerable, ranging from 6.33 to 528.75 mg/l (Figure 132.4). The lowest TSS levels were obtained in the Langat Dam and highest in Teluk Datuk (Station 7) along the Langat River.

Differences in means between stations were highly significant ($p < 0.01$); differences in sampling times and interactions between stations and time (Station * Time) were not significant ($p \leq 0.05$) (Table 132.1). Duncan's multiple-range test grouped mean TSS at the different stations into five. The difference in mean TSS at Teluk Datuk was significantly higher ($p < 0.05$) than at all other stations. Total suspended solids at the Langat Dam, the Semenyih Dam, Labu, Nilai, Kg. Jawa, and Kg. Sg. Serai were significantly lower ($p < 0.05$) than all other stations.

The INWQS level of TSS for supporting healthy aquatic life in a freshwater ecosystem is 150 mg/l. Particular sections of the rivers of the Langat Basin are badly polluted by suspended sediments. A very high TSS was obtained at Kg. Rinching Hilir, with a value of 1704 mg/l for September 1998. However, the sample was collected during storm flow after heavy rain. Furthermore, a rubber plantation was being clear-felled, and soil from bare land was being transported directly to the river with surface runoff. These events explain the high TSS readings from this station. High levels of TSS were also obtained along the Langat River from Kg. Simpang Balak to Teluk Datuk. Upstream of Kg. Simpang Balak (Station 3), a highway leading to Cheras was being constructed. In March 1999, a high level of TSS was obtained from the station at West Country Estate (1549 mg/l) when samples were collected after rain. TSS were repeatedly high at stations Kg. Bukit Changgang and Teluk Datuk. During the study period, development of KLIA was in progress and large tracts of land were not fully protected by vegetation. The highest level of TSS obtained in Teluk Datuk

Figure 132.4 Total suspended solids levels at different stations along the rivers of the Langat Basin.

station was 1030 mg/l in March 1999. Previous studies had reported TSS values ranging from 6.5 to 1059.2 mg/l (DOE, 1997, 1998).

Waters high in suspended solids are aesthetically unsatisfactory for bathing, can harbor harmful microorganisms, deter the hatching of fish eggs, and are lethal to some aquatic organisms. Because sections of the rivers of the Langat Basin are already high in TSS, further deterioration will increase the risk of ecological collapse and make the river dead, without aquatic life.

Volatile Solids and Fixed Solids

The average results of volatile solids and fixed solids along the rivers of the Langat Basin ranged from 6 to 88.86 mg/l and 0 to 428.77 mg/l, respectively. The highest level of volatile solids was obtained in Teluk Datuk (Station 7) and the lowest near Langat Dam (Station 1). On the other hand, high levels of fixed solids were obtained also in Teluk Datuk (Station 7) and low levels in the Semenyih River (Station 9).

Differences in means of volatile and fixed solids between stations were highly significant ($p \leq 0.01$). The means between sampling time and interaction of stations and time (Station * Time) were not significant ($p > 0.05$) (Table 132.1). Duncan's multiple-range test results grouped mean volatile and fixed solids at different stations into five. The difference in mean volatile solids at Teluk Datuk was significantly higher ($p \leq 0.05$) than all other stations. Volatile solids at the Langat Dam, the Semenyih Dam, Labu, Kg. Sg. Serai, and Kg. Jawa were significantly lower ($p \leq 0.05$) than all other stations. On the other hand, the differences in mean fixed solids at Teluk Datuk and Dengkil were significantly higher ($p \leq 0.05$) while fixed solids at the Semenyih Dam, the Langat Dam, Nilai, and Labu were significantly lower ($p \leq 0.05$) than all other stations.

Volatile and fixed solids reflect the organic and inorganic metal oxide contents of suspended solids in the river water. These correlate with DO concentrations in water and organic content in suspended solids. Generally, suspended solids containing highly volatile solids result in low DO and high BOD. In Teluk Datuk, the DO level was persistently low, while BOD levels were persistently high during the study period. INWQS did not propose any threshold level of volatile solids and fixed solids for Malaysian rivers.

Dissolved Oxygen (DO)

Average DO levels in the rivers of the Langat Basin ranged from 1.38 to 7.30 mg/l (Figure 132.5). The acceptable range of DO for Malaysian rivers by INWQS standards is 3 to 5 mg/l. The DO level along the Langat River at West Country Estate (2.72 mg/l), Teluk Datuk (1.38 mg/l), and in Nilai (2.69 mg/l) along the Batang Nilai river were below the INWQS acceptable range. At other stations, DO ranged between 3.78 to 7.3 mg/l and were within acceptable the range for Malaysian rivers. The lowest DO was measured in Teluk Datuk (Station 7). DO ranges between

Figure 132.5 Dissolved oxygen, biochemical oxygen demand, and chemical oxygen demand levels at different stations along the rivers of the Langat Basin.

2.73 to 8.3 mg/l have been reported previously for rivers in the Langat Basin (Ainon and Sukiman, 1987; Anhar et al., 1988; DOE, 1997).

Differences in mean DO between stations and between sampling times were highly significant ($p < 0.01$); interactions between station and time (Station * Time) were not significant ($p > 0.05$) (Table 132.1). Duncan’s multiple-range test grouped mean DO at the different stations into six. Differences in means at Kg. Jawa, the Langat Dam, and Kg. Sg. Serai were significantly higher ($p < 0.05$) than at other stations. DO at Teluk Datuk was significantly lower ($p < 0.05$) than all other stations.

The differences between DO and sampling time indicated that at some locations DO values were lower in the afternoon than in the morning. High temperature in the afternoon releases DO from river water and this could be the reason for the low DO value. On the other hand, at some stations DO value were low even in the morning. Organics from anthropogenic sources can cause low DO in river water even in the morning. Stations with low DO in the morning and afternoon are generally located downstream from urban and industrial areas. Effluents from industries, sewage treatment plants, urban runoff, and pig farm waste containing high levels of oxygen-demanding substances could all contribute to low DO levels in river water.

Generally, 3 mg/l DO or less is stressful to aquatic vertebrates and other aquatic life. DO levels below 2 mg/l kills most fish species. However, a few tropical fish species, especially air-breathing species, can survive at low DO levels of between 0.8 to 1.1 mg/l (Lim, 1974). Water quality criteria for acceptable DO levels that support aquatic life vary from country to country (Anonymous 1976; Hart, 1974; Pescod, 1973).

Ammoniacal-Nitrogen

The average ammoniacal-nitrogen concentration obtained in rivers of the Langat Basin ranged from 0.59 to 4.51 mg/l (Figure 132.6). INWQS recommends a maximum level of ammoniacal-nitrogen for the support of aquatic life in Malaysian rivers of 0.9 mg/l. The lowest level of ammoniacal-nitrogen was obtained in Kg. Sg. Serai (0.59 mg/l) and the highest in Kg. Simpang Balak (4.51 mg/l). Except for stations at Kg. Sg. Serai (0.59 mg/l), the Semenyih Dam (0.67 mg/l), Kg. Jawa (0.75 mg/l), and Labu (0.77 mg/l), ammoniacal-nitrogen levels in all other stations exceeded the recommended INWQS threshold. Many parts of the rivers of the Langat Basin are badly polluted by ammoniacal-nitrogen.

Differences in means between stations were highly significant ($p < 0.01$); interactions of stations and time of sampling (Station * Time) were significantly different ($p > 0.05$) (Table 132.2). Duncan’s multiple-range test results grouped the mean ammoniacal-nitrogen at different stations into six. Mean differences at Kg. Simpang Balak and West Country Estate were significantly higher

Figure 132.6 Ammoniacal-nitrogen, nitrate-nitrogen, and nitrite-nitrogen levels at different stations along the rivers of the Langat Basin.

($p < 0.05$) than all other stations, while ammoniacal-nitrogen at Kg. Sg. Serai was significantly lower ($p < 0.05$) than all other stations.

Simpang Balak is located downstream of the second biggest industrial park in the Balakong industrial area and industrial effluents contribute to the high level of ammoniacal-nitrogen at this station. West Country Estate is located downstream of Kajang, the largest town in the basin. A significant number of industries are located near Kajang town and industrial effluents are likely to contribute to obtain high ammoniacal-nitrogen at West Country Estate.

Previous reports suggested that the ammoniacal-nitrogen levels in the rivers of the Langat Basin ranged from 0 to 5.69 mg/l (DOE, 1997, 1998). In 1997 to 1998, the water quality of the Langat Basin rivers occasionally deteriorated to such an extent that water treatment plants had to cease operation. Conventional water treatment plants cannot treat raw water when ammoniacal-nitrogen concentration is higher than 3 mg/l (DOE, 1998). The 11th-mile Cheras water treatment plant was closed eight times between October 1997 and March 1998 for a total of 96 h, as the ammoniacal-nitrogen and O&G levels in raw river water were higher than this maximum (DOE, 1998). The Bukit Tampoi water treatment plant was closed three times in March 1998 for a total of 27 h for the same reasons (DOE, 1998). Salak Tinggi and Langat water treatment plants were closed once in 1998 due to high O&G and ammoniacal-nitrogen levels (NST, 1998). The aquatic ecosystem of the Langat River Basin is severely polluted with ammoniacal-nitrogen; further deterioration will aggravate matters, prevent rivers from supporting aquatic life, and make them unfit for processing into drinking water.

Nitrate- and Nitrite-Nitrogen

The INWQS levels of nitrate- and nitrite-nitrogen for the support of aquatic life in Malaysian rivers are 10 and 0.4 mg/l, respectively. The average nitrate- and nitrite-nitrogen concentrations in samples of river water from the Langat Basin ranged from 0.56 to 2.14 mg/l and 0.004 to 0.243 mg/l, respectively (Figure 132.6), below INWQS levels. This suggests that the rivers of the Langat Basin are generally not badly polluted by runoff of nitrate- and nitrite-nitrogen.

Differences in means of nitrate- and nitrite-nitrogen between stations were highly significant ($p < 0.01$), while differences between sampling times and interactions between stations and sampling times (Station * Time) were not significant ($p > 0.05$) (Table 132.2). Duncan's multiple-range test grouped mean nitrate- and nitrite-nitrogen at the different stations into four. The difference of mean nitrate-nitrogen at KLIA was significantly higher ($p < 0.05$) than all other stations. The nitrate-nitrogen levels at Semenyih Dam, Langat Dam, and Kg. Jawa were significantly lower ($p < 0.05$) than at all other stations. On the other hand, the difference in means of nitrite-nitrogen at Nilai was significantly higher ($p < 0.05$) than all other stations. The nitrite-nitrogen levels at Kg. Bukit Changgang, the Semenyih Dam, Dengkil, Teluk Datuk, KLIA, the Langat Dam, Kg. Jawa, and Kg. Sg. Serai were significantly lower ($p < 0.05$) than all other stations.

Surface waters normally contain nitrate concentrations up to 5 mg/l nitrate-nitrogen, but often lower than 1 mg/l nitrate-nitrogen. On the other hand, nitrite concentrations in fresh waters are usually very low, about 0.001 mg/l nitrite-nitrogen and rarely higher than 1 mg/l nitrite nitrogen.

Phosphate-Phosphorus

The average phosphate-phosphorus concentration in rivers of the Langat Basin ranged from 0.16 to 0.44 mg/l (Figure 132.7). The highest average concentration was in Nilai (0.44 mg/l), the lowest were in Dengkil (0.16 mg/l), Kg. Bukit Changgang (0.16 mg/l), and Teluk Datuk (0.16 mg/l) along the Langat River, and from the Semenyih Dam (0.16 mg/l) along the Semenyih River. The INWQS level for phosphate-phosphorus in Malaysian rivers is 0.10 mg/l. Phosphate-phosphorus levels exceeded the INWQS level for Malaysian rivers in all the stations studied in the Langat Basin.

Figure 132.7 Phosphate-phosphorus level at different stations along the rivers of the Langat Basin.

Differences in means between stations were highly significant ($p < 0.01$); sampling times and interactions between stations and time of sampling (Station * Time) were not significant ($p > 0.05$) (Table 132.2). Duncan's multiple-range test grouped the mean phosphate-phosphorus at different stations into four. The difference in means at station Nilai was significantly higher ($p < 0.05$) than all other stations. The phosphate-phosphorus means at Kg. Bukit Changgang, Semenyih Dam, Dengkil, Teluk Datuk, KLIA, the Langat Dam, Kg. Jawa, and Kg. Sg. Serai were significantly lower ($p < 0.05$) than all other stations.

With respect to phosphorus, parts of the rivers in the Langat Basin are unsuitable for supporting aquatic life, as the excess phosphorus causes eutrophication and reduced DO. Further deterioration of water quality with respect to phosphate-phosphorus will have adverse effects on the distribution of aquatic life in the rivers of the Langat Basin.

Biochemical Oxygen Demand

The average value of BOD in rivers of the Langat Basin ranged from 4.08 to 15.68 mg/l (Figure 132.5). BOD was lowest in Kg. Jawa (3.4 mg/l) along the Lui River and highest in Nilai (16.4 mg/l) along the Batang Nilai River. The INWQS level for BOD in Malaysian rivers is 6 mg/l. Five stations along Langat River in Kg. Simpang Balak (11.28 mg/l), West Country Estate (9.79 mg/l), Dengkil (7.16 mg/l), Kg. Bukit Changgang (6.64 mg/l), and Teluk Datuk (9.28 mg/l), as well as the Labu River in KLIA (7.67 mg/l) and the Batang Nilai River in Nilai (15.68 mg/l), exceeded the INWQS level for supporting aquatic life.

Differences in means between stations were highly significant ($p < 0.01$), while differences between sampling times and interactions between stations and time of sampling (Station * Time) were not significant ($p > 0.05$) (Table 132.2). Duncan's multiple-range test grouped the mean BOD levels at different stations into five. The difference in means at Nilai and Kg. Simpang Balak was significantly higher ($p < 0.05$) than all other stations. The BOD at Kg. Jawa, Kg. Sg. Buah, and the Langat Dam were significantly lower ($p < 0.05$) than all other stations.

BOD levels in most parts of the Langat River are high. Pollution is attributed to organics discharged by industries, sewage treatment plants, and animal farms as the major causes of high BODs (DOE, 1997). Anaerobic conditions occur in some parts of the Langat Basin rivers and such areas will be unable to support aquatic life. Further deterioration of water quality will increase the adverse impacts on the health of the Langat Basin aquatic ecosystem.

Chemical Oxygen Demand

The average levels of COD obtained in the rivers of the Langat Basin ranged from 9.75 to 37.33 mg/l (Figure 132.5). The INWQS level for COD in Malaysian rivers is 50 mg/l. COD levels in rivers of the Langat Basin were within INWQS recommended levels for the support of aquatic

life. Concentrations of COD in surface waters can range from 20 mg/l or less in unpolluted waters to >200 mg/l in waters receiving effluents.

Differences in means between stations were highly significant ($p < 0.01$). Differences in means between sampling time and interactions between stations and time of sampling (Station * Time) were not significant ($p > 0.05$) (Table 132.2). Duncan’s multiple-range test grouped mean CODs at different stations into three. The mean difference at station Nilai was significantly higher ($p < 0.05$) than all other stations and at Langat Dam, Kg. Jawa, Labu, Kg. Sg.Buah, Kg. Sg. Serai, and Kg. Bukit Changgang mean CODs were significantly lower ($p < 0.05$) than all other stations.

Oil and Grease

The average level of O&G in the rivers of the Langat Basin ranged from 1.97 to 4.43 mg/l (Figure 132.8). The recommended INWQS level to support aquatic life for oil and grease in Malaysian rivers is no more than 0.04 mg/l. O&G levels in the Langat Basin rivers were all above the INWQS recommended level. A visible film of oil was often observed in some sections of the Langat River.

Differences in means between stations were highly significant ($p < 0.01$); differences between sampling times and interactions between stations and sampling times (Station * Time) were not significant ($p > 0.05$) (Table 132.2). Duncan’s multiple-range test grouped means at different stations into three. The means at Nilai station were significantly higher ($p < 0.05$) than all other stations and those at Kg. Rinching Hilir and the Semenyih Dam were significantly lower ($p < 0.05$) than all other stations.

In 1998, accidental spillage of diesel fuel into the river caused the closure of the 11th-mile Cheras water treatment plant (DOE, 1998; NST, 1998) as the level of O&G in raw water was higher than the maximum possible level for treatment.

The permissible level of O&G in water depends on the intended uses for the water. The recommended concentrations for drinking water supplies and fisheries protection are generally between 0.01 to 0.1 mg/l. Concentrations of crude oil greater than 0.3 mg/l can cause toxic effects in freshwater fish (Chapman, 1992). By these criteria the rivers of the Langat Basin are mostly unsuitable for the support of healthy aquatic life.

Figure 132.8 Oil and grease level at different stations along the rivers of the Langat Basin.

Figure 132.9 Total phenol level at different stations along the rivers of the Langat Basin.

Total Phenol

The average level of phenol in rivers of the Langat Basin ranged from 9.36 to 18.59 µg/l (Figure 132.9). The INWQS maximum level of phenol for Malaysian rivers to support aquatic life is 10 µg/l. Samples from three stations (Dengkil, Teluk Datuk, and Kg. Sg. Buah) were below this level, samples from all other stations exceeded the recommended INWQS level. Md. Pauzi Abdullah and Naiggolan (1990) also reported phenol levels in the Linggi River that exceeded the maximum level for raw river water recommended by the Ministry of Health, Malaysia.

Differences in means of phenol between stations and between sampling times were not significant ($p > 0.05$); interactions between stations and sampling times (Station * Time) were highly significant ($p < 0.01$) (Table 132.2).

The presence of phenol causes a marked deterioration in the organoleptic characteristics of water. Concentrations of phenols in unpolluted waters are usually less than 0.02 mg/l. However, toxic effects on fish can be observed at concentrations of 0.01 mg/l and higher.

Trace Metals

The average concentration of Pb, Cd, Fe, and Cu in water samples obtained from the Langat Basin rivers ranged from 0.074 to 0.100 mg/l, 0.016 to 0.032 mg/l, 0.82 to 4.87 mg/l, and 0.034 to 0.201 mg/l, respectively (Figures 132.10 through 132.12). The recommended INWQS maximum levels for Pb, Cd, Fe, and Cu for Malaysian rivers are 0.05, 0.01, 1, and 0.20 mg/l, respectively. The concentrations obtained for these elements from samples collected from all sampling stations exceeded the INWQS recommended levels.

The average level of Ni, Zn, As, Hg, and Al obtained from rivers in the Langat Basin ranged from 16.42 to 31.83 µg/l, 14.63 to 91.56 µg/l, 0.75 to 4.75 µg/l, 0 to 0.67 µg/l, and 0.14 to 0.24 mg/l,

Figure 132.10 Lead and cadmium levels at different stations along the rivers of the Langat Basin.

Figure 132.11 Iron level at different stations along the rivers of the Langat Basin.

Figure 132.12 Copper level at different stations along the rivers of the Langat Basin.

Figure 132.13 Nickel, cobalt, and zinc levels at different stations along the rivers of the Langat Basin.

Figure 132.14 Arsenic and mercury levels at different stations along the rivers of the Langat Basin.

Figure 132.15 Aluminum level at different stations along the rivers of the Langat Basin.

respectively (Figures 132.13 through 132.15). The INWQS maximum levels for Ni, Zn, As, Hg, and Al are 0.90, 5, 0.4, 0.004, and 0.50 mg/l, respectively. Thus, levels of all trace minerals in rivers of the Langat Basin were below the INWQS limits that support aquatic life in Malaysian rivers.

In addition to these findings, Cr was always below detection limit (0.07 ppm); the average Co level ranged from 12.08 to 19.75 ppb. The INWQS has not proposed any maximum levels for these elements. Co was monitored to detect potential discharge from high-tech industries.

Mean differences in Fe between stations and interactions between stations and sampling times (Station * Time) were highly significant ($p < 0.01$); sampling times were not significant ($p > 0.05$) (Table 132.2). Duncan's multiple-range test grouped the mean Fe at different locations into six. Mean iron levels at Teluk Datuk, Kg. Simpang Balak, Dengkil, Kg. Bukit Changgang, and Nilai were significantly higher ($p < 0.05$) than all other stations. The level of iron at the Langat Dam was significantly lower ($p < 0.05$) than all other stations.

Differences in mean of Zn between stations were highly significant ($p < 0.01$); sampling time interactions (Station * Time) were not significant ($p > 0.05$) (Table 132.2). Duncan's multiple-range test grouped mean Zn levels at different stations into three. The mean Zn levels at Teluk Datuk and Nilai stations were significantly higher ($p < 0.05$) than at all other stations; levels at the Langat Dam, Kg. Jawa, Kg. Sg. Serai, the Semenyih Dam, Kg. Rinching Hilir, and Kg. Sg. Buah stations were significantly lower ($p < 0.05$) than all other stations.

The interaction in Al between stations and sampling times (Station * Time) was highly significant ($p < 0.01$); differences between sampling times were not significant ($p > 0.05$) (Table 132.2). Duncan's multiple-range test grouped mean Al levels between stations into five. Duncan's test results indicated that the level of Al between the Semenyih Dam and other stations was significantly higher ($p < 0.05$). Aluminum levels at Teluk Datuk, West Country Estate, and Kg. Sg. Serai were significantly lower ($p < 0.05$) than all other stations.

The differences in means of Pb, Cd, Cu, Co, and Ni between stations and sampling times were not significant ($p > 0.05$) (Table 132.2). While the interactions (Station * Time) for Cd, Cu, and Co were not significant ($p > 0.05$), they were significant for Pb and Ni ($p < 0.01$ and $p < 0.05$, respectively). Some of the stations received industrial effluents in the morning and evening. If industries discharge effluent in the morning, this can lead to high Pb and Ni levels and in the afternoon, due to dilution, levels of Pb and Ni would be lower than in the morning. On the other hand, the high level of Pb and Ni measured in the afternoon at some stations may result from industries discharging their effluents in the afternoon. In addition, high afternoon temperature might raise the amount of Pb dissolved in the river and account for the high afternoon values.

Pollution by Pb, Cd, Fe, and Cu pose considerable health risks to aquatic organisms and organisms higher up the food chain, including humans. The Langat Basin must be considered badly polluted by these trace metals and steps must be taken to determine and eliminate the sources of this pollution.

Water Quality Index Values (WQI)

The calculated DOE-WQI values (Table 132.3 and Appendix 132.IV) for the main rivers in the Langat Basin suggest they would all be classified as polluted and belong to Class II to IV rivers. Of all sampling stations, four gave values that would place them in Class IV: Kg. Simpang Balak, West Country Estate, Nilai, and Teluk Datuk; five qualify as Class III: Kg Rinching Hilir, Kg Sg Buah, KLIA, Dengkil, and Bkt Changgang; the rest would be Class II.

Two water quality monitoring stations are located in Ecological Zone 1, the Langat Dam and Semenyih. Both stations are classified as Class II. Ecological Zone 2 has eight monitoring stations. Among them, three stations are classified as Class IV: Kg. Simpang Balak, West Country Estate, and Nilai; four stations are classified as Class II: Kg. Jawa, Kg. Sg. Serai, Kg. Rinching Hilir, and Labu; one station, Kg. Sg. Buah, is classified as Class III. Ecological Zone 3 has four monitoring

Table 132.3 Water Quality Classification of the Langat River Basin Based on DOE-WQI

Monitoring Station No.	Monitoring Station	Calculated WQI Value	Class
1	Langat Dam	83.45	II
2	Kg. Sg. Serai	80.80	II
3	Kg. Simpang Balak	40.03	IV
4	West Country Estate	48.78	IV
5	Dengkil	56.94	III
6	Kg. Bukit Changgang	57.64	III
7	Teluk Datuk	47.64	IV
8	Kg. Jawa	80.52	II
9	Semenyih Dam	80.33	II
10	Kg. Rinching Hilir	72.14	III
11	Kg. Sg. Buah	67.29	III
12	Labu	81.70	II
13	Nilai	48.91	IV
14	KLIA	60.98	III

Note: DOE-WQI value 91.76 = Class I; 75.37 = Class II; 51.68 = Class III, and 29.61 = Class IV.

stations with three classified as Class III: Dengkil, Bukit Changgang, and KLIA; one station, Teluk Datuk, is classified as Class IV.

HEALTH OF THE LANGAT BASIN RIVER ECOSYSTEM

There are many ways to assess the health of the Langat Basin river system and interpret what that means to the overall health of the basin ecosystem. The approach used in this study relied on the assessment of risk to aquatic life from pollutants in river water. The INWQS gives maximum values for a wide range of chemicals and parameters considered essential for the maintenance of healthy populations of aquatic life, suitability for drinking water, and water for irrigation. As the most-stringent standards are set for the maintenance of aquatic life, maximum levels for this functional category have been used as the basis for assessing the health of the rivers in the basin. Fundamentally, the health of the river ecosystem depends on the absence of pollution, as suggested by Ramade (1995). The concept of functional ecosystem thresholds was first proposed by Schaeffer and Cox (1992). Additionally, the rivers may be exposed to other degradations, such as the spilling of suspended matters or other disturbances impacting both the water column and sediments in the riverbed. Accordingly, a “healthy” aquatic ecosystem has to be devoid of such alterations (Ramade, 1995).

Minns et al. (1990) also used the risk factor approach in assessing aquatic ecosystem health. However, he argued for the incorporation of integrated modeling of ecosystem distress syndromes and the ecosystem’s counteractive capacity in assessing risks in order to obtain a better perspective of the health of aquatic ecosystems. Thus far, studies in the Langat Basin rivers have not reached a stage to enable adoption of this latter approach.

In general, the rivers of the Langat Basin are badly polluted and would not support the range of aquatic life expected if the river were pristine. High organic load, siltation, and the presence of ammoniacal-nitrogen, phosphate-phosphorus, oil and grease, phenol, iron, cadmium, lead, and copper at levels exceeding recommended values contribute to the poor state of many sections of the river.

Highly polluted (Class IV by the DOE river classification scheme) stretches occur along the Langat River in the mukim of Cheras between Kg. Sg. Serai, south to Kg. Simpang Balak, and on to the areas around West Country Estate. At these locations the river passes areas where most manufacturing industries and urban centers are located, and where population densities are high. This stretch of river between Bkt. Changgang and Teluk Datuk also qualifies as highly polluted

but the main contributory factors are the high levels of suspended sediments and low dissolved oxygen. The sediments originate from land that has been laid bare for future development, while low dissolved oxygen reflects a high level of decaying organic matter and possibly iron in the water column. Iron is rapidly oxidized in water, a process that consumes dissolved oxygen. The Batang Nilai River that flows into the Labu River is also highly polluted, owing to a high input of organic waste from domestic and urban sources, as well as waste from upstream industries. The largest industrial park in the Langat Basin is located around Nilai.

The particular sections of the rivers of the Langat Basin classified as Class IV rivers have probably lost their capacity to self-purify, as the level of pollutants they receive exceeds their assimilative capacity. Rivers polluted beyond their counteractive capacity will take a long time to recover naturally. River sections with a lower level of pollution must be prevented from degrading to a lower quality status.

Overall, the Langat Basin river ecosystem is not as “healthy” as it ought to be. Any further deterioration of the quality of its river water will adversely affect the health of the basin as a whole, as these rivers provide clean water for domestic, industrial, agricultural, and other uses, and habitats for the variety of life required to sustain natural processes, such as nutrient and biogeochemical cycles. Approaching basin-wide management of the environment and development from the framework of ecosystem health will enable a better grasp of the essential ecological processes that must be preserved to ensure both sustainability of the environment and development in the Langat Basin.

ACKNOWLEDGMENT

The work reported in this chapter was funded by the MATREM Project of UNEP/ROAP CP/5220-97-02/Rev.1 Research and Training for Measuring and Monitoring Ecosystem Health in a Large-Scale Ecosystem.

The Six River-Use Classifications as Defined by INWQS

River Class	Water Uses
I ^a	Conservation of natural environment Water Supply I: Practically no treatment necessary Fishery I: Very sensitive aquatic species
IIA ^b	Water Supply II: Conventional treatment required Fishery II: Sensitive aquatic species
IIB ^c	Recreational use with body contact Fishery II: Sensitive aquatic species
III ^d	Water Supply III: Extensive treatment required Fishery III: Common and tolerant species Livestock drinking
IV ^e	Irrigation
V ^f	None of the above

^a Class I represents water bodies of excellent quality. Standards are set for the conservation of natural environment in its undisturbed states. Water bodies in this category meet the most stringent requirements of human health and aquatic protection.

^b Class IIA represents water bodies of good water quality. Most existing raw water supply sources come under this category. Class IIA standards are set on the basis of the criteria developed for the protection of human health and sensitive aquatic species known to exist in these waters. In practice, no body-contact activity is allowed in these waters to prevent infection by pathogens.

^c Class IIB standard is based on criteria for recreational use and protection of sensitive aquatic species.

^d Class III is defined with the primary objective of protecting common and moderately tolerant aquatic species with economic value. Water under this classification may be used for water supply with extensive/advanced treatment. This class of water is also suitable for livestock drinking needs.

^e Class IV defines water quality required for major agricultural irrigation activities, which may not cover minor applications to sensitive crops.

^f Class V represents other waters which do not meet any of the above uses.

Best-Fit Equations for the Estimation of the Various Subindex Values of WQI

Subindex for DO (in % Saturation)	
SIDO = 0	for $x < 8$
SIDO = 100	for $x > 92$
$SIDO = -0.395 + 0.030x^2 - 0.00020x^3$	for $8 < x < 92$
Subindex for BOD	
$SIBOD = 100.4 - 4.23x$	for $x < 5$
$SIBOD = 108 * e^{-0.055x} - 0.1x$	for $x > 5$
Subindex for COD	
$SICOD = -1.33x + 99.1$	for $x < 20$
$SICOD = 103 * e^{-0.0157x} - 0.04x$	for $x > 20$
Subindex for AN	
$SIAN = 100.5 - 105x$	for $x < 0.3$
$SIAN = 94 * e^{-0.573x} - 5 * x - 2 $	for $0.3 < x < 4$
$SIAN = 0$	for $x > 4$
Subindex for SS

Forest Areas and Wildlife Diversity in the Langat Basin: Indicators for Assessing Langat Basin Ecosystem Health

Saiful Arif Abdullah

INTRODUCTION

The complex ecosystem of tropical rain forest, which is basically through trophic levels and food web, has contributed to extremely rich fauna and flora. However, the complexity of tropical rain forest around the world has been degraded, especially in the 20th century. In the early stage of the century the major contribution of forest loss in tropical areas was due to human population growth that increased demand on forest resources, especially for fuelwood. Since then, development activities have increased gradually and many forested areas in tropical regions are cleared and converted to agricultural areas, industrial estates, urbanization, and human settlements.

In Malaysia, loss of biodiversity is one of the major issues related to forest loss or degradation. This issue is among a main agenda that has been debated from local to international levels. It is notable that Malaysian tropical rain forest harbors a great diversity of species, including 300 species of mammals, 700 to 750 species of birds, 350 species of reptiles, 165 species of amphibians, and more than 300 species of freshwater fish (Anonymous, 1998).

The Langat Basin, which is situated adjacent to Klang Valley (the most urbanized region in Malaysia), is the most developing area in Malaysia. The basin has experienced intensification of forest conversion to agriculture, which began in the late 1960s (Wong, 1974). The situation began rapidly worsening in the late 1980s as more forested areas were converted into housing and industrial estates and were fragmented by infrastructure projects such as the development of highways. The basin was once totally covered by pristine forests, but with growing human population (Rospidah and Nordin, 2000) and development since the 19th century only 737 km² of forested areas remain (Nordin, this volume). Due to this, there has been a considerable reduction of wildlife habitat and diversity in the basin (Lim, 1997). Saiful and Nordin (2001) reported that the reduction of mammalian diversity was concomitant with depletion of forest cover in the basin. As a large-scale ecosystem, any further disruption or persistent forest clearance and fragmentation will adversely affect the ecosystem health of the basin.

The ecosystem health concept is a new paradigm in environmental management that integrates dimensions of social, economics, biophysical, and human health (Rapport, 1998). In Malaysia, a basic understanding of the concept of ecosystem health that may be applied to environmental management is still in infancy and being developed in the Langat Basin (Nordin and Azrina, 1998). In the ecosystem

health approach, a set of indicators is required as a tool for assessing the health of an ecosystem (Whitford, 1998). The changes of forest areas and wildlife diversity have been identified as indicators for assessing the health of the Langat Basin ecosystem. Those indicators are characteristics of spatial changes that are directly related to ecological services upon which the human community depends (Rapport, 1998). The purpose of this chapter is to present the changes of forested areas in the Langat Basin and the basin's relation to the number of wildlife diversity (with emphasis on mammalian species) and their conservation status. The importance of forested areas and wildlife diversity as indicators in the contexts of assessing ecosystem health of the Langat Basin are discussed.

TREND OF FOREST COVER CHANGES IN THE LANGAT BASIN

Over three decades, the total forested areas in the basin declined by approximately 27%. The reduction of forested areas in the basin occurred especially in Zones 2 and 3. The largest forested area in the basin is in Zone 1 (Figures 133.1 through 133.3). For each decade, secondary forest represented 50 to 70% of forested areas in the basin. The proportion of primary and secondary forests reduced gradually (Figure 133.4). In the period of 1971 to 1972, the proportion of primary forest cover in the basin was approximately 16% (467.6 km²) of the total land area, which consequently declined to 11% (324.2 km²) in the period of 1981 to 1982. By 1991 to 1992, only 8% (243.5 km²) of primary forest remained in the Langat Basin. The proportion of secondary forest in 1981 to 1982 increased by about 6% (676.9 km²) of the total area of the basin compared with 22% (636.9 km²) in 1971 to 1972. The proportion in 1991 to 1992, however, declined nearly 20% (560.3 km²).

The dipterocarp and peat-swamp and mangrove forests are the major types of forest that can be found in the basin. Dipterocarp forests (lowland and hill dipterocarps) are found only in Zone 1, whereas peat-swamp forest are mostly found in Zones 2 and 3 and mangrove are distributed on the coastal islands and margins of the mainland (Zone 3) (Figures 133.5, through 133.7). In three decades, dipterocarp forests remained the main type of forest cover in the basin, making up 40 to 55% of the total forest cover. The proportion of peat-swamp forest declined rapidly and by 1991 to 1992 constituted only 19% (149.4 km²) of the total forest type. The proportion of mangrove forests remained about the same from 1971 to 1982 (207.0 km²), but because of the rapid loss of peat-swamp forests had increased to 27% (215.5 km²) by 1992.

DIVERSITY OF MAMMALIAN SPECIES IN THE LANGAT BASIN

Mammalian species are vital to maintaining the quality, stability, and resilience of forest ecosystems. This group of animal can also provide an indication of the state of health of the ecosystem. Species richness and the number of threatened species are among the most common indicators for the status of biodiversity (Reid et al., 1993) and can provide insight into the health of particular ecosystems.

Based on surveys conducted in the 1950s to 1990s, a total of 140 mammal species from 28 families and 11 orders had been reported to exist in the Langat Basin (DWNP, 1996, and unpublished reports; Fletcher, 1999; Lim, 1997; Ruslan, 1984; Shabrina, 1987; Siti, 1983; Zubaid, 1993; Zubaid and Khairul, 1997). The total represents about 47% of mammal species that have been reported to exist in Malaysian tropical rain forest. The number of families and species for each order of mammals is shown in Figure 133.8.

Threatened Mammals in the Langat Basin

In Malaysia, mammals under threat are known by three sources, as perceived by various researchers, conservation status in Malaysia by the Department of Wildlife and National Parks (DWNP) Malaysia, and their conservation status by the International Union for the Conservation of Nature (IUCN).

Figure 133.8 Number of family and species for each order of mammal in the Langkat Basin.

Perceived by Various Researchers

Threatened species of mammals in the Langat Basin under this category were based from sources first compiled by Ratnam and co-workers (1991), and a second list by Bennet (1991). However, data by later sources were focused only on primate species.

Based on a list by Ratnam and co-workers (1991), 23 species of mammals (6 large and 17 small mammals) from 13 families in the Langat Basin are classified as threatened. Of these, 12 species, or 52%, are classified as likely to become threatened, 9 species are threatened, and 2 species are seriously threatened, whereas no species are classified as endangered. A total of eight species of primates from three families had been reported in the Langat. Based on the conservation status by Bennett (1991), only two species, *Trachypithecus cristatus* (silver-leafed monkey) and *Hylobates syndactylus*, are threatened. The former species is classified as an endangered species, whereas the latter falls into vulnerable species.

Conservation Status in Malaysia

Threatened species of mammals by DWNP Malaysia are divided into five categories: endangered, vulnerable, rare, insufficiently known, and indeterminate. The classification and definition for each category follows the IUCN. Of the total number species recorded, approximately 19%, or 27 species, of mammals in the Langat Basin are classified as threatened. Of these, 20 are small and 7 are large mammals. Table 133.1 shows that most threatened species are categorized as insufficiently known and rare while the rest are vulnerable. No species were classed endangered or indeterminate.

Conservation Status by the IUCN

Based on the IUCN 1994 Red List of threatened animals, a total of 14 species of mammals in the Langat Basin have been identified as threatened. Compared with conservation perceived by various researchers and conservation status in Malaysia, the number of large mammals (nine species) in the Langat Basin that fall into the list of threatened species is greater than small mammals species (four species). Of large mammals, two species (*Panthera tigris* and *Elephus maximus*) are classified as endangered, four are vulnerable (*Macaca nemestrina*, *Neofelis nebulosa*, *Capricornis sumatrensis*, and *Tapirus indicus*), and another three species (*Trachypithecus cristatus*, *Hylobates lar*, and *H. syndactylus*) are near threatened. Two (*Lutra perspicillata* and *Hystrix brachyura*) of four species of small mammals are vulnerable, whereas the other two species (*Macaca fascicularis* and *Manis javanicus*) are classified as near threatened.

IMPACT OF FOREST LOSS ON MAMMAL DIVERSITY IN THE LANGAT BASIN

Depletion of dipterocarp forests in Zone 1 has caused a drastic reduction of animal diversity and abundance in the Langat Basin (Lim, 1997). Several large mammals, such as tiger (*Panthera tigris*), Malayan sun bear (*Helarctos malayanus*), and serow (*Capricornis sumatrensis*) were encountered in a 1980s survey; however, they were not encountered in survey conducted in the 1990s by DWNP Malaysia (Lim, 1997). The Asian elephant (*Elephus maximus*) has not been encountered in the forest since surveys in the 1960s. These observations suggest that the quality of forest habitat in Zone 1 is being degraded and cannot maintain or support a viable population of these mammals.

The reduction of forest areas in Zones 2 and 3 was more intense than in Zone 1, making them more stressed than Zone 1. The forests in Zones 2 and 3 are being fragmented and, as isolated forests, will become too small to support those animals with low population densities that require a large home range (Terborgh 1992). Large animals usually occur in small numbers and require

Table 133.1 Number of Large and Small Mammals under Threat in the Langat Basin

Conservation Status ^a	Large Mammals	Small Mammals
Endangered	—	—
Vulnerable	2	1
Rare	5	6
Indeterminate	—	—
Insufficiently known	1	12
Total	8	19

^a Conservation status is based on categories by the International Union for the Conservation of Nature.

large areas for roaming (Payne, 1990). Thus, these isolated forests will also become too small to support viable populations of larger animals. Forest fragmentation may also affect the diversity and abundance of small mammals in the basin. Studies by Zubaid (1993) on bats in the basin suggest that continuous primary forest had significantly more species and individuals compared with fragmented secondary forest. Fragmentation will also increase risk of exposure to predators and hunting. According to Musa (1983), hunting is one of the major factors contributing to the decline of the wildlife population in Malaysia.

FOREST AREAS AND WILDLIFE DIVERSITY: INDICATORS FOR ASSESSING LANGAT BASIN ECOSYSTEM HEALTH

It is vital to evaluate the health of modified ecosystems such as the Langat Basin (Haila, 1998). One of the tools used to assess the health of an ecosystem is sets of indicators (Whitford, 1998). In the context of Langat Basin ecosystem, the changes of forest areas and the number of species and their conservation status are indicators that can be used.

Natural forests are the finest habitat not only for wildlife to maintain their populations and survive but they also provide ecological services vital for human existence. Destruction and fragmentation of forested areas will reduce the complexity of forest structure and habitat diversity, and affect the interaction between animals and plants. Several studies revealed that fragmentation has some effect on small mammals (Mortberg, 2001) and birds (Lindenmayer and Lacy, 2002). Destruction of forest areas will disrupt ecological processes such as nutrient cycling, energy flow, sequestration of toxic substances, and maintenance of the hydrological cycle. Dysfunction of these features is a characterization of the ecosystem distress syndrome (Rapport, 1998), which affects the biodiversity of forest ecosystem.

Forest areas in the Langat Basin are a habitat for various species of mammalian vertebrates. Several species of mammalian vertebrates are categorized as threatened species; thus they are potential indicators for assessing the Langat Basin ecosystem health.

However, it is also important to evaluate the risk of forest and biodiversity changes in determining the health of an ecosystem (Whitford, 1998). Forest clearance or destruction is mainly due to human activities. In a large-scale ecosystem such as the Langat Basin, we can say that forest is the most integral part in maintaining stability or equilibrium of the ecosystem. Forest degradation will increase the vulnerability of the basin to various geohazard incidents such as soil erosion, flash flood, and mud flood.

Destruction of forested areas will change the landscape composition (e.g., amount of habitat) and configuration (e.g., fragmentation) of the ecosystem. Forest is also a reservoir for various types of bacteria and virus, and several mammalian species are carriers of or hosts for some of them. Studies by Langlois and co-workers (2001) suggest that, when the forest landscape was changed, the transmission of disease (which is harmful to humans and domestic or farm animals) caused by virus accelerated. The bacteria or virus that transmits through air will easily spread; some will find

another host to maintain their life cycle, usually among insects or farm animals such as pigs. Due to this, human and domestic or farm animals will be more exposed to various diseases. When an outbreak occurs, it may cause loss of human life, and ultimately the social, economic, and environment of the Langat Basin large-scale ecosystem is affected as a whole.

CONCLUSION

Clearance of forest areas increases the heterogeneity of the forest landscape and the entire landscape of the Langat Basin. Ecologically, forest is a main element to maintain the equilibrium of some ecological process, such as hydrological cycle of the Langat Basin ecosystem. Thus, any disturbances or changes of forest landscape will affect the equilibrium of ecological processes and, in the context of large-scale ecosystem, the environmental health of the Langat Basin.

On a broader scale, healthy environment not only refers to environmental pollution (air or water pollution) but also to social, economic, biological, and human dimensions. Geohazard events such as siltation, flash flood, mud flood, and soil erosions, as well as disease outbreak, are mainly caused by forest loss or destruction. If measures are not taken, these will ultimately affect the social, economic, and human health of the basin. The direct effect of forest loss in the basin is reduction of wildlife (terrestrial and aquatic) habitat, which will reduce population and diversity. This is another indication of distress syndrome that has occurred in the basin. In conclusion, changes of forest areas and wildlife diversity are vital components of indicators for assessing Langat Basin ecosystem health.

ACKNOWLEDGMENT

This chapter is based on my study, which was funded by UNEP/ROAP under the MATREM project CP/5220-97-02/Rev. 1, Research and Training for Measuring and Monitoring Ecosystem Health in a Large-Scale Ecosystem. I would like to thank Prof. Mohd Nordin Hj. Hasan, Senior Fellow of LESTARI, for his valuable comments.

SECTION III.6

Pollution: MTBE

Overview: Environmental Impacts of a Motor Fuel Additive: Methyl Tertiary Butyl Ether (MTBE)

Daniel P.Y. Chang

The introduction of a chemical into widely used consumer products such as gasoline can lead to the rapid dispersal of the chemical into the environment. The data provided by the U.S. Geological Survey's National Water Quality Assessment (USGS-NAQWA) program, as presented in the work by Moran and co-workers, illustrate how widespread the contaminant methyl tertiary butyl ether (MTBE) has become in U.S. groundwaters. Although we have benefited from the historical lessons of DDT, leaded gasoline, and the appearance of halogenated dioxins and PCBs throughout the global environment, the relatively recent introduction of MTBE into gasoline and its rapid appearance in the environment caught U.S. regulatory agencies by surprise.

At the time MTBE was adopted for use in reformulated gasoline (RFG), it contributed to the reduction of air pollution and resulted in substantial air quality and health benefits — e.g., reduction of benzene in gasoline, reduction of CO emissions, and to a lesser extent, reduction of reactive volatile organic carbon (VOCs), which are ozone precursors. A review of its potential health effects was undertaken, but as a result of its relatively benign acute toxicity in various environmental media, its introduction into gasoline as an additive was not prevented. A reexamination of the means by which regulatory agencies approve the introduction of chemicals into commerce seemed warranted in light of MTBE's now-apparent harmful effects. One purpose of the session was to examine MTBE as a case study of the potential for adverse impacts on ecosystem health, within the context of the relatively comprehensive review process applied in the U.S.

During the companion panel discussion that followed the session, participants achieved consensus in determining the continuing need for screening methods for chemicals that take into account multimedia fate and transport. However, when applied, *those screening procedures must be supplemented by multidisciplinary "expert" review*. As an example, Morgenroth and Arvin discuss recent German experience in their review of MTBE use in Europe. The German review process would find use of MTBE acceptable, even today, because the procedures applied show that it eventually returns to the atmosphere where it is destroyed, while when it is in the aquatic environment its expected levels did not lead to significant environmental impacts. Nevertheless, panelists and investigators were uncertain whether the German people will regard the benefits of continued use of MTBE as sufficient to justify acceptance of low levels of contaminants in their water supplies.

When significant health or environmental toxicity is not demonstrated or does not arouse public concern, chemicals in the current regulatory environment can fall through the cracks. MTBE,

associated largely with aesthetic, “taste and odor” objections despite its economic importance, poses uncertain chronic risks but is not believed to be related to acute health problems. When it was introduced, MTBE was known as a compound that would compromise water quality in the interest of improving air quality. Because the degree of water quality impacts is better understood now, other states and nations considering that trade-off should benefit from the lessons learned in the U.S. As a toxicant, MTBE pales compared to the ecosystem health concerns discussed at this Congress. Nevertheless, study of its regulations provides valuable lessons to improve the process. *Nonhealth-based standards must be considered when reviewing new chemicals; if they are not, the process of evaluation may be much less comprehensive.*

Many of our environmental regulatory agencies have been established along single media lines and — to confuse jurisdictional issues even more — defined by the type of activity, such as solid waste or pesticide regulation. These agencies have been sensitized to the need for multimedia review and improved communication among themselves. Other consumer product reformulations in paints and coatings are being enacted, along with significant changes in the biotechnology and electronic industries. *Ideally, environmental protection agencies would one day become truly multidisciplinary in their thought processes at both the scientific and policy levels.*

In the short term, gasoline will continue to be used worldwide as a motor vehicle fuel. Its constituents and the by-products of its combustion will be present for some time to come. Other countries will be faced with determining the point at which MTBE’s drawbacks outweigh its benefits as discussed by Keller and Fernandez in weighing the costs and benefits in California compared to alternative reformulated gasolines. The short-term answer to the Congress forum question “Environmental Pollutants: Must We Live with Them?” is yes. Nevertheless, the crux of the problem for society boils down to doing a better job of managing chemical introduction and use, particularly in transportation fuels as pervasive as gasoline and in other widely used consumer products, e.g., in electronics and pharmaceuticals.

In retrospect, we can take some consolation that a monitoring network not originally targeted for MTBE, i.e., the USGS NAQWA program, alerted us to its widespread appearance. The current regulatory system in the U.S. responded to the discovery of MTBE in drinking water wells, albeit belatedly. *Monitoring capabilities and means to act upon those data effectively are important if we are to minimize long-term damage to ecosystem health.* We hope that these insights and recommendations will continue to improve our ability to manage chemical introduction and use in our environment, and will serve as a valuable case study for others.

MTBE in Groundwater of the U.S.: Occurrence, Potential Sources, and Long-Range Transport

Michael J. Moran, John S. Zogorski, and Paul J. Squillace

INTRODUCTION

Groundwater is an important and valuable resource in the U.S. To some extent, groundwater is used in all 50 states to provide drinking water. In 1995, more than 50% of the population, more than 130 million people, relied on groundwater for drinking water supplies (Solley et al., 1998). About 30%, or 42 million, of these people obtained their water from privately owned wells (U.S. Geological Survey [USGS], 1999). The remaining 90 million people relied on groundwater from public water suppliers for their drinking water.

The gasoline additive methyl *tert*-butyl ether (MTBE) has been frequently detected in ambient groundwater in areas of the U.S. that use substantial amounts of the compound as a fuel oxygenate. Some of this water is used for domestic and public water supplies. MTBE in groundwater has been associated with taste and odor concerns and potential human-health effects.

The primary purpose of this chapter is to summarize current information on the occurrence and distribution of MTBE in groundwater. Information is also presented on the sources and transport of MTBE to groundwater. Data from the USGS's National Water-Quality Assessment (NAWQA) Program (Gilliom et al., 1995), as well as data from other sources, are summarized to describe: (1) the occurrence and distribution of low concentrations of MTBE in ambient groundwater, (2) the effects of high concentrations of MTBE in groundwater used for domestic and public supplies, (3) the potential sources of MTBE, and (4) the long-range transport of MTBE in groundwater.

BACKGROUND ON MTBE

Compounds that contain oxygen, referred to as oxygenates, are added to gasoline in some areas of the U.S. to reduce ozone formation and carbon monoxide emissions and to enhance the octane level in gasoline. Octane enhancement began in the late 1970s with the phase-out of tetraethyl lead from gasoline. The use of oxygenates was expanded due to enactment of the Clean Air Act (CAA) Amendments of 1990, which required that oxygen be added to gasoline in areas where concentrations of ozone in the summer are most severe or where concentrations of carbon monoxide in the winter exceed air-quality standards. The CAA Amendments mandate that gasoline must contain at

least 2% oxygen by weight in ozone nonattainment areas and at least 2.7% oxygen by weight in carbon monoxide nonattainment areas (USEPA [U.S. Environmental Protection Agency], 1990).

A number of ether and alcohol compounds have been used as oxygenates in commercial applications or in pilot programs (Zogorski et al., 1997). Although the CAA Amendments do not specify which oxygenate must be added to gasoline, the one used most commonly today is MTBE. The second most frequently used oxygenate is ethanol. Under the mandates of the CAA Amendments, two programs of oxygenate use were established: (1) the Oxygenated Fuels Program (OXY) in which 15% MTBE by volume is added for wintertime use in carbon monoxide nonattainment areas, and (2) the Reformulated Gasoline Program (RFG) in which 11% MTBE by volume is added for year-round use in severe ozone nonattainment areas. Most RFG areas use MTBE whereas most OXY areas do not use MTBE in favor of another oxygenate (typically ethanol).

In general, MTBE is preferred over other oxygenates because of its low cost, ease of production, high octane level, lower evaporative emissions in gasoline, and favorable transfer and blending characteristics (Zogorski et al., 1997). Annual production of MTBE has increased from 0.26 billion l/year in 1980 (Chemical Manufacturers Association, 1997) to 11.9 billion l in 1998 (Department of Energy, 1998) (Figure 135.1). The production of MTBE was the fourth largest of all chemicals produced in 1996 (Chemical Manufacturers Association, 1997).

The large-scale production and use of MTBE and its physical and chemical properties have resulted in its detection in many groundwater systems (Squillace et al., 1996; Zogorski et al., 1998). MTBE is highly soluble in water, does not substantially partition to organic carbon in aquifer material, and biodegrades slowly (Squillace et al., 1997; Zogorski et al., 1998). In water at 25°C, MTBE has a solubility of about 5000 mg/l for a gasoline that is 10% MTBE by weight (Squillace et al., 1997). In a sand aquifer with moderate organic carbon content (0.1%), only 8% of the total mass of MTBE will be sorbed to the organic matter whereas 92% remains in solution. By contrast, 39% of the total mass of benzene and 72% of the total mass of ethylbenzene will be sorbed to the organic matter. The high water solubility and low sorption of MTBE allow dissolved plumes of the compound to migrate farther and faster than other common gasoline components such as benzene, toluene, and ethylbenzene in aquifers with moderate to high organic carbon content. The longer travel distances for MTBE can result in an increased probability that it will be detected in a drinking water well.

Figure 135.1 Estimated annual production of MTBE in the U.S. from four sources, 1980 to 1998.

Although rates of biodegradation of MTBE may be high in aerobic aquifer systems (Borden et al., 1997; Schirmer and Butler, 1998; Schirmer and Barker, 1998) or in microbial cultures or biofilters (Eweis et al., 1998; Salanitro et al., 1994; Steffan et al., 1997), most studies indicate relatively slow rates of MTBE removal under the anaerobic conditions that are common to most gasoline releases (Suffita and Mormille, 1993; Yeh and Novak, 1994). Biodegradation rate constants for MTBE are estimated to be several orders of magnitude lower than for other gasoline components such as benzene and toluene (Baehr et al., 1999). Lower biodegradation rates mean that MTBE can persist longer in groundwater and can be transported farther and deeper in an aquifer. In addition, a potential biodegradation product for MTBE is *tert*-butyl alcohol (TBA) (Hyman et al., 1998; Landmeyer et al., 1998), which itself has a relatively long removal time under anaerobic conditions (Suffita and Mormille, 1993; Yeh and Novak, 1994).

MTBE is a concern in drinking water because of its low taste and odor thresholds and its potential human-health effects. The USEPA has issued a drinking water advisory to address taste and odor concerns and recommends a range of 20 to 40 $\mu\text{g/l}$ as a limit to help prevent these organoleptic effects (USEPA, 1997). The USEPA advisory concentration range for MTBE is also thought to provide a safety margin for potential carcinogenic effects and to provide a large margin of safety for noncancer effects (USEPA, 1997). The USEPA has tentatively classified MTBE as a Group C possible human carcinogen (USEPA, 1996). The USEPA defines the carcinogenic potential of a Group C carcinogen as "limited evidence from animal studies and inadequate or no data for humans" (USEPA, 1996).

OCCURRENCE AND DISTRIBUTION OF LOW CONCENTRATIONS OF MTBE IN AMBIENT GROUNDWATER

Groundwater samples were collected from wells that are part of NAWQA Program monitoring networks designed to define ambient water quality in aquifers or parts of aquifers. The wells sampled provide water for a wide range of uses including domestic, monitoring, public supply, irrigation, livestock, and commercial. Ambient refers to groundwater that is not associated with known point-source releases. Table 135.1 lists the frequency of MTBE occurrence at concentrations $\geq 0.2 \mu\text{g/l}$ in water from wells sampled by the NAWQA Program from 1993 to 1998. A minimum concentration of $0.2 \mu\text{g/l}$ was selected for reporting concentrations in this table because most samples were analyzed at a laboratory with a censoring level for MTBE of $0.2 \mu\text{g/l}$; some samples, however, had detectable concentrations less than $0.2 \mu\text{g/l}$.

For all wells sampled, about 5% had detectable concentrations of MTBE greater than $0.2 \mu\text{g/l}$. The concentrations of most detections of MTBE were in the range of 0.2 to $20 \mu\text{g/l}$ with a frequency of detection of these low concentrations of about 5%. Only 0.4% of the detected concentrations were higher than $20 \mu\text{g/l}$. Of the samples in which high concentrations were detected, only one was from a well used for drinking.

Table 135.1 MTBE Detections in Ambient Groundwater^a

Concentration ($\mu\text{g/l}$)	Frequency (%)	Number of Wells
<0.2 ^b	94.7	2598
0.2–20	4.9	133
>20	0.4	12
Total	100	2743

^a USGS NAWQA data, 1993–1998; all water-use categories; concentrations $\geq 0.2 \mu\text{g/l}$. Some information is based on provisional USGS data.

^b These generally represent nondetections; however, data from some samples had detectable concentrations less than $0.2 \mu\text{g/l}$.

Table 135.2 Detection of MTBE in Ambient Groundwater in Areas for MTBE Use and Population Density^a

MTBE Use Areas	MTBE Detected in Groundwater? (No. of Wells)		Frequency of Detection (%)
	Yes	No	
Substantial Use Area^b			
Urban areas ^c	49	135	27
Rural areas ^d	50	246	17
All areas	99	381	21
Nonsubstantial Use Area^e			
Urban areas ^c	14	284	5
Rural areas ^d	32	1933	2
All areas	46	2217	2

^a USGS NAWQA data, 1993 to 1998; all water-use categories; concentration $\geq 0.2 \mu\text{g/l}$. Some information is based on provisional USGS data.

^b Substantial use areas are defined as RFG/OXY areas where the median annual MTBE content in gasoline is $>5\%$ by volume.

^c Urban areas are defined as areas with a population density of ≥ 386 persons per km^2 .

^d Rural areas are defined as areas with a population density of < 386 persons per km^2 .

^e Nonsubstantial use areas are defined as any areas where the median annual MTBE content in gasoline is $\leq 5\%$ by volume.

Low concentrations of MTBE were detected frequently in ambient groundwater in areas that use substantial amounts of MTBE. These include RFG or OXY areas where the median annual MTBE content in gasoline is $>5\%$ by volume. Areas that do not use substantial amounts of MTBE are defined here as any areas in which the median annual MTBE content in gasoline is $\leq 5\%$ by volume. Most areas in this designation use considerably less than 5% MTBE in gasoline. The differentiation of these MTBE use areas is based on currently available information and does not indicate a definitive knowledge of the precise amount of MTBE usage in all designated areas. Table 135.2 lists MTBE detection frequencies in groundwater for areas of MTBE use and population density. This table shows that the distribution of MTBE detections is primarily a function of the use of MTBE but is also related to population density. Urban areas are defined as areas with a population density of ≥ 1000 persons per mi^2 (386 persons per km^2) and rural areas are defined as areas with a population density of < 1000 persons per mi^2 (386 persons per km^2) (Hitt, 1994).

For urban areas, the frequency of detection of MTBE in groundwater in areas of substantial MTBE use was about 27% , whereas the frequency of detection in other areas was about 5% . In rural areas, the frequency of detection of MTBE in areas of substantial MTBE use was about 17% , whereas the frequency of detection in other areas was about 2% . Regardless of population density, the frequency of detection of MTBE in areas of substantial MTBE use was about 21% compared to a frequency of detection of about 2% in other areas. Therefore, being located within an area of substantial MTBE use gives an increased probability of detecting MTBE in groundwater without controlling for any other variables. The relative differences in MTBE detection between areas of substantial MTBE use and other areas are greater than the relative differences in MTBE detection between urban and rural areas (Figure 135.2). In other words, the use of MTBE is a more important factor in determining the likelihood of detecting MTBE in groundwater than is population density.

In addition to differences in frequency of detection between areas of substantial MTBE use and other areas, the question arises as to whether MTBE concentrations differ between the two areas. Figure 135.3 illustrates the frequency of detection of MTBE for selected concentrations for both types of usage. As seen in Figure 135.3, the differences between the frequency of detection of MTBE in different use areas are quite pronounced regardless of the concentration. For each concentration, the frequency of occurrence of MTBE is higher in substantial use areas

Figure 135.2 Frequency of detection of MTBE in ambient groundwater for MTBE use areas and population density, 1993 to 1998.

Figure 135.3 Frequency of detection of MTBE in ambient groundwater in for selected MTBE concentrations, 1993 to 1998.

compared to other areas. The differences in frequency of detection are pronounced at higher MTBE concentrations.

MTBE has been detected at low concentrations in groundwater from public water supply wells throughout the U.S. Of 216 public water supply wells that the NAWQA Program sampled from 1993 to 1998, 15 (6.9%) had detectable concentrations of MTBE without regard to a minimum concentration (based on some provisional USGS data). All of the concentrations were less than 2.0 µg/l and the median was 0.14 µg/l. Table 135.3 lists examples of other instances in which MTBE was detected in public water supplies. The data referred to in Table 135.3 are from a variety of sources outside the USGS and point out the widespread detection of low concentrations of MTBE in groundwater used for drinking water.

HIGH CONCENTRATIONS OF MTBE IN SOME DOMESTIC AND PUBLIC WATER SUPPLIES

High concentrations of MTBE have been reported in groundwater used for some domestic and public water supplies. A number of public water supply systems in Illinois, Texas, and California

Table 135.3 MTBE in Public Water Supplies in the U.S.

Source of Data	Number of Public Water Supply Systems/Wells/Sources with MTBE
Hitzig et al., 1998	251 to 422 wells in 19 states ^a
Zogorski et al., 1997	51 public water systems in 6 of 7 states that provided information ^a
State of Maine, 1998	125 public water-supply systems (16% of tested supplies) ^{a,b}
California Department of Health Services, 1999 ^c	48 sources (0.9% of sources) ^a

^a Most concentrations were less than 20 µg/l.

^b All concentrations were less than 35 µg/l.

^c Monitoring is continuing and number of sources with MTBE may change.

have reported groundwater sources with concentrations of MTBE greater than 20 µg/l (California Department of Health Services, 1999; Zogorski et al., 1997). In most of these cases, treatment of the water was necessary or the wells had to be removed from service. Figure 135.4 illustrates the number of domestic wells, by state, that may have been affected by releases from leaking underground storage tank (LUST) sites. The data in this figure come from a survey completed by the University of Massachusetts in 1998 (Hitzig et al., 1998). The survey queried state LUST programs on the effect of MTBE releases from LUST sites. The concentrations of MTBE in water from these domestic wells are not known; in the vicinity of a LUST site release, however, concentrations can easily exceed 20 µg/l and can be in excess of 1000 µg/l (Buxton et al., 1997; Happel et al., 1998).

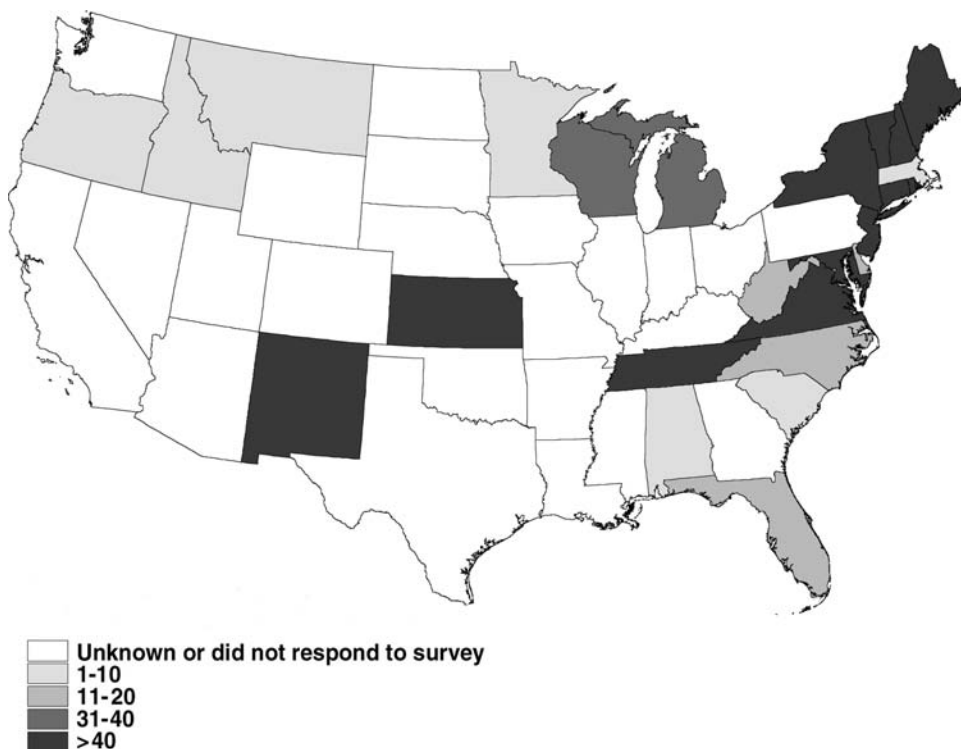

Figure 135.4 Number of domestic wells with detectable MTBE concentrations possibly from LUST site sources. (From Hitzig, R. et al., *Soil Groundwater Cleanup*, August/September, 15–19, 1998. With permission.)

Nationwide data on the occurrence of MTBE in groundwater used for public water supplies are currently not available. The USGS, the Metropolitan Water District of Southern California, and the Oregon Graduate Institute, in conjunction with the American Water Works Association Research Foundation, have initiated a study of MTBE and other volatile organic compounds in raw, untreated ground and surface waters that are sources of drinking water for public supplies. The survey covers the entire U.S. and will focus on groundwater sources serving systems of all sizes (Koch, B., personal communication, 1998).

Additional investigations on the quality of water used for public water supplies are being conducted by the USGS and the USEPA, and include an analysis of MTBE data from wells in 12 states of the northeastern U.S. This additional work consists of two phases: (1) an assessment of existing data on MTBE in finished (treated) water for more than 2000 public water systems, most of which use groundwater as a source; and (2) an assessment of existing data on MTBE in ambient groundwater of the region. The data will be related to land-use patterns, population density, locations of known point-source MTBE releases, and other anthropogenic factors to determine possible sources and transport mechanisms of MTBE in groundwater (Grady, S., personal communication, 1999).

Public water supplies in most states are currently not required to be monitored for MTBE because it is not a regulated chemical; however, regulations by the USEPA place MTBE under the Unregulated Contaminant Monitoring Regulation (UCMR). The regulation requires all large public supplies and some small public supplies to analyze finished (treated) water for MTBE and report the results to the USEPA. These analyses will provide additional information on the occurrence of MTBE in public water systems.

Because domestic wells are not regulated by the USEPA, owners are not required to analyze for MTBE. On the basis of a domestic well survey, the State of Maine estimated that water from 2200 to 6900 domestic wells in Maine may have MTBE concentrations greater than the lower limit of USEPA’s drinking water advisory (State of Maine, 1998).

POTENTIAL SOURCES OF MTBE

A variety of point and nonpoint sources may be responsible for the occurrence of MTBE in groundwater (Table 135.4). For point sources, the 1995 Toxic Release Inventory estimated that 1.7 million kg of MTBE were released into the environment from production sources (USEPA, 1998). Of these releases, 97% went to air and <3% went to surface water. Mobile sources, such as automobiles, are estimated to have released 40 million kg of MTBE to the air of the U.S. in 1996 (USEPA, 1998).

No estimates were available for total releases of MTBE to groundwater from underground storage tanks. Since 1988, however, 330,000 point-source releases from LUST sites have been reported to the USEPA Office of Underground Storage Tanks (USEPA, 1998). It is estimated that 100,000 additional releases will be reported in the future as existing systems are upgraded, closed, or replaced (USEPA, 1998). Some of these future releases may be gasoline containing MTBE.

Table 135.4 Potential Point and Nonpoint Sources of MTBE in Groundwater

Point Sources	Nonpoint Sources
Refineries	Vehicle emissions
Pipelines	Vehicle evaporative losses
Storage tanks (above or belowground)	Atmospheric deposition
Accidental spillage	Urban runoff
Homeowner disposal	
Spillage during fueling	
Fueling evaporative losses	

Although it is difficult to estimate the mass of MTBE released from LUST sites, it is believed that these sources contribute significantly more of the total MTBE mass to the environment than either production or mobile sources.

Releases from LUST sites have affected public water supply wells in different areas of the U.S. (Hitzig et al., 1998). According to a national LUST survey, it was estimated that 65 public supply wells in New Jersey have been affected by MTBE released from LUST sites. In New Hampshire and Vermont, between 31 and 40 public supply wells were estimated to have been affected by MTBE released from LUST sites, and between 21 and 30 public supply wells have been affected in Kansas, Massachusetts, and New Mexico (Hitzig, R., personal communication, 1998).

In some instances, high concentrations of MTBE from point sources have even caused the closure of public supply wells. One well-known example is the city of Santa Monica, CA. In 1997, the city ceased pumping groundwater from two wellfields due to persistent and increasing concentrations of MTBE (Brown et al., 1997). This loss accounted for 50% of the Santa Monica's total drinking water supply. Concentrations of MTBE in water from wells in the two wellfields ranged from 8.2 to 610 $\mu\text{g/l}$. A number of LUST sites and underground petroleum pipelines were identified as potential point sources of the MTBE (Brown et al., 1997).

Concentrations of MTBE may have a hierarchy associated with different potential sources. Figure 135.5 illustrates three ranges of MTBE concentrations and the associated potential sources. The y-axis represents the detection frequency of MTBE in groundwater sampled by the NAWQA Program for the selected concentration ranges.

Concentrations greater than 20 $\mu\text{g/l}$ are generally thought to be associated with point-source releases because it would be unusual for nonpoint sources to cause such high concentrations in groundwater. However, concentrations of MTBE higher than 20 $\mu\text{g/l}$ could be associated with certain high-concentration nonpoint sources. For example, on the basis of partitioning theory and air-quality monitoring, if atmospheric concentrations of MTBE are systematically higher in some local areas such as a parking garage, atmospheric deposition could result in concentrations of MTBE in precipitation and groundwater that are >20 $\mu\text{g/l}$ (Zogorski et al., 1997). Likewise, low concentrations (≤ 20 $\mu\text{g/l}$) could be associated with point sources, such as at the leading edge of a groundwater plume.

In some cases, a potential nonpoint source for MTBE has been identified. Using colocated shallow groundwater and atmospheric concentration data, it has been shown that deposition of MTBE from the atmosphere is one of several possible sources for low concentrations of MTBE in shallow groundwater. Under conditions in which biodegradation is very slow, the source of low concentrations of MTBE in groundwater could be atmospheric deposition (Baehr et al., 1999).

Figure 135.5 Frequency of detection of MTBE in ambient groundwater for selected concentration ranges and associated potential sources, 1993 to 1998.

LONG-RANGE TRANSPORT OF MTBE

At some gasoline release sites, MTBE has migrated much farther than other common gasoline components. In these situations, treatment may be required if the long-range transport of MTBE threatens or affects a drinking water well. Table 135.5 lists some examples of instances in which MTBE has migrated farther than the common gasoline components benzene, toluene, ethylbenzene, and xylenes (BTEX). These observations are consistent with the physical and chemical properties of MTBE that allow it, under certain conditions, to be transported farther than other common gasoline components.

An example of long-range transport of MTBE is the release at the Port Hueneme naval facility in California. Between September 1984 and March 1985, approximately 15,000 l of regular gasoline and 26,000 l of premium unleaded gasoline were released from fuel-delivery lines at the Naval Exchange gasoline station (Kram and Lory, 1998). The exact percentage of MTBE in the released gasoline is not known but is estimated to have ranged between 6 and 11% by volume. The plume of dissolved MTBE occurs in a semiperched aquifer at a depth of about 3 to 6 m below the ground surface, has traveled more than 1300 m, and covers 0.157 km². In addition, the MTBE plume has extended far beyond the BTEX plume that traveled approximately 390 m (Kram and Lory, 1998). It is unknown if the MTBE plume at Port Hueneme has affected any domestic or public water supply wells such that treatment would be required; however, this site illustrates the occurrence of long-range MTBE transport.

In some instances, treatment of MTBE in drinking water supplies has been required even though only a small volume of MTBE was released and it did not migrate a great distance. In December 1997, an example of this occurred in Standish, ME, when a vehicle overturned and lost most of the gasoline from its tank. The gasoline was probably reformulated gasoline containing about 11% MTBE. It was estimated that 26 to 57 l spilled onto the soil (Hunter, B., personal communication, 1998). In May 1998, a Standish resident close to the accident site called the Maine Department of Environmental Protection and complained of a bad odor in his water. Subsequent groundwater sampling in the area revealed that more than 20 domestic wells had detectable concentrations of MTBE. Although the exact area of groundwater that was affected by this spill is unknown, it is estimated to be less than 1 km².

At one point, water samples from 11 wells had concentrations of MTBE greater than the Maine action level of 35 µg/l, and some of the concentrations exceeded 100 µg/l. No common gasoline hydrocarbons such as BTEX were detected in any of the samples analyzed. Point-of-use treatment of water from wells with concentrations of MTBE exceeding 100 µg/l was performed until affected homes were connected to a public water supply. A granular activated carbon system was used at a cost of about \$1600 per year per home (Hunter, B., personal communication, 1998).

SUMMARY

The gasoline additive methyl *tert*-butyl ether (MTBE) has been detected in low concentrations (≤20 µg/l) in ambient groundwater in some areas of the U.S. Some of these occurrences are in

water from wells that are used for domestic and public water supplies. High concentrations (>20 µg/l) of MTBE also have been detected in ambient groundwater, some of which is used for domestic and public water supplies. In some cases, treatment of the water has been necessary for MTBE removal or the wells had to be taken out of service.

The occurrence of MTBE in groundwater is strongly related to the use of MTBE in gasoline. The probability that MTBE will be detected in ambient groundwater is much higher in areas that use substantial amounts of the compound (>5% by volume in gasoline) compared to other areas (≤5% by volume in gasoline). Urban areas are also more likely than rural areas to have detectable concentrations of MTBE in groundwater.

Low concentrations of MTBE may have point or nonpoint sources. The origin of high concentrations is likely some type of point source; however, some nonpoint sources can result in relatively high concentrations of MTBE in groundwater. At some sites, MTBE has migrated much farther than other common gasoline components and those long distances increase the probability that MTBE will be detected in a drinking water well and that treatment may be required.

Data from the NAWQA Program provide insight into the quality of ambient groundwater resources with respect to the occurrence of MTBE. Information from other sources has also helped to reveal the extent and scope of this water-quality issue and to document various sources of MTBE in groundwater. Additional work by the USGS, the USEPA, and others will provide a more detailed and complete understanding of the occurrence of this compound in groundwater resources.

The European Perspective of MTBE as an Oxygenate in Fuels

Eberhard Morgenroth and Erik Arvin

INTRODUCTION

In Europe, methyl *tert*-butyl ether (MTBE) has developed into an important organic, high-production-volume chemical since its introduction into gasolines in the late 1970s and mid-1980s. MTBE was introduced as an octane booster to replace leaded compounds that had to be reduced in gasolines at that time. Unlike in Europe, MTBE is used to a greater extent in the U.S. because the 1990 Clean Air Act Amendments require fuel oxygenates, such as MTBE or ethanol, to be added to gasoline used in some metropolitan areas to reduce atmospheric concentrations of carbon monoxide (CO) or ozone (O₃). However, recent reports on drinking water contaminations in the U.S. (Squillace et al., 1996; Reuter et al., 1998) have raised concerns whether those compounds that help reduce air pollution may, on the other hand, result in severe problems as a groundwater pollutant. Alarmed by the discussion in the U.S., European environmental protection agencies are reviewing their position on MTBE, and new measurement campaigns are currently being initiated. In this chapter, environmental data and policies toward MTBE are reviewed for a number of European countries and are compared to the situation in the U.S.

MTBE IN THE ENVIRONMENT

MTBE is a volatile, flammable, colorless ether, which is miscible in gasoline. It has a relatively high vapor pressure (33,000 Pa at 25°C), a high water solubility (23 to 54 g/l at 25°C), and a low octanol/water partition coefficient ($\log K_{OW} = 0.9$ to 1.2) (Squillace et al., 1996). Reported dimensionless Henry's law constants vary from 0.0069 to 0.0242 for temperatures ranging from 10 to 25°C, respectively (Rippen, 1999). In gasolines, MTBE is the preferred fuel oxygenate because of its low cost, ease of production, and favorable transfer and blending characteristics. MTBE released into the environment can be found in air, soils, and water, but major environmental concerns are related to the contamination of groundwater. For different media, accumulation and degradation of MTBE in the environment are significantly different:

- *Atmosphere.* MTBE is released into the atmosphere from incomplete combustion in cars and during refueling. In addition, MTBE will evaporate into the atmosphere from accidental spills and during the manufacturing process.
- *Surface water.* In surface waters that are used for recreational purposes, watercraft exhausts have been identified as the major source of MTBE. Two-stroke engine, personal watercraft such as jet skis release approximately 25% of their fuel directly into the water, unburned (McCord and Schladow, 1998). In addition, MTBE can be transported into surface waters through direct diffusion from the atmosphere, through rain, stormwater runoff, and with groundwater.
- *Soil and groundwater.* Major sources of MTBE in groundwater, when it occurs at relatively high concentrations ($\mu\text{g/l}$ to mg/l), are leaking gasoline storage tanks with connecting piping (Squillace et al., 1996). Exchange of MTBE between atmosphere and groundwater through direct diffusion or rain is only a minor source of MTBE that can be expected solely for shallow groundwaters (Pankow et al., 1997). However, those widespread occurrences of MTBE in groundwater resources in low concentrations (around the detection limit of $0.1 \mu\text{g/l}$; e.g., Miljøstyrelsen, 1998) can raise concerns of decision makers and the public.

Degradation. Different mechanisms lead to a removal of MTBE from the environmental compartments. In the atmosphere, MTBE is removed through photochemical degradation at rates of 3 d^{-1} (Squillace et al., 1997). In soil and groundwater environments, reports on biological degradation of MTBE range from very slow degradation to no detectable biological degradation at all (Landmeyer et al., 1998; Squillace et al., 1997). In one field study, higher degradation rates were observed (0 to 0.001 d^{-1} first-order degradation rate; Borden et al., 1997). Bradley and co-workers (1999) showed in a microcosm study that 30 to 70% of MTBE was oxidized to CO_2 over a period of 100 days. In engineered reactors, a number of reports have shown that MTBE can be degraded biologically, which can make biological processes in soil remediation a feasible option (Eweis et al., 1998).

It can be concluded that, for groundwater protection, control of underground storage tanks and the rapid detection of leaks and spills followed by effective soil and groundwater remediation are of prime importance. Emissions into the atmosphere based on normal use in car engines are not expected to result in a significant contamination of groundwater. However, deposition from the atmosphere can be the cause of widespread occurrence of MTBE traces in groundwater.

Benefits of using MTBE in gasolines include more complete combustion leading to a reduction of CO emissions, a reduced emission of precursors for ozone formation, and also a reduction of benzene and other toxic compounds. The California Air Resources Board predicted that the addition of oxygenates to fuels would reduce ozone precursors by 15%, reduce benzene emissions by 50%, and reduce CO emissions by 11%; these reductions are equivalent to removing emissions from 3.5 million vehicles. Expected air quality benefits were the basis for introducing a minimum oxygen content for gasolines with the 1990 Clean Air Act Amendments. However, benefits and risks of adding high amounts of MTBE to gasolines have recently come under discussion.

USE OF MTBE IN EUROPE

In the late 1970s, Italy was the first country in Europe to introduce MTBE into gasolines, and was followed by other countries where introduction of MTBE took place mainly in the mid-1980s. MTBE was introduced as a replacement for leaded compounds to increase the octane level to prevent engine knocking. Before regulations required the decrease of the lead content, leaded compounds constituted a major contribution to the octane level in gasolines. To prevent technical problems in automobile engines and fueling system components, gasoline producers initially added very high amounts of MTBE and also increased the aromatics content. With experience, refiners decreased the MTBE content of gasoline, as MTBE is, next to alcyate, the most expensive gasoline-blending component (Pahlke, G., personal communication, 1999). A major reason for a decreased overall consumption of MTBE has, however, been the introduction of many new cars with improved

Table 136.1 Maximum Concentrations of Gasoline Compounds in E.U. and U.S. Regulations

^c No minimum oxygen required in summer.

engine technology, which run on 95 octane gasoline. In many countries, a downward trend in the MTBE content of gasolines has been observed over the past 10 years. However, with new EU regulations for gasoline this downward trend is currently being reversed. Other compounds that added to the octane rating of the gasoline, such as benzene and overall aromatics, have to be reduced in steps by the years 2000 and 2005 (Table 136.1), which in turn is expected to result in an increase in MTBE consumption.

European guidelines for gasoline compositions include a maximum MTBE concentration of 15% by volume (Table 136.1). However, in Europe there is no minimum requirement for MTBE. In the U.S., high amounts of MTBE are added to gasolines due to minimum requirements for oxygen in oxygenated and in reformulated gasolines of 2.7 and 2.0% by mass, respectively (Squillace et al., 1996). An overview of gasoline use and MTBE content of gasolines is provided for individual European countries in Appendix 136.I. The MTBE content calculated as an average for all grades of gasolines is below 4% by volume, except for Finland where the overall MTBE content was estimated to be 8.8% by volume based on the high MTBE content of 12.4% by volume in their 98 grade gasoline (Figure 136.1). Based on an estimate from Fortum Oil (Kekalainen, J.P., personal communication, 1999), in 1998 roughly 3 million tons of MTBE were produced in the EU, 0.8 million tons were exported, 0.15 million tons were imported. Overall 2.4 million tons of MTBE were consumed within the EU, compared to an estimated consumption of 8 to 10 million tons of MTBE per year in the U.S. Thus, even with uncertainties for individual estimates for individual countries (Appendix 136.I), the overall order of magnitude appears reasonable (Vahervuori, H., personal communication, 1999). It can be concluded that concerns and problems with respect to MTBE come with a time lag in Europe where MTBE was introduced at a later time and in smaller concentrations compared to the U.S.

MONITORING OF MTBE IN THE ENVIRONMENT

Very limited monitoring data on MTBE in air, soil, or water are available and have been published for European countries because MTBE has not been routinely monitored. National environmental protection agencies are only slowly starting to realize the extent of problems connected to drinking water contamination with MTBE. However, water suppliers in Europe are becoming concerned about possible MTBE contaminations leading to a growing demand for measuring campaigns and a clear policy toward MTBE. Only now are those measuring campaigns being initiated in some countries. In the following discussion, some data for selected European

Figure 136.1 Use of MTBE in gasoline calculated as total volume of MTBE per total volume of gasoline consumed (data for 1996 from Appendix 136.1). Note that, according to Fortum Oil and Gas (Vahervuori, H., personal communication, 1999), the use of MTBE is underestimated for Belgium and Great Britain and overestimated for Denmark. In Finland, *tert*-amyl methyl ether (TAME) is added in the same order of magnitude as MTBE (Kekalainen, J.P., personal communication, 1999).

countries are presented that reveal that MTBE is ubiquitously present in very small amounts but it is also found in the mg/l range in connection to gasoline spills.

Denmark

Recently a report from the Danish Environmental Protection Agency on MTBE was published (Miljøstyrelsen, 1998). Analysis of MTBE in groundwater started in the early 1990s. From 1997, the Danish EPA has required that MTBE must be included in the monitoring programs for all wellfields that might be influenced by gasoline storage tanks. MTBE has been found in some counties in very low concentrations, i.e., $\mu\text{g/l}$ range. In one major water supply, some of the drinking water contains $-0.1 \mu\text{g/l}$ (Table 136.2). At several locations downstream of leaking underground storage tanks, concentrations are in the mg/l range and some contain up to several hundred mg/l (Table 136.3). The concentrations of MTBE were not correlated to other gasoline hydrocarbons (e.g., BTEX compounds) for those few simultaneously measured data sets available in Denmark.

This discrepancy has also been observed in a very comprehensive investigation for Texas (Mace and Choi, 1998).

Germany

According to the German Environmental Protection Agency (Umweltbundesamt), no coordinated screening for MTBE has been done (Pahlke, G., personal communication, 1999). In Bavaria, samples from drinking water supplies were tested for MTBE and concentrations were below the detection limit. However, from the vicinity of gasoline stations no data are available. High concentrations of MTBE were discovered in the groundwater at two contaminated industrial sites (Pahlke, G., personal communication, 1999). One site is a former Russian gasoline storage and experimental station in Thüringen that was operated during World War II. Even today after 50 years, large amounts of MTBE can be found in the groundwater at that site. The other contaminated site where MTBE has been identified in the groundwater is the refinery and fuel storage at Leuna, located in the former German Democratic Republic. At the industrial site at Leuna, a large refinery was put into operation in 1965 where unleaded gasoline with an MTBE content of 5 to 6% by volume was produced for the transit highway connection to West Berlin. In the groundwater, BTEX and MTBE are today found in the mg/l range.

Switzerland

Since 1996, representative groundwater and springwater supplies used for drinking water in the district of Zürich were analyzed for MTBE and other volatile contaminants (Schmidt, T.C., personal communication, 1999). In 1996 and 1997, concentrations of MTBE were below the detection limit of 0.05 µg/l for all 62 samples analyzed (EPA method 524.2). However, in

1998 MTBE was found in 18 of 100 samples with concentrations ranging from 0.07 to 0.81 µg/l. No benzene was found in any of the samples for the entire period. It turned out that MTBE was, after trichloroethylene and perchlorethylene, the third most abundant volatile compound before 1,1,1-trichlorethane and chloroform. It should be noted that samples containing MTBE were found in very different groundwater supplies and some of the samples containing MTBE were drawn from very deep groundwaters. No explanation can be given why MTBE concurrently appeared in deep and shallow groundwater supplies after the first sampling campaign in 1996.

United Kingdom

According to a survey of the U.K. Environment Agency in 1995, only 6% of water companies are routinely analyzed for MTBE, although 15% intended to start or increase monitoring. For 9% of all water companies, instances of contamination with MTBE have been reported (Harris, 1999).

REGULATIONS AND POLITICAL DIRECTION

In a recent report prepared for the World Health Organization (IPCS, 1998), it was stated that under common exposure conditions it appears unlikely that MTBE alone induces adverse acute health effects in the general population. However, low threshold values for odor and taste make water inappropriate for drinking water supplies before toxic levels have been reached. So far, there are no coordinated regulations for MTBE in water, air, and soil in Europe, and there also is not a common policy toward the development of MTBE as a fuel oxygenate.

Denmark

To reduce the amount of MTBE released into the environment, the Danish EPA plans to improve the safety of existing and newly built gasoline storage tanks. However, alternatives for MTBE in gasoline are also being investigated, and the use of high-octane fuels may be discouraged in the future through increased taxes. In addition, an initiative to encourage the use of new engine technology that does not require 95 octane fuels is being discussed. With respect to guideline concentrations for MTBE in drinking water (Table 136.4), maximum MTBE concentrations in the future may not be determined by toxicity or taste considerations, but by the contribution of MTBE to the available organic carbon in the water. The available organic carbon determines the potential for microbiological growth in the water distribution network. Virtually 100% of the Danish drinking water is produced from groundwater and is not chlorinated prior to distribution. If an MTBE degrading culture establishes in a water pipeline, its growth will lead to increased bacterial numbers in the water. With a guideline value of 30 µg/l MTBE, this could lead to unacceptable secondary bacterial contaminations. A guideline value of 10 µg/l of assimilable organic carbon (AOC) is considered reasonable for drinking water (van der Kooij, 1992); therefore, in many cases there is only a small margin, probably a few µg/l, left for MTBE from that point of view. Political consideration may also lead to much lower guideline values for MTBE in the future. In Denmark,

Table 136.4 Comparison of Suggested Maximum Target Concentrations for MTBE in Different Environmental Media for Denmark and the U.S.

	Air	Soil	Water	Ref.
Denmark ^a	0.26 mg/m ³ (toxicity) 0.03 mg/m ³ (odor)	500 mg/kg (toxicity) 0.3 mg/kg (odor)	350 µg/l (toxicity) 30 µg/l (odor)	Larsen, 1998
U.S. ^b	n.a.	0.2–3300 mg/kg	20–510 µg/l	Leonard, 1998

^a Always two concentrations are given based on toxicological concern and on odor threshold.

^b Overall range for different states. For soil: range of cleanup levels; for water: drinking water standards.

guideline values for chemicals in groundwater are in the order of 1 µg/l, for pesticides in the order of 0.1 µg/l. Political considerations play a significant role for pesticides, and according to the political will they should not be present in the groundwater at all. The same argument may be applied for MTBE in the future. In October 2001, Denmark established a new maximum concentration for MTBE in drinking water of 5 µg/l.

Remediation

As in other European countries, there are no specific measures on groundwater remediation of MTBE. MTBE is removed to some extent when the groundwater is remediated for gasoline compounds by air-sparging, soil-ventilation, by pump-and-treat, etc., but it is not well documented how efficiently MTBE can be removed by those conventional methods. Investigations are in the planning phase in Denmark.

Substitution of MTBE with Ethanol

The discovery of significant groundwater contamination with MTBE in Denmark has initiated a discussion of alternatives to MTBE. The most obvious substitute is ethanol. There is a strong interest from agricultural organizations to produce ethanol from various plant materials in the search for new markets. However, there are several reservations:

1. The oil companies prefer MTBE to ethanol because MTBE is less costly, ethanol causes problems in relation to compliance with vapor-pressure regulations during the summertime, and the use of ethanol becomes complicated when water is present in pipelines and storage tanks.
2. From an environmental point of view, it is poorly documented how ethanol affects the natural degradation of gasoline compounds in the subsurface when they leak from underground storage tanks. In otherwise aerobic aquifers, the ethanol will consume the oxygen and change the redox condition to anaerobic, which will slow the natural degradation of the gasoline hydrocarbons. If the leak happens in an anaerobic aquifer, it is not known whether the ethanol will retard or stimulate the natural anaerobic attenuation of gasoline compounds.
3. Another environmental concern is the production of the plant material, which is the raw material for ethanol production. The production may require significant use of pesticides, which may convert the MTBE problem into a pesticide problem.
4. Moreover, since the price of ethanol from agricultural production is significantly higher than the price of MTBE, the taxes on gasoline may have to be lowered in case of ethanol use, which leads to a reduced revenue to the state.

Germany

The German Environmental Protection Agency (Umweltbundesamt) has the position that contamination of drinking water supplies can be effectively prevented if direct contamination into the ground can be prevented. For MTBE that is spilled and is in contact with the atmosphere, a Mackay distribution (Mackay, 1991) was calculated, resulting in a distribution with 94% in air, 5.9% in water, 0.1% in soil, and 0.1% in sediments (Pahlke, G., personal communication, 1999). Based on the photochemical degradation of MTBE in the atmosphere with a half-life of 3 to 7 days, it was concluded that no significant contamination of ground or surface waters can be expected from the atmosphere. Thus, the threat of MTBE to drinking water supplies can be controlled if a direct contamination of the groundwater can be prevented. In the U.S., leaking underground storage tanks have been identified as a major source of MTBE in the groundwater. In recent years, all German gasoline stations had to be restructured according to stricter standards with a waterproof ground cover and with double-wall storage tanks. With the higher standards of leak prevention at gasoline stations, it is stated that MTBE contamination of water is of lesser

concern than in the U.S. where the standard of gasoline stations is believed to be inferior. As carcinogenic effects of MTBE remain unclear, in 1995 MTBE was added to the German MAK-List (list of maximum workplace concentrations) as a potential carcinogen that should be further evaluated. In conclusion, it can be stated that the threat of MTBE to groundwater is evaluated to be not as severe as in the U.S. as effective measures have been taken to prevent direct contamination of the groundwater. Also the extent of MTBE used in Germany is only approximately 1.3% by volume MTBE per total gasoline sold (Figure 136.1). The German Environmental Protection Agency does not encourage an increased use of MTBE but also does not take steps against the current use patterns.

Finland

In a reaction to the increasing concern about MTBE, the Finnish Ministry of the Environment stated that pollution of groundwater must be prevented independent of the type of contaminant (Kekalainen, J.P., personal communication, 1999). Biodegradability and transport properties of the component in groundwater are not taken into consideration and it is stated:

[I]t is not necessary to distinguish the question of the MTBE from the overall groundwater protection in Finland. The release of gasoline to groundwater is prohibited even if it contains no additional substances. When the pollution of groundwater by gasoline is prevented, it is not relevant whether or not the gasoline contains MTBE. On the basis of the facts the Finnish Ministry of the Environment does not, for the time being, consider that the use of MTBE in gasoline should be restricted because of groundwater protection in Finland.

Strict safety regulations are enforced and “as a rule, new liquid-fuel distribution stations are located outside groundwater areas. If this is not possible, risks to groundwater are eliminated by structural protection measures.”

United Kingdom

Air quality is a major concern for the U.K. Environment Agency and the use of improved fuel technology is part of its strategy. Thus, the currently relatively small MTBE content in gasoline (Figure 136.1) is likely to increase in the future. At the moment, the threat to groundwater supplies from MTBE is of comparatively low profile in the U.K. In the last few years, a number of pollution incidents have occurred in the U.K. where gasoline containing MTBE has contaminated groundwater. These pollution incidents may represent only a fraction of the total groundwater polluted with MTBE. The U.K. environment agency is stating that the scale of MTBE pollution may be grossly underestimated in the U.K. for a number of reasons (Anonymous, 1999c). One of the most significant is the comparatively recent appearance of MTBE. To date, regulators and water supply companies have not responded to reports suggesting a risk to groundwater from MTBE and hence many laboratories do not routinely screen for this pollutant. The major focus to decrease groundwater pollution by MTBE is on the improvement of gasoline storage safety. One obstacle in establishing a high safety standard for underground storage tanks at gasoline stations is that, in the U.K., 30% of the gasoline is sold at supermarkets where the environmental concern is less than compared to oil companies (Harris, B., personal communication, 1999).

There is currently no control on MTBE in drinking water in the U.K. This is probably because the available toxicity data derived from both inhalation and oral routes of exposure suggest that MTBE is of low acute and subacute toxicity. It does not appear to be either a reproductive toxicant or a mutagenic. There are equivocal data relating to the carcinogenicity of MTBE. Despite the current scientific debate, it appears that the threshold taste and odor concentration of MTBE (around 15 µg/l) is likely to be lower than a future health-based guideline value (Anonymous, 1999c).

CONCLUSION

- Introduction of MTBE into gasolines in Europe lagged behind the U.S., as does current use. As a result, concerns and possible problems with MTBE develop in Europe with a time lag.
- Very little monitoring data for MTBE in groundwater, surface waters, soil, or air are available for Europe. However, recent discussions in the U.S. have increased public attention on fuel additives, and many European environmental protection agencies are currently initiating monitoring programs for MTBE.
- While there is no minimum requirement for MTBE, its future use is expected to increase in Europe due to its properties as an octane booster. Upcoming EU regulations require a decrease of benzene and overall aromatics content, which contribute to the octane rating of the gasoline. For decision makers, this situation poses a political dilemma in which the reduction of one unwanted compound in gasoline can be the cause for an increased use of another unwanted compound.
- In many European countries, improved gasoline technology is seen as an important contribution to the reduction of air pollution. The position is that fuel oxygenates such as MTBE should be used because they help increase combustion and reduce emissions of carbon monoxide and organic compounds. The increased risk associated with leaking underground storage tanks is generally seen as a technical problem that can be managed by implementing improved safety regulations.
- In a recent study in Denmark, it was shown that MTBE concentration in groundwater used as a source for drinking water were usually below the detection limit (0.1 µm). However, in water samples from the vicinity of gasoline stations, concentrations up to a few hundred mg/l were measured. Thus, it may be only a question of time until MTBE contaminations reach drinking water resources. Groundwater problems are largely unknown and therefore groundwater remediation of MTBE has not yet started.

Sum			122.3			1949.6

Note: n.d. = not determined; RON: Research Octane Number.

^a Note that the total amount of MTBE used in Europe varies with time and that amount may be higher than the given figure because in some countries no data is available on the average MTBE content of gasoline (France, Portugal) and a number of countries are missing in the statistics (eastern European countries, Ireland, Luxembourg).

^b According to Fortum Oil and Gas (Kekalainen, J.P., Fortum Oil and Gas, Finland, personal communication, 1999), data compiled in this table are in the right order of magnitude even though, according to their sources, the use of MTBE is underestimated for Belgium and Great Britain and overestimated for Denmark.

^c In addition *tert*-amyl methyl ether (TAME) is added in the same order of magnitude as MTBE in Finland (Vahervuori, H., Fortum Oil and Gas, Finland, personal communication, 1999). It was estimated that Finland uses 95,000 tons of TAME per year (Anonymous, 2000).

^d It was estimated that France uses 151,000 tons of MTBE and 157,000 tons of ETBE per year (Anonymous, 2000).

^e The share of premium gasoline (98 RON) was estimated to be 10%.

Compiled by Torsten C. Schmidt (EAWAG, Switzerland) based on CONCAWE (1998) and Anonymous (1997).

Cost–Benefit Considerations for the Introduction of Gasoline Additives Such as MTBE

Arturo A. Keller and Linda Fernandez

INTRODUCTION

The search for solutions to air quality problems has led to the development of gasoline additives that can have a positive impact on the combustion efficiency, significantly reducing emissions of carbon monoxide, ozone precursors, and hazardous air pollutants, such as benzene. However, a careful consideration of the impact of these gasoline additives on other media must be made for each circumstance. The case of methyl *tert*-butyl ether (MTBE) has served to highlight the potential for cross-media contamination when the environmental impact assessment is incomplete.

A recent study by Keller and co-workers (1998a), as part of a wider evaluation of the health and environmental impacts of MTBE (Keller et al., 1998b), concluded that the air quality benefits for California derived from the use of MTBE as a gasoline additive at 11 to 15% by volume, are relatively small and are decreasing with time. The decrease is based on the fact that other policies and technologies implemented to reduce air emissions are becoming more important as the vehicle fleet modernizes. Older vehicles (pre-1990) do not have many of the emissions control devices (e.g., advanced catalytic converters, oxygen sensor feedback, fuel injection), and thus may emit large amounts of carbon monoxide and other air pollutants. The addition of MTBE (or other oxygenated compounds) can reduce the emissions of carbon monoxide from older vehicles. In addition, MTBE is used to replace some of the high-octane ratings that benzene and other aromatics provide; the substitution reduces the aromatic fraction of the gasoline and thus lowers the emission of air toxics.

The cost–benefit analysis conducted for California (Keller et al., 1998a) examined the human-health benefits derived from controlling air pollution, and systematically analyzed the costs associated with the use of MTBE across the following categories:

- Human health costs due to air pollution from MTBE and its combustion by-products
- Human health costs due to water pollution derived from MTBE
- Water treatment or alternative water supply costs
- Fuel price increase costs
- Costs due to increased fuel consumption
- Monitoring costs
- Recreational costs
- Ecosystem damages

Table 137.1 Composition of Gasoline Formulations

Property	Typical Conventional Gasoline	Oxygenated CaRFG2	Typical CaRFG2 with MTBE	Nonoxygenated CaRFG2 ^a
Aromatics, (vol.%)	32	max. 25	25	22.7
Olefins, (vol.%)	9.2	max. 10	4.1	4.6
Benzene, (vol.%)	1.53	max. 1	0.93	0.94
Oxygen content (%)	0	1.8 to 2.7	2.1	0
Sulfur (ppm by weight)	339	max. 40	31	38
Reid vapor pressure (psi)	8.7	max. 7	6.8	6.9
T90, °F	330	max. 300	293	297
T50, °F	218	max. 210	202	208

^a Based on AQIRP (1997).

Although cost–benefit analysis has been used extensively to evaluate alternative policies, there have been no studies to date that examine the cross-media implications of different gasoline (or other fuel) formulations. For example, a recent study focused on the costs and benefits of the Clean Air Act of 1970 (USEPA, 1997), but considered only the impact of reducing criteria air pollutants on human health. The study did not address specific policies to achieve the reductions, such as modifications to fuel formulations, new vehicle technologies, or emission control technologies on stationary sources. Schwing and co-workers (1980) used cost–benefit analysis to compare leaded and unleaded fuels, but did not consider the impact of leaded fuels on water supplies. In developing countries where MTBE is being evaluated as a substitute for tetraethyl lead, the water quality damages associated with the use of leaded fuels must also be considered. Krupnick and Walls (1992) compared methanol to conventional gasoline in terms of reducing motor vehicle emissions and urban ozone, yet avoided discussing health effects or potential impacts on water quality.

For policy makers charged with deciding between gasoline formulations to achieve improved air quality, a cost–benefit analysis can provide answers to the following questions:

Do the costs of using MTBE outweigh the benefits it produces?

What are the policy options that are available to reduce the costs of using MTBE and what are the trade-offs?

How do alternative formulations compare in terms of costs and benefits?

METHODOLOGY

The first step in the analysis is to identify the benefit and cost categories. In addition to the categories indicated in the introduction, it is possible to add other costs, such as litigation, or replacement land for sites contaminated with MTBE, or the cost of drilling new wells for public drinking water supply. The number of categories considered depends to a large extent on the availability of adequate data; some cost categories have too much uncertainty associated with them, or may be deemed not as significant as the principal cost categories. Although there may be cultural differences that place a different value on some of the cost categories, we believe that for most studies the categories we have identified will serve to make adequate policy decisions.

The next step is to identify alternative policies, or in our case, alternative formulations. In the case of MTBE, there are gasoline formulations that use ethanol, toluene, or iso-octane, which can provide essentially the same air quality benefits with different costs (AQIRP, 1997; Koshland et al., 1998). In addition, since we were interested in determining the cost of adding MTBE, we used as our baseline conventional unleaded gasoline, which was the gasoline formulation sold prior to the introduction of the reformulated oxygenated gasolines in California and other parts of the U.S. Table 137.1 presents the typical composition of these gasoline formulations.

Complete details of the methods used to value each benefit or cost category are presented in Fernandez and Keller (2000) or Keller and co-workers (1998a). Briefly, health benefits were valued using cost of illness (Abdalla et al., 1992) or the value of a statistical life (Fisher et al., 1989), depending on whether the pollutant causes morbidity, mortality, or both. The health effects associated with MTBE and other pollutants were derived from the study by Froines (1998). Water treatment costs were based on experimental and field studies conducted by Keller and co-workers (1998c), plus data from Reuter and co-workers (1998) on the number of water reservoirs that are contaminated, and Fogg and co-workers (1998) on the number of groundwater sites requiring treatment. With this information, we were able to integrate an estimate of the cost of water treatment for the State of California.

Market prices were used to estimate the direct cost paid by consumers at the pump due to the mandated use of oxygenated fuels. The increase in gasoline consumption was based on engineering estimates of the decrease in fuel energy content (NSTC, 1997), which result in an increased cost of operation. Market prices were also used to calculate monitoring costs incurred to track the extent of contamination in surface and groundwaters, or in ambient air concentrations. We use the travel cost method to value recreational costs from possible restrictions of boats and jet-skis on bodies of water which also serve as drinking water sources. The factor income and restoration cost methods are used to value environmental health costs, which account for damage to important environmental goods, such as fish and other sensitive fauna and flora (Anderson and Rockel, 1991; Bell, 1989; Shabman and Batie, 1987).

Conceptually, the valuation of environmental impacts of each alternative is straightforward. In practice, there are significant difficulties because important elements of the valuation process are not measured or have large uncertainties associated with them. For example, although MTBE may be associated with asthma, conclusive epidemiological studies have not been conducted. Similarly, there is a large uncertainty in the valuation of the effects on human health of reducing air pollutant levels when they are below the air quality standards, or even slightly above, because the toxicological data are derived from much higher concentrations.

RESULTS

Details of the assumptions used for constructing the figures can be found in Keller and co-workers (1998a). We present here the main features of our results. Figures 137.1 through 137.3 present the

Figure 137.1 Cost and benefits of reformulated gasoline with MTBE. A low and a high estimate were made based on the uncertainties associated with our assumptions. The air quality benefits are quite small, while the various cost categories add up significantly, in particular the water treatment costs.

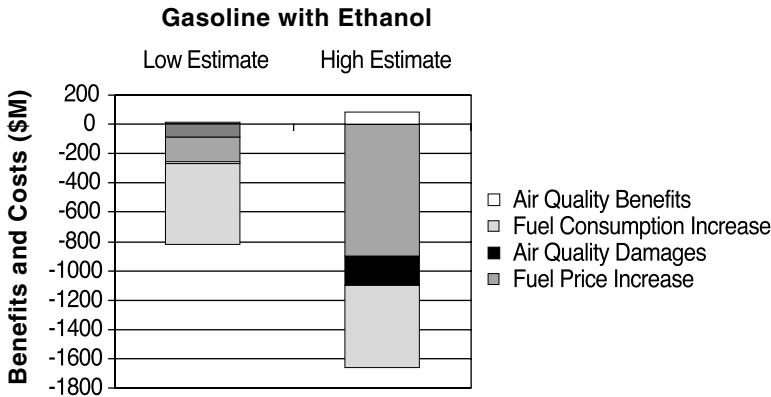

Figure 137.2 Cost and benefits of reformulated gasoline with ethanol. The same air quality benefits are assumed for this formulation. The major cost categories are the fuel price increase and the increased fuel consumption. Air quality damages may be large if significant amounts of acetaldehyde are produced as a result of incomplete combustion.

Figure 137.3 Cost and benefits of nonoxygenated reformulated gasoline. Air quality benefits are the same as for the other reformulated gasolines, but in this case the fuel consumption decreases and thus is an added benefit. This may be offset if the fuel price increases significantly.

costs and benefits for the three formulations studied (gasoline with MTBE, gasoline with ethanol, and nonoxygenated gasoline, with either toluene or iso-octane). The health benefits are essentially the same across all three formulations, because studies have shown that all these formulations achieve essentially the same carbon monoxide and ozone precursors emissions reductions, within statistical significance. An additional benefit achieved in the California Phase II Reformulated Gasoline formulations (CARB, 1991), is the reduction of benzene content. Benzene is a known human carcinogen (ATSDR, 1991; IARC, 1985), and the reduced content (less than 1%) in reformulated gasoline results in decreased volatile emissions. We have estimated that this alone reduces 33 to 920 cancer cases per year in California, which are valued at \$165 million to \$4.6 billion over a lifetime (70 years) using the value of a statistical life of \$5 million. On an annual basis, this represents \$2 to \$66 million in savings. The uncertainty in this estimate is derived largely from the uncertainty in the cancer potency factor. In addition, we estimate that the reduction in carbon monoxide may have decreased the number of hospital admissions due to congestive heart failure by up to 840 cases per year. Similarly, the reductions in ozone concentrations may lead to a reduction in hospital admissions due to acute respiratory illnesses of up to 300 cases per year. However, it is difficult to determine the fraction of the air pollutant's reduction due strictly to the fuel formulation, or due to other factors such as vehicle technology, meteorology, driving patterns, economic activity, etc. Thus, these estimates should be

seen as an upper bound. Significant as they are with respect to human health, we estimate that these benefits only represent around \$14 to \$78 million per year.

There are several reasons these benefits are small in California.

- There have been many programs successfully implemented by the California Air Resources Board to reduce the emissions of air pollutants, and thus the overall concentrations of carbon monoxide and ozone are much lower than in previous decades. For example, carbon monoxide levels prior to the introduction of the current version of oxygenated, reformulated gasoline were less than 12 ppm in practically all air basins in California. The National Ambient Air Quality Standard (NAAQS) for carbon monoxide is 9 ppm for an 8-h average. Only three monitoring stations in California exceeded the NAAQS in 1996, and the downward trend in concentrations since the late 1970s continues (USEPA, 1999). At present, there is only one nonattainment area in California for carbon monoxide, namely, the South Coast air basin. The maximum carbon monoxide concentrations registered in this region since 1994 are around 11 ppm; these levels are only observed a few days during each month, and are concentrated in episodes when adverse meteorological conditions intersect with high levels of emissions. Thus, the benefit of oxygenating the gasoline is small, since it is generally considered that the NAAQS are set such that, if they are attained, there is no health impact even to sensitive populations. A decrease of 2 ppm in peak carbon monoxide concentrations would only benefit people with ischemic heart disease, who represent around 3% of the population. Only a fraction of this population would be affected enough to require hospitalization (Graves and Owings, 1998; Morris et al., 1995).
- Similarly, ozone concentrations have been declining even in the South Coast region over the past two decades. However, in this case, although the number of days the California standard is exceeded has decreased noticeably, from a high of 261 days of exceedance in 1981 to around 135 to 180 days of exceedance in recent years (CARB, 1999), the levels are significantly above the California standard of 0.09 ppm (1-h average) during the summer months, peaking at 0.18 to 0.20 ppm. The decrease in ozone concentrations due to the oxygenate could be up to 0.015 ppm, which would benefit sensitive populations with reduced respiratory function (Burnett et al., 1997).
- The average age of the vehicle fleet has decreased in recent years, due to the economic recovery in southern California since 1993. This means that newer vehicles with improved emissions controls are replacing older vehicles. In addition, programs implemented to remove older vehicles are reducing the number of high emitters.
- The emissions from stationary sources and other mobile sources (trucks, airplanes, ships, trains, etc.) are becoming more important relative to emissions from vehicles that use gasoline with MTBE. Programs to control emissions from these other sources lag the successful control of emissions from vehicles.

These conditions may be quite different in other cities and air quality basins, especially in developing countries. For example, Mexico City has seen increasing ozone and carbon monoxide concentrations in the past few years. A program targeted at these air pollutants would have a major impact on human health. In addition, the vehicle fleet is much older, and instead of a somewhat steady-state vehicular population, it is increasing rapidly. Transportation bottlenecks and adverse meteorological conditions compound the problem. Thus, a full evaluation of the health benefits for these situations should be conducted prior to making any decision to use or ban MTBE. Alternative formulations (e.g., nonoxygenated) should also be considered.

There are air quality costs associated with the new gasoline formulations. For example, the use of MTBE results in volatilization of MTBE (from fuel lines, fueling stations, pipelines, etc.). In addition, the combustion of MTBE increases the emissions of formaldehyde (AQIRP, 1997; Koshland et al., 1998) in controlled combustion studies. Formaldehyde is a known human carcinogen (IARC, 1985; USEPA, 1988, 1993a). Although the observed MTBE concentrations are below the cancer risk level (Froines, 1998), the potential increase in formaldehyde concentrations could result in up to 380 cancer cases per year, negating some of the benefits of reducing benzene emissions. It should be noted that, to date, the concentration of formaldehyde in various California cities has shown no upward (or downward) trend since the introduction of MTBE.

Similarly, adding ethanol to gasoline (as a replacement for MTBE) increases the emissions of acetaldehyde (AQIRP, 1997; Gaffney et al., 1997; Koshland et al., 1998). Acetaldehyde is also a probable human carcinogen (CARB, 1993; IARC, 1985; USEPA, 1987, 1993b). If the concentrations were to increase as they did in New Mexico during the introduction of ethanol-gasoline mixtures, by 1 to 2 ppb, the number of cancer cases could increase to 2800 per year. However, it should be mentioned that ethanol has been used in the midwestern U.S. with no noticeable increase in acetaldehyde concentrations. A more complete study is required to determine whether there is really a concern with the use of ethanol.

If either toluene or iso-octane is used to replace MTBE in nonoxygenated formulations, the concentrations of either chemical would increase in ambient air. However, the levels of toluene would probably be below the reference concentration (RfC) in air of 0.4 mg/m³ or 400 µg/m³ (ATSDR, 1992; USEPA, 1993c). In California, the mean concentration in air is 8.5 µg/m³. This concentration could increase significantly and still not be close to the RfC at which adverse effects would be measurable. None of the data suggests that toluene is carcinogenic. Iso-octane is not classified as a hazardous air pollutant by USEPA, and there is no toxicological information from the Agency for Toxic Substances and Disease Registry (ATSDR). It is a normal component of gasoline, and can produce acute effects on the central nervous system when inhaled at high concentrations, but the risk is similar to conventional gasoline. There have been limited studies of the combustion by-products of these formulations, so it is highly advisable to make a full assessment before proceeding to their widescale introduction.

The introduction of reformulated gasoline with MTBE resulted in an estimated price increase of 1 to 5 cents per gallon. This translates into a cost to the economy of \$135 to \$675 million. In addition, due to the lower energy content of MTBE (NSTC, 1997), there is an additional cost to the California economy of \$300 to \$380 million due to the increase in fuel consumption to maintain the same driving pattern. A recent study by the California Energy Commission (CEC, 1999) estimated that the cost of using ethanol as a substitute for MTBE would be around 1.9 to 6.7 cents per gallon, or an annual cost of \$260 to \$900 million. The increase in fuel consumption due to the use of ethanol would cost an additional \$560 million (a 3% increase in consumption). For nonoxygenated gasoline, CEC (1999) estimates a price increase from 0.9 to 8.8 cents per gallon, or \$121 million to \$1.3 billion per year. The CEC estimates that in the short term (1 to 3 years), the price increase would be at the high end of the range (4.3 to 8.8 cents per gallon), whereas once refiners have been able to install the necessary equipment or long-term import contracts are established (3 to 6 years), the price increase should be only around 0.9 to 3.7 cents per gallon. However, in this case, the use of either toluene or iso-octane would result in decreased fuel consumption, due to the higher energy content of these chemicals, a savings of \$150 to \$220 million.

Fogg and co-workers (1998) and Reuter and co-workers (1998) estimated the number of groundwater supplies, leaking fuel tanks, and surface water reservoirs that are currently contaminated with MTBE. Based on their information, and the study by Keller and co-workers (1998c), we made an estimate of the aggregate cost of water treatment in California of around \$340 to \$1480 million per year (Figure 137.1). These costs are based on the premise that contaminated water must be treated to a concentration below the 5 µg/l level set by California's EPA as the Secondary Water Quality Standard, based on taste and odor considerations.

A literature review indicates that the cost of using ethanol, in terms of risk to the water supplies, is low. Ethanol plumes biodegrade fairly rapidly. In the event that water supplies become contaminated with ethanol, the available toxicological information does not support treating the water to the low levels required by MTBE, and filtration in biologically active granular activated carbon (GAC) would probably be a cost-effective option. We consider the incremental costs of water treatment to be negligible relative to conventional gasoline, since BTEX compounds in the gasoline fraction would determine the treatment design, rather than ethanol.

For nonoxygenated gasoline, the differential cost of remediation and water treatment relative to conventional gasoline is small. The increased volumetric fraction of toluene in nonoxygenated

California Reformulated Gas Phase II (CaRFG2) will result in higher initial toluene concentrations, but toluene is easily biodegraded by the intrinsic microbial communities. If iso-octane is used instead of MTBE, it has a very low solubility in water, and it is readily biodegraded along with other components of conventional gasoline. It is likely that natural attenuation will be applicable at the same rates as for conventional gasoline. Aboveground treatment costs may increase at most 10% relative to treating water contaminated by conventional gasoline.

Some utilities may be forced to purchase water from other supplies, at least in the short to intermediate term. For example, the city of Santa Monica has been purchasing water from the Los Angeles Metropolitan Water District due to the contamination of most of its drinking water wells with MTBE. The cost per year for alternative water supply, assuming that 20% of the contaminated water has to be replaced at a cost of \$1.65 per 1000 gallons that Santa Monica pays for water from the Metropolitan Water District (Rodriguez, 1997), is around \$1 to \$30 million. These costs would not be significant for other gasoline formulations, relative to conventional gasoline.

There are some incremental monitoring costs, because water utilities are required to sample more frequently, in particular in surface water reservoirs where boating is allowed. Statewide, this cost is expected to amount to \$1 to \$4 million. For groundwater sources, the current costs could increase to \$1 and \$2 million annually. Monitoring air quality is done by collecting samples on a regular basis and running a standardized analysis, which provides information on a number of air toxics. We do not expect any additional costs will be incurred to monitor ambient air concentrations of MTBE, formaldehyde, acetaldehyde, benzene, or combustion by-products. We consider that this cost would not be significant for ethanol-based gasoline formulations or nonoxygenated gasoline, relative to conventional gasoline.

One alternative that can be considered for minimizing the impact of MTBE is banning motorcraft from surface water reservoirs. If boating was completely eliminated from all the reservoirs in California, we estimate that the cost, in terms of recreational value lost, would be on the order of \$160 to \$200 million. It is likely that only a partial ban would be implemented, and probably not a year-round ban. MTBE is volatile enough to quickly escape to the atmosphere from a contaminated reservoir, in the order of weeks. We consider that this cost would not be significant for ethanol-based gasoline formulations or nonoxygenated gasoline, relative to conventional gasoline.

Ecological risk assessment studies by Werner and Hinton (1998) indicate that the concentrations of MTBE that have been detected in lakes and water reservoirs should not result in significant damages to biota in aquatic ecosystem. Localized spills may have an impact, but there are insufficient data to estimate the ecosystem damages, and they are likely to be small relative to other MTBE costs. Note that all damages and costs are estimated relative to the use of conventional gasoline. For example, local ecosystem damages due to a pipeline rupture would be similar whether the gasoline contained MTBE or not. We consider that this cost would not be significant for ethanol-based gasoline formulations or nonoxygenated gasoline, relative to conventional gasoline.

DISCUSSION

Comparing the bottom line for each formulation (Figure 137.4), it is clear that, for California, using MTBE in reformulated gasoline is a very expensive option. The costs far outweigh the benefits. More significantly, the benefits are small and decreasing with time, as the vehicle fleet modernizes, incorporating emissions control technologies. The main cost driver is water treatment, based on the very tight standards set for MTBE in California. Ethanol-based formulations do not fare much better, although the midpoint of the costs range is smaller than the midpoint of the MTBE formulation. The biggest uncertainty is the impact of a much larger demand for ethanol, which could drive prices up significantly, at least in the short term. One hidden advantage of ethanol is the fact that it can be produced from agricultural wastes such as rice straw, reducing greenhouse

Figure 137.4 Comparison of net benefits or costs for the various gasoline formulations.

emissions. Many developing countries have the potential of producing ethanol from these sources, thus reducing their dependence on imported oil, while improving their air quality.

Nonoxygenated gasoline formulations are apparently the best option for California. There is currently one refiner commercializing a nonoxygenated formulation that meets the strict California Phase II Reformulated Gasoline specifications, except for the oxygen content, presumably at a profitable price. However, the technologies may not be available to the entire industry. Capital expenditures are needed to convert to these formulations. In the meantime, imported toluene or iso-octane may drive the costs toward the high end of the range. If air quality must be maintained, this appears to be the lowest-cost strategy for California. An important consideration is the need to evaluate the toxicology (human and ecological) and fate and transport of any gasoline additives before making drastic changes. The mistakes made with MTBE should be avoided at all costs.

For developing countries, there are a number of factors that must be considered when choosing gasoline formulations. First, an assessment of the air quality benefits must be made to evaluate whether the change in formulations is warranted. This requires information on trends of ambient air concentrations of pollutants, average vehicle age and technology, as well as number of hospitalizations from congestive heart failure and acute respiratory illnesses, and their cost. Next, an assessment of the vulnerability of water sources must be made. The use of geographical information systems, which can overlay well locations with the location of underground storage tanks, can serve to make an assessment of vulnerability. An inventory of leaking tanks is also needed. California was able to reduce the impact on water resources due to the decade-long program to upgrade underground storage tanks. If the tanks do not have double-containment and leak detectors, the probability of failure is around 2% per year (Couch and Young, 1998), and the water treatment costs will certainly overwhelm the air quality benefits.

Managing *for* Healthy Ecosystems

One of the critical issues of our time is the dwindling capacity of the planet to provide life support for a large and growing human population. Based on an international congress on ecosystem health, *Managing for Healthy Ecosystems* identifies key issues that must be resolved if there is to be progress in this complex area, such as:

- *Evolving methods for regional ecosystem health assessment employing complex adaptive systems coupled with adaptive technologies to permit accurate determination of changes in regional and global environments*
- *Issues and methods for assessing, monitoring, and managing diversity and its impact on human health in the context of climate change, agroecosystems, restoration of forests, politics, culture, and tradition*

Leading thinkers in the field provide a coherent synthesis and a benchmark for the practice of this emerging field worldwide. More than 130 peer-reviewed papers are grouped into three major parts. The first part, *Emerging Concepts*, explores the diverse meanings of ecosystem health within ecological, socioeconomic, and human health perspectives, and the linkages to related concepts such as ecological integrity, sustainable development, and ecological footprints. The second part, *Issues and Methods*, introduces methods for assessing and monitoring ecosystem health, including strategies for gaining political and stakeholder input and support for science-based ecosystem management. The final part, *Case Studies*, reports experiences of interdisciplinary teams grappling with specific issues in a variety of aquatic and terrestrial ecosystems.

Features

- Illustrates practical approaches to integrating the socioeconomic, ecological, and human health implications of environmental degradation
- Includes over 300 illustrations and 200 tables
- Brings together information previously scattered among a variety of scientific journals and agency reports
- Presents peer-reviewed contributions from leading thinkers in the field
